Springer Handbook of Optical Networks

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Optical Networks

Biswanath Mukherjee, Ioannis Tomkos,
Massimo Tornatore, Peter Winzer, Yongli Zhao
(Eds.)

With 838 Figures and 102 Tables

Foreword

Optical networks have moved beyond traditional applications in telecommunications to become the infrastructure of choice whenever large amounts of information need to be transmitted. The broad spectrum inherent in the use of light and the unparalleled capability to spatially pack many parallel paths into fiber cables have led to an ever-broadening range of applications. Thousands of fibers interconnect buildings full of servers in massive datacenters that underlie internet services such as search and social media. Cables with hundreds of fibers form the backbone of metropolitan access networks and interconnect wireless base stations. At the same time, traditional long-haul services—both undersea and terrestrial—demand ever more capacity. Recent years have also seen a revolution in the technology of optical networking with the advent of coherent detection, which is now ubiquitous in long-haul and metro networks and advancing into more applications as costs decline.

This new handbook on optical networks provides a broad perspective on the field, offering a survey of the fundamental technologies of optical networks: fiber, devices, and subsystems through to systems based on those technologies, and finally to the architecture and applications of the networks themselves. The editors—Peter Winzer on subsystems and technologies, Biswanath Mukherjee on core networks, Ioannis Tomkos on datacenter and supercomputer networks, and Massimo Tornatore on access and wireless networks—have assembled an impressive list of chapter authors who have made important contributions to their fields. This volume provides a valuable look at today's optical networks.

Director of Advanced Photonics Research
Nokia Bell Laboratories

September 2020 Robert W. Tkach

Preface

Optical communication systems form the backbone of today's communication and information society. Several billion kilometers of optical fiber are installed around the globe today—enough to wrap a string of glass as thin as a human hair around the globe more than 100 000 times. A cutting-edge optical communication system can transmit tens of terabits per second over trans-Pacific distances through a single strand of optical fiber, taking a mere 50 ms to link North America with South East Asia. Today's globally installed base of optical communication transponders is collectively capable of transmitting more than an exabit (an exabit is 1 000 petabits, 1 000 000 terabits, 1 000 000 000 gigabits, or 1 000 000 000 000 megabits) of information per second over short links (between tens of meters and a kilometer long) within a data center, tens of kilometers in mobile backhaul or fiber-to-the-home applications, hundreds of kilometers in metropolitan and regional networks, thousands of kilometers in transcontinental and submarine backbones, and even tens of thousands of kilometers or more in spaceborne satellite systems using free-space laser communications. In short, almost every bit of information we touch or consume today, whether it belongs to an Internet search, to a streamed video, or to a cellphone call, lives part of its life as an infrared photon within a gigantic global optical communications infrastructure.

It is the role of this Handbook to comprehensively describe and review the many underlying technologies that enable today's global optical communications infrastructure, as well as to explain current research trends that target continued capacity scaling and enhanced networking flexibility in support of unabated traffic growth fueled by ever-emerging new applications. Each chapter, written by world-renowned experts in its subject area, tries to paint a complete picture of that subject, from entry-level information to a snapshot of the respective state-of-the-art technologies and emerging research trends, in an effort to provide something useful for every reader—ranging from the novice who wants to get familiar with the field to the expert who wants a concise perspective on future trends.

Part A of this Handbook considers *optical subsystems for transmission and switching*, with chapters focusing on topics ranging from optical fibers and cables to optical amplifiers and switches, optical transponders and their various subsystems, as well as fiber-optic communications systems, their scalability limitations, and ways to overcome these limitations in future system designs.

Part B of this Handbook reviews *core networks*, with chapters devoted to managing the vast fiber-optic communication infrastructure at the network-wide level. Topics range from the standards required to sustain an economically viable supplier ecosystem to algorithms used to route traffic and assign infrastructure resources within optical networks, cross-layer design, and network virtualization.

Part C of this Handbook is concerned with *datacenter and supercomputer networking*, which has design requirements and solutions that differ in several ways from those of other segments of the network. Topics include reviews of industry trends and requirements as well as transponder and switching considerations specific to those applications.

Part D of this Handbook addresses *optical access and wireless networks*, and is mostly geared towards solving the last-mile problem: connecting backbone networks to end users. This may be achieved directly via fiber or visible-light free-space communications, or indirectly over a mobile wireless radio infrastructure that is heavily supported by an associated fiber-optic network. Emerging areas such as spaceborne laser communications and optical communications in avionics and autonomous vehicles round off this part of the Handbook.

The Editors gratefully acknowledge all the valuable contributions from authors and peer reviewers who took much time out of their busy schedules to write or review chapters of this Handbook. The Editors also cordially thank Judith Hinterberg and Mary James from Springer for keeping everybody aligned, on time, and happy during the process.

About the Editors

Biswanath Mukherjee is a Distinguished Professor Emeritus at the University of California, Davis, CA, USA. He holds a PhD from the University of Washington, Seattle (1987) and a BTech (Hons) from the Indian Institute of Technology, Kharagpur (1980). He is also a Distinguished Professor and Founding Director of the Institute for Broadband Research and Innovation (IBRI) at Soochow University in China. He has been involved in several successful optical startups, including Ennetix, a SBIR-funded company specializing in AI-powered, application-centric network analytics for optimizing the user experience. Biswanath Mukherjee has served as program chair for several OFC, IEEE INFOCOM, and IEEE Advanced Networks and Telecom Systems (ANTS) conferences, and cofounded the latter. He is a Series Editor for Springer's book series on optical networks, and has served on several journal editorial boards, including *IEEE/ACM Transactions on Networking* and *IEEE Network*. He has received multiple awards for his scholarly and educational achievements, and was the winner of the IEEE Communications Society's inaugural (2015) Outstanding Technical Achievement Award "for pioneering work on shaping the optical networking area." He was made an IEEE Fellow in 2006.

Ioannis Tomkos is a Professor of Optical Communications at the Department of Electrical and Computer Engineering at the University of Patras, Greece. His current research focuses on the use of optical communications systems for 5G/6G and datacenter networks. He has held numerous positions in industry and academia in various countries around the world (e.g., USA, Spain, Cyprus, Italy, and Greece). His research group plays a consortium-wide leading role in over 25 EU-funded research projects, and he serves as Technical Manager on 10 major EU projects. His published works have received around 10,000 citations (h-index = 47). In 2018, Dr. Tomkos was elected an IEEE Fellow "for contributions in dynamic optical networks." He is also an IET Fellow (2010) and a Fellow of the Optical Society (2012).

Massimo Tornatore is an Associate Professor in the Department of Electronics, Information, and Bioengineering at Politecnico di Milano, where he received a PhD degree in 2006. He is also an Adjunct Professor at the University of California, Davis, CA, USA and a Visiting Professor at the University of Waterloo, Canada. His research interests include performance evaluation, the optimization and design of communication networks (with an emphasis on the application of optical networking technologies), cloud computing, and the application of machine learning to network management. He has participated in several EU R&D projects as well as several other projects in the US, Canada, and Italy. Massimo Tornatore is a member of the journal editorial boards of *IEEE Communication Surveys and Tutorials*, *IEEE Communication Letters*, *Photonic Network Communications*, and *Optical Switching and Networking*. He is also an active member of the tech nical program committees of various networking conferences, and a Senior Member of the IEEE.

Peter J. Winzer received his PhD in electrical engineering from the Technical University of Vienna, Austria, in 1998. Supported by the European Space Agency, he investigated spaceborne Doppler lidar and laser communications. From 2000 to 2019, he worked at Bell Labs (NJ, USA), where he focused on fiber-optic communication systems and networks and contributed to many high-speed optical transmission records and field trials of up to 1 Tbit/s per carrier. Peter Winzer is actively involved with the IEEE Photonics Society and the Optical Society (OSA). He has served as Editor-in-Chief of the IEEE/OSA *Journal of Lightwave Technology* and was Program/General Chair of ECOC and OFC. Dr. Winzer is a highly cited researcher, a Bell Labs Fellow, an IEEE Fellow, and a Fellow of the OSA, as well as an elected member of the US National Academy of Engineering. He has received multiple awards, including the John Tyndall Award.

Yongli Zhao is a Full Professor in the State Key Laboratory of Information Photonics and Optical Communications at Beijing University of Posts and Telecommunications (BUPT). He is a Senior Member of the IEEE and an IET Member. Yongli Zhao received his PhD from BUPT in 2010. He has received support from the Youth Talent Plan of Beijing City (2013) and the National Science Fund for Excellent Young Scholars in China (2018). In the past five years, he has chaired and participated in more than 30 research projects, including the National High Technology Research and Development Program in China, the National Basic Research Program of China, and National Natural Science Foundation of China (NSFC) projects. He was a Visiting Associate Professor at UC Davis in 2016–2017. His current research focuses on software-defined optical networks, elastic optical networks, datacenter networking, machine learning in optical networks, optical network security, and quantum key distribution networking.

Contents

Part D Optical Access and Wireless Networks

List of Abbreviations

3R	reamplification–reshaping–retiming
4-PAM	4-ary pulse amplitude modulation
4QD	four-quadrant detector
5G NR	5G New Radio
5GC	5G core

A

A-RoF	analog radio over fiber
AAA	authentication, authorization and accounting
ABNO	application-based network operation
ABRT	assured bandwidth restoration time
ACF	autocorrelation function
ACFS	approximate closed-form solution
ACL	access control list
ACN	access cloud network
ACO	analog coherent optics
ACT	active control technologies
ACTN	abstraction and control of transport networks
ADC	analog-to-digital converter
ADCT	adaptive diversity combing technique
ADM	add-drop multiplexer
ADSL	asymmetric digital subscriber line
AES	advanced encryption standard
AFDX	avionics full-duplex switched Ethernet
AFPM	asymmetric Fabry–Perot modulator
AGC	automatic gain control
AIMD	additive-increase-multiplicative-decrease
AIR	achievable information rate
AMCC	auxiliary management and control channel
AMP	asynchronous mapping procedure
ANN	artificial neural network
AOC	active optical cable
AoD	architecture-on-demand
AOM	acousto-optic modulator
AON	active optical network
APD	avalanche photodiode
APSK	amplitude and phase-shift keying
ARON	application-driven reconfigurable optical network
ARP	address resolution protocol
ARPANET	Advanced Research Projects Agency Network
AS-PCE	active stateful path computation element
ASE	amplified spontaneous emission
ASI	asymmetric information
ASIC	application-specific integrated circuit
ASON	automatic switched optical network
ASTN	automatic switched transport network
ATM	asynchronous transfer mode
ATMOS	asynchronous-transfer-mode optical switching
AUI	attachment unit interface
AWC	automatic wavelength controllers
AWG	arrayed waveguide grating
AWGN	additive white Gaussian noise
AWGR	arrayed waveguide grating router

B

BBG	baseband group
BBU	baseband unit
BDA	backbone destination address
BDD	bounded distance decoding
BDI	backward defect indication
BEC	binary erasure channel
BEI	backward error indication
BER	bit error rate
BFD	bidirectional forwarding detection
BFS	breadth-first search
BGA	ball grid array
BGP	border gateway protocol
BICM	bit-interleaved coded modulation
BIF	bend-insensitive fiber
BIM	baseband intensity modulation
BIP	bit-interleaved parity
BLSR	bidirectional line-switched ring
BMP	bit-synchronous mapping procedure
BMRx	burst-mode receiver
BOTDR	Brillouin optical time domain reflectometry
BP	belief propagation
BPD	balanced photodetector
BPDU	bridge protocol data unit
BPM	business process management
BPON	broadband PON
BPS	blind phase search
BPSK	binary phase-shift keying
BR	border router
BRAS	broadband remote-access server
BRF	bend-resistant fiber
BRPC	backward recursive path computation
BS	base station
BSA	bit-stream access
BSC	binary symmetric channel
BSS	business support software
BTC	block turbo code
BTS	base transceiver station
BTT	blade tip timing
BU	bandwidth update
BVT	bandwidth-variable transponder
BW	bandwidth
BXC	waveband cross-connect

C

C-MCF	coupled multicore fiber
C-RAN	centralized radio access network
CA	carrier aggregation
CA/CDA	channel aggregation/deaggregation
CaaS	computing-as-a-service
CAGR	compound annual growth rate
CAP	carrierless amplitude and phase modulation
CAPEX	capital expenditure
CaTV	cable TV
CAWG	cyclic arrayed waveguide grating
CB	coordinated beamforming
CBM	condition-based maintenance
CBR	constant bit rate
CC-MCF	coupled-core multicore fiber
CCDM	constant composition distribution matching
CCM	connectivity check message
CCR	carrier-to-crosstalk ratio
CCS	centralized CS
CCSDS	Consultative Committee for Space Data Systems
CD	chromatic dispersion
CDC	colorless, directionless and contentionless
CDF	cumulative distribution function
CDM	code-division multiplexing
CDN	content distribution network
CDR	clock and data recovery
CE	carrier-Ethernet
CEI	common electrical interfaces
CEI IA	Common Electrical I/O Implementation Agreement
CFI	canonical format indicator
CFM	connectivity fault management
CFP	40G/100G form-factor
CFP	C form-factor pluggable
CICQ	combined input-crosspoint queuing
CIOQ	combined input–output queuing
CIR	committed information rate
CLI	command line interface
CMA	constant-modulus algorithm
CMC	ceramic matrix composites
CMIS	common MIS
CMOS	complementary metal–oxide–semiconductor
CMP	chip multiprocessor
cMTC	critical machine-type communication
CO	central office
Co-DBA	cooperative dynamic bandwidth assignment
COI	channel-of-interest
CoMP	coordinated multipoint
COP	Control Orchestration Protocol
CORBA	common object request broker architecture
CORD	central office rearchitectured as data center
COTS	commercial off-the-shelf
CP	control plane
CPE	carrier-phase estimation
CPLD	complex programmable logic device
CPM	cross-phase modulation
CPO	co-packaged optics
CPRI	common public radio interface
CPS	confidential path segment
CPU	central processing unit
CQI	channel quality indicator
CR-LDP	constrained routed label distribution protocol
CRC	cyclic redundancy check
CRI	color rendering index
CRR	corner retroreflector
CRUD	create, read, update, delete
CRZ	chirped return-to-zero
CS	coordinated scheduling
CSC	customer SDN controller
CSCG	circularly symmetric complex Gaussian
CSF	cutoff-shifted fiber
CSI/CQI	channel state information channel quality indicator
CSK	color-shift keying
CSM	circuit switch manager
CSMA	carrier sense multiple access
CSP	constrained shortest path
CSRZ	carrier-suppressed RZ
CTAG	customer tag
CTS	clear to send
CU	central unit
CW	continuous wave
CWDM	coarse wavelength-division multiplexing

D

D-CPI	data-controller plane interface
D-RAN	distributed radio access network
D-RoF	digital radio over fiber
DA-RSA	distance-adaptive RSA
DAC	digital-to-analog converter
DAS	distributed antenna system
DBA	dynamic bandwidth assignment/allocation
DBORN	dual-bus optical ring network
DBP	digital backpropagation
DBR	distributed Bragg reflector
DBRu	dynamic bandwidth report upstream
DCAE	data collection analytics and events
DCC	digitized component carrier
DCF	dispersion-compensating fiber
DCI	datacenter interconnection
DCM	dispersion-compensation module
DCN	data center network
DCO	digital coherent optics
DCT	dispersion compensation technique
DCU	dispersion-compensating unit

DD	direct detection
DD-LMS	decision directed least mean squared
DDoS	distributed denial of service
DECS	distributed engine control system
DEI	drop eligibility indicator
DEMUX	demultiplexer
demux	wavelength demultiplexer
DetNet	deterministic networking
DFB	distributed feedback
DFE	decision-feedback equalizer
DFTS-DMT	discrete Fourier transform spread DMT
DGD	differential group delay
DGEF	dynamic gain equalizing filter
DiffServ	differentiated services
DL	downlink
DMD	differential mode delay
DMF	dispersion-managed fibers
DML	directly modulated laser
DMSC	discrete memoryless symmetric channel
DMT	discrete multitone
DN-MZM	double-nested Mach–Zehnder
DNN	deep neural network
DNS	domain name server
DOCSIS	data over cable service interface specification
DoD	Department of Defense
DOQ	distributed output-queued
DP	dual-polarization
DPI	deep packet inspection
DPM	demarcation point monitor
DPSK	differential phase-shift keying
DQPSK	differential quadrature phase-shift keying
DR	dynamic range
DRBS	double Rayleigh backscattered signal
DS	downstream
DSB-AM	double-sideband amplitude modulation
DSCP	differentiated services code point
DSF	dispersion-shifted fiber
DSL	digital subscriber line
DSLAM	digital subscriber line access multiplexer
DSO	digital storage oscilloscope
DSP	digital signal processing
DU	distributed unit
DVB	digital video broadcasting
DWA	dynamic wavelength assignment
DWBA	dynamic wavelength and bandwidth allocation
DWDM	dense wavelength-division multiplexing
DXC	digital cross-connect

E

E-NNI	external network-to-network interface
E-PON	Ethernet PON
E/O	electro-optic
EAM	electroabsorption modulator
EAT	electroabsorption transceiver
EB	electronic buffer
eBCH	extended BCH
ECL	external cavity laser
ECMP	equal cost multipath
eCPRI	enhanced CPRI
EDB	electrical duobinary
EDC	electronic dispersion compensation
EDFA	erbium-doped fiber amplifier
EDRS	European data relay system
EEPROM	electronically erasable programmable read-only memory
EF	exaFLOPS
EFEC	enhanced forward error correction
EGN	enhanced GN
EGT	exhaust gas temperature
EHF	extremely high frequency
EIRP	equivalent isotropically radiated power
ELF	extremely low frequency
EM	expectation-maximization
eMBB	enhanced mobile broadband
EMI	electromagnetic interference
EML	externally modulated laser
EMP	extrinsic message passing
EMS	element management system
ENOB	effective number of bits
EOM	external optical modulator
EON	elastic optical network
EPC	evolved packet core
EPON	Ethernet PON
EPS	electronic packet switching
ERO	explicit route object
eRP	enhanced RP
ERPS	Ethernet ring protection switching
ES	intercluster optical switch
ESCON	enterprise systems connection
ESS	emission sensing system
ETS	engineering test satellite
EVC	Ethernet virtual circuit
EVM	error vector magnitude
EXP	experimental

F

FADEC	full authority digital electronic controller
FASA	flexible access system architecture
FB	flattened butterfly
FBG	fiber Bragg grating
FBL	fly-by-light
FBNQ	fitting-based nonlinear quantization
FBW	fly-by-wire
FCAPS	fault identification, configuration, accounting, performance, security
FCS	frame check sequence
FDL	fiber delay line
FDM	frequency-division multiplexing
FEC	forward error correction
FER	frame error rate
FFE	feed-forward equalizer
FIB	forwarding information base
FIC	fabric interface chip

FICON	fibre connection
FIR	finite impulse response
FIT	failures in time
FLOPS	floating point operations per second
FLOW_MOD	flow table modification message
FM-HD	field modulation and heterodyne detection
FM-MFC	few-mode multicore fiber
FMDF	fiber main distribution frame
FMF	few-mode fiber
FML	frequency modulated laser
FOADM	fixed optical add/drop multiplexer
FOBS	fast optical burst selector
FOIC	FlexO interface
FOM	figure-of-merit
FOSS	fiber-optic sensing system
FOV	field of view
FP	Fabry–Pérot
FPA	focal-plane array
FPGA	field-programmable gate array
FPM	four-photon-mixing
FRLP	frequency-resolved LP
FRR	fast reroute
FSAN	full-service access network
FSC	fiber-switch capable
FSE	fast statistical estimation
FSO	free-space optics
FSOC	free-space optical communication
FSR	free spectral range
FTTH	fiber-to-the-home
FTTP	fiber to the premises
FTTx	fiber-to-the-home/building
FWA	fixed wireless access
FWI	forced wake-up indication
FWM	four-wave mixing

G

G-ACh	generic associated channel
G-LDPC	generalized LDPC
G-PON	gigabit-capable PON
GBIC	gigabit interface converter
GE-PON	gigabit Ethernet PON
GEM	G-PON encapsulation method
GEO	geostationary equatorial orbit
GF	gigaFLOPS
GFP	generic framing procedure
GigE	gigabit Ethernet
GMD	generalized minimum distance
GMI	generalized mutual information
GMP	generic mapping procedure
GMPLS	generalized multiprotocol label switching
gNB	next-generation node B
GOLD	ground/orbiter lasercomm demonstration
GPC	generalized product code
GPON	gigabit-capable PON
GPRS	general packet radio service
GSM	Global System for Mobile Communications
GTC	G-PON transmission convergence
GVD	group velocity dispersion

H

HAF	hole-assisted fiber
HALL	hierarchical all-to-all
HAP	high-altitude platform
HARQ	hybrid automatic repeat request
HC-PBGF	hollow-core PBGF
HDD	hard-decision decoding
HF	high-frequency
Hi-LIONS	hierarchical low-latency interconnect optical network switch
HICALI	high-speed communication with advanced laser instrument
HNLF	highly nonlinear fiber
HOM	high-order modulation
HOPR	hybrid optoelectronic router
HOS	hybrid optical switching
HOSA	hybrid optical switch architecture
HPC	high-performance computing
HPCG	high-performance conjugate gradient
HR-OSA	high-resolution optical spectrum analyzer
HSS	home subscriber server
HTS	high-throughput satellites
HTTP	hypertext transfer protocol

I

I-*L*PPM	inverted-*L*PPM
I-NNI	internal network-to-network interface
IA-RWA	impairment-aware routing and wavelength assignment
IaaS	Internet-as-a-service
IAD	intelligent access device
iBDD	iterative BDD
Ibpa	interblade phase angle
ICI	intercell interference
ICMP	internet control message protocol
ICR	integrated coherent receiver
ICT	information and communication technologies
ICTP	inter-channel termination protocol
ID	identification
IDA	ideal distributed amplification
IDC	inter-data-center
IE	information element
IF	intermediate frequency
IFFT	inverse fast Fourier transform
IFWM	intrachannel four-wave mixing
iGMDD-SR	iterative GMD decoding with scaled reliability
IGP	interior gateway protocol
IIR	intensity impulse response
IL	insertion loss

ILC	illumination-light communication
ILM	incoming label map
ILP	integer linear programming
IM	intensity modulation
IMS	Internet protocol multimedia subsystem
IoT	Internet of things
IP	Internet protocol
IP/MPLS	Internet protocol over multiprotocol label switching
IPC	input port interface card
iPLC	integrated planar lightwave circuit
IPoDWDM	IP over DWDM
IPR	intellectual property rights
IPSec	IP security
IS-IS-TE	intermediate system to intermediate system traffic engineering
ISG	industry specification group
ISI	intersymbol interference
ISIS-TE	intermediate system with traffic engineering
ISM	intelligent splitter monitor
ISP	Internet service provider
ITAG	intermediate service tag
ITU-T	International Telecommunication Union-Telecommunications
IXP	internet exchange point
IXPM	intrachannel cross-phase modulation

J

JDRS	Japan data relay system
JSF	Joint Strike Fighter
JSON	JavaScript object notation

L

L2SC	layer-2-switch capable
LAG	link aggregation group
LAN	local area network
LBS	location-based service
LC	line card
LCAS	link capacity adjustment scheme
LCE	laser communication equipment
LCOS	liquid crystal on silicon
LCP	local connection point
LCRD	laser communications relay demonstration
LCT	laser communications terminal
LDACS	L-band digital aeronautical communications system
LDC	linear divider/combiner
LDGD	largest differential group delay
LDP	label distribution protocol
LDPC	low-density parity check
LER	label edge router
LH	long-haul
LiFi	light-fidelity
LION	large-scale interconnect optical network
LIONS	low-latency interconnect optical network switch
LLDP	Link Layer Discovery Protocol
LLID	logical link identifier
LLN	linear lightwave network
LLR	log-likelihood ratio
LLU	local loop unbundling
LMP	link-management protocol
LMS	least mean squares
LNA	low-noise amplifier
LO	local oscillator
LOGON	locally-optimal globally-optimal Nyquist
LPF	low-pass filter
LR-PON	long-reach passive optical network
LSA	link state advertisement
LSC	lambda-switch capable
LSE	least-squares equalization
LSP	label-switched path
LSR	label-switched router
LTE	long term evolution
LTM	linktrace message
LUCE	laser-utilizing communications equipment

M

M2M	machine-to-machine
MAC	media access control
MAI	multiple access interference
MAN	metropolitan area network
MANO	management and network orchestration
MC-nodes	metro/core nodes
MCF	multicore fiber
MCLCD	Micius coherent laser communication demonstration
MCP	multiconstrained path
MCS	multicast switch
MCSB	maximal contiguous slot block
MD	mode dispersion
MD-ROADM	multidegree ROADM
MDIO	management data input/output
MDL	mode-dependent loss
MDM	mode division multiplexing
MDRU	movable and deployable resource unit
MDS	maximum distance separable
MDU	multiple dwelling unit
MEF	Metro Ethernet Forum
MEMS	microelectromechanical system
MEN	metro Ethernet network
MEP	maintenance end point
MET	multi-edge type
MFAS	multiframe alignment signal
MFD	mode-field diameter
MFH	mobile fronthaul
MGTC	minimum guaranteed transmission container content
MI	mutual information
MIB	management information base
MILP	mixed integer linear program

MIMO	multiple-input multiple-output
minEMBc	minimum effective modal bandwidth
MIP	mixed integer program
MLC	multilevel coding
MLD	multilane distribution
MMC	metal matrix composites
MMF	multimode fiber
MMT	multiple match table
mMTC	massive machine-type communication
MMUX	mode multiplexer
MMW	millimeter wave
MNH	multidomain network hypervisor
MOD	optical intensity modulator
MONET	multiple wavelength optical network
MP	minimum path
MPCP	multipoint control protocol
MPEG	Moving Picture Experts Group
MPI	multiple-path interference
MPLC	Multiplane light convertor
MPLS	multiprotocol label switching
MPO	(multifiber) connector
MPSK	*M*-level PSK constellation
MPTCP	multipath TCP
MR	maximum reach
MRR	microring resonator
MS	maximum scattering
MSA	multisource agreement
MSM	metal-semiconductor-metal
MSN	multiservice node
MSTE	minimum spanning tree with enhancement
MSTP	multiple spanning tree protocol
MT	match table
MTBF	mean time between failures
MTSO	mobile telephone switching office
MTTR	mean time to repair
MTU	maximum transmission unit
MZI	Mach–Zehnder interferometer
MZM	Mach–Zehnder modulator

N

NBI	northbound interface
NC	node controller
NCG	net coding gain
NCO	number-controlled oscillator
ND	nodal diameter
NETCONF	network configuration protocol
NetOS	network operating system
NF	noise figure
NFDM	nonlinear frequency-division multiplexing
NFS	Network File System
NFV	network function virtualization
NFVO	NFV orchestrator
NG-PON	next-generation PON
NG-RAN	next-generation radio access network
NGMI	normalized generalized mutual information
NGMN	next-generation mobile network
NIC	network interface card
NLFT	nonlinear Fourier transform
NLI	nonlinear interference
NLPN	nonlinear phase noise
NLRI	network layer reachability information
NMS	network management system
NOC	network operation center
NOMA	nonorthogonal multiplexing and multiple access
NRZ	nonreturn-to-zero
NSMS	nonintrusive stress measurement system
NSNI	nonlinear signal–noise interaction
NTE	network terminating equipment
NTP	network time protocol
NVM	nonvolatile memory
NZDSF	nonzero dispersion-shifted fiber

O

O/E	optic-electro
OA	optical amplifier
OADM	optical add-drop multiplexer
OAI	open air interface
OAM	operation, administration and maintenance
OAP	optical access point
OBI	optical beat interference
OBLC	optical burst line card
OBO	on-board optics
OBS	optical burst switching
OBSAI	Open Base Station Architecture Initiative
OBSC	optical burst switch card
OC	OpenFlow controller
OCDM	optical code division multiplexing
OCDMA	optical code division multiple access
OCh	optical channel layer
OCM	optical channel monitor
OCS	optical circuit switching
ODB	optical duobinary
ODN	optical distribution network
ODU	optical data unit
OE-PCB	optoelectronic printed circuit board
OEM	original engine manufacturers
OEO	optical–electrical–optical
OF	OpenFlow
OF-CONFIG	OpenFlow Configuration
OFDM	orthogonal frequency-division multiplexing
OFDR	optical frequency domain reflectometry
OFL	overfilled launch
OFLL	optical frequency locked loop
OFS	optical flow switching
OGS	optical ground station
OICETS	optical inter-orbit communications engineering test satellite
OLM	Optical Layer Monitoring
OLO	optical local oscillator
OLS	optical latching switch

OLT	optical line terminal
OM	output module
OMBc	overfilled modal bandwidth
OMCI	ONU management and control interface
OMM	ODN management module
OMS	optical multiplex section
ONAP	open network automation platform
ONOS	open network operating system
ONU	optical network unit
OOK	on–off keying
OPA	optical parametric amplifier
OPEX	operational expenditure
OPLL	optical phase locked loop
OPS	optical packet switching
OPU	optical channel payload unit
OQ	output-queuing
ORI	open radio equipment interface
OSFP	octal small form-factor pluggable
OSNR	optical signal-to-noise ratio
OSPF	open shortest path first
OSS	operations support system
OTDR	optical time domain reflectometry
OTL	optical trunk line
OTL	optical transport lane
OTLC	optical transport lane
OTN	optical transport network
OTS	optical transmission section
OTSiG	optical tributary signal group
OTU	optical transport unit
OVS	OpenVSwitch
OXC	optical cross-connect

P

PA	power amplification
PAM	pulse-amplitude modulation
PAM4	four-level pulse-amplitude modulation
PAPR	peak-to-average power ratio
PAS	probabilistic amplitude shaping
PBB	provider backbone bridging
PBC	polarization beam combiner
PBG	photonic band gap
PBGF	photonic band-gap fiber
PBS	polarization beam splitter
PBX	private branch exchange
PCB	printed circuit board
PCBd	physical control block downstream
PCC	path computation client
PCE	path computation element
PCEP	path computation element protocol
PCIe	peripheral component interconnect express
PCT	paired channel technology
PDCP	packet data convergence protocol
PDF	probability density function
PDG	polarization-dependent gain
PDH	plesiochronous digital hierarchy
PDL	polarization-dependent loss
PDM	polarization division multiplexing
PHY	physical layer
PIC	photonic integrated circuit
PL	photonic lantern
PLI	physical-layer impairment
PLL	phase-locked loop
PLOAM	physical-layer operations, administration and maintenance
PLOu	upstream physical layer overhead
PLZT	planar lightwave circuit
PM	polarization multiplexing
PMD	polarization mode dispersion
PMF	probability mass function
PNF	physical network function
POADM	packet optical add/drop multiplexer
POD	portable data center
POF	protocol oblivious forwarding
POL	passive optical LAN
PON	passive optical network
PON-ID	PON identifier
POS	packet-over-SONET
POTP	packet optical transport platform
PPM	pulse-position modulation
PPRN	phase and polarization-rotation noise
PQ	priority queuing
PRBS	pseudo-random binary sequence
PRC	primary reference clock
PROnet	programmable optical network
PSBT	phase-shaped binary transmission
PSD	power spectral density
PSF	point spread function
PSK	phase-shift keying
PSP	principal states of polarization
PTMP	point to multipoint
PTP	precision time protocol
PtP	point-to-point
PTS	partial transmission sequence
PUCCH	physical uplink control channel
PUSCH	physical uplink shared channel
PVC	permanent virtual circuit
PW	pseudowire
PWM	pulse-width modulation

Q

QAM	quadrature amplitude modulation
QKD	quantum key distribution
QoS	quality of service
QoT	quality of transmission
QPAR	quasi-passive reconfigurable node
QPSK	quadrature phase-shift keying
QSFP	quad small form-factor pluggable

R

RAID	redundant array of independent discs
RAM	random-access memory
RAN	radio access network
RAU	radio access unit
RCC	radio cloud center

RDC	regional datacenter
RDS	relative dispersion slope
RE	radio equipment
REC	radio equipment controller
REN	research and education network
REST	representational state transfer
RF	radio frequency
RFC	request for comments
RFL	reflection
RH	remote hub
RH-LIONS	reconfigurable hierarchical low-latency interconnect optical network switch
RIN	relative intensity noise
RLC	radio link control
RLS	recursive least squares
RMS	root mean square
RMSA	routing, modulation, and spectrum assignment
RMT	reconfigurable match table
RN	remote node
RNG	regional network gateway
ROADM	reconfigurable optical add-drop multiplexer
RoF	radio over fiber
ROLEX	rapid optical layer end-to-end X-connection
RPC	remote procedure call
RRC	radio resource control
RRH	remote radio head
RRU	remote radio unit
RS	Reed–Solomon
RSA	routing and spectrum assignment
RSCA	routing, spectrum and core assignment
RSOA	reflective semiconductor optical amplifier
RSP	restricted shortest path
RSSI	received signal strength indication
RSTP	rapid spanning tree protocol
RSVP	resource reservation protocol
RTS	request to send
RTT	round-trip time
RV	random variable
RWA	routing and wavelength assignment
RX	receiver

S

SAG	separated absorption and gain
SAN	storage area network
SAR	segmentation and reassembly
SBI	southbound interface
SBS	stimulated Brillouin scattering
SBVT	sliceable bandwidth variable transponder
SCM	subcarrier multiplexing
SD-WAN	software-defined wide-area network
SDA	software-defined access
SDH	synchronous digital hierarchy
SDM	space-division multiplexing
SDN	software-defined network
SDN	software-defined networking
SE	spectral efficiency
SER	symbol error rate
SERDES	serializer/deserializer
SFC	service function chain
SFF	small form-factor
SFL	substrate fiber link
SFP	small form-factor pluggable
SG-DBR	sampled-grating distributed Bragg reflector
SILEX	semiconductor laser inter-satellite link experiment
SINR	signal interference-to-noise ratio
SISO	soft-input soft-output
SLA	service level agreement
SMF	single-mode fiber
SMSR	side-mode suppression ratio
SNA	switched network access
SNIA	Storage Networking Industry Association
SNMP	simple network management protocol
SNR	signal-to-noise ratio
SOA	semiconductor optical amplifier
SONET	synchronous optical network
SPM	self-phase modulation
SRAM	static random access memory
SRLG	shared-risk link group
sRN	smart remote node
SRS	stimulated Raman scattering
SSG-DBR	super-structure grating DBR
SSH	secure shell
SSM	synchronization status message
SSMF	standard single-mode fiber
STAG	service tag
SWDM	short-wave wavelength-division multiplexing

T

T-API	transport application program interface
TAOGS	transportable adaptive optics ground station
TAPI	transport application programming interface
TCAM	ternary content-addressable memory
TCM	trellis-coded modulation
TCO	total cost of ownership
TCP	transmission control protocol
TDHF	time-domain hybrid format
TDM	time-division multiplexing
TDMA	time-division multiple access
TE	traffic engineering
TE	bridging-traffic engineering
TEC	thermoelectric cooler
TED	traffic engineering database
TFF	thin-film filter
TIA	transimpedance amplifier
TIR	total internal reflection
ToR	top-of-rack

TP	transport profile
TPC	turbo product code
TRCV	transceiver
TRX	transceiver
TSN	time-sensitive networking
TTT	timing transparent transcoding
TWC	tunable wavelength converter
TWDM	time and wavelength division multiplexing
TX	transmitter

U

U-MCF	uncoupled multicore fiber
UART	universal asynchronous receiver-transmitter
UCB	uncorrectable block
UCLP	user-controlled lightpath
UDWDM	ultra-dense wavelength-division multiplexing
UE	user equipment
UL	uplink
UL-JR	uplink joint reception
ULH	ultra-long-haul
UMTS	Universal Mobile Telecommunications Service
UNI	user–network interface
UPSR	unidirectional path-switched ring
URLLC	ultra-reliable low-latency communication
US	upstream
UVLWC	underwater visible-light wireless communication

V

VCAT	virtual concatenation
VCO	voltage-controlled oscillator
VCSEL	vertical-cavity surface-emitting laser
VDSL	very high speed digital subscriber line
VHTS	very-high-throughput satellites
VID	VLAN ID
VLAN	virtual local area network
VLC	visible light communication
VLM	virtual link mapping
VLSI	very large-scale integration
VLW-LAN	visible-light wireless LAN
VM	virtual machine
VNF	virtualized network function
VNM	virtual node mapping
VNTM	virtual network topology manager
VOA	variable optical attenuator
VOL	virtual optical link
VON	virtual optical network
VSOTA	very small optical transponder

W

W-LAN	wireless local area network
WA	wavelength assignment
WAN	wide area network
WBA	wavelength and bandwidth allocation
WDM	wavelength-division multiplexing
WR	wavelength routed
WRON	wavelength-routed optical network
WSS	wavelength-selective switch
WXC	wavelength cross-connect

X

XENPAK	10 Gb Ethernet transceiver package
XFP	10 Gb small form-factor pluggable
XG-PON	10-gigabit-capable PON
XGEM	10G encapsulation method
XGS-PON	10-gigabit-capable symmetric PON
XGTC	XG-PON transmission convergence
XML	extensible markup language
XOR	exclusive OR
XPM	cross-phase modulation

Y

YANG	yet another network generator

1. The Evolution of Optical Transport Networks

Rod C. Alferness

This introductory chapter describes the role of optics in networks, their capabilities, and their scaling limitations (different multiplexing techniques, i.e., TDM (time-division multiplexing), CDM (code-division multiplexing), FDM (frequency-division multiplexing), SDM (space-division multiplexing)). Types of optical networks installed around the globe are summarized, as well as their impact on society, market structure, and future perspectives.

Optical fiber transmission links were first deployed in the mid 1970s to provide 45 Mb/s capacity in metropolitan networks at a time when most traffic was wireline telephone communication. Few would have imagined then, when bandwidth demand on the telephone network was growing only as rapidly as population growth, that this new technology would radically alter business and everyday life by enabling the worldwide Internet. As the Internet grew in popularity and extended to all parts of the world, new devices and transmission technologies were invented and developed to cost-effectively achieve the required higher capacity transmission, and fiber was laid across continents and under the oceans to cover the globe. Thus began a virtuous cycle of higher capacity optical transmission systems and, ultimately, reconfigurable optical networks enabled by new technologies to meet increased demand, which resulted in new applications and services, such as video, which drove ever greater capacity and flexibility demand, which was, again, achieved via new technology innovation at significantly lower costs/capacity.

First-era systems grew the capacity of optical links by increasing the bit rate of information carried on the fiber. The second era, which was achieved cost-effectively by the optical fiber amplifier, increased capacity by multiplexing many wavelengths, each carrying independent information, onto a single fiber. The result was an increase in single fiber transmission equal to the number of wavelength channels and long spans over which all the wavelength channel signals could be periodically boosted with a single optically-powered optical fiber amplifier. The next era took the giant step of moving optics from transmission links only to fully reconfigurable, wavelength-channel-based networks to achieve higher efficiency (and, therefore, capacity), flexibility, and restorability by allotting and managing network capacity at the optical layer level.

This step required cost-effective optical switching components to provide the reconfigurable wavelength add/drop and cross connect functions. Today's optical networks provide superhighways of information bandwidth of the order 100 wavelength-defined lanes each providing hundreds of Gb/s information capacity. These networks provide network optimization to address changing capacity needs under software control via configurable wavelength on-and-off ramps and route switching centers. Without these optical networks, the global internet, cloud computing, and high bandwidth mobile services, including video, would not be possible. This chapter provides a view of the evolution of these optical networks—the market drivers, network architectures, transmission system innovations and enabling devices, and module technologies—which was a result of the efforts of a global community of researchers, developers, and, ultimately, manufacturers.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_1

1.1 Fundamental Developments

It is hard to imagine a world without optical communication networks. While commercial fiber optic transmission systems were introduced less than 50 years ago, today, because they underpin the global Internet, optical communications networks enable and enhance nearly every part of our daily lives. They are virtually invisible to the public because they are often in buried ducts or embedded in telco central offices. Yet, optical networks, including the fiber cables and the optoelectronics and optical switches that light and guide them, provide an infrastructure of long haul, metro, access, and, increasingly, local data-center networks, that have enabled broadband local and global information and communication and data interconnecting highways that drive the economy and have enhanced our daily lives. Now ubiquitously deployed under the oceans, across continents, and deep into metropolitan areas, fiber optics networks provide the high-bandwidth pipes over which all communication and data and Internet services are carried. To cost-effectively meet the bandwidth requirements of the incredible service demand growth, especially driven by video and more recently cloud services, the research and development community has been able to increase the capacity carried on a single fiber roughly a hundredfold every 10 years. The result of that invention, innovation, and commercialization is that new generations of optical networks to meet consumer demand for capacity growth have been deployed at costs that have grown at a substantially lower rate than the capacity demand. The result is that costs to the ultimate consumer for every expanded broadband service have been kept under control.

This sustained increase in the information bandwidth achieved on a single fiber is a result of continuous device invention and system innovation and introductions of new technologies. It is worth noting that to meet this demand, rather than increasing the capacity on a single fiber, one could employ multiple parallel fiber transmission systems. In this case, the network cost would grow roughly at the same rate as capacity. As we will see, the advantage of maximizing the capacity on a single fiber is, of course, avoidance of the extra cost and space of additional fibers to meet capacity demands. Yet what is even more important is to do so economically by cost-effectively scaling the other components and networking functions on the transmission links, rather than duplicating them on a second, parallel fiber.

An excellent example is the invention and development of the fiber optic amplifier that, together with wavelength multiplexing technologies, enabled the cost-effective commercialization of wavelength-division multiplexed (WDM) transmission. Innovation of wavelength add/drop and optical cross connects systems together with automated control software subsequently enabled fully reconfigurable optical networks that enable flexible bandwidth management and restoration capability in today's global networks. The currently-deployed optical networks have transmission links that are able to operate at Tb/s capacity on a single fiber by combining many wavelengths, each operating today at rates as high as 100 Gb/s with 400 Gb/s on the way. These networks are reconfigurable, under network control, at a wavelength granularity whose capacity is based upon the information bit rate carried by the wavelength channel [1.1, 2].

Without cost-effective high-capacity optical networks that span continents and connect them via undersea routes, the worldwide Internet would not be possible. Optical access systems are also essential to bring broadband access to that global Internet all the way to the home and to businesses. Increasingly important is that ubiquitous broadband optical networks provide the high-bandwidth backhaul essential for wireless access networks that have enabled today's smartphone users. These networks also provide the always-available, broadband access that will make cost-effective and energy-efficient cloud services available to all in the future.

Fundamental to the development and application of optical communications systems is the inherent ability to encode high-capacity information on an optical carrier. Additional fundamental enablers include the ability to achieve low transmission loss and low chromatic dispersion in silica fiber—to minimize pulse spreading and resulting interpulse (bit) interference during transmission over large distances—in a silica fiber fabricated as an optical guided-wave media. Finally, with

the addition of potentially low cost, low power, and small footprint semiconductor lasers, high-speed optical modulators and sensitive photo detectors, we have the key technologies to achieve bandwidth and distance performance that greatly exceeds that possible with electrical or microwave-based communication links.

These advantageous characteristics of optical communication can be achieved across the full spectrum of communication networks, undersea, terrestrial long haul, metro, access and for local networks, including data centers, but the great potential for advantage and first applications have been for high capacity over long distances—initially for long-haul undersea and terrestrial applications. With increasing bandwidth demands these advantages became cost-effective for the more modest distances of metropolitan networks as well. In this introductory chapter, we focus on optical transport networks for metro, national, and undersea applications, where the impact has been absolutely transformational.

1.2 Transport Networks

To appreciate the value of optical networks and, especially, to understand the importance of optical-switching (reconfigurability) elements in these networks, a short overview of transport networks is helpful. In the telecommunication network architecture, transport networks provide the very high capacity highways that enable logical pairwise connectivity (for simplicity assumed to be duplex) between all nodes. Large cities of the national network, as well as larger hubs in metropolitan networks, are the primary nodes in these networks. In Fig. 1.1 the key hardware elements of a transport network are shown [1.3]. Ultimately, transport networks provide high-capacity connections between all node pairs on the network. Rather than actually deploying a dedicated, separate physical connection (wire, cable, or fiber) between each node pair, which would be very expensive and operationally rigid, transport networks provide the connectivity between node-pair endpoints with virtual channels, each of which takes only a fraction of the capacity of the transmission medium. To be cost effective and to efficiently utilize the bandwidth of the transmission medium these lower-capacity channels (often referred to as *circuits* or *lines*) are multiplexed (aggregated) together on a single physical medium via a multiplexer (Fig. 1.1a) to provide connectivity via node-to-node links that operate at that bundled or aggregated bandwidth.

This aggregated information/data stream, encoded onto a carrier (radio-frequency, microwave, or optical) is sent over a transmission link on which the signal is re-

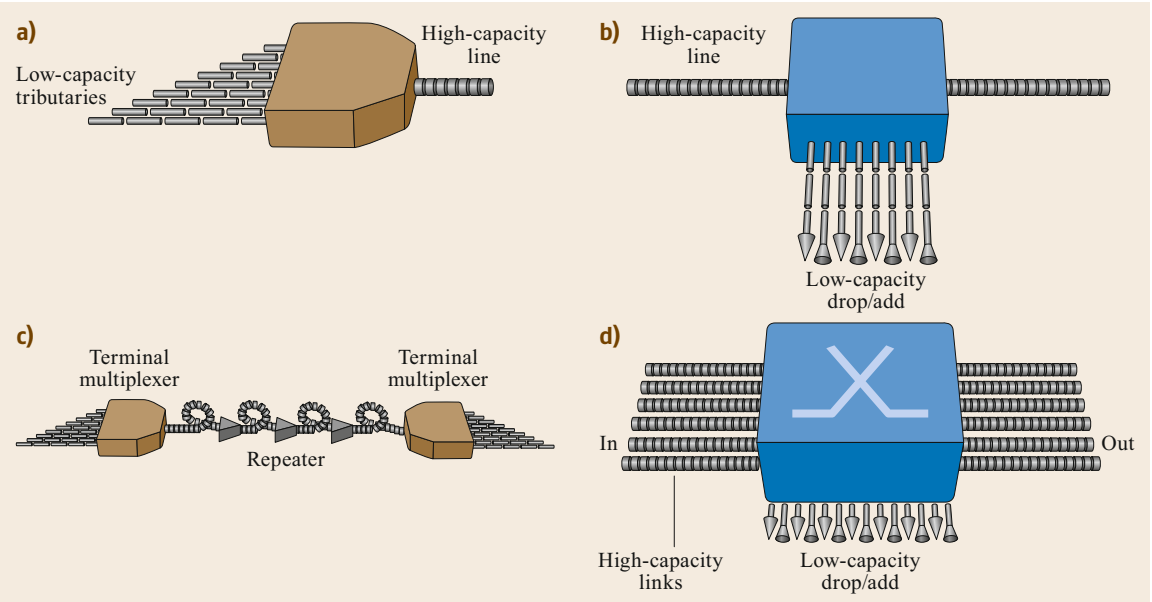

Fig. 1.1a–d Functional elements of telecommunication transport networks. **(a)** Terminal multiplexer, **(b)** add/drop multiplexer, **(c)** high-capacity transmission link, **(d)** cross-connect

generated periodically to compensate for transmission loss and impairments (Fig. 1.1c). At any node on the network, there are logical connections that represent the pairwise connectivity between that node and all other nodes on the network. Those logical connections need to be made at the destination node. This is achieved by unbundling the aggregated channels to access the channels that represent the pairwise connections to that node from the other network nodes. Those channels are then terminated, i.e., *dropped* at that node. Other pairwise connections may also be *added* at that node.

An important feature of transport networks is the different topologies of the interconnection of the transmission links between the nodes. Linearly connected architectures like a bus or a ring (typical for metropolitan networks) are characterized by a single link in and out of the node. In that case, terminated channels must be *dropped*, and all others are simply *passed through*. In addition to providing connectivity between that node and other nodes on the *output* side of the node, channels originating at the node must be added to the output link. The network element that performs this function in transport networks is an add/drop multiplexer (Fig. 1.1b).

In mesh-configured networks (used in national networks), each node may be connected by links to more than just the two nearest neighbors used for linear and ring networks. In mesh networks, multiple links (transmission routes) enter and exit the node. The transport switch element to route-aggregated traffic is more sophisticated in this case because in addition to providing the add/drop function for tributary channels for each transmission link entering the node, there is also the need to switch/route some disaggregated tributary (lower bit-rate *circuits* in the TDM case) traffic between output links to provide the desired pairwise connectivity across the network. The network switch element that provides this functionality is the cross connect (Fig. 1.1d). Because of the need to switch, at the tributary rate, between any of multiple input routes to any output route and do add/drop for all routes, cross connects are significantly more complex than add/drops, generally requiring more extensive switching fabrics. Both reconfigurable add/drops and cross connects are essential to provide the ability to change the network connectivity or the bandwidth of that connection to address capacity demand changes (increase) between node pairs or to facilitate the addition of nodes or to configure capacity around a network failure (restoration).

In early transport networks, prior to the use of optical transmission, the transmission was purely electrical, and the method of aggregation was electrical time-division multiplexing (TDM) where multiple lower bit-rate information-bearing channels were combined to form a single higher bit-rate channel (represented schematically in Fig. 1.1a). To do so requires synchronization of the lower bit-rate channels that depended upon distribution of centralized clock and electronics to do pulse narrowing and bit stream interleaving to form the higher rate-aggregated stream.

1.3 Enter Optical Fiber Transmission

The use of optical carriers to increase transmission capacity in transport networks was very natural because its higher carrier frequency inherently offered higher signal encoding bandwidth. Indeed, microwave frequency line-of-sight systems had already been investigated, as had exploration of a microwave that offers both ultralow loss and low chromatic dispersion. As was noted earlier, the latter results in minimal pulse spreading and resulting interpulse (bit) interference during transmission over large distances. At its most basic implementation, an optical transmission system requires an optical source whose generated dc optical signal can be modulated with information at the information bandwidth of interest, a low-loss fiber and an optical detector and receiver. First field trials were demonstrated in the mid 1970s. For example, AT&T demonstrated 45 Mb/s over one of its loop routes in Chicago in 1977 [1.4].

Today's networks provide tens of Tb/s capacity on a single fiber with nearly 200 wavelengths, each carrying an information capacity of 100 Gb/s. New products are pushing to 250 Gb/s, and shorter-reach systems operate at 400 Gb/s per wavelength [1.1]. In many cases, those optical signals—with the application of optical fiber amplifiers—travel over a thousand kilometers without the need for electrical regeneration. We have been able to reach this capability, driven by society's demand, by a virtuous cycle over the years of increased market demand driving innovations to cost-effectively increase capacity, which, in turn, drove the ability for the network to provide new applications, which then drove another round of market demands, etc.

The ability of fiber optics systems, and ultimately, reconfigurable wavelength-routed networks to respond to the increasing demand for ever higher capacity with increased reach and without depending upon power hungry and costly electronic regeneration, is a result of global efforts to continuously invent and innovate at the material, device, transmission system, network, and manufacturing level.

1.4 Single-Fiber Capacity as the Key Metric for Cost-Effective Optical Transmission Systems

To examine the evolution of optical transmission systems and, ultimately, reconfigurable optical networks, over the decades since the initial deployments, it has been useful to track a parameter that provides some measure of the cost-effective value that optical systems offer. That figure of merit is the information capacity that can be sent over a single fiber.

As we have noted, the communication transport architecture depends heavily on aggregation and the network demand to transmit information over relatively long distances. Furthermore, there is significant cost advantage when the transmitted information can be reconditioned—either regenerated or simply amplified—at the aggregated rate rather than requiring demultiplexing and reconditioning multiple signals at the tributary rates. This is the case regardless of the multiplexing parameter, time, wavelength or, potentially, as we note later, space. As a result, from the very beginning of innovation on optical fiber transmission systems, researchers have focused on the device and system technologies and transmission techniques that have enabled ever-higher aggregated transmission capacity that can be carried over a single fiber. Essential for this metric to provide the important economic value is that the technologies to cost-effectively recondition at the aggregated rate are commercially available.

In Fig. 1.2, we show the *hero* research transmission experiment summary of the maximum information capacity carried on a single fiber versus the year those results were achieved [1.1, 2]. These extraordinary *hero* transmission systems experiment results became the highlight of the postdeadline sessions at international fiber optics conferences, including the Optical Fiber Conference (OFC), the European Conference on Optical Communications (ECOC), and the Asia Communications and Photonics Conference (ACP). Commercial results typically followed a number of years later. For the purposes of this chapter, it is convenient and informative to describe the progress in information distribution capacity over the years in generations or eras of fiber optic transmission and, ultimately network, capacity increases. Those generations include time-division multiplexed systems, wavelength-division multiplexing, which includes also the introduction of reconfigurable optical networks, and, most recently, very high speed WDM networks. Each generation has built on top of the capability of earlier generations. We use these roughly-defined eras to provide an overview of the advances and achievements in optical communications over the years. Importantly, we also note the set of critically important optical component or system technology innovations that enabled each era.

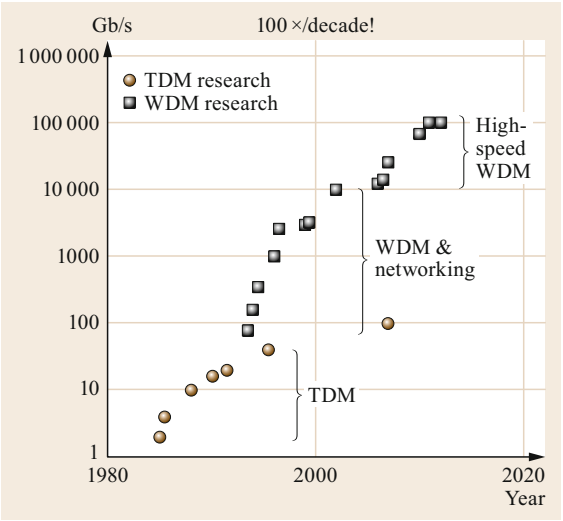

Fig. 1.2 Summary of trends of high-capacity *hero* transmission experimental results on a single fiber over recent decades

1.5 High-Speed Time-Division Multiplexing (TDM) Transmission Systems

Following the first field trials and initial deployment at rates of $\approx 50\,\mathrm{Mb/s}$, transmission capacity was increased by increasing the bit rate. The application was primarily long haul, where traffic from all users in a large city was aggregated together and sent over a fiber destined for other metropolitan areas. The basic service at that time was voice, which required only several kb/s, and demand was over local and regional distances. Aggregated rates on the long-haul fiber represented many aggregated voice sessions. Increase in capacity demands was still driven mostly by population growth, as well as some increase in new services such as fax. As capacity demand increased, given the broad bandwidth capability of fiber, new systems or upgrades of deployed systems could be achieved by increasing the speed of the transmitter and receiver and the regenerators. In the early days, the capacity increase per product generation was typically fourfold. That was

a number that had generally been large enough to handle demand for some time (typically ≈ 7 y) while not being overly demanding of the required advances in electronics. Of course, the economics demanded that cost of new systems scaled sublinearly with capacity, so that as systems moved to higher capacity to meet demand, the cost per bit was decreased.

Assuming higher bit-rate electronics (say $\times 4$) were available, or could be cost-effectively developed, as were the optical transmitter and photodetector, upgrading to a $\times 4$ transmission systems was more cost effective than building four-parallel transmission systems at the lower rate. The typical rule of thumb was that, once one paid for the cost of developing the next generation of electronics, a fourfold increase in transmission capacity could be achieved with only a roughly twofold increase in cost, resulting in a cost per bit that was reduced by a factor of 2.

The emergence and growth of multinational companies around the world put increased pressure on the transoceanic undersea-transmission facilities that had moved to optical fiber in 1988 on the TAT-8 undersea system. In addition, as computers began to become more common in business, the vision of data networks—computers talking to computers—began to suggest the need for an acceleration in network capacity. These new technology advances, together with growing global business opportunities, would dramatically change the global communication needs and, in turn, drive the demand for ever higher connection bandwidth.

After several generations of increasing the capacity by increasing the transmission bit rate, by the end of the 1980s commercial systems were operating at roughly 1 Gb/s. The first systems deployed were designed to be as simple as possible and to minimize the components. Information encoding was achieved by directly modulating the output power of the source laser by modulating the drive current. That function was accompanied with an undesirable wavelength *chirp* that resulted in optical pulse spreading (see below) if the transmissions fiber was dispersive at the transmission wavelength. To avoid that issue, especially at initial bit rates of less than ≈ 1 Gb/s, these early systems were dispersion limited and, thus, operated at fiber zero dispersion, 1.3 μm, wavelength.

To reach higher TDM rates required first and foremost the next generation high-speed electronics. In addition, for the same distance between electrical regeneration, both the signal strength relative to noise and quality of the detected signal with respect to interference are important. For the same fiber loss over a fiber optic link, the received electrical power scales as the inverse square of the signal bit rate. To help overcome the reduced receiver power at higher bit rates, researchers focused on systems operating at the lowest loss wavelength window around 1.55 μm. However, for the standard single-mode fiber deployed in the early 1990s, there was significant chromatic dispersion in the 1.55 μm window. This dispersion was problematic when using direct laser modulation where creating digital zeros and ones was by modulating the drive current of the semiconductor laser source to go from *low* output to *high* output. Unfortunately, to achieve a high *on/off* ratio, it was necessary to reduce the *off* drive current to the point where the laser was nearly turned off. As a result, in addition to the desired transition between a *zero* and *one*, there was also a small change in output wavelength. This wavelength *chirp* together with the chromatic dispersion at a wavelength of 1.55 μm resulted in pulse broadening, which limited transmission performance.

Three technology advances were instrumental to strongly mitigate these limitations and enable long-haul bit rates to go above roughly 1 Gb/s. (Fig. 1.3) First, to avoid chromatic dispersion, it was critical that the semiconductor laser operating at 1.5 μm be truly single frequency. Thus, laser structures, such as the distributed-feedback (DFB) laser that provided single longitudinal mode operation were critical.

Secondly, external optical modulators that provided optical information encoding without the *chirping* effects proved to be essential for data rates above several Gb/s. In particular, electro-optical modulators based on waveguide Mach–Zehnder (MZ) interferometers fabricated using titanium-diffused lithium niobate waveguides were shown to offer zero chirp and high on/off modulation with low insertion loss. With a traveling-wave electrode structure, such devices were shown early on to be capable of operating at ≈ 10 Gb/s with relatively low (3−5 V) drive voltage [1.5]. Hero systems experiments demonstrated that external modulators for information encoding became advantageous compared to direct laser modulation and, indeed, required for bit rates above about 4 Gb/s for long-haul applications [1.6]. Because of the ability to integrate multiple modulators, both amplitude and phase, this technology would also serve well the later generation systems' needs for advanced modulation formats, as we will see later.

Finally, optical detectors capable of operating at high bit rates and with reasonable optical to electrical conversion efficiency were also needed for high-speed TDM systems. High-gain, high-bandwidth avalanche photodiodes with separated absorption and gain regions SAG-APDs provided both [1.7]. The combination (Fig. 1.3) of single-frequency lasers operating at 1.5 μm externally modulated with waveguide modulators and detected with SAG APDs resulted in record transmis-

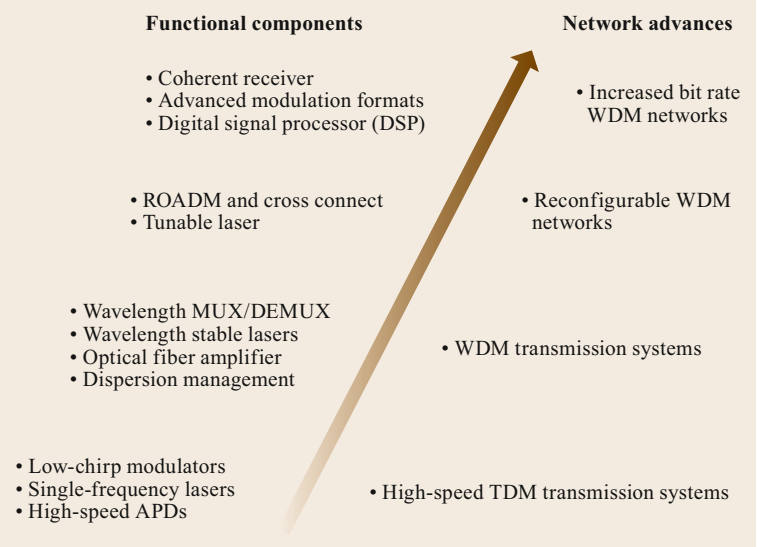

Fig. 1.3 Evolution of key underlying technologies that have enabled enhanced transmission systems and optical network functionality

sion experiments (2−16 Gb/s) in the late 1980s to early 1990s which led to commercially-deployed 10 Gb/s systems in the mid to late 1990s.

In TDM systems, leveraging improvements in the sources, receivers, and regenerators, the system's cost scaled roughly as the square root of the carried information capacity as long as the increased cost of these new higher-speed components (at volume) was not too high, and transmission impairments at the higher speed did not preclude the achievement of the fixed span distance between regenerator huts. So, starting with the first systems at 45 Mb/s to 2.5 Gb/s and 10 Gb/s, each generation at a higher bit rate substantially reduced the cost per bit of transmitted information. Thus, this, roughly, factor of 200 increase in capacity was achieved very cost-effectively.

In these TDM systems, electronics was still used to aggregate data to high data rates to take advantage of the bandwidth of fiber and TDM add/drop multiplexers, and cross connects continued to be done electronically. As we will see, that changed as the optical fiber amplifier and wavelength-division multiplexing were introduced, providing an additional layer of multiplexing and bandwidth management.

1.6 Wavelength-Division Multiplexed Transmission Systems

Increasing the TDM bit rate beyond a few Gb/s with the standard single-mode fiber that was, for the most part, the only fiber type commercially deployed in the mid 1990s, proved to be very challenging. To achieve the necessary loss budget with the laser launch power available or necessary to avoid fiber nonlinear effects, operation at 1.5 μm was essential. However, the high chromatic dispersion in standard single-mode fiber was challenging even with nonchirp external modulators. In addition, it became apparent that much of the deployed single-mode fiber displayed polarization mode dispersion that further impaired the transmitted signal. A potential solution to the first impairment was to use so-called dispersion-shifted fiber in which the zero-chromatic dispersion point is moved to the 1.5 μm window by choosing the appropriate material refractive indices and the fiber core dimensions. This approach was heavily researched and ultimately deployed for 10 Gb/s-TDM systems, especially in Japan.

The concept of wavelength-division multiplexed (WDM) transmission systems where multiple wavelengths, each separately encoded with information, are passively multiplexed together onto a single single-mode fiber, transmitted over some distance, then wavelength demultiplexed into separate channels whose information is detected and received, was well known from microwave transmission systems. While similar systems had been proposed for optical transmission systems in the early years, they had not gained popularity, partially because the necessary optical components were not available. More importantly, compared to increasing capacity via TDM, the approach did not scale capacity as cost-effectively as TDM, because signal regeneration required an array of electronics regenerators,

one for each wavelength rather than a single regenerator operating at the higher aggregated capacity. In addition, in such systems, a transmitter, a receiver, and a regenerator are needed for each wavelength on the fiber at each regenerator site. Thus, for electrically regenerated transmission systems, WDM did not offer a significant cost-effective capacity upgrade option.

That fundamental practical limitation to the use of WDM transmission systems changed dramatically with the demonstration and development of the erbium-doped fiber amplifier. While not a pulse regenerator, the optical amplifier provides a relatively low-noise 20–30 dB amplification, see, for example, [1.8]. From a system's value-add point of view, the optical amplifier offers the simultaneous amplification of multiple wavelengths, each carrying a high-capacity TDM signal. Importantly, there is no mixing of the information that is carried by the individual wavelengths. In addition, the fiber amplifier provides amplification for signals at essentially arbitrarily high bit rates for each wavelength. This is an enormously important and valuable feature of optical amplifiers that enables the upgrade of appropriately designed optical transmission systems to higher per wavelength bit rates without the need to replace amplifiers.

The earliest and most successful optical fiber amplifier is the erbium-doped amplifier in which the preform is doped with erbium prior to the fiber draw. When pumped with an intense laser source in the 0.98 or 1.48 μm region, the erbium-doped fiber amplifier provides optical gain over a, roughly, 40 nm-bandwidth centered around 1.55 μm, fortuitously well matched to the loss minima of single-mode transmission fiber. A gain of 20–30 db is achievable with reasonable pump power and is sufficient to compensate for loss of an ≈ 100 km span. Typical fiber amplifier length is 10–20 m. Amplifiers based upon Raman gain, which offer flexibility to control the center wavelength of the gain spectrum by tuning the pump laser, have also been deployed.

These gain characteristics combined with the other features above, make the optical amplifier an ideal amplifier for high-capacity WDM transmission systems. Long-haul transmission systems—including undersea ones that can greatly benefit from the ability to upgrade capacity by simply increasing the bit rate at the land-based transmitters and receivers—were the first natural application areas for this new multiplexing technology. Amplified WDM transmission systems, while still having competition from single-channel 10 Gb/s over the rather limited installed fiber plant that would support it, took off in the marketplace. It is important to note that from a market value point of view, it was not just increasing the network capacity that was important but the drastic reduction in the cost per bit of transmission capacity that this new WDM, fiber amplified technology made possible. It was not WDM alone, but rather the elimination of a number of single-channel electronic regenerators and transceivers with a single-multi-wavelength fiber amplifier enabled by WDM that provided a significant increase in cost-effective transmission capacity that made this new technology transformational for optical transport networks.

The other key enabling technologies for WDM transmission systems are the wavelength multiplexing and demultiplexing devices and single-frequency lasers that can be precisely set to a wavelength grid that allows matching source wavelengths to mux/demux devices wavelength response (Fig. 1.3). It is essential for these devices and for the entire value proposition of WDM to be viable that there was the agreement and standardization of the wavelength grid to ensure that devices from different vendors could be used by systems' vendors. A variety of technologies have been employed for wavelength multiplexers (mux) and demultiplexers (demux). Waveguide grating routers based on silica waveguide technology were typically employed for large wavelength applications. The 80-wavelength output from an early silica-based arrayed waveguide gratings router is shown in Fig. 1.4. Also important are the high-power (≈ 100 MW output power) semiconductor lasers to pump the optical fiber amplifier. Because fiber-amplified transmission systems are essentially analog systems, amplifier noise from each repeater builds up, as does dispersive and nonlinear pulse spreading. Therefore, low-noise amplifier operation and careful dispersion management are also important. Such considerations also make high-performance optical modulators that enable long-distance transmission especially important for signal encoding as one seeks to leverage the cost-effectiveness of the amplifier over longer distances without the need for costly electrically regenerators.

While the fiber-amplifier enabled the cost-effective deployment of WDM, there was another factor that drove lightwave systems to WDM. That was the performance of *standard* single-mode fiber that was in the field in the early 1990s. The deployed fiber had its minimum loss at 1.55 μm with the zero-dispersion wavelength of 1.32 μm. Prior to the WDM deployment, as work was focused on increasing fiber capacity by increasing the bit rate from 2.5 to 10 Gb/s, workers were hampered by deleterious pulse interference effects. Further study found that the limitations resulted from polarization mode dispersion—an effective mode refractive index that was polarization dependent. These results suggested that for such fibers—which represented a significant portion of the buried fiber—increasing TDM capacity beyond, roughly, 2.5 Gb/s

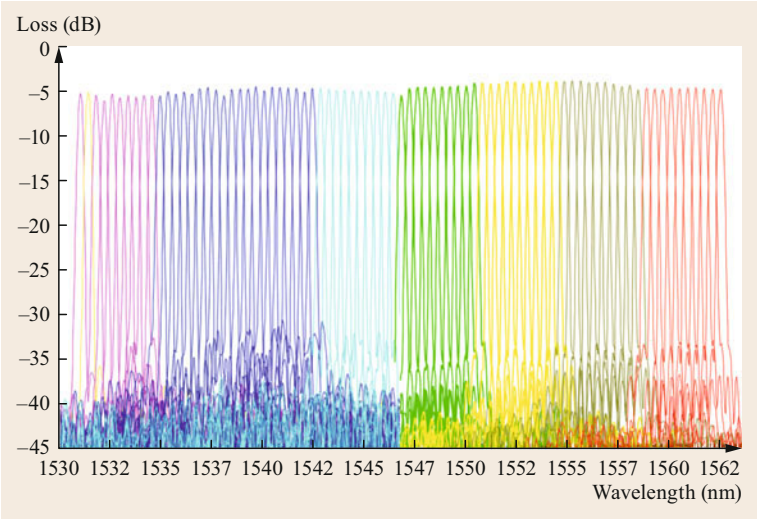

Fig. 1.4 Measured wavelength spectrum of a silica waveguide-based grating router 80-wavelength multiplexer/demultiplexer with 50 GHz channel spacing. Courtesy of Chris Doerr

over distances of typical regenerator spans would not be possible. Polarization dispersion limitations were not necessarily an issue for all embedded fiber at that time, and some single-channel 10 Gb/s-systems were deployed.

Another important enabler for WDM transmission systems was the nonzero dispersion shifted fiber [1.9]. For high-bit-rate systems, low chromatic dispersion is important to avoid the pulse spreading that results in interbit overlap and loss of information. However, in wavelength-division multiplexed systems a small amount of chromatic dispersion is useful. The nonlinearity of single-mode fiber is small but over distances of hundreds of kilometers typical of long-haul systems that four-wave mixing between wavelengths generate waves that spectrally overlap existing wavelength channels causing signal interference and degradation. A carefully designed small amount of chromatic dispersion can provide enough phase mismatch to effectively eliminate such deleterious effects.

Nonzero dispersion-shifted fiber can be designed as the transmission fiber, in which case the fiber is designed with sufficiently high dispersion in the 1.55 μm-wavelength region to minimize deleterious effects of four-wave mixing while ensuring that the dispersion is low enough to minimize pulse spreading for the planned per wavelength bit rate. Nonzero dispersion-shifted fibers can also be used as dispersion compensating fiber placed at the amplifier site to undo dispersion in the transmission fiber. In this case, the transmission fiber has sufficient dispersion over the transmission distance to avoid four-wave mixing, but the resulting pulse spreading is undone by the compensating fiber.

As alluded to earlier, undersea lightwave systems were an important driver and early adopter of fiber-amplified WDM transmission technology. An important issue for deployment of undersea TDM optical transmission systems was the length of time to develop and do reliability and accelerated aging for the new electronics and optoelectronics devices to be deployed in the submerged regenerator pods because of the high cost to replace undersea electronics should it fail prematurely. This requirement meant that every new generation of higher capacity required the higher-speed electronics needed to pass stringent reliability standards. With fiber-amplified WDM systems, there are no high-speed electronics under water, so issues associated with reliability testing required less lead time. The first such system—a transatlantic system—included 16 wavelengths at 2.5 Gb/s, each with repeater spacing of 100 km.

As multiplexing devices and amplifier performance were improved and techniques to mitigate dispersive and nonlinear transmission impairments developed, single/fiber transmission capacity results in research labs around the world improved—sometimes quite dramatically—every year. These extraordinary *hero* transmission-systems' experimental results became the highlight of postdeadline sessions at major optical conferences around the world (Fig. 1.2). Increased capacity in transmission systems' experimental results over the years (Fig. 1.2) were achieved by increasing the per-wavelength bit rate from 2.5 to 10 to 100 Gb/s and by increasing the number of wavelength channels. The latter was also achieved by adding additional gain bands. With respect to increasing the capacity on each wavelength, the issues that needed to be addressed included demonstrating the high-speed electronics, modulator, and receivers at the higher rates, mitigating fiber nonlinearities and managing dispersive effects. Increasing

the total single-fiber capacity by increasing the number of wavelengths was achieved either by enhancing the spectral efficiency, i.e., reducing the wavelength spacing, without reducing the information rate/wavelength or by increasing the spectral bandwidth of the amplifier.

The first WDM commercial systems, deployed in terrestrial long-haul applications in the mid-1990s, employed eight wavelengths at 2.5 Gb/s, a tenfold improvement over the single-channel systems previously available. The typical amplifier span distance was 50−100 km, and the maximum distance between regenerators was typically roughly 600 km—a distance that was limited more by network considerations than the maximum achievable distance before full regeneration was necessary. (That network consideration was that for distances longer than 600 km, typically some portion of the traffic needed to be dropped and traffic added for the route to be cost-effective. Prior to adoption of optical wavelength add/drops, as discussed below, that could only be done electronically, in which case it made sense to do full electrical regeneration.) As multiplexing devices and amplifier performance were improved, the number of wavelengths was soon doubled and then quadrupled. In research labs, work focused on WDM transmission at higher TDM rates—10 Gb/s and 40 Gb/s. In addition, wavelength mux/demux technology was improved, so that by the early 2000s commercial amplified WDM systems with 160 wavelengths at rates of 10 Gb/s per wavelength for 1.6 Tb/s total capacity were being deployed. These systems also operated over a distance of about 600 km, again limited mostly by network connectivity constraints, as noted. Tunable lasers have also become essential for cost-effective WDM systems [1.10, 11]. Having a single laser that can be tuned to any of the wavelengths carried by a given system drastically reduces the cost of excess inventory of lasers needed both for the system's vendors during deployment and also for network carriers for replacement or for adding wavelengths. The latter became even more important as reconfigurable networks evolved, as we will see below.

1.7 Bandwidth Management at the Optical Layer Via Optical Add/Drops and Cross Connects

The adoption of wavelength-division multiplexed transmission enabled by multiwavelength optical amplifiers has, in line with our earlier discussion of the general features of transport networks, rather naturally led to wavelength-based reconfigurable optical networks that provide high-level, cost-effective network bandwidth management, including restoration after fiber cuts or equipment failures. The roadmap of that evolution is shown schematically in Fig. 1.5 [1.2].

These optical layer networks, as noted earlier, are the optical wavelength-based equivalent to the time slot-based electrical TDM networks. However, this is a higher layer transport network whose networking granularity is a wavelength channel with its rate dictated by the TDM channel it is carrying. For a given wavelength, TDM networks continued to be used to provide bandwidth management at a lower total capacity and at finer bandwidth granularity via TDM add/drops and cross-connects.

Initially, WDM was employed over linear transmissions links where all wavelengths were aggregated onto the fiber at one node and carried with periodic amplification to an end node, where all wavelength channels were terminated (Fig. 1.5a). At those nodes, typically signals on a wavelength would be received and converted to electrical signals demultiplexed into lower TDM tributaries, some of which were dropped locally; others might be cross connected to other routes via TDM cross connects. In the mid to late 1990s, on average the longest distance over which the long-haul transmission went before it passed a major node at which traffic needed to be dropped or added was about 600 km. Amplified WDM systems that leveraged the value of the amplifier could carry signals to longer distances without regeneration but without the ability to get traffic on and off the line; it was not cost-effective to do so. Optical wavelength-add/drop multiplexers (Fig. 1.5b) provide those high-capacity on/off ramps with a full wavelength of capacity and allow all other wavelengths to pass through the node, benefiting from the amplification of the optical amplifier but not requiring it for each by-passed wavelength. This ability to optically add and drop selected wavelengths and at the same time allow the *pass-through* wavelengths to leverage the amplifier and not require a regenerator for each wavelength provides the ability to reduce opto-electronic regenerators while meeting the connectivity requirements of the network nodes. The result is the elimination of regenerators and extension of the basic value proposition of the amplifier to a multinode linear network rather than to a single node-to-node link.

Initially, to minimize capital costs, these add/drops were fixed in the sense that the number and actual wavelengths that could be added or dropped was set at

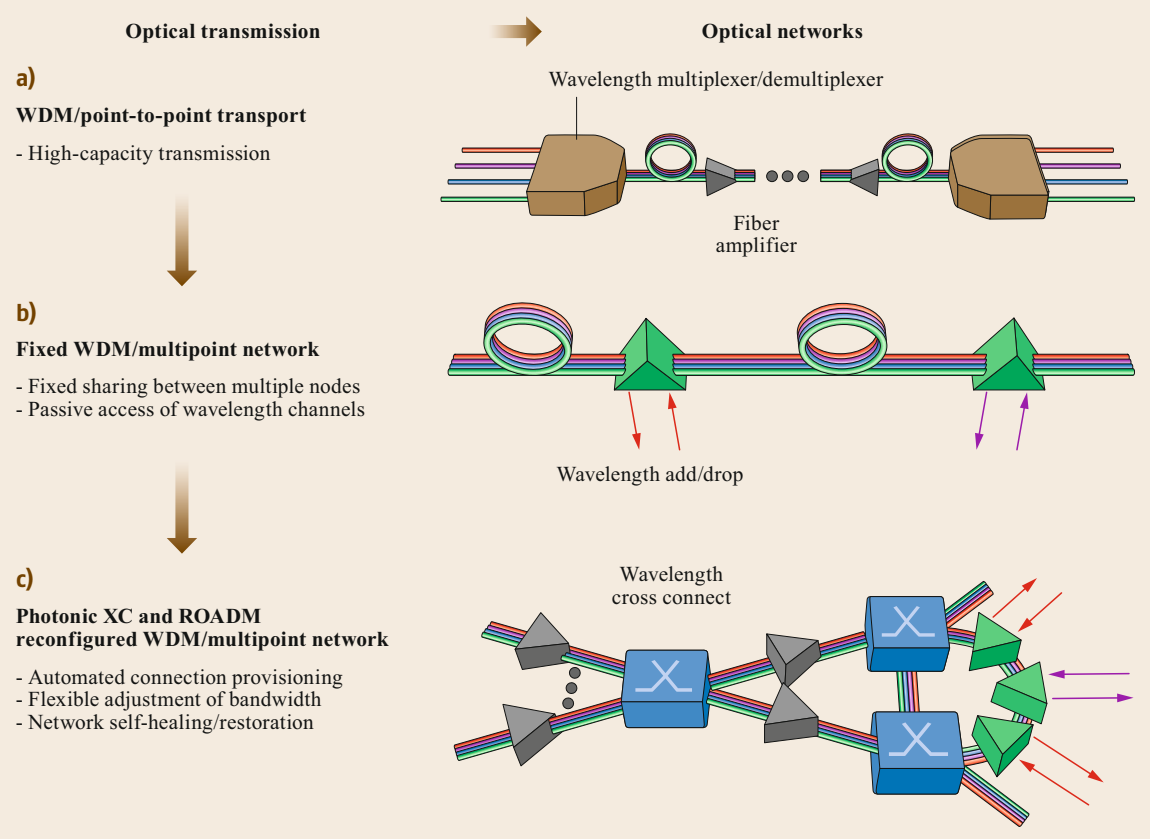

Fig. 1.5a–c Evolution path from WDM transmission systems to fully reconfigurable wavelength-routed optical networks that employ ROADMs and optical cross connects

deployment. Typically, the number of possible added or dropped channels is only a fraction of the total number of wavelengths on the fiber, enough to serve the traffic demands of that node. However, capacity requirements change, and service providers want the ability to change the configuration. Therefore, even though most of the add/drop multiplexers were initially fixed to contain cost, the direction toward reconfigurable optical add/drop multiplexers, referred to as ROADMs (reconfigurable wavelength add/drop multiplexers) was clear (Fig. 1.5c). As technology has improved and costs been reduced, ROADMs with their flexibility for remote reconfigurability have become central to commercially deployed networks. In mesh networks at nodes where two or more routes enter and exit (Fig. 1.5c) reconfigurable cross connects provide the ability to add/drop wavelengths of capacity for each route in each direction and also provide the ability to directly cross connect wavelengths between routes.

The vision of reconfigurable optical layer networks did not come out of a vacuum. Prior to the amplifier and commercial introduction of WDM transmission systems there was considerable research activity to explore reconfigurable optical networks, but mostly for LAN and local-access applications. Optical 2×2 space-division switches and switch arrays using integrated optics techniques, especially using titanium-diffused lithium niobate waveguide technology, were demonstrated with both time-multiplexed switching and transport network cross-connect applications as potential drivers [1.12]. Tunable wavelength-selective 2×2 waveguide switches that demonstrated the ROADM function were also demonstrated [1.13, 14]. So, innovating and applying optical switching technologies to achieve reconfigurable optical networks were explored. However, without deployed or planned networks whose multiplexing to aggregate bandwidth was based upon an optical parameter, all that work was a solution looking for a problem.

The emergence of the optical amplifier and the commercial deployment of WDM transmission systems dramatically changed that picture. The multiplexing parameter by definition becomes the parameter around which network bandwidth management is achieved via

add/drop and cross connection. In addition, the availability of highly efficient, high-gain optical amplification provides loss compensation for both the transmission losses, as well as the inevitable loss in the optical switching elements.

WDM transmission systems and the emerging optical networking vision came at a time (mid to late 1990s) when globalization and computer networks were driving predictions of high network capacity demand and reach. It was also a time of intense venture investment. The WDM optical networking vision gained the support of funding agencies and companies in Europe, the United States, and Japan. Several generations of optical cross connects and WDM network projects were funded by the European Framework Programs that fostered cooperation between universities and corporations. Japan initially chose the strategy to higher bit rates and deployed dispersion-shifted fiber to mitigate signal distortion issues at bit rates beyond 2.5 Gb/s. Nevertheless, there was considerable interest in WDM-network research in Japan as well. In the US, DARPA (Defense Advanced Research Project Agency) funded several generations of WDM and optical switching programs, including both local-area network and switched-network programs even before it was clear that WDM transmission would break into commercial deployment, see, for example [1.15]. While a couple of simple metrics—total bandwidth per fiber and distance without requiring regeneration—define transmission systems' performance, networks are more complicated. To help understand the initial challenges and hurdles that needed to be overcome to pave the way for commercial networks, below we describe the DARPA-funded MONET (multiple wavelength optical network) project that was an early research, prototyping, and field trial example of a reconfigurable WDM transport network.

DARPA, through its ARPANET (Defense Advanced Research Project Agency Network) programs had been a strong champion of packet-based data networks that gave them a vision of the importance and requirements for future data networks. Aware of the growing future needs for defense, they understood the communication bandwidth that would be needed to support communications, as national security networks increasingly moved from person-to-person to machine-to-machine connections. They were especially interested in a network model that would meet demanding government needs and grow cost-effectively. There was experience at the time with so-called *dual-use-networks* using TDM technology. The idea was for commercial service providers to build and operate a network that could have secure, separate subnetworks for government and normal commercial traffic. Included in this model was the view that under unusual circumstances of heavy demand, the partitioning of the network could be reconfigured to give priority capacity where needed by government offices. In the case of a WDM network that suggested full wavelengths, literally *virtual fibers*, that could be used for the subnetworks.

A consortium that included United States service providers—AT&T, Bell Atlantic (now Verizon), Bell South (now AT&T) and Southwest Bell (now AT&T), and Bellcore, the regional service providers research arm—was one of the awardees of the DARPA call to drive the vision outlined above. The consortium's program was called the multiple wavelength optical network (MONET). AT&T was also the parent of the AT&T Network Solutions business, which built optical infrastructure (including, shortly after the call, one of the first WDM transmission systems) and Bell Labs, the research arm. On the government side, in addition to DARPA, there was strong partnering and close field trial collaborations with NSA, NRL, DISA, and others. The overall goal, through test beds and field trials, was to demonstrate the technical feasibility of national and metro reconfigurable WDM networks with prototype network elements—ROADM and optical cross connects—that could be prototyped with the research-grade components that were available at the time [1.16].

MONET was vertically integrated. The program included research, network architecture design, and the necessary prototyping of ROADMs and reconfigurable optical cross connects and network elements. Both metropolitan and long-haul networks were built and ultimately connected via the cross connect test bed in a metro to long haul to metro (actually the same metro) end-to-end network. The network management system controlled the network elements to provide the desired end-to-end configuration. Bellcore's metro network and the long-haul and optical cross connect test beds of AT&T, including Bell Labs, were connected by fiber to demonstrate end-to-end networking [1.17]. Later, over commercially laid (Bell Atlantic) fiber connections, several US government agencies in the Washington DC area, a successful field trial of a reconfigurable optical network that included both ROADMs and a reconfigurable [1.18] optical cross connects was achieved.

The work included careful consideration of network operations and management that resulted in device requirements previously not recognized as important. As an example, in a discussion between device researchers and carrier network operators, the question was raised about how the amplifier gain characteristics might change in time as several input wavelength channels were suddenly dropped out of the input stream. Research identified the time-dependent gain changes to the pass-through wavelengths when the number of wavelengths input to the amplifiers changed rapidly.

Research further showed that these gain transients were unacceptable, and mitigation techniques to circumvent them had to be developed [1.18].

As noted above, the MONET network element prototyping was done with available lab prototype optical component technologies. Liquid crystal technology was used as the active optical switching element in the metro ROADM. For the wavelength cross connect and larger ROADMs, a wavelength demux/mux combined with a layer of space-division switches for each wavelength was selected. Lithium niobate-integrated optic switch matrices were employed as the space switches [1.12]. Some research was also performed on new component technologies that offered greater promise for the future. As an example, MONET researchers demonstrated one of the first multiwavelength receivers on a chip [1.18].

The program, which gave strong support for the potential value and practical feasibility of reconfigurable, wavelength-routed networks was completed in the end of the 1990s, just as globalization and the Internet were driving increased focus on ever-higher capacity demands for national and international networks,

It is important to emphasize that several conditions do need to be met for the use of add/drop multiplexers to be preferred to full demultiplexers at each network node. To be cost-effective, a significant fraction of network node pairs should have capacity demands that require or will soon require a full channel (wavelength) at the maximum supported TDM. Adequate transmission reach to ensure that the information-bearing wavelengths launched at one end of the network can be transmitted across the network without unacceptable noise or distortion is also necessary. Even though they carry digitally-encoded information, the transmission links of optical networks with optical amplifiers for gain and transmission-induced distortions are inherently analog-like systems. Consequently, optical signal-encoding technologies that are least susceptible to transmission impairments are essential to achieve increased reach and the economic benefit that results because of eliminating costly regenerators. In the early days of optical transmission, that really meant no chirp in the modulated signal—something that could be achieved with external electro-optic modulators but not with directly-modulated lasers. The evolution to optical networks with their ability to get traffic on and off the network optically meant that reach well beyond 600 km could also bring value by reducing electronic regenerators while meeting the network-access and connectivity requirements. That drove the demand for even longer optical layer reach. Today's optical networks span the nation, providing optical wavelength connectivity between major cities without requiring electronic regeneration in the transmission path. This ability of externally modulated signals to travel over long distances with limited transmission-induced distortion is valuable to cost-effective optical networks. It has assured an important place in the marketplace for optical modulators. That trend has held up even today as at modulation rates of 100 and 400 Gb/s advance modulations schemes that use both amplitude and phase modulation in nested configuration are required. These critically-important modulation techniques can only be achieved with electro-optic modulators.

Relatively low-cost ROADMs are also important to make the *optical bypass* value proposition complete. Roughly, the cost of ROADM plus the high-gain amplifier should to be less than that of a simple multiplexer/demultiplexer pair plus the cost of the N electrical regenerators and N transceivers, where N is the total number of wavelengths on the line. It is important not to forget that at the system level as one tries to extend the optical bypass value proposition by extending the reach of the network there is also potential additional transmission cost to enable optical signals to travel over the extended length without unacceptable noise accumulation and signal distortion. This becomes particularly important at elevated TDM rates. Some optical line-conditioning elements, such as dispersion-compensating fiber, e.g., maybe required. Such cost, normalized by the number of nodes (add/drop sites), should really be added to the add/drop multiplexer plus amplifier cost when doing the comparison with full regeneration cost.

Given the above caveats, it is reasonable that if the amplified WDM-transmission system wins over a regenerated system for intracity systems separated by several hundred miles, then, if achievable from a transmission reach point of view, a linear WDM network extending over several thousand miles, with wavelength add/drop to allow on and off traffic at cities along the route, will also provide a good business case, perhaps an even better one. This is the amplified WDM value proposition extended to the linear multinode network enabled by a reconfigurable wavelength add/drop multiplexer (ROADM) switch.

With the understanding and appreciation of the value of ROADMs in a linear network, including a ring, one can see that a similar value proposition applies to mesh-based architectures (Fig. 1.5c) where any node can be connected directly to several other nodes. It is important to keep in mind that optical cross connects provide both wavelength-based route switching, as well as the local wavelength add/drop. As an example, consider a national network with a node (medium to large city) that serves as a hub with connections to other cities via a north/south route and an east/west route going through it. At this hub, there may be traffic terminating at the node from both the north/south traffic and from the east/

west traffic. There is also *pass-through* traffic that maybe passing through on the same route or passing through from one route to another (switching routes). Given the multitude of possible pathways, this is a much more complex switching function than a ROADM. Nevertheless, the optical cross connect that includes local wavelength add/drop that provide this function achieves value in the same way as the ROADM—eliminating costly regenerators at branching points in the network. It also offers the direct value of switching a wavelength between routes. If there were no optical switching layer, and in the absence of line rate electrical cross connects (the case in the early days of 2.5 and 10 Gb/s and today at 100 Gb/s), the signals on wavelengths that needed to be switched to a different route would have to first be detected and demultiplexed down to an electrical TDM rate for which digital cross connect fabrics are available.

The enabling technologies for ROADMs and cross connects (Fig. 1.3) are electrically-controlled optical switches, either broadband space switches together with a wavelength multiplexer/demultiplexer component or a single-module wavelength-selective switch (WSS). Integrated wavelength-selective switch modules that include an internal grating-based free-space wavelength to position mapping onto an array of electrically-controlled variable angle-deflecting elements provide a modularized $1 \times N$ WSS that is a compact building block for both ROADMS and for full optical cross connects, see, for example, [1.19, 20]. The N output fibers in this case can include multiple wavelengths on bypass fibers that represent the different network routes. In a simple ROADM on a ring topology, there would be only one of these, whereas for cross connects there may be several, reflecting the different output routes. The other output fibers from this module would typically be single-wavelength client-side drop (add) ports. A variety of technologies have been used for optical switch fabrics, including micromechanical adjustable angle mirrors (MEMs) on silicon, liquid crystal on silicon (LCOS), and electro-optical or thermo-optical waveguide space switches, see, for example, [1.19, 20].

Commercial wavelength-reconfigurable optical networks have been widely deployed. Initially, these networks were deployed in national networks, but with the dramatic growth in transport bandwidth needs driven by video and broadband wireless, reconfigurable optical networks are now massively deployed in metropolitan applications as well.

There have been significant advances in both the architecture and the component technologies of both ROADMs and cross-connect systems since the initial deployments. With the high-performance $1 \times N$ wavelength-selective switch (WSS) components described above, the add/drop architecture becomes one in which only the added or dropped wavelengths are simultaneously mux/demuxed and switched to the desired output port. All the other wavelengths remain on the output fiber. This provides a significant component count and cost reduction, especially for the case where the percentage of the channels added or dropped at any given node is small. It also provides a powerful component for the creative design of optical cross connects for applications in network nodes where a limited number of routes intersect.

Overall, the design considerations and tradeoffs for ROADMs and cross connects are very similar to those of their electronic predecessors. At the highest level, there is a tradeoff between operation flexibility versus complexity, size, and cost. In general, the complexity, and thus the cost, of wavelength add/drop modules increases with the number of wavelengths on the transmission fiber, the fraction of wavelengths that can be added/dropped, and the fraction of wavelengths from which one can chose to add/drop. While systems are designed with node-to-node connection capacity requirements in mind, the ability to accommodate unpredicted capacity needs is inevitable. Network operators need to balance that potential need against the initial increased cost to provide it.

As with electronic add/drops and cross connects, operators want operational ease and flexibility with ROADMs and optical cross connects. That has driven the requirement that it should not be necessary, as it was in first-generation optical add/drop multiplexers, to require the assignment of any particular spatial slot on add/drop frame to be used only for a specific transmitted wavelength. That is, there should be complete freedom to insert a transmitter line card of any wavelength into any available line-card slot. ROADMs that provide this capability are referred to as colorless ROADMs. To provide this flexibility and ease of use generally requires additional optical-switch fabric with its additional cost. Once the line card has been inserted, internal software controls this optical-switch fabric to achieve the desired connectivity.

A simple way to think about this is the example of a simple $M \times 1$ passive wavelength multiplexer, for example a waveguide-grating router, that multiplexes M different colors onto a fiber. To operate effectively the right color has to be launched into a particular input port on that multiplexer. Alternatively, if in front of the M input lines to that mux you have an $M \times M$ switch (or, perhaps, M $1 \times M$ switches), you could insert any of the M colors into the switch at any port and under switch control get it to the right port on the mux to work.

Similar operational advantages exist for placing no restrictions on line-card placement based upon the ultimate route direction or any internal blocking or

contention. Therefore, there has been considerable research and development over recent years to design and manufacture cost-effective colorless, directionless and contentionless optical ROADMs. These so-called CDC ROADMs offer flexibility and simplify operations in ways that carriers have come to expect based upon their experience with TDM (SONET) add/drop multiplexers (ADM). While they provide substantial operational flexibility, these CDC ROADMS do require substantial increase and complexity of the optical switch fabric. To achieve this capability cost-effectively will require continued innovation in ROADM architecture and WSS technology.

Another feature available in electrical digital add/drop multiplexers is the ability to do bandwidth defragmentation as well as bandwidth concatenation. Several approaches to implement this function in ROADM have been proposed, including the use of time-slotted WDM and add/drop elements that have adjustable bandwidth per wavelength. The latter enable wavelength channels to be dynamically allocated only the bandwidth needed for the bit rates to be carried. This would provide more efficient utilization of the bandwidth in networks for which the bandwidth demands between node pairs differs across the network, which, as noted above, is typically the case [1.2].

Overall, the value that reconfigurable WDM networks bring in the marketplace can be summarized [1.2]:

- They provide high-level (wavelength) bandwidth management at relatively low cost, power, and space requirements.
- They provide traffic on/off ramps to satisfy network connection demands while extending the value of the multiwavelength amplification via optical bypass of the pass-through wavelengths.
- They reduce network costs and power by eliminating O-E-O conversion and electrical regeneration.
- They offer the opportunity to simplify and reduce the costs of capacity upgrades.

The second point suggests that the cumulative benefit increases with network reach. That is moderated at some point, as the extra cost to increase the reach is greater than the O-E-O reduction savings. An example of the fourth point above is that a reconfigurable WDM network designed for 10 and 40 Gb/s and with reserve gain in the amplifier could be upgraded to 100 Gb/s by simply adding long-reach 100 Gb/s transmitters and receivers, and providing additional power to the optical amplifier suggests significant potential value for network operators [1.21]. This is especially the case for undersea optical networks. This capability is a natural and fortuitous consequence of the ability of the fiber amplifier to amplify arbitrarily high bit channels carried by the wavelengths. In addition, the performance of the optical switching elements used for add/drop and cross connects are, of course, independent of bit rate.

As was noted earlier, in general for optical networks, it is necessary that a significant number of the network node pairs have a capacity demand between them equal to or exceeding the information bandwidth to be carried by a wavelength. It is also important to map TDM channels into wavelength expeditiously. If either of these is not the case, insufficient wavelengths will not be fully packed when they depart a node and will have to be dropped and groomed electronically with additional traffic destined to the same endpoint to effectively utilize the bandwidth of the transmission links. In this situation, few wavelengths will effectively benefit from optical bypass, and the fundamental value proposition of optical networks is lost.

At the time of this writing, the commercial reconfigurable optical networks available and deployed for national and metro applications have capacities of ≈ 10 Tb/s (100–160 wavelengths at 100 Gb/s) with fully reconfigurable wavelength add/drop capability. Transoceanic commercial systems, which include undersea ROADMs, are operating at capacities of ≈ 4 Tb/s. Increasingly, the ROADMs in these networks provide some CDC capability.

1.8 Driving Ultrahigh-Speed WDM and Beyond

The ubiquitous deployment of broadband wireless systems together with massive sharing of consumer-produced video and the growing demand to access *cloud*-based computational services continues to drive bandwidth demand. The next generation of wireless, 5G, networks will drive the capacity demands on optical networks even further. There is every indication that demand will continue to grow $\approx 100\times$ over the next 10 years. Given the state of current commercial systems this suggests the need for 1 Pb/s per-fiber systems in the not-too-distant future.

As the practical implementation of wavelength networking was being pursued during this period, the quest to increase the capacity per wavelength also continued. The next goal beyond 40 Gb/s eventually became 100 Gb/s. The issues that needed to be ad-

dressed the implied 2.5 ×-increase in the bit rate were similar to those for earlier generations of TDM—higher-speed modulators, photodetectors, and, most importantly, electronics to operate at 100 Gb/s. As has happened repeatedly over the decades of evolution of optical systems, researchers addressed those issue directly but also looked to alternative approaches that would not require the 2.5 × increased electronics speed.

To achieve higher effective per-wavelength channel capacity beyond the 10 and 40 Gb/s level, while limiting the bit-rate requirement, research focused on advanced modulation techniques that depend upon encoding information on both amplitude and phase information as offered by coherent detection techniques. In addition, polarization multiplexing to double the per-wavelength capacity without increasing the bit rate has always been viewed as a potential option, but its implementation using direct-detection techniques had been problematic. Coherent detection techniques were explored extensively in the late 1980s and 1990s, especially as a means to achieve higher receiver sensitivity than what was achievable with direct detection. That advantage became much less important with the advent of the fiber amplifier. Coherent detection also requires mixing with a local oscillator that must be frequency and phase-locked to the received signal wavelength. The linewidth of early lasers made that impractical. Today, using lasers with reduced linewidth (≈ 1 GHz), advanced modulation formats, polarization multiplexing, and high-performance digital signal to processors (DSPs) to facilitate frequency-locking transmission systems with an effective information capacity of 100 Gb/s are achievable with electronic speeds of 25 Gb/s or less. The higher-order modulation formats require nested circuits of waveguide Mach–Zehnder modulators (MZM) and phase modulators to provide both amplitude and differential phase modulation. An added benefit of this approach is that the DSP can also be used to mitigate deleterious chromatic and polarization dispersion effects (Fig. 1.3). This solution to achieve 100 Gb/s per wavelength has been massively deployed in both national and metro WDM networks [1.1].

Research efforts continue to focus on both increasing the number of wavelengths and the bit rate per wavelength. Commercially, the next targeted bit rate is likely to be 400 Gb/s, potentially followed by 1 Tb/s. To achieve these higher speeds requires continued advancement in high-speed electronics, photodetectors, and modulators. It also requires the ability to launch higher optical power into the fiber without causing nonlinear effects. This is an area where new fibers maybe beneficial. The number of wavelength channels is limited by the required bandwidth per channel and the total transmission bandwidth, which is limited by the amplifier bandwidth. The goal is to optimize spectral efficiency. To leverage the value of optical amplifiers and to avoid electrical regeneration, the ability to achieve long-distance transmission is also important.

These modulation formats, including quadrature phase-shifted keying (QPSK) and quadrature amplitude modulation (QAM) require the use of high-speed digital signal processors to convert the input signal information to the coded amplitude and phase modulation signals to drive complex nested amplitude and phase optical modulators to encode the optical signal. As an example, with polarization multiplexing and 64-QAM (64 symbols per bit) one can transmit at an effective rate of 320 Gb/s with electronics, modulator and receiver operating at only 80 Gbaud/s [1.1]. Unfortunately, the benefits come with transmission tradeoffs, as well as the complexity, power requirements, and cost of high-speed digital signal processors.

1.9 Space-Division Multiplexing: The Next Era of Optical Networking

As has been a common theme throughout the evolution of optical networks, there is growing concern that to keep up with bandwidth demand another major technological leap—an additional dimension of multiplexing—will be needed. Arguably, the only remaining dimension is space. There has been keen interest and growing activity in using space division as implemented either via multiple cores in a fiber or multimodes of a single-core fiber (Fig. 1.6), see, for example, [1.22]. As we learned with WDM, for space-division multiplexed (SDM) transmission systems to be cost effective compared to simply building parallel fiber optic systems of the current type, it likely will be essential to also demonstrate optical amplifiers that provide uniform gain simultaneously for all spatial modes of a single-core fiber or multicore transmission medium. There has been extensive activity over the past nearly 10 years to demonstrate suitable multicore or multimode fibers, means to selectively couple into the spatial modes, as well as suitable optical amplifiers. As an example of recent research progress in this area, a 10 Pb/s SDM/WDM transmission demonstration over limited distance (11 km) was achieved using a 6-mode 19-core fiber and a C_L band optical amplifier [1.23].

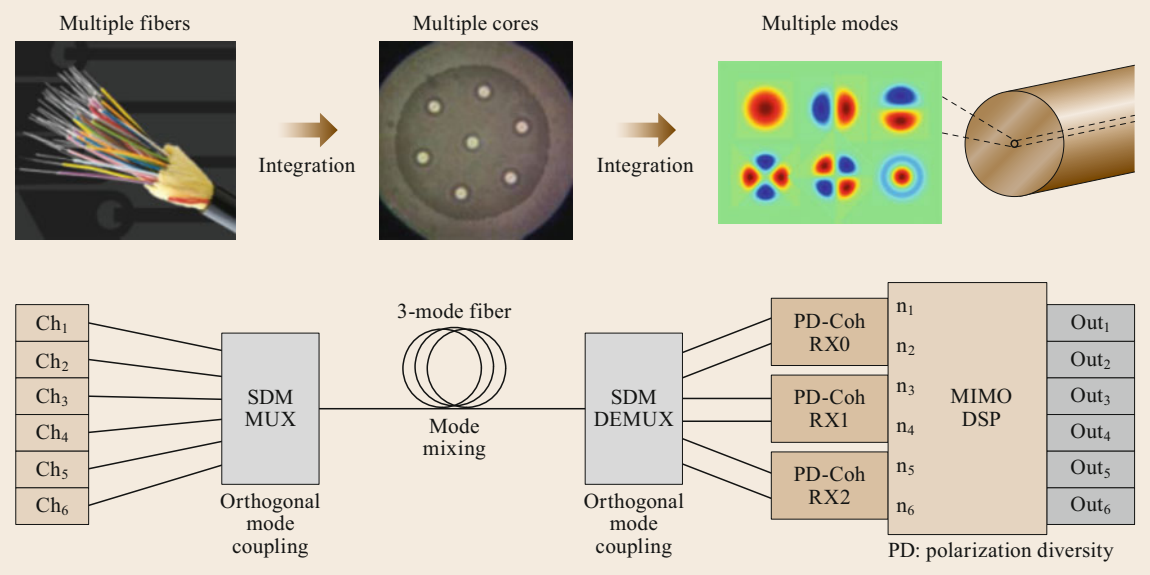

Fig. 1.6 Optical space-division multiplexed transmission. Adapted from [1.22], © 2012 IEEE

As we saw in the case of WDM, in addition to a cost-effective multiwavelength, multispatial mode amplifier, to reap the full benefit of a reconfigurable network to manage bandwidth at the optical wavelength and spatial modes layer, components and modules that would allow reconfigurable add/drops and cross connection with respect to spatial modes, as well as wavelength, would also be required. Ultimately, one would like these to work in a hierarchical manner with channels defined by both wavelength and spatial mode to achieve the best granularity of bandwidth management. It is also useful to note that the spatial modes of a multimode fiber may have some level of coupling over typical transmission distances. While these coupling effects can be mitigated with MIMO-like electronic processing, see for example [1.24], any need to do so would require demultiplexing other spatial modes and would result in a reduced ability to reap the full benefit of optical by-pass. While work remains to explore and demonstrate these additional add/drop and cross-connect functions and to demonstrate the practical, cost-effective value of SDM for flexible optical networks, given the continuing growth in bandwidth demand, the potential for a factor of 10 or more in network bandwidth offers strong potential for opening the next era of optical communications [1.4].

1.10 Optical Networking Applications Beyond Global Transport Networks

We have focused here on the role of optics in long-haul and metro transport networks because to date they have had the largest deployment and have clearly demonstrated the value of not only optical transmission but also reconfigurable networks for cost-effective, very high capacity networks. As discussed elsewhere in this book, there is growing application of optics in residential and small business access, wireless backhaul, and last mile to residential consumers. In addition, much of the cable distribution network up to the last link to the home is already fiber-based, and fiber-to-the-home continues to grow. Researchers are tapping into the massive deployment of LEDs for lighting in homes and businesses as a platform for optical-based LANS, so-called *LI-Fi*, which leverage the ability of the light output of LEDs to be modulated at relatively low speeds.

However, perhaps the biggest opportunity for optics to show its value for high-capacity interconnectivity is in the rapidly growing number of data centers around the US and the world, which increasingly provide the computing power that underpins the e-services that consumers, companies, and governments depend upon in their daily lives. Of course, these data centers are only viable because of the *cloud* provided by the global transport networks described above and the data network that runs over it. These data centers are home

to literally hundreds of thousands of servers that need to be interconnected where the total internal information capacity flow is substantially larger than that coming in or going out of the data center. Low-cost optical transmitters and receivers will be essential to provide the required massive low-power connectivity. Given the limited distances, the role of optical amplifiers and WDM needs to be more fully demonstrated. Once that has been established, the value of reconfiguring optical interconnectivity, even if initially only relatively infrequently, as is the case for the optical cross connect in transport networks. Time-slotted interconnection leveraging high-speed optical switching is also being explored to rapidly set up and take down high-capacity interconnections pipes, see, for example, [1.2].

Rod C. Alferness is the Richard A. Auhll Professor and Dean of the College of Engineering at the University of California, Santa Barbara. He received his BS in Physics and Math (1968) from Hamline University and his MS and PhD in Physics from the University of Michigan. He has authored over 100 papers and 5 book chapters and holds over 30 issued patents. He has given numerous plenary and invited lectures.

Optical Su

Part A

Part A Optical Subsystems for Transmission and Switching

Ed. by Peter J. Winzer

The Internet, with its myriad of applications and services that fuel today's communication and information society, is used on an everyday basis by more than half of the world's population, and this number continues to grow. Despite its deep penetration, few people are aware that *fiber-optic networks* are at the heart of the Internet. In fact, without its utilization of highly cost-efficient and energy-efficient fiber-optic transmission and switching technologies, the Internet would not have been able to grow the way it has to become a ubiquitous and universally accessible resource serving the global population. For instance, global optical fiber deployments have exceeded 4 billion km, meaning that the resulting fibers could be wrapped around the globe approximately 100 000 times. Using infrared light, more than three exabits (one exabit $= 10^{18}$, bits) of traffic are transported per second through these fibers between users, datacenters, machines, and (increasingly) things. Essentially every bit of information that is transmitted beyond the confines of a home or enterprise, and virtually every phone call (whether placed from a fixed or wireless telephone), spends part of its life as a photon in an optical fiber. How would global societies have evolved without this amazing fiber-optic infrastructure?

Chapter 2 of this Handbook examines the evolution of optical fibers, from Charles Kao's prediction of low-loss optical fiber in 1966—for which he was awarded the 2009 Nobel Prize in Physics—to the state-of-the-art commercial telecommunications fibers that are widely deployed today. The chapter presents key performance characteristics of optical fibers in a communication systems context and discusses the outlook for fiber technologies that are currently being explored within the fiber-optic research community, such as photonic bandgap fibers, multicore fibers, and few-mode fibers. The chapter also covers optical fiber cabling technologies and deployment-related aspects, thus providing a comprehensive account of this key medium for information transmission.

Despite the low loss afforded by modern optical fibers, the maximum achievable transmission distance between two fiber-optic transponders remains loss limited to about 100 km. Since an optical fiber supports the simultaneous transmission of up to a few hundred signals at slightly different wavelengths (wavelength-division multiplexing, WDM), up to a few hundred optical transponders would be needed every 100 km were it not for optical amplification techniques. These permit the simultaneous low-noise amplification of all wavelength signal channels by a single, highly efficient amplification device inserted into the link about every 100 km, enabling transcontinental transmission distances of several thousand km and even transoceanic links exceeding 10 000 km. Chapter 3 focuses on the two most commercially important optical amplification technologies: the erbium-doped fiber amplifier (EDFA) and Raman amplification. A brief overview of other amplification techniques, such as semiconductor optical amplifiers and parametric amplification, is also presented.

In order to actually transmit optical signals, transponders are needed to encode light waves with digital information through modulation. In its simplest form, modulation is accomplished by switching the light on and off, but modern optical transponders also use the optical phase and polarization of the light wave to convey information more efficiently, allowing WDM systems to reach about a hundred terabits per second (one terabit $= 10^{12}$ bits) over a single conventional optical fiber. Chapter 4 discusses various transponder technologies, ranging from short-reach client interfaces that connect servers to nearby Internet routers (for example) to long-haul line interfaces that are able to send signals across the Pacific.

The key components of an optical transponder are reviewed in Chapter 5, including lasers, optical modulators of various kinds, and photodetectors to convert received optical signals back into electrical signals. The chapter also shows how those components are assembled into transponder subsystems to enable the modulation performance addressed in Chapter 4. Typical component and subsystem characteristics are discussed for state-of-the-art commercial products as well as recently demonstrated research systems.

Enormous advances in integrated electronic chips have enabled optical transponders to perform the complex digital signal processing (DSP) functions that are needed to implement the modulation formats discussed in Chapter 4. Chapter 6 focuses on those DSP functions, showing the internal workings of modern coherent optical transponders, how they mitigate optical signal impairments, and how they adaptively equalize the optical fiber channel to achieve transmission performance close to the fundamental limits of the fiber channel.

In addition to DSP, forward error correction (FEC) is a key enabler of modern optical transponders, and FEC is discussed in Chapter 7. Modern error-correcting codes allow full bit stream correction even when several percent of the received signal is erroneous bits. In combination with modulation and DSP, coding allows transponders to achieve their optimal transmission performance.

The hundred (or even hundreds of) WDM signals supported by optical fibers and amplification technologies carry more traffic than needed for today's point-to-point demands. Individual wavelengths or groups of

wavelengths are therefore assigned to each point-to-point connection within a network. In order to avoid the need for costly transponders to reroute wavelengths within the network, optical switching nodes are employed to route individual wavelength signals to the desired fiber in a network node as well as to add and drop wavelengths at local transponders at their final destination. Chapter 8 discusses the architecture and implementation of optical switching nodes.

The optical field that propagates within an optical fiber has a diameter that is on the order of 10 μm. This means that the optical intensity within the fiber core approaches the MW/cm^2 level, even for individual WDM signal powers of only 1 mW. At such high intensities, the refractive index of glass varies with optical power, leading to power-dependent optical phase shifts along the fiber, which accumulate over the thousands of kilometers propagated and produce severe signal distortions, especially when coupled with chromatic dispersion. Chapter 9 focuses on the effect of fiber Kerr nonlinearity, which has limited fiber-optic communication systems since the invention of optical amplifiers. The chapter presents analytical and numerical models of fiber nonlinearities as well as the means to combat their performance-degrading effects in the context of modern optical transmission systems, and it describes the limits of nonlinear transmission performance.

Conventional optical fibers support a fundamentally limited information capacity, which practical systems are already approaching. Therefore, as network traffic continues to increase, fiber-optic networks are nearing a 'capacity crunch.' The only way to scale networks beyond the limits of conventional fibers is to use spatial parallelism (space-division multiplexing, SDM) techniques. Such approaches range from employing bundles of conventional fibers for parallel transmission all the way to using individual transverse modes of few-mode fibers as parallel channels. The latter leads to crosstalk between those parallel paths, meaning that DSP techniques such as multiple-input multiple-output (MIMO) are needed to combat crosstalk. Chapter 10 discusses SDM techniques that are at the forefront of fiber-optic transmission and network research.

2. Optical Fiber and Cables

Takashi Sasaki, Takemi Hasegawa, Hiroki Ishikawa

This chapter gives an overview and introduces application scenarios for optical fibers and cables in optical communications. The use of single-mode optical fibers for both short-reach and long-haul applications is growing due to continually increasing demand for higher bandwidth optical communication systems. To better understand fiber-based optical communications the chapter first focuses on the design of the single-mode fiber while the latter half focuses on the design of optical fiber cable. A wide variety of optical fiber cables have been designed and installed to meet the needs of various applications and this chapter reviews the many types of cables for fiber to the home as well as for datacenter connectivity.

We will start with a section showing the history of optical loss improvement. Then, the categories of optical fibers and their cross-sectional structure are explained. Next, the main features of single-mode fibers such as standard single-mode fiber (SSMF), bend-insensitive fiber (BIF), cutoff-shifted fiber (CSF), dispersion-shifted fiber (DSF), and nonzero dispersion-shifted fiber (NZDSF) are summarized with their major optical characteristics. Then, features of each fiber type are explained. In particular, the cutting-edge application of low-loss fiber in ultralong-haul systems such as subsea systems are discussed and the importance of their system impact is also described. Thereafter, the key characteristics of multimode fiber are explained. In the final part of the optical fiber section, emerging fiber types are introduced such as fiber for space-division multiplexing (SDM) systems, for example multicore fiber, few-mode fiber, or coupled multicore fiber.

Thereafter, in the optical fiber cable section, we start with the classification of use cases such as indoor or outdoor cables and their features. Next, we introduce the optical fiber unit, a basic element used to bundle the fiber into cable, such as an optical fiber ribbon or loose tube. Following this we present many examples of optical fiber cables and their features, such as the slotted-rod cable, loose-tube cable, central-tube cable, layered fiber core cable, and direct-jacketed cable. Next, we present key considerations in optical cable design, such as fiber density, environment conditions, temperature change, water durability, biological attacks, and mechanical durability (bend, impact, torsion, crush). Finally, specific fiber cable use cases such as air-blown fiber cables and ultrahigh-density fiber cables for datacenter applications are introduced.

For more information about the basics of optical fibers and cables, we refer the reader to text books such as [2.1, 2]

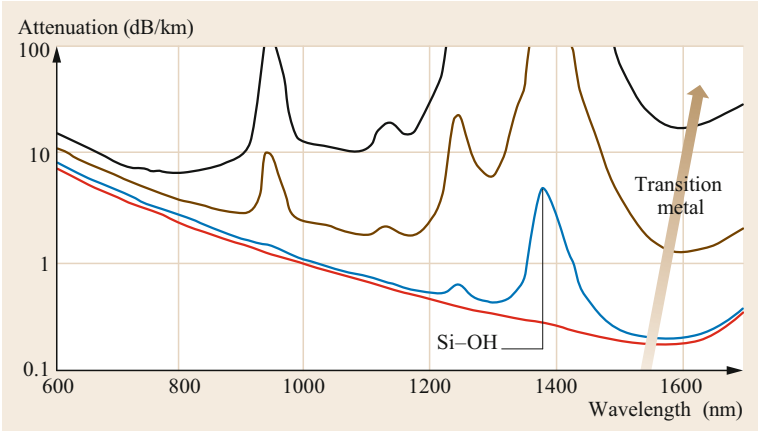

Fig. 2.1 History of loss improvement in optical fiber

Optical fibers comprise an indispensable part of the network infrastructure required to support current data services like the internet and wireless communication systems. Silica-based optical fiber is a unique transparent medium that is readily manufacturable and reliable, and both of these characteristics are required to enable global terrestrial and subsea networks to be interconnected.

In 1966, Dr. Kao at Standard Telecommunication Laboratories in the UK predicted that silica-based optical fiber would function as a low-loss transmission media equal to or less than 20 dB/km [2.3]. In 1970, Corning Glass Works demonstrated a low-loss (less than 20 dB/km at 630 nm) fiber that proved optical fiber could replace existing electric wired transmission networks [2.4]. Since then, as Dr. Kao forecasted, many enterprises worldwide have conducted comprehensive research to reduce the impurities (e.g., transition-metal and Si–OH absorption) and achieve significant improvements in regard to loss, as seen in Fig. 2.1.

In addition to the advancements in optical fibers, the steady performance improvement for semiconductor-based lasers, photo diodes, and modulators has also enabled optical communications networks to increase fiber bandwidth.

To replace traditional electric-wired transmission networks, optical fiber not only proved to be much lower loss, but it also had the advantages of wider bandwidth, lighter weight, smaller diameter, and no electrical inductance while experiencing no optical crosstalk between fibers. These features combined with silica's abundance and stability as material enabled optical fiber cables to significantly contribute to today's worldwide network connectivity and overall improvement to peoples' quality of life.

2.1 Transmission Fibers

2.1.1 Overview

As the geographical coverage and density of optical networks has increased, optical fiber links in data networks are growing in both quantity and diversity. The annual global supply of optical fibers was estimated to be approximately 511 million km in 2019 and growing by 10% annually [2.5]. Among the global supply, approximately 99% is single-mode fiber that transmits a single waveguide mode without impairment by modal dispersion (detailed in Sect. 2.2). The remaining 1% is multimode fiber, which transmits typically more than 100 waveguide modes, thereby facilitating low-cost optical coupling with devices, (detailed in Sect. 2.3). However, since the demand for capacity is expected to keep growing, a technical breakthrough in fiber will be necessary to meet the demand. Potential breakthroughs such as spatial-division multiplexing fiber and photonic band-gap fiber are described in Sect. 2.3. See Table 2.1 for the categories of transmission fibers and the sections containing corresponding descriptions.

Table 2.1 Categories of transmission fibers

	Conventional fibers		Emerging fibers

Structure					Refractive index profile (typical)					Usage	General	Short reach	Spatial division multiplexing		Low latency
Sect.	2.2	2.3	2.4.1		2.4.2

2.2 Single-Mode Fibers (SMFs)

In this section, the general properties of SMFs, their classification (standardization) and application are described.

2.2.1 Common Properties

Single-mode fiber (SMF) is a glass fiber whose cross-section is normal to the length is composed of a circular core and an annular cladding surrounding the core. The refractive index of the core is higher than that of the cladding, so that the light wave is confined in the core and guided along the fiber length. Whereas the diameter of the core varies among the subtypes of SMF, it is typically in the range 5−15 μm corresponding to the 1.3−1.6 μm wavelength of light to be guided. As a result, only a single fundamental mode per wavelength of an electromagnetic wave can be guided in the core. Note that the two polarization modes are counted as a *single* guided mode because the two polarization modes form a pair of degenerate modes due to the rotational symmetry of the optical fiber structure.

Since the number of modes that can be guided by a finite core area increases almost in proportion to the inverse square of the wavelength, single-mode guidance is enabled within the wavelengths longer than a threshold, called the cut-off wavelength. In the industry, two definitions of cut-off wavelength are commonly used [2.6, 7]. One is the fiber cut-off wavelength often denoted as λ_c, and the other is the cable cut-off wavelength often denoted as λ_{cc}. In either case, the cut-off wavelength is defined as the minimum wavelength at which any mode other than the fundamental mode is attenuated by more than 19.3 dB by the designated transmission medium. In the case of the fiber cut-off wavelength λ_c, the transmission medium is defined as a 2 m fiber wound for one turn around a 280 mm diameter spool. In the case of the cable cut-off wavelength λ_{cc}, it is defined as a 22 m cable whose central 20 m length is wound around a 280 mm diameter spool and both 1 m length ends wound for one turn around an 80 mm diameter spool.

The core and cladding of an SMF are composed of silicate glass (SiO_2), which enables low optical attenuation. They often contain small amounts of dopants such as germania (GeO_2) and fluorine (F) which change the refractive index. The industry-standard diameter of the cladding is typically 125 μm. Since such a bare thin glass fiber is too fragile to handle, it is usually covered by a polymer coating of approximately 250 μm diameter, which is also treated as a common industrial standard. Since even coated fibers are not mechanically robust enough for deployment, they are incorporated in a protective cable whose structure depends on the environment in which it is to be deployed (details are provided in Sect. 2.5).

Because the fiber is composed of silicate glass, optical fibers have a wavelength window of low attenuation, as shown in Fig. 2.2. Typically, the attenuation is lower than 0.5 dB/km over the 1.2−1.7 μm range, that is, equal to 73 THz in the frequency domain. Within this broad bandwidth, the conventional C-band (1530−1565 nm) is the most frequently used band especially for long-distance transmission because of the coincidence of low attenuation and the gain window of the erbium-doped fiber amplifier (EDFA). The long wavelength L-band (1565−1625 nm) is also becoming common for long-distance transmission because the EDFA can be optimized to cover this wave-

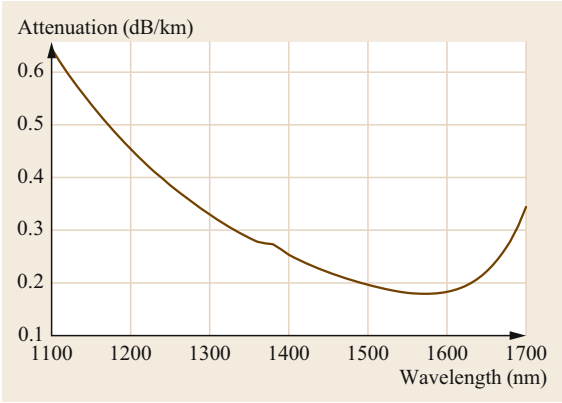

Fig. 2.2 Typical transmission loss spectra of current optical fiber

length. The original O-band (1260–1360 nm) is most frequently used for short-distance transmission without amplification because of low chromatic dispersion and low waveform distortion. The short wavelength S-band (1460–1530 nm) and extended E-band (1360–1460 nm) are also used for short-distance transmission. The above nomenclature of wavelength bands is standardized by the ITU-T (International Telecommunication Union Telecommunication Standardization Sector) [2.8].

2.2.2 Classification

In this section, classification of SMFs is described with industry standardization associated with their typical use case.

There are several types of SMF optimized for specific use cases such as fiber to the home (FTTH) and long-haul transmission. Choosing the best fiber for a specific application is important to achieve competitive cost-benefit and reliable networks. Conversely, some fiber types in use for terrestrial or subsea systems are becoming less popular for new deployment because they are optimized for legacy transmission technologies. For example, dispersion-shifted fiber, DSF (ITU-T G.653) suffers from nonlinear effects, and it has become suboptimal after the launch of wavelength-division multiplexing-transmission technologies for higher bandwidths. However, legacy fibers have been deployed in substantial volume, so that understanding the characteristics of those fibers is still important to make the most of the deployed fiber asset.

Table 2.2 summarizes the subtypes of SMF, their typical structure and characteristics. It should be noted that CSF has advantages of low attenuation, a large effective core area (A_{eff}), a low nonlinear refractive index (n_2) and large absolute chromatic dispersion, all of which improve the capacity of digital coherent transmission, as described in Sect. 2.2.6. A more detailed description of each subtype will be given in the following sections.

2.2.3 Standard Single-Mode Fiber

Standard single-mode fiber (SSMF) is the most often used fiber and often called just *single-mode fiber* (SMF). SSMF is typically composed of a core made of GeO_2-doped SiO_2 and a cladding made of pure SiO_2. Sometimes the inner part within the cladding is doped with fluorine and has a slightly lower index than the outer part, thereby improving bending loss performance. The optical and mechanical characteristics of SSMF are standardized by ITU-T G.652.D recommendations [2.9]. Compared to the other SMFs, SSMFs have the lowest cost because they are produced and employed in the largest volumes worldwide. They can be used generally for transmission across a wide wavelength range from 1.3 to 1.6 μm because the cable cut-off wavelength is shorter than 1.26 μm, and the extrinsic bending loss is low up to a wavelength of around 1.625 μm.

Mode-field diameter (MFD), a parameter representing how widely the optical energy is distributed laterally

Table 2.2 Characteristics of SMF by subtypes

	SSMF	BIF	CSF	DSF	NZDSF
ITU-T	G.652	G.657	G.654	G.653	G.655–656
Refractive index profile (typical)					
Typical attenuation (dB/km)	0.18–0.20	0.18–0.20	0.15–0.16	0.22	0.19–0.22
A_{eff} (μm^2)	80	80	80–153	46	55–72
$n_2 10^{-20}$ (m^2/W)	2.3	2.3	2.2	2.5	2.5

Usage	General	FTTX	Submarine long haul	–	Long haul

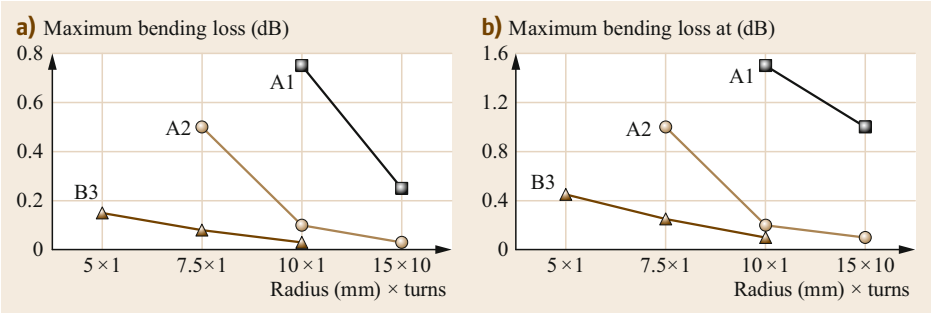

Fig. 2.3a,b Maximum bending losses of bend-insensitive fibers specified by ITU-T G.657: **(a)** at 1550 nm; **(b)** at 1625 nm

across the core [2.7], is standardized by G.652.D to be between 8.6 and 9.2 μm with a nominal tolerance of less than 0.4 μm. In that range, most of the commercial SSMFs are specified to have a 9.2 μm nominal MFD [2.8–12]. A large MFD has the advantage of lower coupling losses when coupled to another fiber with the same MFD because coupling losses due to lateral misalignment are reduced in proportion to the inverse square of MFD [2.13]. However, it should be noted that a larger MFD can cause a high coupling loss in waveguide devices or lasers, which typically have a much smaller MFD than SSMF [2.13].

2.2.4 Bend-Insensitive Fiber (BIF)

Bend-insensitive fiber (BIF), sometimes also referred to as bend-resistant fiber (BRF), is the second most frequently used fiber next to SSMF. Compared to SSMF, BIF has a lower bending loss that meets one of the ITU-T G.657 recommendations [2.14]. G.657 specifies the subclasses A1, A2 and B3, having lower bending losses in that order (B3 is the lowest), as summarized in Fig. 2.3. In terms of use, G.657.A1 is the most frequently used, and G.657.A2 is the next. These fiber types are mainly used for applications in fiber to the home (FTTH) or to the premise (FTTP), sometimes also called FTTX. In any of these applications, fibers are deployed near to the user and can be exposed to tight bends and localized loss because they are integrated into thin cables that are deployed in narrow pathways, and users often handle the cables harshly.

G.657.A1 fits for usage in a bending radius larger than 10 mm. Some G.657.A1 products have 9.2 μm MFDs compatible with typical G.652.D products [2.15, 16], whereas others have slightly smaller 8.9–9.0 μm MFDs [2.10, 17].

G.657.A2 fits for usage in a bending radius larger than 7.5 mm. Most G.657.A2 products have 8.6–8.8 μm MFDs, still in the range of G.652.D recommendations [2.10, 18–20].

G.657.B3 has the most advanced bend insensitivity and fits for usage in a bending radius larger than 5 mm. Like G.657.A2, most G.657.B3 products have 8.6–8.8 μm MFDs in the range of G.652.D recommendations [2.21–23].

As indicated by the MFDs of G.657 subclasses, reducing MFD and confining the light in the core is one of the effective ways to reduce bending loss of the fundamental mode, while enhancing the bending losses of higher order modes so that single-mode operation is maintained. The trade-off among bending loss, higher order mode cut-off, and mode-field diameter is described by the MAC factor

$$\mathrm{MAC} = \frac{\mathrm{MFD}}{\lambda_c}\,, \tag{2.1}$$

where it is empirically known that bending loss decreases as the MAC factor decreases [2.24].

Another way to reduce bending loss of the guided fundamental mode is to reduce the refractive index of a selected annular region in the cladding, which is often referred to as a trench [2.25, 26]. Such a trench can be made by synthesizing SiO_2 glass, including a large amount of fluorine, for example, using the plasma-enhanced chemical-vapor deposition (PCVD) technique [2.26].

Incorporating voids or air holes in SiO_2 fiber glass is another effective way to substantially reduce refractive index because the relative refractive index between SiO_2 glass ($n = 1.45$) and air ($n = 1$) is as large as 26%, in contrast to less than the 1% that is available by practical fluorine doping. Hole-assisted fiber (HAF), having several air holes of micrometer-order scale, is known to have very low bending losses [2.25, 27]. Further, optimized bending loss performance can be realized by using an effective trench made by a plurality of voids having tens or hundreds nanometer-order sizes [2.28].

2.2.5 Reduced Outer-Diameter Fiber

Whereas the outer diameter of coated optical fibers has typically been 250 μm, reduced-diameter fibers having an approximately 200 μm diameter are becoming commercially available. Their glass optical properties

are almost the same as those of one of the typical 250 μm products and comply with G.657.A1 [2.29, 30] or A2 [2.31, 32] recommendations. Also, their core glass diameter is kept unchanged at 125 μm, so only the outer coating thickness has to be reduced. Even with reduced thickness, the coating has to protect the inside glass fiber from breakage or microbending loss even under external forces in actual deployment conditions.

Microbending loss is an extrinsic loss caused by longitudinally distributed microbends of the glass waveguide that couples the fundamental mode to higher order modes [2.1, 33]. Those microbends are the outcome of the combination between external disturbances on the outer surface of the coated fiber and the mechanical characteristics of the coating that diminish the disturbances felt by the internal glass fiber. Therefore, the thicknesses and elastic moduli of the layers composing the coating should be designed optimally to keep low microbending loss [2.34, 35]. In addition, optimized waveguide designs, such as a trench-assisted structure [2.26], are also effective in suppressing microbending loss [2.36]. Either by improved coating or glass, 200 μm reduced-diameter fibers have been successfully demonstrated to exhibit comparable optical and mechanical performances compared to the conventional-diameter fibers [2.37].

2.2.6 Cutoff-Shifted Fiber (CSF)

Cutoff-shifted fiber (CSF) is a single-mode fiber that has an upper limit of cutoff wavelength equal to 1530 nm, shifted from the 1260 nm of SSMF. Although the longer cutoff wavelength reduces the wavelength range of operation, it enables an increase in the effective core area (A_{eff}) [2.38], which reduces the density of guided optical power and hence nonlinear optical effects. Such an increase in A_{eff} is enabled because larger core diameter accompanies longer cutoff wavelength. It can be understood if one assumes a simple matched-cladding step index profile, the theoretical cutoff wavelength λ_{ct} is given by

$$\lambda_{\text{ct}} = \frac{2\pi a}{2.405} n_1 \sqrt{2\Delta}\,, \tag{2.2}$$

where a is the core radius, n_1 is the core refractive index, and Δ is the refractive index difference between core to cladding.

Such low nonlinearity allows higher signal power to be launched into the fiber and thus benefits longer distance transmission by reducing the number of amplifiers and/or enhancing the signal power at the receiver. As a result, CSF is optimal for submarine and long-haul terrestrial transmission using the C-band and/or L-band, where erbium-doped fiber amplifiers can be used as repeaters. Moreover, since digital coherent transmission is widely adopted and its performance strongly depends on the optical signal-to-noise ratio (OSNR), CSFs are becoming even more important because of their low nonlinearity and low attenuation.

CSFs are usually composed of a pure silica (SiO_2) core and a fluorine-doped cladding. The pure silica core, in contrast to a relatively lossy GeO_2-doped silica core, enables low attenuation and low nonlinear refractive index. Typical refractive index structures of CSFs have a W-shaped depressed cladding or a trenched cladding [2.39–41], to achieve a suitable balance between large effective area, low bending loss of the fundamental mode, and a short cut-off wavelength. An intuitive explanation is that higher order modes have a longer tailed electric field encroaching into the outermost elevated cladding and are influenced by W-shaped or trenched cladding more than by the guided fundamental mode. As a result, a W-shaped or trenched cladding can reduce the bending loss of the fundamental mode relative to the higher order modes.

In addition to the cladding structure, a ring-shaped core is also used for some types of CSF [2.42, 43]. A ring core causes the intensity distribution of the fundamental mode to deviate slightly from that of a Gaussian distribution. As a result, if one keeps a constant MFD, a ring core has a larger effective area than a simple-step index core, as shown in Fig. 2.4. Since an increase in MFD for a CSF causes a higher loss when it is spliced to the SSMF typically used in repeater interfaces, the ring core provides an effective means to enlarge the effective area without a large penalty in terms of increased splice losses.

As the effective area gets larger (and its electromagnetic field gets spread more broadly), the fibers become more sensitive to microbending loss. Hence it is important when enlarging the effective area to improve the fiber coatings that isolate the glass waveguide from the

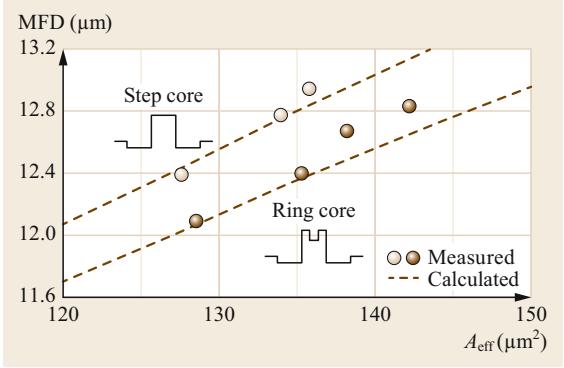

Fig. 2.4 The effect of a ring-shaped core to expand A_{eff} with the same MFD (at 1550 nm)

Table 2.3 ITU-T G.654 by subclass

ITU-T	G.654.B	G.654.C	G.654.D	G.654.E
MFD at 1550 nm (nominal) (μm)	9.5–13	9.5–10.5	11.5–15.0	11.5–12.5

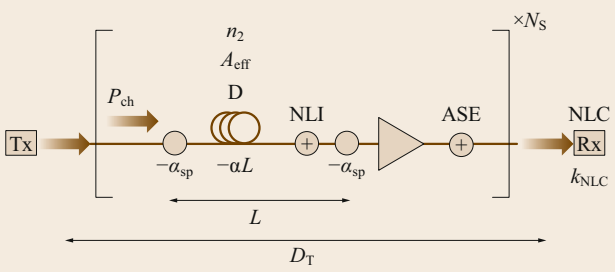
Bending loss $r = 30\,\text{mm} \times 100$ turns (dB)	≤ 0.50	≤ 0.50	≤ 0.50	≤ 0.1
Usage	Regional and middle-distance	Submarine	Long-distance submarine	Terrestrial long haul

external disturbances that cause microbending and as a result, an increase of loss. A fiber coating is typically composed of an innermost soft layer, a middle hard layer, and an outermost colored thin hard layer, typically called the primary, secondary, and ink layers, respectively. The state-of-the-art CSFs have a primary coating with a reduced elastic modulus that enables an increase in effective area to $130\,\mu\text{m}^2$ [2.43] or $150\,\mu\text{m}^2$ [2.44] without compromising microbending loss performance.

The characteristics of CSFs are standardized by ITU-T G.654 recommendations [2.45], as summarized in Table 2.3. Among them, G.654.D is the most popular standard for long-distance submarine transmission to an extent of, or greater than, several thousand kilometers because its large MFD correlates to a large A_{eff}. The latest G.654.D products have effective areas of $130–153\,\mu\text{m}^2$, the largest among SMFs and attenuations of 0.152–0.157 dB/km, also the lowest among SMFs [2.46–48]. Because of such advanced characteristics for attenuation and A_{eff}, CSFs have been contributing to the *hero* transmission experiments in laboratories [2.49–51] and also in submarine applications [2.52].

Whereas submarine cable use has been the main application of G.654 fibers, a subclass G.654.E intended for long-haul terrestrial transmission was newly defined in 2016 to have a tighter MFD range and lower bending loss. Field trials are also underway to verify the performance of G.654.E fibers in real terrestrial transmission links in China [2.53, 54]. In this trial, the fibers from seven vendors were cabled, deployed, and used for transmitting 400 Gb/s signals. The results have shown stable performance even under varying environmental conditions.

The value of low attenuation and large effective-area transmission fiber can be expressed in terms of improvement in generalized OSNR, which includes nonlinear impairment as additive noise to the conventional amplified-spontaneous-emission (ASE) noise [2.55]. As the generalized OSNR increases, the theoretical upper limit of transmission capacity increases almost in proportion to its logarithm [2.56], and one can increase the actual capacity using advanced modulation format signals such as higher order quadrature-amplitude modulation (QAM) and/or probabilistic shaping [2.57]. In addition, digital coherent WDM transmission provides another benefit because nonlinear impairment noise can be approximated by an additive white Gaussian noise described by an analytical formula, the so-called Gaussian noise model (GN-model) [2.55]. Because of this property, the generalized OSNR can be approximated by a simple formula called the fiber figure-of-merit (FOM) [2.58–60]. Assuming a definition of symbols as



$$L_{\text{eff}} = \{1 - \exp[-(0.1\ \ln 10)\alpha L]\}/[(0.1\ \ln 10)\alpha]$$
$$\gamma = 2\pi\, n_2/(\lambda\, A_{\text{eff}})$$
$$F = h\nu B\,\text{NF}$$
$$D_{\text{T}} = N_{\text{S}} L$$

A_{eff}	Fiber effective core area (μm^2)
B	Reference band width of OSNR (Hz)
D	Fiber chromatic dispersion (ps/(nm km))
D_{T}	Transmission distance (km)
F	ASE coefficient (W)
h	Planck constant (J s)
L	Span length (km)
k_{NLC}	NLI mitigation coefficient
L_{eff}	Effective span length (km)
n_2	Fiber nonlinear refractive index (μm^2/GW)
NF	Amplifier noise figure (linear)
N_{S}	Number of spans
P_{ch}	Launched signal power per channel (W)
α	Fiber loss coefficient (dB/km)
α_{sp}	Dissimilar splice loss (dB)
γ	Fiber nonlinear coefficient ($\text{W}^{-1}\text{km}^{-1}$)
λ	Signal wavelength in vacuum (μm)
ν	Optical frequency of signal (Hz)

Fig. 2.5 Link model in fiber FOM theory

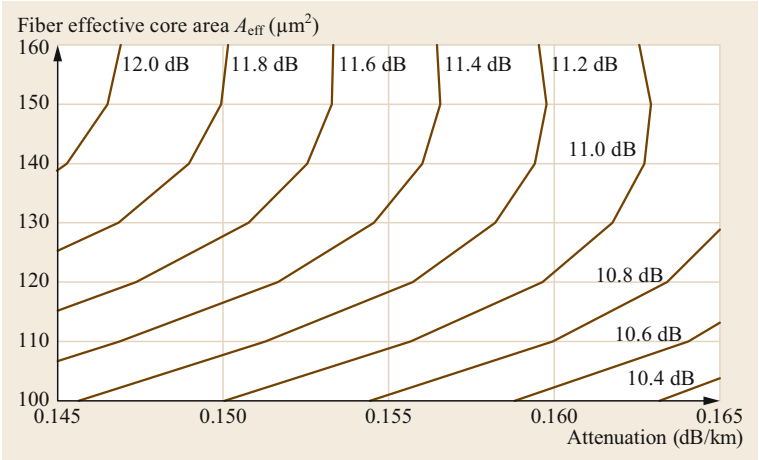


Fig. 2.6 Example FOM map on 80 km span system

shown in Fig. 2.5, the FOM is calculated as

$$\mathrm{FOM\ (dB)} = -\frac{10}{3}\log\left(\gamma^2 L_{\mathrm{eff}}|D|^{-1}\right) - \frac{2}{3}\alpha L - \frac{2}{3}\alpha_{\mathrm{sp}} + 10\log L\,, \qquad (2.3)$$

where the symbols are defined as dimensionless numbers defined by dividing the designated physical quantity by the designated unit. This formula gives an intuitive idea of the better fiber for digital coherent transmission systems. For example, if one assumes a repeated transmission system with a span length of 80 km and maximum signal power of −2 dBm/ch, typical for submarine transmission, the FOM can be calculated as a function of fiber attenuation and effective area and expressed as a contour map as shown in Fig. 2.6. On the basis of this kind of FOM map, one can intuitively understand the performance merits provided by using advanced fibers. Note that the exact shape of contours can vary depending on system assumptions such as span length, maximum signal power, and nonlinear compensation [2.60].

Last but not least, CSF is one of the most active fields of development in transmission fibers because CSFs with lower attenuation and nonlinearity are the most practical and effective way to expand the transmission capacity for the long-distance submarine cables which interconnect the world. In the most state-of-the-art CSF (Fig. 2.7), the attenuation at 1550 nm is 0.1424 dB/km and the lowest attenuation is 0.1419 dB/km at 1560 nm [2.44]. Such low losses are realized by reducing the Rayleigh scattering caused by microscopic inhomogeneity in the density of SiO_2 glass, and this can be ascribed to the manufacturing technology that has been continuously refined due to increasing demand since digital coherent transmission became the mainstream in long-distance submarine transmission. As a result, improvement in lowest attenuation has accelerated in recent years.

2.2.7 Dispersion-Shifted Fiber (DSF)

Dispersion-shifted fiber (DSF) is an SMF whose zero dispersion wavelength is shifted to near 1550 nm wavelength, from near 1310 nm typical of SSMF [2.61], as

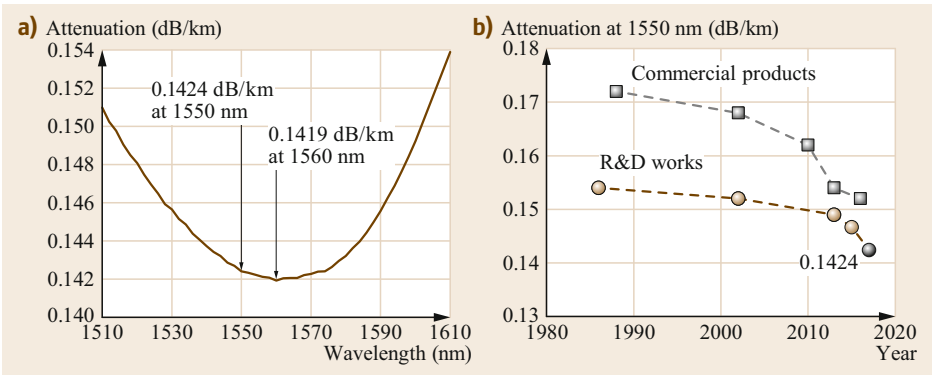

Fig. 2.7a,b The lowest attenuation fiber **(a)** and the history of reduction in attenuation **(b)**

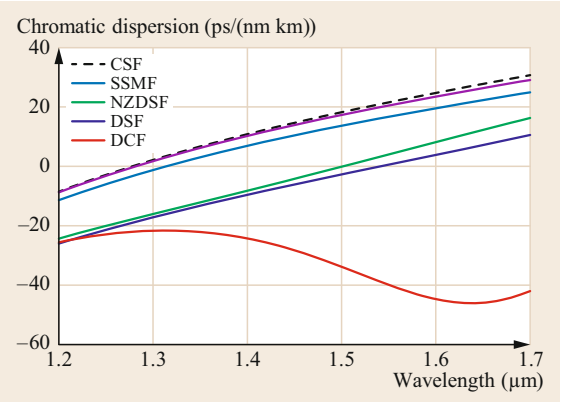

Fig. 2.8 Examples of chromatic dispersion characteristics for different materials

shown in Fig. 2.8. Such a shift in chromatic dispersion can be realized by increasing the refractive-index difference between the core and the cladding and decreasing the diameter of the core [2.62]. Since 1550 nm is the wavelength where the attenuation of optical fiber is the lowest, having the smallest chromatic dispersion at this wavelength could benefit transmission performance. However, in the case of wavelength-division multiplexed (WDM) transmission, the smaller chromatic dispersion generates crosstalk noise due to four-wave mixing, meaning that DSF is not usually suited for WDM transmission near the 1550 nm wavelength. For this reason, DSF is no longer actively deployed, but legacy fibers remain in the field.

2.2.8 Nonzero Dispersion-Shifted Fiber (NZDSF)

Nonzero dispersion-shifted fiber (NZDSF) is an SMF whose absolute chromatic dispersion over the C-band is smaller than that of SSMF but is not actually zero, so that it can support WDM transmission in the C-band. Whereas either positive or negative dispersion can support WDM, most products have positive chromatic dispersion in the C-band because getting positive dispersion requires less of a shift in dispersion than getting negative dispersion. Those dispersion characteristics can be tailored by using complex refractive-index profiles [2.63], but they also induce a smaller effective core area, or equivalently a higher nonlinearity. In addition, although the small dispersion reduces the need for dispersion compensation, it also increases the nonlinear impairment in WDM transmission [2.55]. Therefore, NZDSF has an advantage over other SMFs in cases where one must rely on costly optical-dispersion compensation solutions. Conversely, in cases where one can compensate dispersion electronically instead of optically, the merit of NZDSF decreases and the penalty of higher nonlinearity increases. The former was the case before the mid-2000s when long-distance transmission relied on intensity-modulated direct-detection (IM-DD) techniques, but after the mid-2000s the latter has become the case because digital coherent techniques are used in long-distance transmission.

Although NZDSFs are becoming a legacy for the above reasons, they have already been deployed widely and are still supplied by several vendors [2.64–67]. Among the various products, some have relatively large effective areas but large dispersion slope [2.64, 65], whereas others have small dispersion slopes but small effective areas [2.66], or intermediary characteristics between these extremes [2.67]. In contrast to the above-mentioned NZDSFs having positive dispersion, some NZDSF has negative chromatic dispersion [2.47] that suffers less from modulation instability even when high-power signals are launched for submarine transmission.

2.2.9 Dispersion-Compensating Fiber (DCF)

Dispersion-compensating fiber (DCF) is an SMF that has negative chromatic dispersion and dispersion slope. Since most transmission fibers, such as SSMF, BIF, CSF, and NZDSF have positive dispersion and dispersion slope, the overall amount of accumulated dispersion can be reduced over a wavelength range by joining a DCF with the transmission fiber [2.68]. In order to reduce the accumulated dispersion over a wide wavelength range, it is important to have a suitable relative dispersion slope (RDS), which is defined by normalizing the dispersion slope by the dispersion to be matched between the transmission fiber and DCF. Since RDS varies among transmission fibers such as SSMF and NZDSF, DCF is designed to compensate specific transmission fibers. There are two ways to use DCFs. One is a discrete DCF module where a length of DCF is coiled and packaged [2.69]. Another is a cabled DCF where DCF composes a span of a transmission link in combination with a matched positive-dispersion transmission fiber [2.47], such a transmission link is also called a dispersion-managed link.

Since the chromatic dispersion and dispersion slope of SiO_2 composing DCFs are both positive, a complex waveguide structure, such as a triple clad design, is used for DCF to realize the large negative dispersion and controlled dispersion slope [2.68]. However, such complex index profiles and high-density dopants also cause a slightly increased fiber attenuation and decreased effective area for a cable-type DCF [2.70]. The result is that a dispersion-managed link is now less often adopted for new deployment than positive-dispersion CSFs which perform better with digital coherent techniques.

2.3 Multimode Fibers (MMFs)

This section describes MMFs applied to short-reach transmission applications. Multimode fiber (MMF) is, in the context of transmission fiber, a glass fiber having a circular core and an annular cladding surrounding the core, where the refractive index of the core is higher than that of the cladding and has a graded profile expressed by αth power of radius. Typically, the diameter of the core is 50 μm and the core-cladding relative index difference is 1%. The αth power profile can suppress modal dispersion that is the difference in group delay among guided modes. The optimum α that minimizes modal dispersion is approximately 2 [2.71], but the precise value depends on the operating wavelength and the dopants in the SiO_2 core, which affects the material chromatic dispersion [2.72]. The MMF core is typically composed of GeO_2-doped SiO_2, whereas additional codoping of F can widen the wavelength range with low modal dispersion [2.72–74]. Regarding the cladding, an F-doped trenched cladding is widely used to provide a lower bending loss [2.75, 76].

MMFs are typically used for short-reach transmission at 850 nm wavelengths in combination with a vertical-cavity surface-emitting laser (VCSEL) transceiver, because of the high-energy efficiency [2.77] and cost efficiency [2.78, 79]. The maximum possible transmission distance, typically less than 2 km, is inversely proportional to the transmission bandwidth so that the transmission performance of MMFs are generally specified by a bandwidth–distance product. Whereas MMFs with precisely fabricated index profiles generally have larger bandwidth–distance products, the exact values of bandwidth–distance products can vary from VCSEL to VCSEL, which excite different populations of modes in the MMF. To cope with this problem, it has been agreed in the industry to specify the bandwidth–distance product of an MMF based on the measurement of the differential mode delay (DMD), a series of time-domain impulse responses by radially offset SMF launches [2.80] and assumption of several patterns of predetermined launching conditions. One widely used metric is its calculated minimum effective modal bandwidth (minEMBc), which is obtained by calculating virtual impulse responses to various assumed launching conditions and then taking the worst-case value [2.81, 82]. The second and traditionally used metric is the overfilled launch (OFL) modal bandwidth, which is defined as the bandwidth when all the guided modes are excited [2.81]. Conversely, OFL is fairly realistic when the signal is launched into MMF from a light-emitting diode (LED) [2.83]. It generally underestimates the performance when the MMF is excited by a VCSEL. OFL can be substituted by a calculated overfilled modal bandwidth (OMBc), which can be calculated from DMD measurements [2.81].

Among several equivalent standards of MMF, ISO/IEC 11801 and TIA-568.3-D are the most frequently [2.84, 85] used. MMFs are classified into four subclasses, OM1 to OM4. OM1 has a large 62.5 μm diameter core, which is optimal for LED rather than VCSEL signals, and has an OFL bandwidth of 500 MHz km at 1300 nm. OM2, OM3 and OM4 have a 50 μm core and have OFL bandwidths at 850 nm of 500, 1500 and 3500 MHz km, respectively. OM4 is backward compatible to the other two subclasses and is supplied by several vendors [2.86–88].

Whereas OM2 to OM4 specifies modal bandwidths only at 850 and 1300 nm, the growing need for short-wave wavelength-division multiplexing (SWDM) means a further advanced subclass of MMF that supports SWDM in the wavelength range between 850 and 950 nm is required. Such an advanced MMF, called a wideband MMF (WB-MMF) or OM5, is also becoming commercially available [2.89–91] and a state-of-the-art transmission experiment using four wavelength and four-level pulse amplitude modulation (PAM4) verified 206 Gb/s transmission over a distance of 150 m [2.92].

2.4 Emerging Fibers

This section describes new state-of-art fibers for future optical communication systems. There have been significant advances in transmission fibers with low attenuation and low nonlinearity that increase the theoretical capacity limit. However, the demand for capacity has expanded at a much faster rate, so that it is anticipated that we will soon face the challenge of an increasing gap between demand and supply [2.93].

2.4.1 Space-Division Multiplexing (SDM) Fiber

In the past, advances in transmission techniques, such as WDM and digital coherent transmission, contributed to significant expansions in capacity. However, the C and L bands supported by the EDFA are already fully used and leave almost no room for an increase in capacity by WDM, and digital coherent transmission using

Table 2.4 Comparison of SDM schemes

	FMF	U-MCF	C-MCF
Reference	[2.94]	[2.95]	[2.96]
Structure			Propagation			Cladding diameter (μm)	125	188	125
Attenuation (dB/km)	0.23	0.168	0.158
A_{eff} (μm^2)	108	125	112
Need MIMO	Yes	No	Yes
Differential mode delay (ps/km)	20	–	6.1

advanced modulation format signals is also approaching the theoretical nonlinear Shannon limit. Therefore, expanding the number of spatial channels represents the last available dimension to increase capacity.

For this purpose, various types of space-division multiplexing (SDM) fibers have been proposed and demonstrated [2.97]. Among the wide variation, realistic candidates for long-distance transmission fiber include few-mode fiber FMF [2.94], uncoupled multicore fiber (U-MCF) [2.95], and coupled multicore fiber (C-MCF) [2.96], as summarized in Table 2.4.

FMF supports several guided modes and therefore is similar to MMF. Actually, a standard MMF can also be used as FMF [2.98]. However, whereas every guided mode of legacy MMF carries the same signal, each guided mode of FMF is loaded with a different signal. Although those signals are mixed during transmission, because of mode-coupling in FMF, multi-input multi-output (MIMO) digital signal processing can unbundle the mode-coupling and recover the original signal. Since MIMO processing becomes more complex with larger differential mode delay (DMD), it is important to reduce the DMD of FMF. To reduce DMD, it is effective to concatenate two FMFs having DMDs of opposite signs. With this technique, a low DMD of 20 ps/km has been achieved [2.94].

U-MCF contains multiple independent cores in its cross-section. Since it can be treated simply as parallel fibers, it has the advantage that conventional transceivers can be used without change. However, the challenge is that isolation between the cores requires a large separation and/or a deep depression in the cladding index. A large separation can result in a cladding diameter larger than the conventional 125 μm, which might affect reliability due to enhanced bend-induced stress. A deep depression in the cladding might degrade productivity and cost-efficiency. Therefore, significant work will be necessary before practical use as transmission fiber.

C-MCF contains multiple cores that are positioned closely enough to experience mode-coupling during transmission. It has the advantage that the conventional 125 μm diameter cladding can contain as many as 12 cores [2.99]. Whereas it requires MIMO processing as FMF does, the cost of the MIMO calculation is expected to be lower than that in the case of FMF because the DMD of C-MCF is smaller than that of FMF. Since the spatial modes of C-MCF propagate having random coupling with each other, the differential delay between the modes accumulates with random changes in the sign and magnitude of the coupling, so that the DMD grows in proportion to the square root of the distance, not directly in proportion to the distance as in the deterministic case [2.96]. In addition to these advantages, it was also demonstrated that a C-MCF can be fabricated with an attenuation as low as 0.158 dB/km at 1550 nm, this

is comparable to those of the most advanced CSF products for submarine applications [2.96]. Further, a lab transmission experiment achieved 5500 km transmission over a C-MCF and superior transmission quality that is presumed to be due to the reduced nonlinearity caused by mode coupling [2.100]. In spite of those promising results, many challenges still remain, such as integration of a suitable multicore amplifier, low-loss and low-cost splice techniques, and control of the mode-coupling characteristics of cabled fiber before this new fiber may be used in the field.

2.4.2 Photonic Band-Gap Fiber (PBGF)

In this section the features of PBGF are described. Photonic band-gap fiber (PBGF) is an optical fiber that guides light by the photonic band gap (PBG) effect, in contrast to the conventional optical fiber that guides light by total internal reflection (TIR) [2.101]. Whereas TIR guidance requires the core to have a higher refractive index than the cladding, PBG guidance requires the cladding to have a micron-scale periodic structure that prohibits propagation of light in a range of frequency that is the photonic band gap. The unique guiding mechanism generates an important advantage of PBGF in that it can guide light in a low-index hollow core [2.102]. Guidance in a hollow core could have a great impact over a conventional glass core due to low attenuation, low nonlinearity, low latency, and low sensitivity to environmental disturbances such as temperature and radiation. Although the lowest achieved attenuation of a hollow-core PBGF (HC-PBGF) is still as high as 1.2 dB/km at 1620 nm, and presumed to be limited by the surface roughness of the hollow core [2.103], nevertheless the advantage of low latency have been demonstrated by transmitting a 10 Gb/s signal at 1550 nm over 11 km of HC-PBGF, resulting in more than a 15 μs reduction in latency [2.104].

2.5 Optical Fiber Cables

Optical fiber cables are produced to protect the optical fibers in the field, for example outside the plant, intrabuilding, or central office. Hence, by considering the use case, several factors need to be considered and optimized:

- Number of fibers per cable
- Environmental conditions
- Mechanical durability
- Fire retardancy.

Fiber count can be defined by use case. A *drop cable* is used to connect the subscriber's house and is typically a single fiber-cable, while a *feeder cable* is used to distribute fibers to a residential area and contains several hundred to one thousand fibers.

The environmental conditions can affect the design of the cable structure. The key considerations are temperature and moisture (or surrounding water) or tensile force in the case of an aerial cable. Optical cables are designed to maintain their performance under the anticipated environmental conditions.

Mechanical durability has two aspects. One is a durability during deployment, and the other is residual external forces after being deployed.

Fire retardancy is required in order to avoid fire propagation along the cables and smoke and/or toxic gas generation.

In this section the structure of optical cables is described, and we present a variety of actual optical fiber cables in use, highlighting in particular FTTH (fiber-to-the-home) network and intrabuilding network applications.

2.5.1 Cable Structure Used in Access Network and Intrabuilding Network

The *access network* is built to bring fiber(s) from the central office to the customer's residence, multi-dwelling unit, or business office. Figure 2.9 schematically describes the FTTH access network and the intrabuilding network. Here the fibers are connected via feeder cable, distribution cable, and drop cable [2.105–107].

The intrabuilding network consists of a backbone cable and horizontal cable. The backbone cable carries fibers to higher floors. Horizontal cables are connected from the branching point of the backbone cable to each subscriber.

Types of Optical Cables

Various kinds of optical cables are used to build an optical network, Table 2.5 summarizes the relationships about usages, cable types and design factors.

2.5.2 Cable Types

In this section, several types of optical fiber units and cable structures are described.

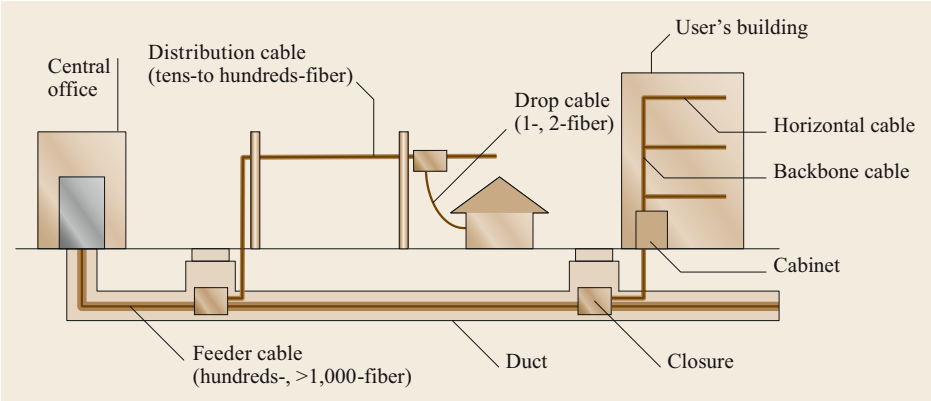

Fig. 2.9 FTTH access network and intrabuilding network

Table 2.5 Usages, cable types, and design factors in the FTTH access network

Cable/usagel		Fiber count	Cable types	Additional design factors
Outdoor network	Feeder	Hundreds, > 1000	• Ribbon slot • Loose tube • Central tube	• Tensile strength for installation • Water blocking • Armored
	Distribution	8 to hundreds	• Ribbon slot • Loose tube • Central tube • Direct jacketed	• Self-supporting • Durability to sunshine • Fire retardancy • Biological attack
	Drop	1–2	• Direct jacketed	
Intrabuilding network	Backbone	8, 12, 100–300	• Layered • Ribbon slot • Loose tube • Central tube	• Fire retardancy • Smoke/gas generation
	Horizontal	1–12	• Direct jacketed • Loose buffered	

Optical Fiber Unit

An optical fiber *unit* is a preassembled cable consisting of a plurality of fibers that are bonded, bundled, or tubed. To avoid misconnections during deployment, identification of each fiber in the cable is critical.

The unit helps operators organize and identify each fiber before and after installation. Identification of each fiber in the unit is usually conducted by visually checking the color of the fiber coating.

There are two types of units deployed into the field, consisting of either optical fiber ribbon or loose tube.

Optical Fiber Ribbon. Optical fiber ribbon is a unit in which a number of optical fibers are arrayed and held together using resin. The number of optical fibers in one ribbon typically available in the market are 4, 8, 12, and 24. If one cable needs many fibers, a higher count fiber ribbon can be selected.

It should be noted that the ribbon structure makes fiber identification easy, as the colored fiber can show the fiber number and ribbon number. Additionally, they can be connected by using mass-fusion splicers [2.108–111], and this serves as an efficient deployment method. Examples of fiber ribbons are shown in Fig. 2.10.

Loose Tube. A loose-tube unit comprises a plastic tube filled with a buffer compound and a number of fibers. The compound is typically a jelly-like material and acts

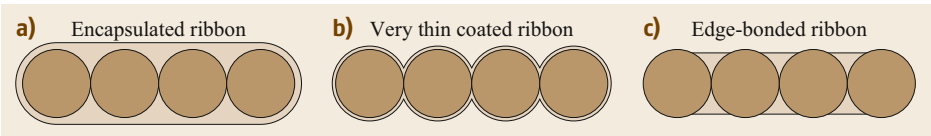

Fig. 2.10a–c Cross-sections of examples of optical fiber ribbons

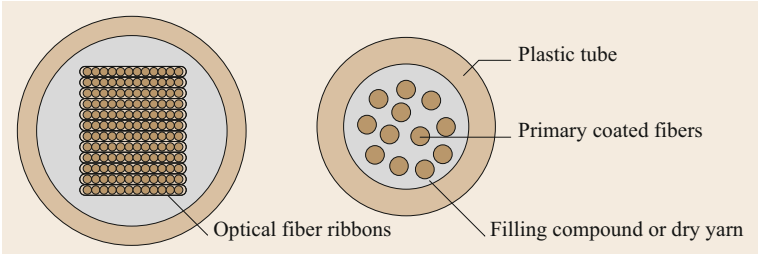

Fig. 2.11 Cross-sections of examples of loose tubes

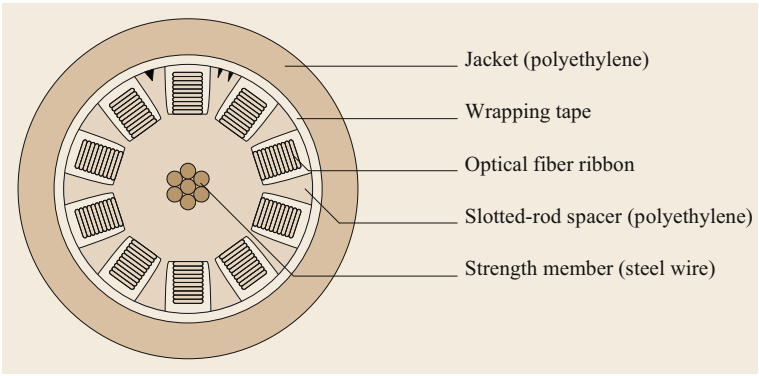

Fig. 2.12 Example of a cross-section of a cable with a slotted-rod spacer

as a lubricant that ensures fibers are free to move inside and prevents an attenuation increase by local fiber bending. In addition, the compound helps prevent longitudinal water penetration and improves mechanical stability.

For higher fiber counts, a stacked and twisted number of fiber ribbons is used to facilitate fiber identification and mass-fusion splicing.

Figure 2.11 shows an example of a ribbon-type and nonribbon-type loose-tube unit.

Cable Structure

Cable structure is classified by the differences in the cable core located at the center of the fiber cable. The cable core consists of one or more *units* and elements, such as a strength member, spacer, wrapping tape, or filling material. Usually, a cable core forms a cylindrical shape and is surrounded by a protective sheath.

The cable-core structure is selected by considering the fiber count, installation, jointing, and required environmental conditions.

Slotted-Rod Cable. A slotted-rod structure consists of a spacer with a central strength member and a polyethylene rod with slots trenched helically. The unit(s) are located in the stiff slot to avoid external forces being applied to the cable; it also makes identifying the fiber easy because the slots can bundle the fiber units independently. Figure 2.12 shows an example of a ribbon slotted-rod cable [2.112, 113].

Loose-Tube Cable. A loose-tube-cable core is formed by stranding a number of loose-tube units around a central strength member. For this cable, the tube itself needs to be stiff enough to protect the fibers from external forces.

In some cases, a jelly-like water blocking material or water-swellable material is applied within the space between the tubes and the strength member.

It is relatively easy to avoid loss increases caused by cable temperature changes or bending in a loose-tube cable because the jelly-like compound enables the fibers to move freely, therefore mitigating fiber-bending and the effect of environmental condition change. Conversely, the jelly-like compounds require extra cleaning when jointing. Figure 2.13 shows examples of loose-tube cables [2.114–122].

Central-Tube Cable. In a central-tube cable, typically 12-, 24-, or 36-fiber ribbons are stacked and twisted within a plastic tube. There are two typical structures: in one the tube space is filled with a jelly-like compound and in the other yarn with water-swellable material is applied to prevent longitudinal water penetration.

Figure 2.14a shows a 576-fiber cable with aramid-yarn strength members surrounding the central tube. Figure 2.14b shows another example of an 864-fiber ca-

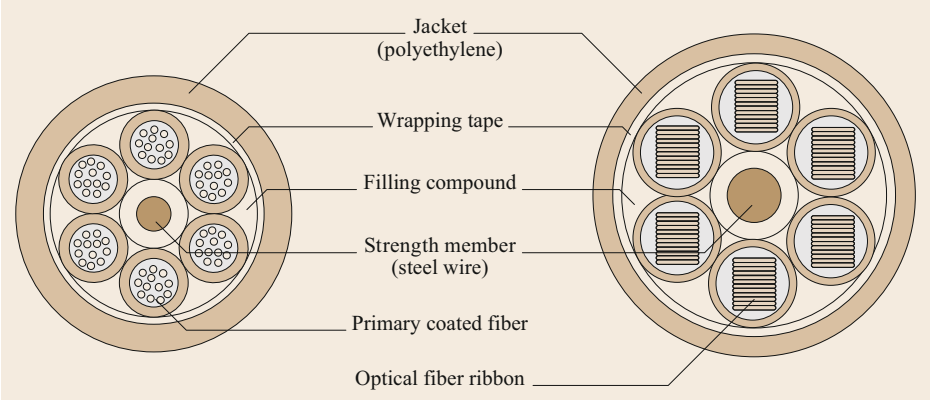

Fig. 2.13 Examples of cross-sections of loose-tube cables

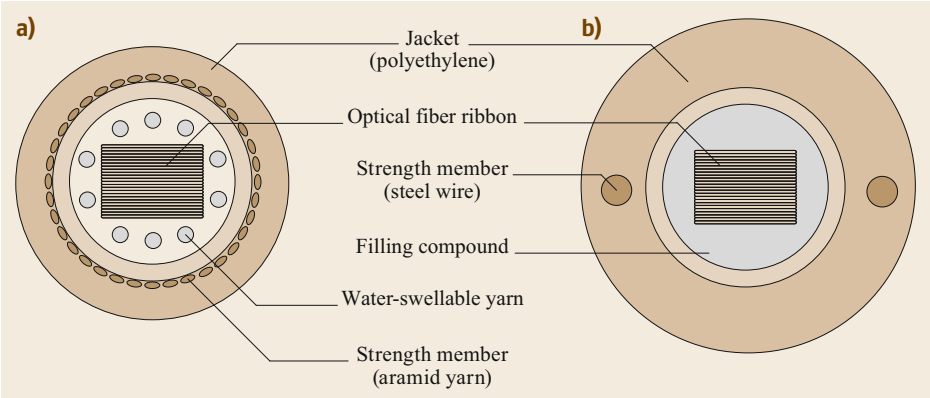

Fig. 2.14a,b Examples of cross-sections of central-tube cables: **(a)** 576-fiber cable; **(b)** 864-fiber cable

ble with two steel strength members contained in the sheath [2.123–125].

Layered Fiber Core Cable. Layered fiber core cable is formed by stranding the fibers around a central strength member; it is used for smaller fiber-count cables such as 6- to 12-fiber cables. Usually, 900 μm-diameter primary coated fiber is used for this type of cable. Figure 2.15 shows an example of a layered fiber cable.

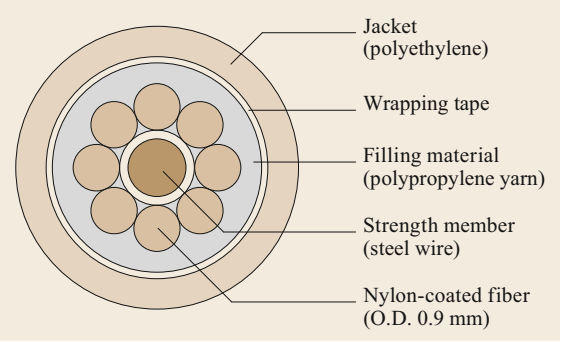

Fig. 2.15 Layered fiber cable

Direct Jacketed Cable

For fewer fiber count cabling, a direct jacketed cable structure is also used. This jacket is applied directly to the primary coated fiber(s) or fiber ribbon(s).

Because this structure is of lighter weight, it is suitable for aerial drop and indoor cable applications. Thinner and lighter cable also enables the suspension wire of an aerial drop cable to be thinner. For indoor cable that is installed on the room wall, thinner cable is more aesthetically pleasing and involves a lower risk of becoming an *eyesore*. Figure 2.16 shows examples of cross-sections of direct jacketed cables [2.126–133].

2.5.3 Cable Design

Each optical fiber cable should be designed to achieve the required performance and reliability under field conditions. This section describes the factors that should be considered in cable design.

Optical Fiber Density

If high optical fiber density in a cable is required, the fibers can experience random lateral forces from neighboring fibers or the walls of the slotted-rod spacers. This

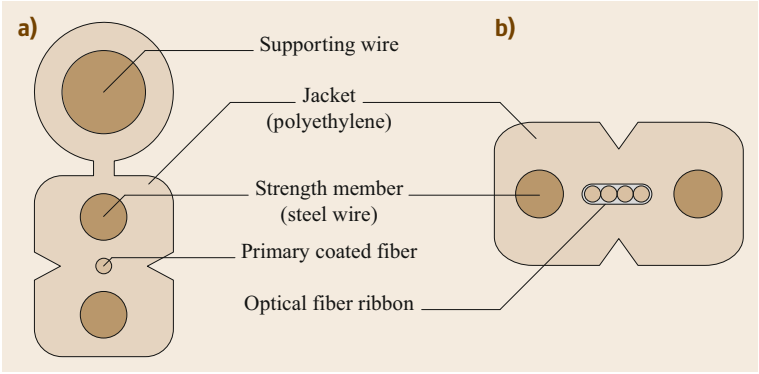

Fig. 2.16a,b Examples of cross-sections of direct jacketed cables: **(a)** drop cable, **(b)** indoor cable

force results in microdeformation of the fiber, called microbending, that causes attenuation to increase. To avoid microbending loss, the optical fiber density of a cable is selected within the appropriate range [2.6, 134, 135].

Environment Conditions

This section describes how cables need to be optimized for various environmental conditions in order to ensure stable loss performance.

Temperature Change. Temperature change results in stresses on the cable, such as elongation or shrinkage of the components within a cable caused by the differences in coefficients of thermal expansion between the fiber and the cable elements (normally made from polymer plastic). This stress may cause microbending to fibers and loss increases. Especially at low temperature, cable elements shrink and therefore create an excess length of fiber that then needs to be accommodated within the cable. This causes microbending in the fibers and increased loss.

Therefore, optical fiber cables should be designed so that the fibers have enough space not to experience the stresses or microbending within the expected temperature range [2.136].

Surrounding Water (Water Blocking). When the cable is installed in an underground duct, the cable can unintentionally get soaked with water when the ducts are flooded by groundwater. Once a part of the cable jacket is damaged, water penetrates into the cable and may reach the fibers. The existence of water or moisture around optical fibers may cause the degradation of fiber strength because water molecules react with silica (SiO_2) and accelerate the growth of glass-surface microflaws. To prevent this, underground cables require a water-blocking function.

To protect against water penetration, ribbon slotted-core cable wraps use water-swellable tapes, while loose-tube cables use jelly-like filling compound as a water-blocking material.

Biological Attacks. For outdoor cables, especially the aerial cable type, these may suffer biological attacks from mammals, birds or insects, so cables are designed to have effective protection [2.137–145].

One example of a mammal pest are squirrels that bite aerial cables and cut the fiber. Woodpeckers have been known to peck the cables and make holes in the jackets. Some types of cicada have been known to lay eggs within thin drop cables and so break the fibers.

For protection against these pests, wrapping the cable with metallic tape or net will work. To avoid cicadas laying eggs in drop cables, harder jacket material has been shown to be effective. Figure 2.17 depicts the example of a cicada attack on a drop cable.

Mechanical Durability

Optical fiber cables incur various external forces during both installation and operation, hence the cables need to be designed to maintain the required properties even when external forces are being applied [2.146, 147].

Tensile Forces in Installation. To install a cable in a building duct, the cable is connected to a preinstalled rope and is pulled through. During this pulling operation, the cable experiences tensile forces due to friction inside the duct. If the cable piece is elongated by the tensile force, the optical fibers in the cable may be broken. Therefore, the tension member(s) in the cable should be designed to limit cable elongation during this operation. For example, a backbone intrabuilding cable is specified to withstand the weight of itself because it is installed by being pulled vertically from the top of the building, as shown in Fig. 2.18 [2.148].

For the strength member, steel wire is commonly used. If electric induction needs to be avoided, then aramid, FRP (fiber reinforced plastic), or yarn is used.

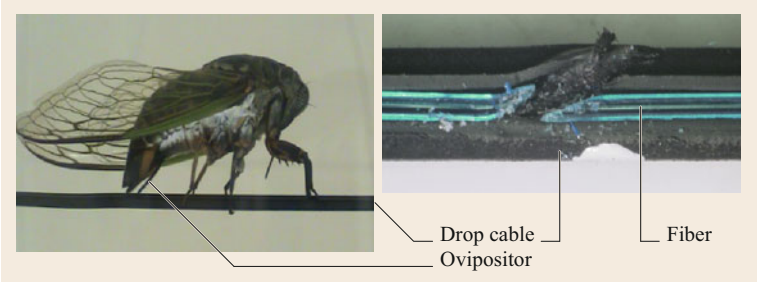

Fig. 2.17 Cicada attack on a drop cable

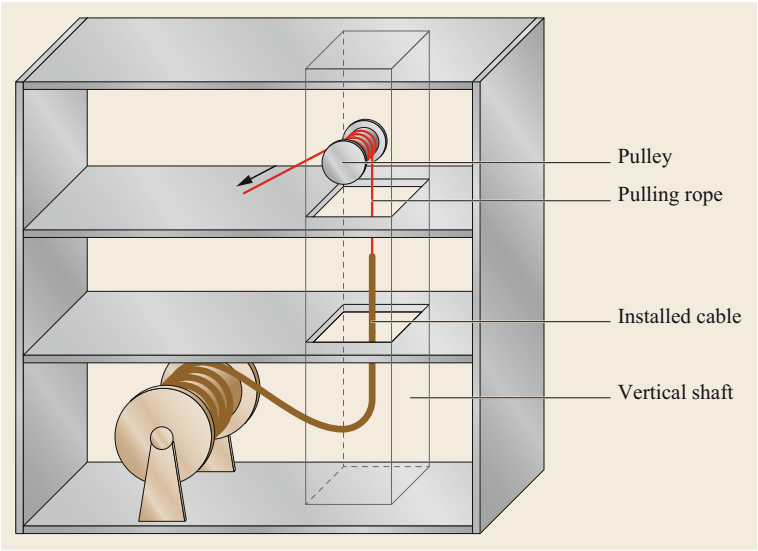

Fig. 2.18 Schematic layout of vertical installation in building

External Forces During Installation. In addition to tensile stress during the installation, operation cables are subjected to various external forces, such as crushing, twisting, bending, and impact. Cables should provide an effective protective means against the expected external forces.

As for the slotted-rod cable, the spacer wall should be thick and hard enough to withstand crushing and impact, and the size of slot should be large enough to withstand stress on the fibers under twisting and bending. Conversely, loose-tube and central-tube cable protects the fiber due to the hardened tube material.

The mechanical strength requirements are standardized by the IEC (International Electrotechnical Commission). Table 2.6 shows examples of the IEC standards for each external force. There are various conditions or criteria described in IEC 60794-3-10, as well as other standards.

Fire Retardancy

Because the outermost cable material is usually made of plastic, fire retardancy is required to avoid fire propagation along the cables and toxic gas and/or smoke generation, especially for office buildings with high-rise multidwelling units, or tunnels. The regulations on fire

Table 2.6 Example of IEC standards for external forces

External force	Test condition	Criteria
Bend	Radius: 20 times cable diameter Bend angle: 180°	No increase in attenuation at 1550 nm during and after the test.
Impact	Impact energy: 3 J (300 g hammer drop from 1 m height)	Under visual examination, there shall be no damage to the sheath or to the cable elements.
Torsion	180° twist over 2 m length	
Crush	Load: 1.5 kN/100 mm plate Duration: 1 min	

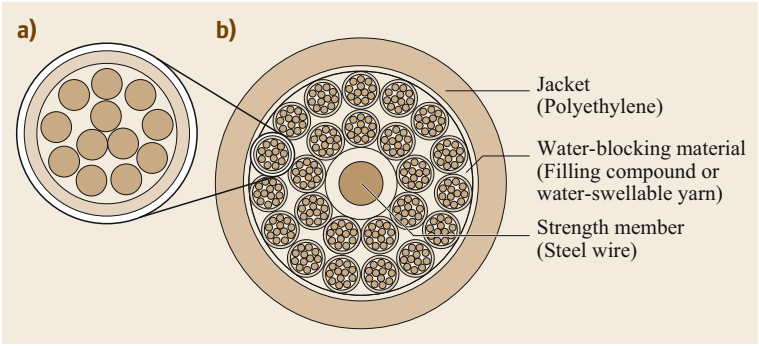

Fig. 2.19a,b An example of microduct cable **(a)** and micromodule cable **(b)**

retardancy may differ by country or usage [2.125, 149, 150].

If fire retardancy is required, fire-retardant materials are selected for the outer sheath. Usually these are made from polyethylene with the addition of some self-extinguishing material.

2.5.4 Cables for Specific Needs

Cables for Air-Blown Fiber Installation

Air-blown fiber cable is applied because of the simplicity of fiber deployment in buildings. The cable is literally blown into the duct or tube by applying high-pressure air; this operation greatly reduces the tension during installation. Moreover, the length of cable installation is known to be longer and the operation time shorter than for conventional pulling operations. This is beneficial for simplicity of the installation operation [2.151–162].

In the case of outside plant installations, microduct cables are used. An example of the structure of a microduct cable is shown in Fig. 2.19. This cable can be installed up to lengths of several kilometers.

As seen in Fig. 2.20, a fiber bundle unit is also used. Here, the bundle unit means a number of fibers that are sheathed with thin polyethylene formers in order to improve installation. This technique is very suitable for intrabuilding installations because tube cables are installed beforehand. Fiber bundles are installed when fiber needs arise and, if needed, bundles can be removed from the tube cable by applying an air flow in the opposite direction [2.106, 163–167].

Ultrahigh-Count Density Cable

Ultrahigh density and high-count fiber cable are among the newest products. This cable adopts the ribbon-slotted-rod type or central-tube-type structure, however the optical fiber ribbon is different from conventional cables. The applied ribbon unit has a feature of ultrahigh density known as *pliable ribbon*.

The ribbon arrays of fibers are incorporated in a mesh-like structure, as shown in Fig. 2.21. Pliable ribbons can be packed tighter than ordinary one-

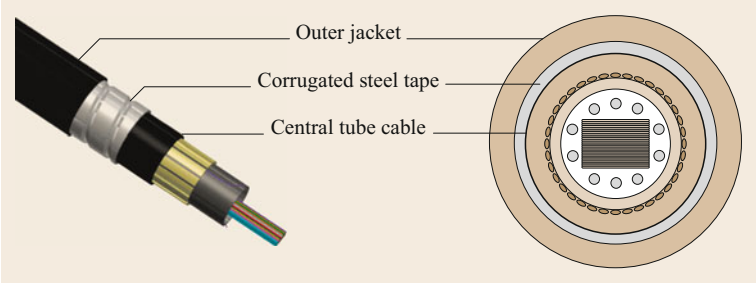

Fig. 2.23 Example of armored-sheath cable

dimensional ribbon units because they can pile the fiber from a one-direction array into a second dimension, thus filling the empty space. One of the highest fiber-count cables is a 3456-fiber cable with a 34 mm diameter that can be installed into a two-inch duct [2.107, 108, 168–174] as seen in Fig. 2.22.

Armored Sheath

In rural areas, to reduce cost and increase efficiency, the cable will occasionally be directly buried and installed into the ground by trenching during fiber-cable deployment, in contrast to urban-area deployments where fiber is placed within high-cost, but protective, conduits. Additional protection of the buried ground cable is required for it to withstand ground pressure and other elements. The most commonly used protection is a corrugated metallic-tape armored sheath over the ordinary jacket.

This kind of cable can also be used for duct, aerial or indoor installation, in the case of harsh conditions or where rodent attacks are expected [2.175, 176]. An example is shown in Fig. 2.23.

Induction-Free Cable

Optical fiber cable may be installed close to a high-voltage power cable. To avoid the electrical induction between a steel strength member and the power cable, an induction-free cable is required. This type is free from metal elements and instead uses aramid, FRP, or yarn applied as the strength member.

2.5.5 ITU-T Technical Reports

ITU (International Telecommunication Union) is the United Nations' specialized agency for information and communication technologies—ICTs, and ITU-T is the telecommunication standardization sector in the ITU. The ITU-T provides international standards for telecommunication systems and facilities *recommendations*. Besides the recommendations, technical re-

ports and technical papers are also published for guidance or reference. Among the technical reports, *ITU-T Technical Paper on Optical Fibres, Cables and Systems* is a very useful overview of optical-fiber cable structure, installation, connection, and systems [2.177–179].

3. Optical Amplifiers

Michael Vasilyev, Stojan Radic

The principles, design, and operation of erbium-doped and Raman amplifiers, two of the most important classes used in modern lightwave communication, are described. Developed over two decades, erbium-doped fiber devices act as lumped optical gain elements in terrestrial, submarine, and access networks, underpinning nearly all commercial data traffic today. Raman amplifiers have allowed significant reach and capacity increases and, unlike erbium-doped devices, are not confined to a specific lightwave band. In contrast to alternatives such as parametric and semiconductor amplification technology, erbium-doped and Raman amplifiers have been commoditized and can be readily designed and constructed from a mature set of components that includes specialty fibers, semiconductor pumps, dedicated filters, and passive elements. The design of both types of amplifiers is described, along with the most important engineering rules that allow for optimal device construction. Mitigation of noise and distortion mechanisms is detailed for both types of amplifiers when operating with commercial fiber plants.

Similar to their electronic counterparts, optical amplifiers are intended to regenerate signal power and can be classified according to the role they play in lightwave networks. An end-of-the-link gain element, referred to as a preamplifier, is used to amplify a weak channel prior to its conversion from the photonic to electronic domain. This type provides high gain (> 30 dB), operates with a small-signal input ($P_{in} < -25$ dBm), and adds minimal excess noise. Repeatered optical transmission relies on in-line amplifiers, intended to regenerate signal power after each fiber span. An in-line amplifier must match span-induced and in-line element loss, typically providing gains greater than 20 dB. In contrast to a preamplifier, which can be dedicated to a single channel, an in-line amplifier is designed and operated as a multichannel gain block in wavelength-division-multiplexed (WDM) links. Finally, a booster (or power amplifier) is deployed at the beginning of the WDM transmission to launch elevated channel power and preserve signal integrity deep into the lightwave link. In general, these designations are reserved for lumped gain elements, characterized by an internal optical path that is much shorter than the typical transmission span. Conversely, distributed amplification takes place over distances that are comparable to the transmission span, as discussed in Sect. 3.2.

In addition to this functional distinction, optical gain elements can also be categorized according to the underlying physical platform used to achieve photon amplification. During the four decades that mark the evolution of modern optical networks, amplification using semiconductor, rare-earth-doped, Raman, Brillouin, and parametric platforms has been investigated. While these possess unique sets of distinguishing characteristics, only two types, viz. rare-earth doped and Raman amplifiers, have seen widespread deployment in commercial optical networks. Consequently, this chapter focuses on these two technologies and describes the principles, operating characteristics, design, and performance limits of Raman and erbium-doped fiber amplifiers (EDFA). Indeed, while semiconductor, Brillouin, and parametric amplifiers offer performance in terms of response time, band selectivity, and phase-sensitive processing that neither EDFA nor Raman amplifiers can match, they are not used at present, nor are they expected to be deployed in near-future optical networks.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_3

To proceed, we first define commonly used parameters applicable to any optical gain element, regardless of the underlying physical mechanism responsible for signal amplification. The optical gain (G) is defined as the ratio between the output and input optical signal powers

$$G = \frac{P_{\text{out}}}{P_{\text{in}}} . \tag{3.1}$$

This relation expresses the gain on a linear scale, while amplifier design often calls for a logarithmic (dB) scale – the remainder of chapter will make this distinction explicit in specific cases. In its simplest form, the gain definition in (3.1) implies a quasimonochromatic signal. However, when the signal has a nonnegligible spectral width, a more general expression must be used, including the gain spectral dependence, often referred to as gain ripple.

The noise figure (NF) is defined by the input and output signal-to-noise ratios (SNR), under the assumption that the input signal possesses the maximal (shot-noise limited) *SNR*

$$\text{NF} = 10 \log \left(\frac{\text{SNR}_{\text{in}}}{\text{SNR}_{\text{out}}} \right) . \tag{3.2}$$

In accordance with convention, noise figures expressed on a linear scale are denoted by F throughout Sect. 3.1. In Sect. 3.2, the notation *NF* will be used for both linear- and log-scale noise figures. In analogy with electrical amplifiers, the gain bandwidth represents the frequency (wavelength) range over which a predefined (minimal) gain is maintained. However, in contrast to electrical amplifiers, the optical gain elements of interest (EDFA and Raman) possess bandwidths measured on the THz rather than GHz scale. As an example, the spectrally equalized EDFA bandwidth is engineered between 1528 and 1620 nm (≈ 10 THz) – nearly two orders of magnitude wider than ultrawideband electrical amplifier responses. Finally, the gain saturation characterizes the compression mechanism that applies to all types of optical amplifier. This effect originates from the inability to amplify an arbitrarily large signal power, signifying the difference between small- and large-signal levels. Specifically, gain saturation occurs when the input signal is large enough to appreciably deplete the inversion level of the gain medium [3.1, 2]. Gain saturation is a direct function of the signal power and is defined by

$$g = \frac{g_{\text{s}}}{1 + (P/P_{\text{S}})} , \tag{3.3}$$

where g_{s} is the small-signal gain measured on the dB scale, while the saturation power P_{S} indicates the input signal power at which the amplifier gain is compressed by 3 dB. Note that the simple definition (3.3) also implies a lumped (two-port) amplifier but does not account for spectral or spatial gain variation in a finite-length amplifier device.

3.1 Erbium-Doped Fiber Amplifiers

EDFAs represent the dominant amplifier technology that drives all aspects of optical networks, from short-range (access/metro) to ultralong-haul links in submarine transmission. Commercially introduced more than quarter of a century ago, EDFAs currently power both uni- and bidirectional transmission architectures, as shown in Fig. 3.1.

Modern fiber amplifiers operate within the 1550-nm transparency band of silica and are the result of multiple technological advances that matured simultaneously during the 1990s. First, extensive research on rare-earth (lanthanide) emission led to Er^{3+}-, Nd^{3+}-, and Pr^{3+}-doped fibers [3.3–5] that combine high gain coefficients, simple interfacing with passive (transmission) fibers, and compatibility with semiconductor pump technology. The energy levels of Er^{3+}, shown in Fig. 3.2, with its inherent 1550-nm transition, have served as the impetus for EDFA development. Er^{3+} emission/absorption covers the minimum-loss transmission window in silica fibers almost entirely and currently defines the most important transmission bands, viz. C-band (1530–1562 nm) and L-band (1565–1610 nm). C/L-band amplification in Er-doped fibers is supported by both short- (980 nm) and long-wavelength (1480 nm) semiconductor pump diodes that match the $^4I_{11/2}$ and $^4I_{13/2}$ Er^{3+} transitions required for 1550-nm signal amplification. Multiple silica doping and EDF fabrication techniques [3.2] have been developed, enabling wide variation in the Er concentration which governs the emission (absorption) strength, variable mode confinement, and negligible passive (background loss). As a result, these advances have enabled the realization of high-gain devices in only a few meters of doped fiber and in any band spanning 1530–1610 nm. With the maturation of doped fiber fabrication technology, the EDFA designer can demand not only specific emission (absorption) levels but also tailored dispersive and birefringent characteristics. As a consequence, lightwave networks currently deploy a wide variety of isotropic (non-birefringent) and polarization-maintaining (PM) EDFAs, with gains that vary from 10 to 50 dB and output powers that range from a few mW to over a watt.

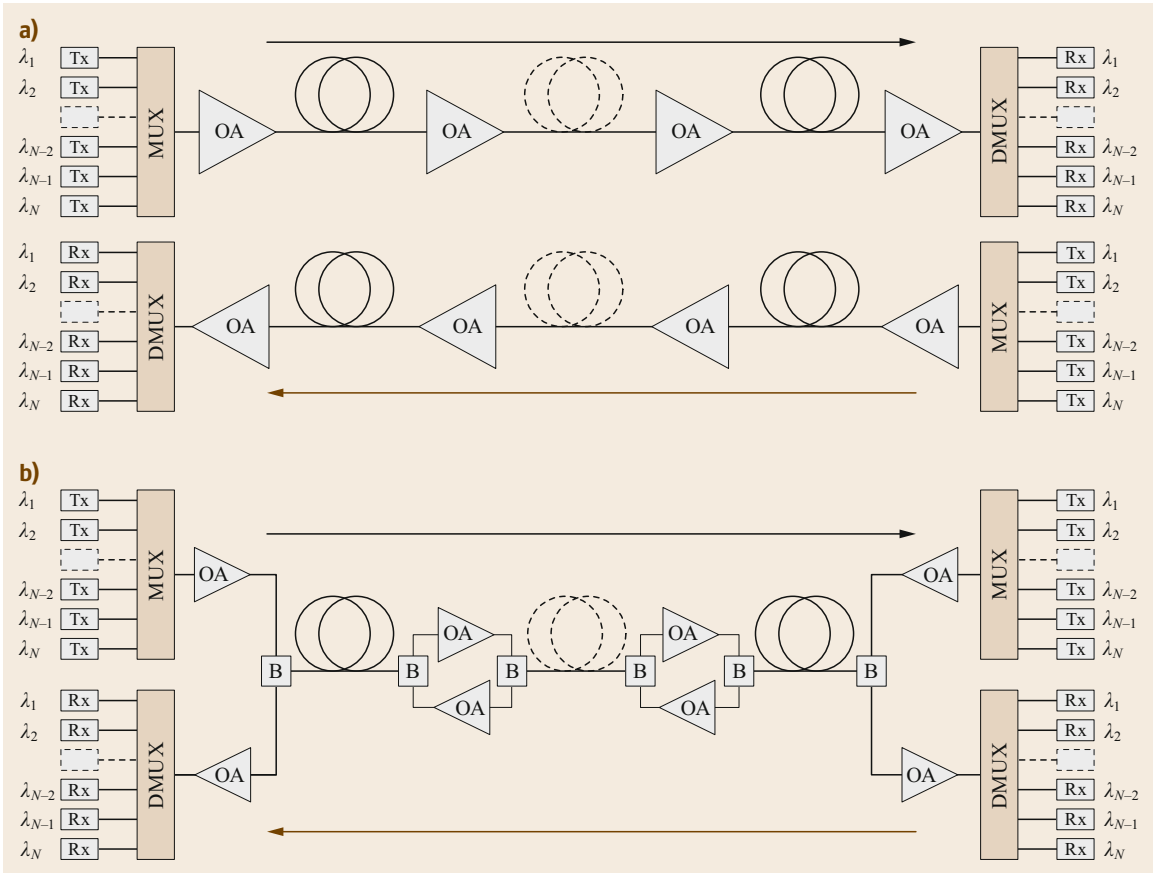

Fig. 3.1a,b Repeatered amplified WDM lightwave transmission: Channels are transmitted over a unidirectional architecture that uses a dedicated fiber for transmission in each direction **(a)** or over a bidirectional topology **(b)** that allows counterpropagating traffic to share a single fiber strand

3.1.1 EDFA Design and Characterization

In cases where an EDFA operates in the stationary regime, its gain and noise response can be accurately described by a two-level model, neglecting the third-level population [3.7–9], as illustrated in Fig. 3.3. The use of such a two-level inversion model is justified in most cases of practical interest and assumes, among other conditions [3.10], that the input signal and pump powers are static or fluctuate on faster than a microsecond scale. Under this approximation, the third-level ion population is negligible and decays rapidly, justifying the simple inversion model that accounts only for single upper (N_2) and lower (N_1) levels. Surprisingly, while this approximation appears to be simplistic, it is also remarkably accurate for nearly all WDM amplifier architectures of interest utilizing subwatt pump levels and Er-doped fibers with peak absorption below 30 dB/m.

The two-level inversion model allows an Er-doped waveguide to be considered as a distributed amplifier that can be easily described by balancing the local emission and absorption rates. In a stationary state, any mechanism leading to decay from the upper-level population (N_2) is offset by excitation from the ground level along the length of the fiber. The rate of each process varies along the fiber and changes with the local signal, pump, and noise levels. More importantly, the inversion level and photon count are closely coupled: to describe the longitudinal inversion variation, full knowledge of all three radiation types must be available; moreover, the longitudinal inversion function must be known to calculate the signal, pump, and noise levels. Figure 3.4 illustrates the relation between the spatially dependent inversion and distributed optical power levels. In the general case, the forward- and backward-propagating beams have temporal, spectral, and spatial dependence: $P_{\pm} = P_{\pm}(z, \lambda, t)$. In the sta-

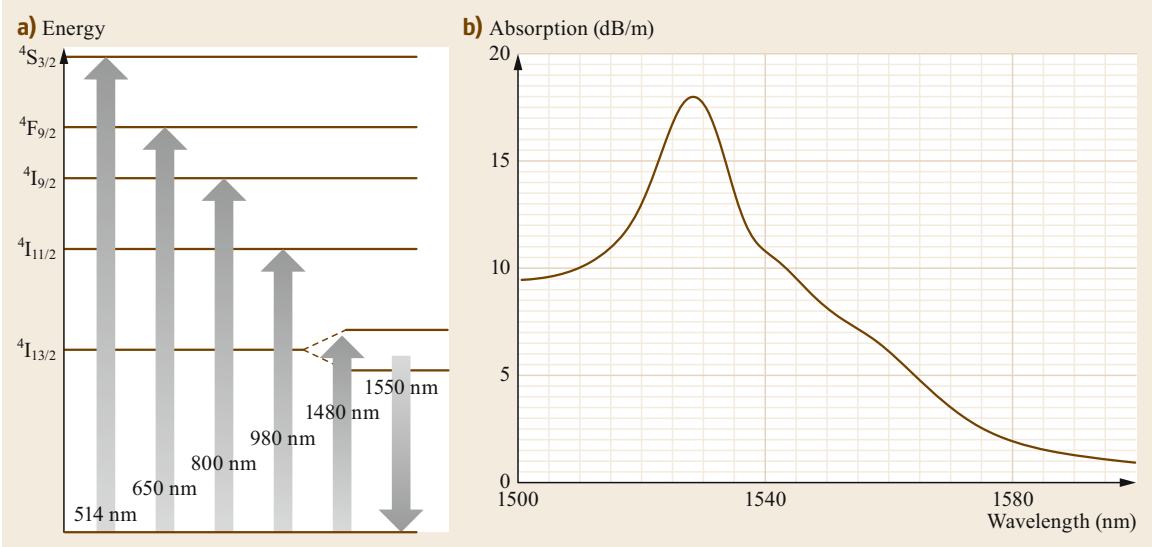

Fig. 3.2 **(a)** Er^{3+} energy level diagram, indicating viable pump and amplification bands. Fine (Stark) level splitting of the $^4I_{13/2}$ level is responsible for the large tolerance in 1480-nm pumping and allows for a wide emission band in the low-loss silica band (1550 nm); **(b)** absorption of a commercial Er-doped fiber [3.6]

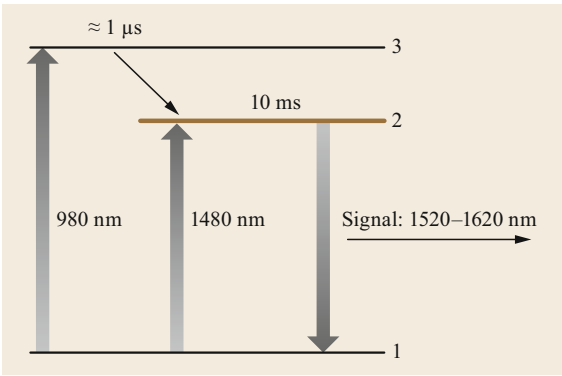

Fig. 3.3 In the two-level approximation, the significant discrepancy between lifetimes is used to justify the assumption of a vanishing upper-level population ($N_3 \to 0$), allowing the total ion population to be distributed between the ground and excited level: $N_T = N_1 + N_2$

tionary case that is of primary interest in EDFA design, the rate equation coupling the inversion level and counterpropagating beam powers is particularly simple

$$\frac{N_2(z)}{\tau_0} = -\frac{1}{\rho A}\sum_{i=1}^{N} u_i \frac{\mathrm{d}P_i(z)}{\mathrm{d}z} , \qquad (3.4)$$

where N_2 represents the normalized upper-level ion population, τ_0 is the spontaneous lifetime of the upper level, A is the waveguide effective cross-section area, and ρ is the ion density. This relation implies spectral beam dependency by channelizing propagating beams ($i = 1, N$), where the index corresponds to a specific wavelength (frequency). The ion population is normalized and is defined by scaling both by the total ion count: $N_1 + N_2 = 1$. Finally, the directional coefficients ($u_i = \pm 1$) account for the propagation direction along the z-axis, as defined in Fig. 3.4. Note that the left term in (3.4) represents decay from the upper level, while the right term accounts for signal- and noise-induced depletion and pump-induced repletion of the upper-level population.

The signal, pump, and noise power levels are directly governed by the local ion population in the ground and excited levels

$$\frac{\mathrm{d}P_n(z)}{\mathrm{d}z} = u_n\gamma_n N_2(z)P_n(z) - u_n\alpha_n N_1(z)P_n(z) , \qquad (3.5)$$

where γ_n and α_n are the emission and absorption constants of the EDF [3.10], often referred to as Giles coefficients. Note that (3.5) has a straightforward interpretation: The photon annihilation (generation) rate is directly proportional to the population of the ground (upper) level and the local photon flux. This relation is often written in a form that emphasizes only the upper-level dependence

$$\frac{\mathrm{d}P_n(z)}{\mathrm{d}z} = u_n(\gamma_n+\alpha_n)N_2(z)P_n(z) - u_n\alpha_n P_n(z) . \qquad (3.6)$$

By simultaneously solving (3.4) and (3.6), it is possible to obtain the inversion, signal, pump, and noise levels at any point along an Er-doped waveguide. While multiple

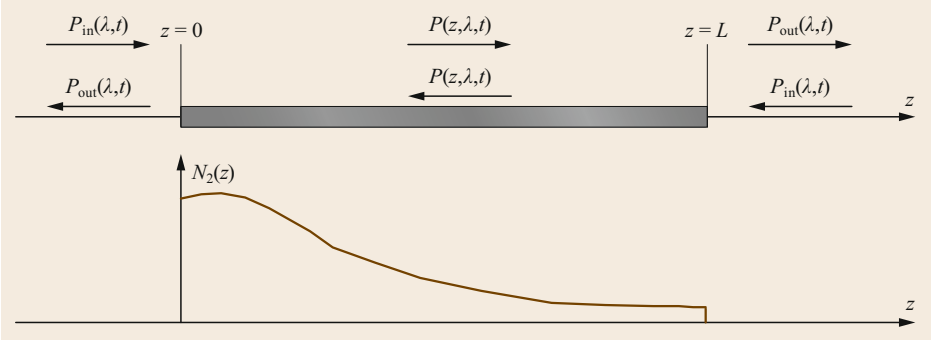

Fig. 3.4 Two-port, two-level bidirectional EDF model coupling signal, noise, and pump levels (P) and the inversion population (N_2)

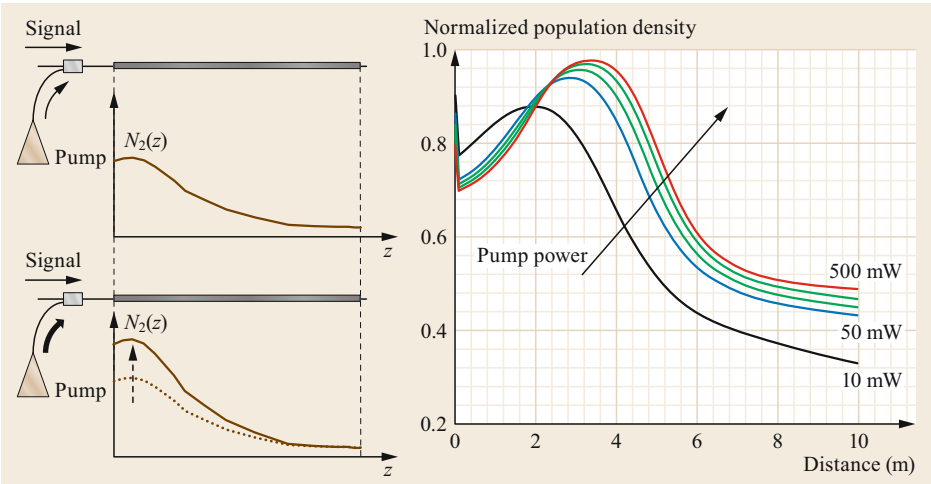

Fig. 3.5 Inversion dependence on pump power: An increase in pumping level results in a simultaneous increase of the inversion $N_2(z)$ peak and its longitudinal shift along the EDF section

techniques for analytic and semianalytic solutions have been developed in the past [3.8, 9, 11], rigorous numerical solutions are typically preferred during the EDFA design process.

Such two-level modeling of the localized inversion and photon flux provides important insights into EDFA operation regimes, which can then be used to create a design rule framework for the analysis and construction of complex, multistage amplifier subsystems. To develop an intuitive notion of EDFA behavior, consider the interdependence that exists between the pump/signal levels and the population inversion function $N_2(z)$. For the former, consider a pump level variation while the signal input is kept constant, as illustrated in Fig. 3.5. Since the pump provides the sole mechanism for ion excitation, it is naturally expected that the inversion will increase monotonically with the pump power.

While valid, this assumption is also somewhat simplistic: the ion inversion peak increase that occurs with an elevated pump power is also accompanied by a longitudinal shift of the peak along the fiber. This behavior cannot be accounted for by considering only the signal–pump interaction, as the amplitude spontaneous emission (ASE) in both propagation directions must also be included. However, Fig. 3.5 still provides one of the most important notions related to EDFA design: An increase in both the front-end and total inversion level must be guaranteed by a higher pumping level.

The second EDFA design notion relates to its response to an increased signal level, as illustrated in Fig. 3.6.

Assuming that the input signal is increased while the pump level is maintained at a constant level, it is reasonable to expect that the average inversion will decrease as stimulated emission grows. Again, this intuitive notion, while generally correct, is also an oversimplification; instead, an increase in the signal level will result in a total decrease of excited ions, but the local inversion level will be depleted much faster, shifting the peak of the inversion function peak closer to the EDF input. Similar to the case in which the pump is varied, an accurate description requires that the model for the signal–pump interaction also accounts for ASE generation.

A further insight into EDFA operation and response prediction can be gained by recognizing the unique role

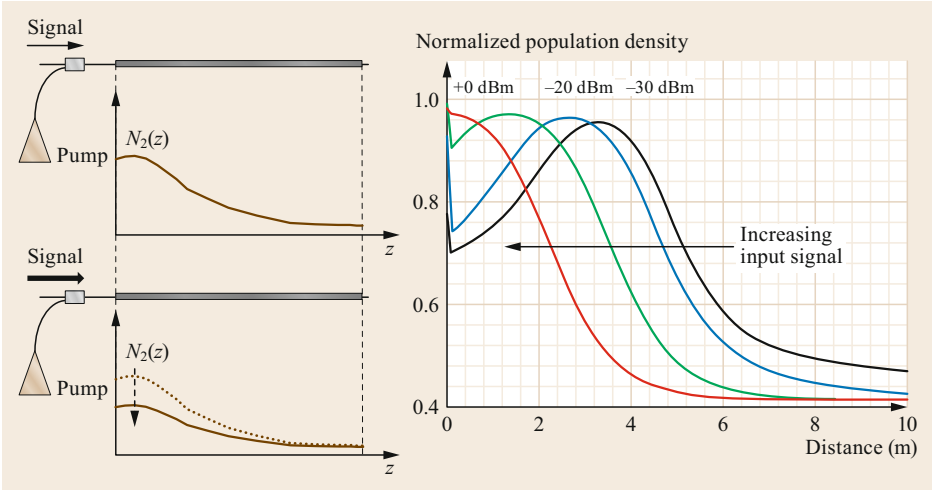

Fig. 3.6 Inversion dependence on input signal power: An increase in input level results in a decrease in the total inversion level N_2, resulting in rapid depletion along the EDF length

played by average rather than localized (spatially dependent) inversion [3.12]. This fact is counterintuitive and requires revisiting (3.4) and (3.6), after introducing the notion of the average inversion parameter $\overline{N}_2$

$$\overline{N}_2 = \frac{1}{l}\int_0^l N_2(z)\mathrm{d}z\,, \tag{3.7}$$

where l is the length of the Er-doped waveguide. Integration of (3.4) along the entire EDF length yields

$$\begin{aligned}\frac{1}{\tau_0}\int_0^l N_2(z)\mathrm{d}z &= -\frac{1}{\rho A}\int_0^l \sum_{i=1}^{N} u_i \frac{\mathrm{d}P_i(z)}{\mathrm{d}z}\mathrm{d}z \\ &= -\frac{1}{\rho A}\sum_{i=1}^{N}(P_{i,\mathrm{out}} - P_{i,\mathrm{in}})\,. \end{aligned} \tag{3.8}$$

Now, defining the average gain as

$$\overline{g}_n = \frac{1}{l}\ln\frac{P_{i,\mathrm{out}}}{P_{i,\mathrm{in}}}\,,$$

it is possible to relate the average inversion level to the EDFA gain and input optical powers by the simple relation

$$\frac{1}{\tau_0}\overline{N}_2 = -\frac{1}{l\rho A}\sum_{i=1}^{N} P_{i,\mathrm{in}}(\mathrm{e}^{\overline{g}_n l} - 1)\,. \tag{3.9}$$

The average gain, also referred to as the global (port-to-port) gain, can be measured easily to provide the EFFA average inversion level. However, during the design process, the output power levels are not known in advance and must be replaced by physical parameters tied to the EDF. This can be accomplished by integrating (3.6) along the entire EDF length

$$\int_0^l \frac{\mathrm{d}P_n(z)}{\mathrm{d}z}\mathrm{d}z = u_n\int_0^l [(\gamma_n + \alpha_n)N_2(z) - \alpha_n]P_n(z)\mathrm{d}z\,, \tag{3.10}$$

which when combined with the definition of the average gain $\overline{g}_n$, results in the simple inversion–gain relationship

$$\overline{g}_n = (\gamma_n + \alpha_n)\overline{N}_2 - \alpha_n\,. \tag{3.11}$$

This allows a single, master EDFA equation to be written only in terms of the average inversion [3.12]

$$\overline{N}_2 = -\frac{\tau_0}{lA\rho}\sum_{i=1}^{N} P_{i,\mathrm{in}}(\mathrm{e}^{[(\gamma_i+\alpha_i)\overline{N}_2 - \alpha_i]l} - 1)\,. \tag{3.12}$$

It is difficult to overstate the importance of (3.12), since its solution not only allows for complete EDFA analysis but also provides important insights that aid the amplifier design process. With the emission (absorption) parameters, uniquely defined by the selected Er doping level and specified input signal/pump powers, one can, at least in principle, calculate the average inversion level in any EDFA operating regime. While $\overline{N}_2$ is a single, scalar parameter, its knowledge uniquely defines the EDFA response across the entire spectral range. Remarkably, even though the above derivation discards the information on *local* inversion in order to calculate the *global* ion inversion, the amplifier gain, spectral response, and noise characteristics can still be calculated in an unambiguous manner.

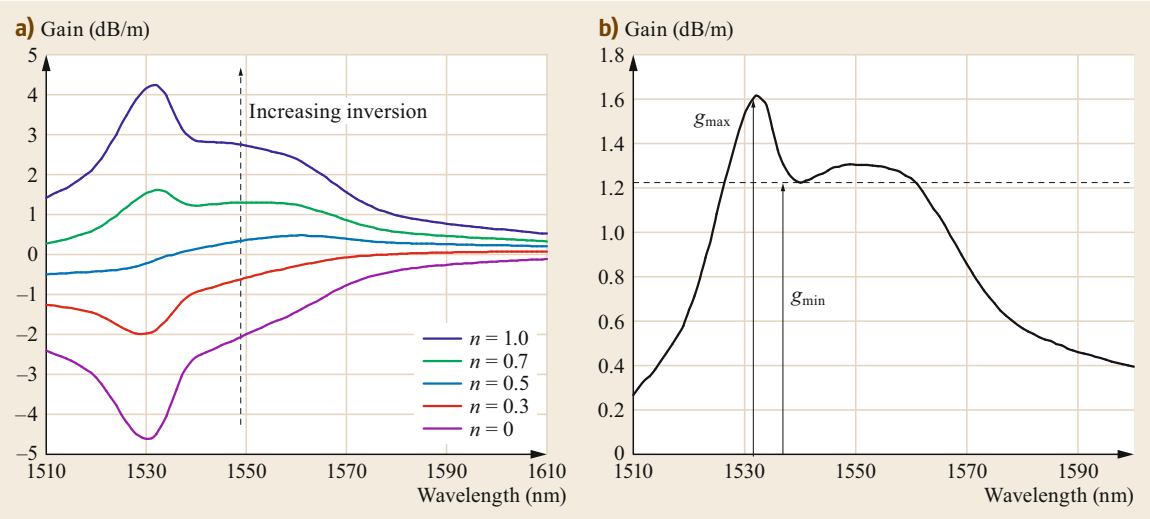

Fig. 3.7 **(a)** EDF gain dependence on average inversion level. **(b)** The selection of a specific inversion value uniquely defines the gain ripple and total attenuation that must be applied to equalize the EDFA spectral response $g_{max} - g_{min}$

Knowledge of $\overline{N}_2$ also allows the calculation of the EDFA gain at any wavelength of interest. Indeed, it is sufficient to note that (3.11) implies an ability to calculate the gain at an arbitrary wavelength as

$$G(\lambda_n) = \{[\gamma(\lambda_n) + \alpha(\lambda_n)]\overline{N}_2 - \alpha(\lambda_n)\}l\,. \qquad (3.13)$$

A direct and practical implication is that one only needs to measure the gain at a single wavelength in order to calculate the EDFA gain at any other wavelength, commonly referred to as gain ripple. Indeed, assuming that the gain is measured at λ_n, then the gain at any other wavelength λ_m is given by

$$G(\lambda_m) = \frac{[\gamma(\lambda_m) + \alpha(\lambda_m)]}{[\gamma(\lambda_n) + \alpha(\lambda_n)]} \times [G(\lambda_n) + \alpha(\lambda_n)l] - \alpha(\lambda_m)l\,. \qquad (3.14)$$

However, one also needs to be cautioned that the predictive accuracy of (3.8) and (3.9) greatly depends on that of the emission and absorption parameters. The last relation is also often used for the characterization of black-box EDFA devices, where no knowledge about the EDF length is available and one only has access to the input/output ports with a single, fixed-wavelength laser. To illustrate its utility, let us assume that a gain increase (decrease) has occurred, resulting in a change in the average inversion of the amplifier. In this case, the gain change measured at the probe wavelength (λ_p) is

$$\Delta G(\lambda_p) = [\gamma(\lambda_p) + \alpha(\lambda_p)]\Delta\overline{N}_2 l\,. \qquad (3.15)$$

The gain difference at any other wavelength can then be calculated as [3.12]

$$\Delta G(\lambda) = \frac{[\gamma(\lambda) + \alpha(\lambda)]}{[\gamma(\lambda_p) + \alpha(\lambda_p)]}\Delta G(\lambda_p) = T(\lambda)\Delta G(\lambda_p)\,, \qquad (3.16)$$

where $T(\lambda)$ is referred to as the gain tilt function. Consequently, if the EDFA is regarded as a black-box, two-port module, it is only necessary to measure the port-to-port gain response at two wavelengths to obtain the gain tilt function and subsequently determine the full gain spectrum.

Determining the average inversion plays a crucial role in any EDFA design, and its importance can be easily visualized by plotting the average (unit-length) gain as a function of the normalized inversion level, as shown in Fig. 3.7.

In a general EDFA design problem, a target gain, bandwidth, and noise response are given, subject to predetermined pump and signal budgets. The design process is initiated by selecting the specific inversion level, under the assumption that all the physical constraints can be met. To illustrate the iterative design methodology, let us assume that a line-amplifier element should generate 25 dB of gain in the C-band ($1530 < \lambda < 1560$ nm). In the first step, one chooses the average inversion level and uniquely defines a native (unequalized) spectral response of the amplifier, as illustrated in Fig. 3.7b. At this inversion level, the minimum gain ($g_{min} = 1.21$ dB/m) occurs at 1542 nm, dictating that the EDF length must be at least 25 dB/(1.12 dB/m) = 20.67 m. At the same time, the maximal unit gain

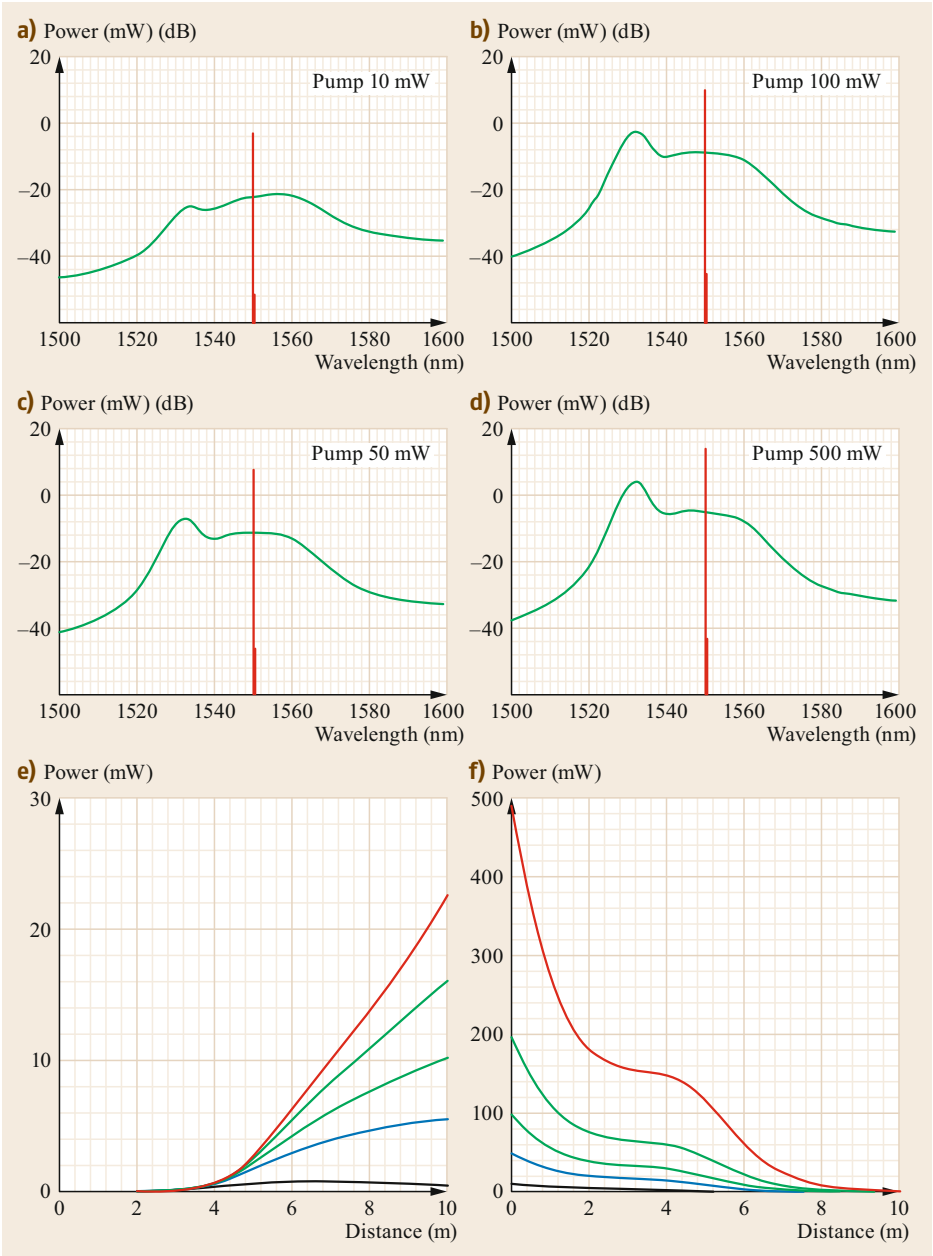

Fig. 3.8a–f Pump power and inversion: An increased pump level guarantees a higher signal gain **(a–d)** (signal at 1550 nm, *red curve*) and higher inversion level, as indicated by ASE (*green curve*). However, an increased pump level also changes the effective EDF length, as indicated by the signal **(e)** and pump **(f)** evolution

($g_{max} = 1.67\,dB/m$) will result in a peak amplifier gain of 34.52 dB, inducing a gain ripple of 14.52 dB.

The latter imposes the first decision during the design process; if such a ripple is not acceptable (because it exceeds the maximal loss of the gain-flattening filter or compromises the EDFA noise performance), a new inversion level is selected to reduce the gain ripple. Even if the average inversion level meets the ripple requirement, the design must still meet the available pump budget. Indeed, the desired inversion level also defines the required pump budget, which becomes progressively higher with increasing EDF length and signal power. To illustrate this challenge, consider a fixed EDF section ($l = 10\,m$), intended to amplify a typical signal level at the end of the transmission span ($P_{in} = -25\,dBm$). Figure 3.8 shows the progressively higher pump requirement as the average inversion is increased in order to meet the high gain condition. In this particular example, a gain increase from 20 to 35 dB mandates a 50-fold (17 dB) pump increase, indicating

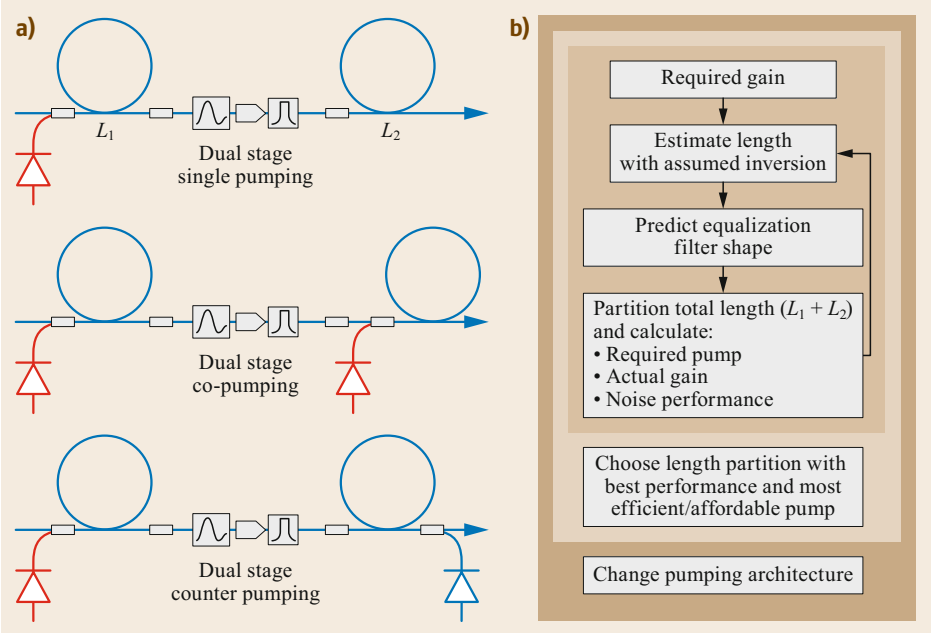

Fig. 3.9a,b Multistage EDFA design as iterative process: multiple pumping strategies and ASE management architectures **(a)** must be evaluated during a physical parameter search that include pump powers, EDF section lengths and partitioning, and feasibility of ASE filter implementation **(b)**

an approximate scaling law, when ASE generation is discounted.

Unfortunately, the design considerations discussed so far are applicable only to single-stage EDFA devices but do not correspond to practically useful gain blocks. Indeed, all three types of amplifier (preamplifier, line amplifier, and boosters) are designed and constructed using multiple EDF stages in order to manage ASE generation, impose local control over inversion levels, manage crosstalk and impairments, bury passive optical loss, and distribute pumps efficiently. As a result, the design process becomes considerably more complex, even in the case of simple, two-stage devices, as illustrated in Fig. 3.9. This flowchart illustrates a general design methodology, albeit still not incorporating crosstalk management or distortion suppression, that provides a systematic path to achieve the desired EDFA performance.

However, in practice, the design challenge is considerably greater, since amplifiers comprise more than two EDF stages. Figure 3.10 illustrates an example of a banded line amplifier capable of supporting 27 dB port-to-port gain along with buried (interstitial) loss in order to accommodate wavelength add/drop or dispersion-compensating modules. In this case, the parameter search space spans four distinct EDF segments that share co- and counterdirectional pumping and ASE management. While the detailed design strategy is considerably more complex than the procedure outlined in Fig. 3.9, it shares the common traits of first setting the average inversion, followed by iterative attempts to maintain the spectral equalization and gain targets.

3.1.2 Noise Characteristics

In addition to its spectral and gain response, an EDFA amplifier should be designed to generate minimal noise under given physical constraints. In the context of lightwave communications, this means that the signal integrity should not be substantially degraded during the amplification process, by either additive mechanisms such as ASE or intraamplifier nonlinear distortions such as cross-phase modulation or four-wave mixing. In nearly all practical cases of interest, EDFA noise is dominated by ASE generation and is uniquely defined by the input signal and the inversion level of the amplifier. Comprising spontaneously emitted photons, ASE manifests as forward- and backward-propagating fields that are both unpolarized (in a non-PM EDF) and uncorrelated to the input signal. ASE occurs due to the large number of Er ion emitters that, in the absence of cooperative effects [3.10, 13], can be modeled under the assumption of random phase and position. As a consequence, the distributed EDF ASE gives rise to nearly ideal, white noise that is easily characterized by measuring the spectral power density, distributed between the two polarizations in an isotropic (non-birefringent) EDF.

To characterize the impact of ASE on the signal, it is common to consider the field received by an ideal

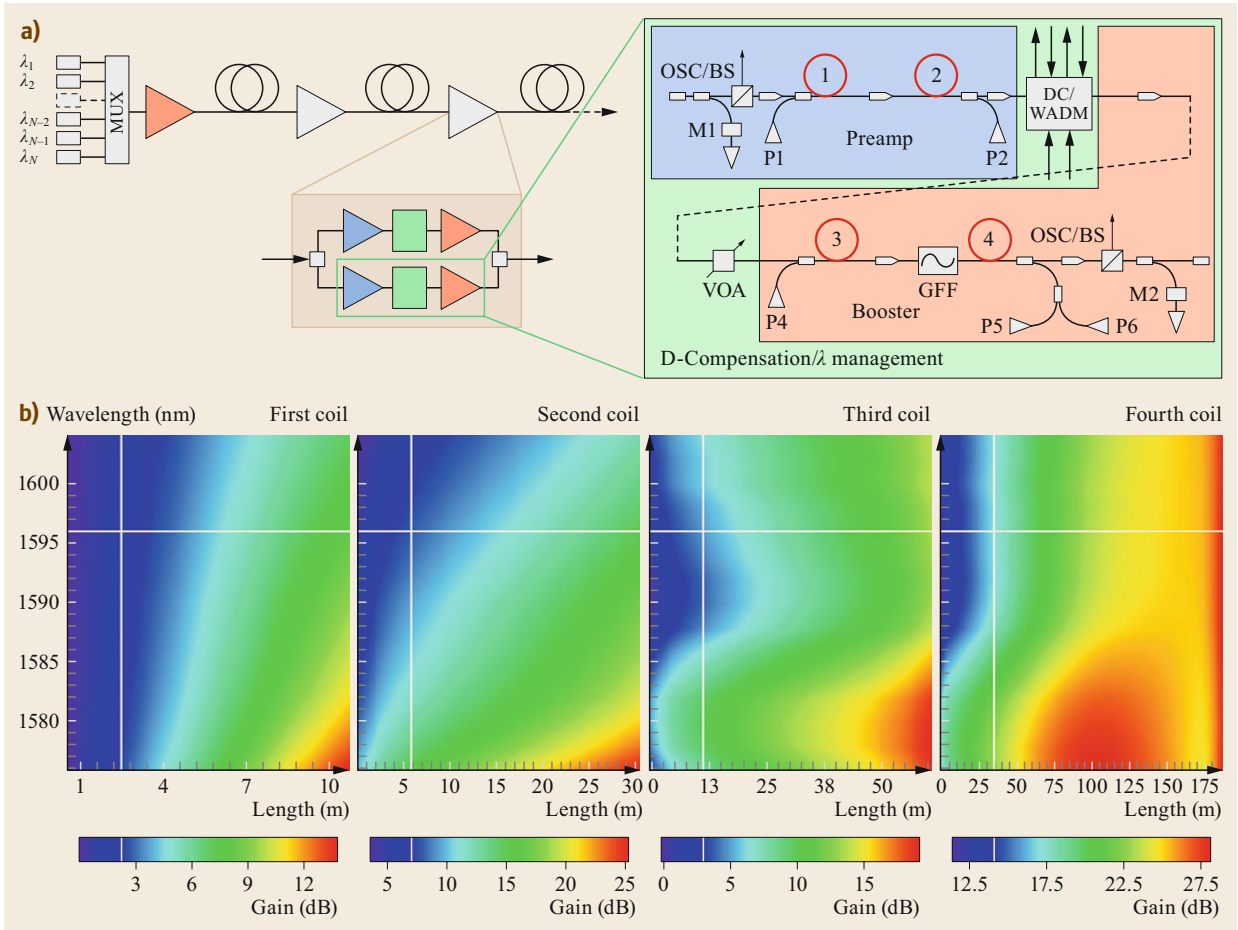

Fig. 3.10a,b Multistage EDFA with interstitial loss **(a)** and **(b)** optimal signal/pump evolution in each section

detector modeled as a band-limited, square-law opto-electronic converter. In this case, the received current can be expressed as

$$I_{\mathrm{det}}(t) = \eta \frac{1}{2T} \int_{-T}^{T} |\boldsymbol{E}_{\mathrm{sig}}(t+t') + \boldsymbol{E}_{\mathrm{ASE}}(t+t')|^2 \mathrm{d}t' \,, \quad (3.17)$$

where η is the detector efficiency, T is the detector response time, E_{sig} is the signal, and E_{ASE} is the ASE field contribution. Following the Wiener–Khintchine theorem, the spectral density of the detector current is defined by the Fourier transform of its correlation, giving rise to three distinct spectral components

$$S(f) = (P_{\mathrm{sig}} + P_{\mathrm{ASE}})^2 \delta(f) + P_{\mathrm{sig}} \rho_{\mathrm{ASE}}(f_{\mathrm{sig}}) + \int_{f_{\mathrm{sig}}-\Delta f}^{f_{\mathrm{sig}}+\Delta f} \rho_{\mathrm{ASE}}(f)^2 \mathrm{d}f \,, \quad (3.18)$$

where P_{sig} and P_{ASE} represent the average received powers, ρ_{ASE} is the ASE spectral power density, and f_{sig} is the signal frequency. The first term in (3.18) represents the total direct-current (DC) power received at the detector, the second term is readily recognized as the signal–spontaneous beat noise, while the last term is the spontaneous–spontaneous beat noise. In almost all cases of interest, channel reception is limited by the signal–ASE beat noise, allowing for a simplified quantification of the characteristics of the EDFA noise and its impact on the performance of the lightwave link. Following this approach, a general notion of the noise figure as the ratio of the input to output signal-to-noise-ratio (SNR) F can be defined as

$$F = \frac{\mathrm{SNR}_{\mathrm{in}}}{\mathrm{SNR}_{\mathrm{out}}} \,. \quad (3.19)$$

In contrast to (3.2), the noise figure is expressed on a linear rather than dB scale here. To make this defi-

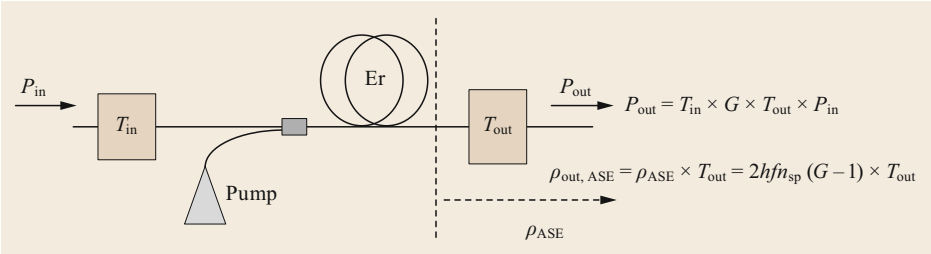

Fig. 3.11 Single-stage EDFA noise generation and noise figure, accounting for input and output insertion losses

nition valid, the input SNR must be referenced to the least-noisy (shot-noise-limited) signal

$$\mathrm{SNR}_{in} = \frac{P_{in}^2}{2P_{in}hfB_{el}}\,, \tag{3.20}$$

where h is the Planck constant, f is the signal carrier frequency, and B_{el} is the detector bandwidth. The output SNR, dominated by the signal–ASE beat, is defined as

$$\mathrm{SNR}_{out} = \frac{P_{out}^2}{P_{out}\rho_{ASE}B_{opt}}\,. \tag{3.21}$$

This last relation is written under the assumption that the bandwidth of the optical filter preceding the detector and its electrical bandwidth are matched as $B_{opt} = 2B_{el}$, avoiding mismatch correction factors. In this case, the ratio of (3.21) and (3.20) gives rise to a remarkably simple expression for the EDFA noise figure

$$F = \frac{\rho_{ASE}}{Ghf}\,. \tag{3.22}$$

Substituting the value of the ASE spectral power density ($\rho_{ASE} = 2n_{sp}(G-1)hf$), where n_{sp} represents the spontaneous emission factor [3.10], into the last equation yields the well-known expression that relates the noise figure and gain of an EDFA

$$F = 2n_{sp}\frac{G-1}{G}\,. \tag{3.23}$$

In the case when $G \gg 1$, and with near full inversion ($n_{sp} \approx 1$), the EDFA noise figure approaches 2 (or 3 dB in logarithmic terms), which is often referred to as the practical noise limit of a well-designed amplifier. Indeed, it can be shown that this limit cannot be violated for phase-insensitive amplifiers while any further reduction requires the introduction of a phase-sensitive physical process such as parametric interaction. However, in special circumstances, such as when the EDFA operates with low gain ($G < 10$), its noise figure can be lower than 2 (3 dB) without resorting to phase-sensitive amplification.

In practice, the noise figure of an EDFA must be expressed in terms of readily available physical parameters that can be measured using conventional instruments, such as the optical signal-to-noise ratio (OSNR). By expressing the OSNR of the EDFA in terms of the signal power and ASE spectral power density as

$$\mathrm{OSNR} = \frac{P_{sig}}{\rho_{ASE}\Delta f|_{B_{opt}}} \tag{3.24}$$

and eliminating the ASE spectral power density, a particularly simple expression for the output OSNR can be written

$$\mathrm{OSNR} = \frac{GP_{in}}{\rho_{ASE}\Delta f|_{B_{opt}}} = \frac{GP_{in}}{hfGF\Delta f|_{B_{opt}}}\,, \tag{3.25}$$

allowing the NF to be expressed as

$$\mathrm{NF} = P_{in} - \mathrm{OSNR} - 10\log\left(\frac{hc^2\Delta\lambda}{\lambda^3}\right). \tag{3.26}$$

A direct relationship between the OSNR, signal power, and noise figure is particularly useful when considering a practical EDFA device that must account for finite losses associated with signal insertion, pump multiplexing, and any passive elements required within the optical path. To illustrate its utility, consider a simple, single-stage EDFA amplifier, as shown in Fig. 3.11.

A composite noise figure for the gain element (the Er-doped fiber section) with accompanying passive losses can be calculated by noting that the output SNR can be expressed in terms of the amplified signal level and output ASE

$$\mathrm{SNR}_{out} = \frac{P_{out}}{2\rho_{ASE}B_{el}} = \frac{T_{in}GT_{out}P_{in}}{4hfn_{sp}(G-1)T_{out}B_{el}}\,. \tag{3.27}$$

Consequently, an aggregate noise figure can be readily calculated by combining (3.14) and (3.21)

$$F = \frac{\mathrm{SNR}_{in}}{\mathrm{SNR}_{out}} = \frac{1}{T_{in}}\frac{2n_{sp}(G-1)}{G}\,. \tag{3.28}$$

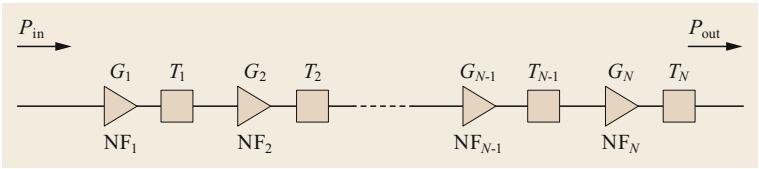

Fig. 3.12 EDFA cascade: Noise and signal power accounting

This last relation is particularly simple when written on the decibel scale

$$\mathrm{NF} = \mathrm{NF}_{\mathrm{EDFA}} - T_{\mathrm{in}}|_{\mathrm{dB}} \,, \tag{3.29}$$

where $T_{\mathrm{in}}|_{\mathrm{dB}} < 0$ represents the insertion loss on the dB scale. The last relation states that the aggregate EDFA noise figure does not depend on the output loss but does increase directly with addition of the input loss, regardless of the gain block architecture. Using a similar rationale, an aggregate noise characteristic of a cascade of EDFA gain blocks with interstitial losses, which corresponds to a typical transmission link, can be easily characterized, as shown in Fig. 3.12.

The transmitted signal power at the end of a gain-balanced ($G = 1/T$) link is $P_{\mathrm{out}} = G^N T^N P_{\mathrm{in}} \xrightarrow{G=1/T} P_{\mathrm{in}}$. The case in which each the gain block matches the subsequent loss exactly $G_{\mathrm{i}} = 1/T_{\mathrm{i}}$ is of particular interest. In such a link, the ASE spectral density emitted by the first EDFA

$$\rho_{\mathrm{ASE}}^{(1)} = 2hfn_{\mathrm{sp}}(G-1) \tag{3.30}$$

is attenuated by the first interamplifier loss (T_1) and then amplified by the second gain element (G_2)

$$\rho_{\mathrm{ASE}}^{(2)} = 2hfn_{\mathrm{sp}}(G-1)T \times G + 2hfn_{\mathrm{sp}}(G-1) \,. \tag{3.31}$$

By propagating the ASE spectral density along the entire link, the final (end-of-link) spectral density can be expressed as

$$\rho_{(\mathrm{out}),\mathrm{ASE}} = 2hfn_{\mathrm{sp}}(G-1)T \sum_{i=1,N} (GT)^N \xrightarrow{G=1/T} 2hfn_{\mathrm{sp}}(G-1)NT \,, \tag{3.32}$$

leading to a simple expression for the aggregate noise figure of the link

$$F = 2n_{\mathrm{sp}}(G-1)NT \,. \tag{3.33}$$

While simple, this last relationship has important implications: it states that the aggregate noise figure of a transparent transmission link grows directly with the number of gain elements, as expected intuitively.

3.1.3 Distortion Mechanisms

In addition to ASE noise, the integrity of the amplified signal is also impaired by scattering and nonlinear mechanisms along the optical path. The first of these, commonly referred to as multiple-path interference (MPI) [3.14], is illustrated in Fig. 3.13.

MPI is generated by reflection from optical interfaces along the optical path and can originate from both inside and outside the gain element. In practice, even if an EDFA is constructed using only all-fiber components, connectorization between dissimilar fiber types [such as a single-mode fiber (SMF) and an Er-doped fiber] will result in finite facet reflectivity. This effect is much stronger if fusion splicing cannot be used and the fiber optical path has to be closed using fiber connectors or interfaces with free-space optical elements such as gain-flattening filters, isolators, or filters. Even if such (discrete-type) reflection is eliminated, an in-line amplifier is still surrounded by long fiber spans that inherently act as distributed Rayleigh mirrors [3.15]. This is a particularly challenging impairment in bidirectional transmission links that must amplify signals in both directions. In this case, a signal traveling in one direction will be scattered by a distributed Rayleigh mirror, aligning its reflection with the counterpropagating signal flow. In nearly all cases of practical interests (i.e., when

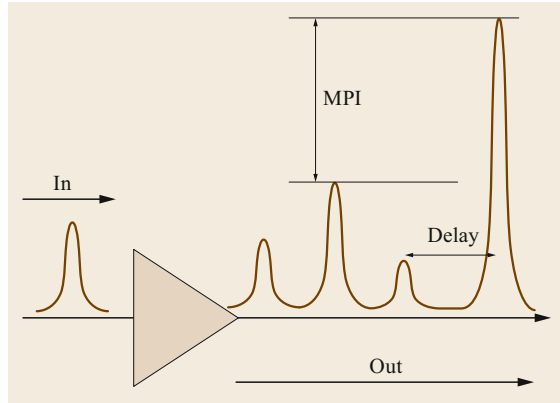

Fig. 3.13 Multiple-path interference (MPI) is generated by multiple reflections off discrete facets of distributed reflectors. The effect is amplified when reflectors are either embedded into or surround an amplifier device

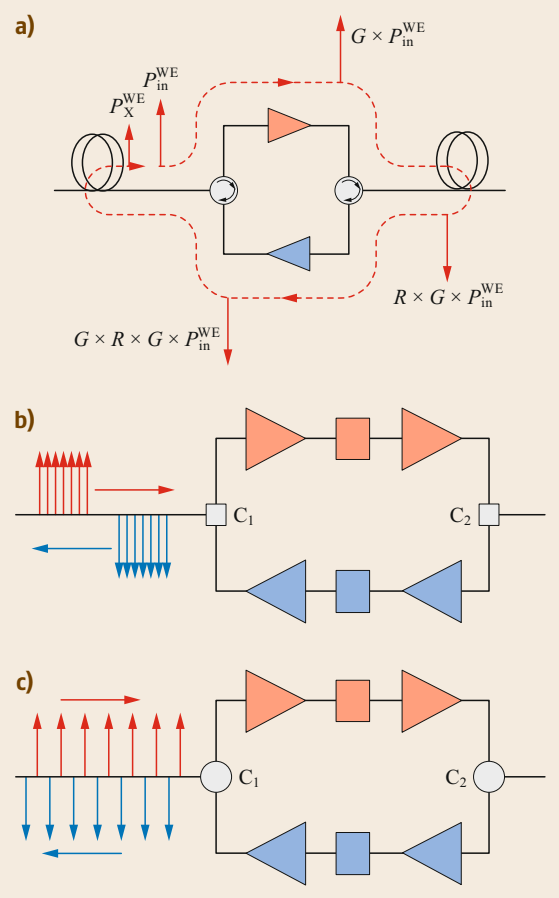

Fig. 3.14 **(a)** MPI induction path in bidirectional amplifier node. **(b)** Banded MPI-mitigation architecture relying on band-splitting (band-combining) elements $C_{1,2}$. **(c)** Interleaved MPI mitigation using interleaved optical filters

the fiber span is longer than 20 km), a Rayleigh mirror will return a reflection that is attenuated by approximately 30 dB with respect to the launched signal and subject it to an amplification pass. Consequently, a conventional in-line amplifier designed to offset a typical ($\approx 80-100$ km) span, will necessarily generate an in-band crosstalk that is only 10 dB lower than the signal power. This is clearly not acceptable, since the effective OSNR, now defined by the crosstalk, would be only 10 dB after traversing a single amplification node.

To address this problem in bidirectional amplified transmission links, counterpropagating channel plans must be frequency (wavelength) nondegenerate, as shown in Fig. 3.14. Banded bidirectional transmission, the preferred implementation for this architecture, has been widely deployed and provides an elegant solution that mitigates MPI induced by either discrete or distributed reflectors. In contrast, an interleaved channel plan can also achieve the same goal, allowing, at least in principle for higher channel density before the onset of a four-photon mixing penalty [3.16, 17]. However, it must be noted that the banded scheme requires only band-splitting (band-combining) elements, while interleaved bidirectional transmission relies on more complex optical filters that have larger insertion loss and lower spectral isolation [3.18].

When used in unidirectional lightwave transmission, an EDFA is a single-pass, traveling amplifier that does not generate internal optical powers comparable to those found within laser cavities with comparable output. An EDFA amplifier is also considered to be a lumped network element, since its effective length is considerably smaller than that of any transmission span of interest. Consequently, it is reasonable to assume that no intra-EDFA nonlinear effects will make a significant contribution to signal impairments, as neither its effective length nor the intradevice power levels appear sufficient to generate large nonlinear phase shifts [3.19].

Unfortunately, this is not always a valid assumption, particularly in the case of L-band EDFA devices [3.20]. Since L-band absorption (emission) is much weaker than in the C-band, the EDF must be correspondingly longer, increasing the effective power–length product that governs the efficiency of the nonlinear interaction in the fiber. This is particularly true in the case when a dense WDM channel plan is combined with L-band EDFA amplification, creating the potential for nonnegligible four-photon mixing (FPM) inside the amplifier. However, intra-EDFA FPM analysis is considerably more complex than that of a passive (transmission) fiber where the signal evolution is monotonically decreasing. This notion is illustrated in Fig. 3.15, showing the direct correspondence between a specific EDFA design that governs the signal evolution and the induced FPM penalty [3.21].

The intraamplifier signal evolution function $G(\omega, z)$, uniquely defined by the local inversion level (i.e., the specific EDFA design) also determines the local power for all the amplified channels. By segmenting the EDFA into a set of quasiuniform sections, it is possible to calculate the FPM efficiency for any combination of channels ω_p, ω_q, and ω_r. By integrating these contributions along the entire EDFA length, the aggregate FPM efficiency can be expressed in the simple form [3.21]

$$\eta = \Omega \left| \int_0^L e^{j\Delta\beta z} \sqrt{\frac{G_p(z)G_q(z)G_r(z)}{G_F(z)}} dz \right|^2 , \qquad (3.34)$$

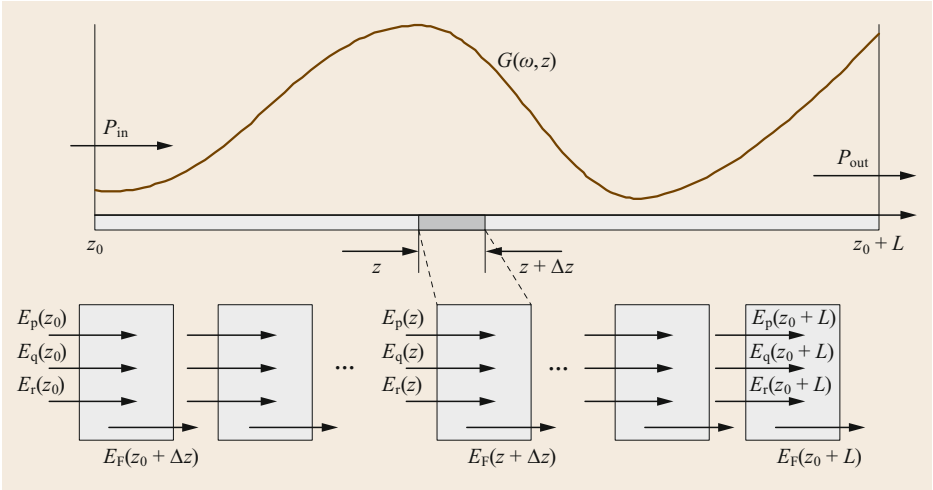

Fig. 3.15 The localized gain function $G(\omega, z)$ within an EDFA uniquely governs the FPM efficiency. By segmenting the EDF into sufficiently small sections, concatenated FPM analysis can be derived and applied to any intraamplifier signal evolution

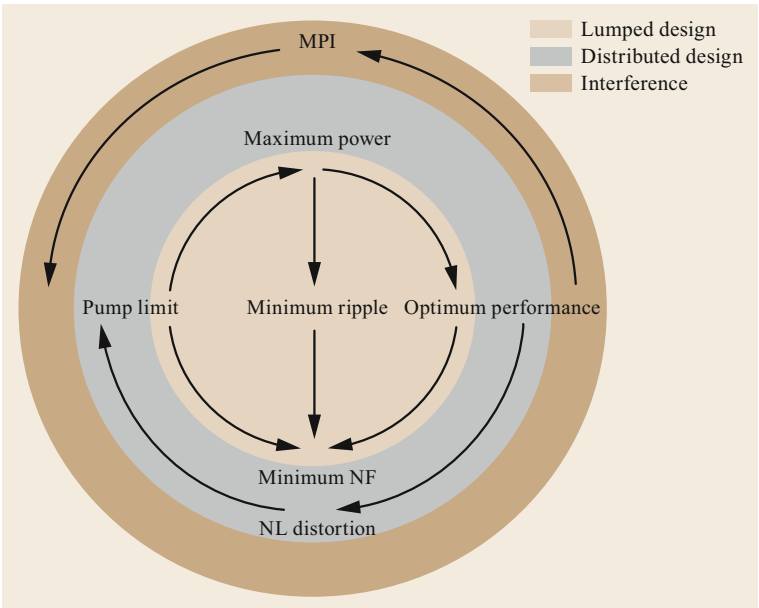

Fig. 3.16 Generalized EDFA design strategy combining conventional (gain/noise/ripple) and advanced network-imposed constraints (signal distortion)

where the scaling factor Ω and mismatch $\Delta\beta$ are given as

$$\Omega = \frac{1024\pi^2 D_\chi^2 P_p(0) P_q(0) P_r(0)}{n^4 \lambda^2 c^2 A_{\text{eff}}^2} G_F(L)$$

$$\Delta\beta \approx \frac{2\pi\lambda^2 \Delta f_{pr} \Delta f_{qr}}{c} \times \left[D(\lambda) + \frac{\lambda^2}{2c} (\Delta f_{pr} + \Delta f_{qr}) \frac{dD(\lambda)}{d\lambda} \right].$$

Consequently, to minimize intra-EDFA FPM distortion, it is necessary to increase the effective area (A_{eff}) and chromatic dispersion (D) of the EDF. Unfortunately, this is not always possible, since the EDF doping level imposes its own constraints on the fiber index profile, leaving FPM minimization to gain-function optimization. Indeed, (3.34) states that FPM can be effectively minimized without affecting the optical properties of the EDF by minimizing the path integral defined by the gain function $G(\omega, z)$.

As a consequence, the design and construction of an optimal EDFA requires much more than a determination of the optimal inversion level. Figure 3.16 illustrates this challenge by outlining an iterative design strategy that aims to produce an amplifier with desired gain and minimal spectral ripple and noise figure while simultaneously suppressing MPI and nonlinear distortions.

3.2 Raman Amplifiers

The phenomenon of scattering of light of frequency ν_0 on molecular vibrations of frequency ν_R, which has become known as *Raman scattering*, was originally discovered in 1928 independently by C.V. *Raman* and K.S. *Krishnan* in India [3.22] and L. *Mandelstam* and G. *Landsberg* in the Soviet Union [3.23]. Raman scattering produces new sidebands with frequencies $\nu_0 - \nu_R$ (the downshifted, or Stokes, wave) and $\nu_0 + \nu_R$ (the upshifted, or anti-Stokes, wave) around the *pump* frequency ν_0. From the quantum-mechanical point of view, the difference between the energy of the pump photon $h\nu_0$ and the Stokes photon $h(\nu_0 - \nu_R)$ is used to excite a phonon with energy $h\nu_R$. To generate the anti-Stokes photon with energy $h(\nu_0 + \nu_R)$, the pump photon energy has to combine with the energy of an existing phonon $h\nu_R$, which means that the anti-Stokes process is $\exp[-h\nu_R/(k_B T)]$ times less probable than the Stokes one, making it possible to carry out precise temperature measurements based on the anti-Stokes/Stokes intensity ratio. With the invention of the laser, it became possible to observe not only spontaneous Raman scattering (where the process starts with no Stokes and anti-Stokes waves at the input) but also stimulated Raman scattering (SRS) [3.24], where the pump wave provides gain for the input Stokes wave. Soon after the invention of the low-loss optical fiber, SRS was observed and characterized in fibers [3.25, 26]. The potential of SRS in fibers for distributed amplification within the transmission span was understood and demonstrated in the 1980s [3.27–29], but it was not until the mid-1990s that the availability of high-power semiconductor laser pumps thrust Raman amplification into the mainstream of optical fiber communications (see [3.30–33] for review). Distributed Raman amplifiers are now widely used both in repeaterless transmission (e.g., festoon-type submarine links) and in repeatered communication systems, while discrete (i.e., lumped) Raman amplifiers are used to overcome the loss of fiber-based components (e.g., dispersion-compensating modules) and to create optical gain at wavelengths outside of the EDFA gain window.

3.2.1 Advantages of Raman Amplifiers

Although Raman amplifiers have lower pump efficiency compared with EDFAs, which requires higher pump powers and/or longer gain fibers, they also offer a number of advantages, which can be summarized as follows:

- Raman gain can be provided to the signal within the transmission fiber span (distributed amplification), which can dramatically improve the signal-to-noise ratio.
- Raman gain can also be implemented in a lumped (discrete) amplifier by employing a relatively short length of a small-effective-area fiber, such as a dispersion-compensating fiber (DCF) or highly nonlinear fiber (HNLF).
- The Raman effect can amplify signals at any wavelength (e.g., outside the EDFA C- and L-bands), as long as the pump wavelength is available one anti-Stokes shift away from it.
- An arbitrarily small gain ripple can be achieved by wavelength-division multiplexing (WDM) of the pumps.
- By employing many fewer optical components in the signal path (essentially only the pump/signal WDM multiplexer), Raman amplifiers can yield lower polarization mode dispersion (PMD) and polarization-dependent gain (PDG) or loss (PDL) than EDFAs, which is important at high symbol rates.

The rest of Sect. 3.2 is organized as follows: Sect. 3.2.2 reviews the basic principles of Raman amplification and its leading noise mechanisms; Sect. 3.2.3 describes practical design issues such as flattening the gain and noise figure, improving the signal-to-noise ratio, avoiding transfer of pump noise, and using numerical modeling; and Sect. 3.2.4 provides a summary and outlook.

3.2.2 Fundamentals

Basic Theory

When a pump beam at frequency ν_0 and a signal beam at frequency $\nu_S = \nu_0 - \nu_R$ propagate in the same optical fiber, their evolution along the fiber is described by the following set of equations for the signal (here $z = 0$ and $z = L$ at the beginning and end of the fiber, respectively)

$$\frac{dP_S^+}{dz} = \left[\overbrace{-\alpha_S}^{\text{Fiber loss}} + \overbrace{\frac{g_R(\nu_R)}{A_{\text{eff}}}}^{\text{Raman gain}} P_P \right] P_S^+ + \underbrace{\alpha_{RBS}}_{\text{Rayleigh scattering}} P_S^- + \underbrace{2n_{sp} h\nu_S \Delta\nu \frac{g_R(\nu_R)}{A_{\text{eff}}} P_P}_{\text{Raman ASE}} ,$$

$$\frac{dP_S^-}{dz} = -\left[-\alpha_S + \frac{g_R(\nu_R)}{A_{\text{eff}}} P_P \right] P_S^- - \alpha_{RBS} P_S^+ - 2n_{sp} h\nu_S \Delta\nu \frac{g_R(\nu_R)}{A_{\text{eff}}} P_P \qquad (3.35)$$

and the pump $P_P(z) = P_P^+(z) + P_P^-(z)$

$$\frac{dP_P^+}{dz} = -\left[\overbrace{\alpha_P}^{\text{Fiber loss}} + \overbrace{\frac{g_R(\nu_R)}{A_{eff}}\frac{\nu_0}{\nu_S}(P_S^+ + P_S^-)}^{\text{Pump depletion}}\right] P_P^+ ,$$

$$\frac{dP_P^-}{dz} = \left[\alpha_P + \frac{g_R(\nu_R)}{A_{eff}}\frac{\nu_0}{\nu_S}(P_S^+ + P_S^-)\right] P_P^- , \quad (3.36)$$

where the subscripts S and P refer to the signal and pump, while the superscripts + and − denote the components of each beam propagating in the $+z$ (forward) and $-z$ (backward) direction, respectively [3.30]. In (3.35) and (3.36), $\alpha_{S(P)}$ represents the fiber attenuation coefficient at the signal (pump) wavelength, $g_R(\nu_R)$ is the Raman gain coefficient for the Stokes shift $\nu_R = \nu_0 - \nu_S$, A_{eff} is the effective area of the fiber, and α_{RBS} is the Rayleigh backscattering coefficient that couples the forward- and backward-propagating waves. A graph of the Raman coefficient $g_R(\nu_R)/A_{eff}$ in several optical fibers is shown in Fig. 3.17, demonstrating broadband gain with a peak near the Stokes shift $\nu_R = 13\,\text{THz}$, which around a signal wavelength of 1550 nm corresponds to a wavelength shift of $\approx 100\,\text{nm}$ (i.e., the pump wavelength has to be $\approx 1450\,\text{nm}$). The relatively small value of the Raman gain coefficient in optical fibers makes Raman amplifiers less power-efficient than EDFAs and requires kilometer-scale fiber lengths at reasonable pump power levels (hundreds of mW). The second term in the bracket of (3.35) describes the Raman gain, which depends on the total power of the forward- and backward-propagating pumps. The similar term in (3.36) corresponds to the pump depletion by the amplified signal. The Raman gain coefficient in a fiber is highly polarization dependent, with the highest gain for a copolarized and the smallest for a cross-polarized signal and pump. However, the fiber PMD along with the large wavelength separation ($\approx 100\,\text{nm}$) between the signal and pump, as well as the use of backward pumping, essentially result in averaging of the Raman gain coefficient over all relative states of polarization of the signal and pump. The use of polarization-multiplexed pumps and/or pump depolarizers makes the Raman gain polarization independent even for a closer-spaced signal and pump and for the forward-pumping configuration. Thus, in (3.35) and (3.36), it can be assumed that the pumps are unpolarized and that the Raman gain coefficient $g_R(\nu_R)$ is polarization independent and equal to approximately one-half of that for a copolarized signal and pump.

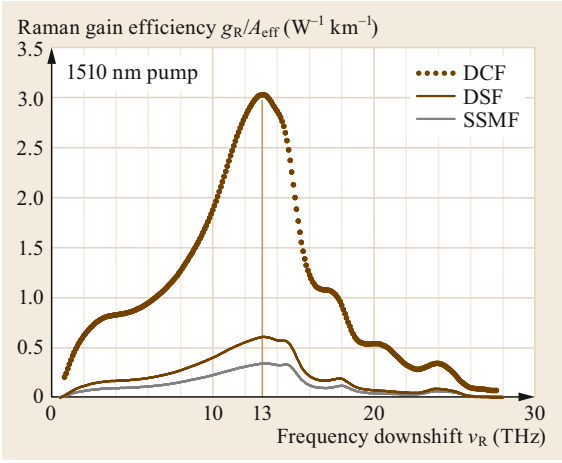

Fig. 3.17 Raman gain spectra in optical fibers. DCF – dispersion-compensating fiber, DSF – dispersion-shifted fiber, SSMF – standard single-mode fiber. (© 2001 IEEE. Adapted, with permission, from [3.31])

The final term in (3.35) represents the ASE power generated by the Raman gain in the optical bandwidth $\Delta\nu$. The factor of 2 describes the total ASE power contained in both polarizations. The spontaneous emission factor $n_{sp} = 1/(1 - e^{-h\nu_R/k_BT})$ has the same meaning as n_{sp} for an EDFA and represents the Raman equivalent of the extra noise due to incomplete inversion, arising from the nonzero phonon population at temperature $T > 0$ ($n_{sp} = 1$ for $T = 0$). At room temperature ($T = 300\,\text{K}$), $n_{sp} \approx 1.14$ for the Stokes shift $\nu_R = 13\,\text{THz}$ corresponding to the peak of the Raman gain in a silica fiber. In (3.36), the Rayleigh scattering of the pump and the pump depletion by the ASE noise are neglected.

Equations (3.35) and (3.36) can first be solved for the evolution of the signal and pump without the Rayleigh backscattering and ASE noise terms, which can be subsequently added to (3.35) as small perturbations of the obtained first-order solutions. For the first-order solution, the evolutions of the signal $P_S^\pm(z)$ and pump $P_P(z)$ are related as

$$P_S^-(z) = 0 ,$$
$$P_S^+(z) = P_S^+(0)g(z) , \quad (3.37)$$

where the signal evolution profile $g(z)$ is given by

$$g(z) = e^{-\alpha_S z}\exp\left[\frac{g_R(\nu_R)}{A_{eff}}\int_0^z P_P(z')\,dz'\right]$$
$$= e^{-\alpha_S z}G_R(z) , \quad (3.38)$$

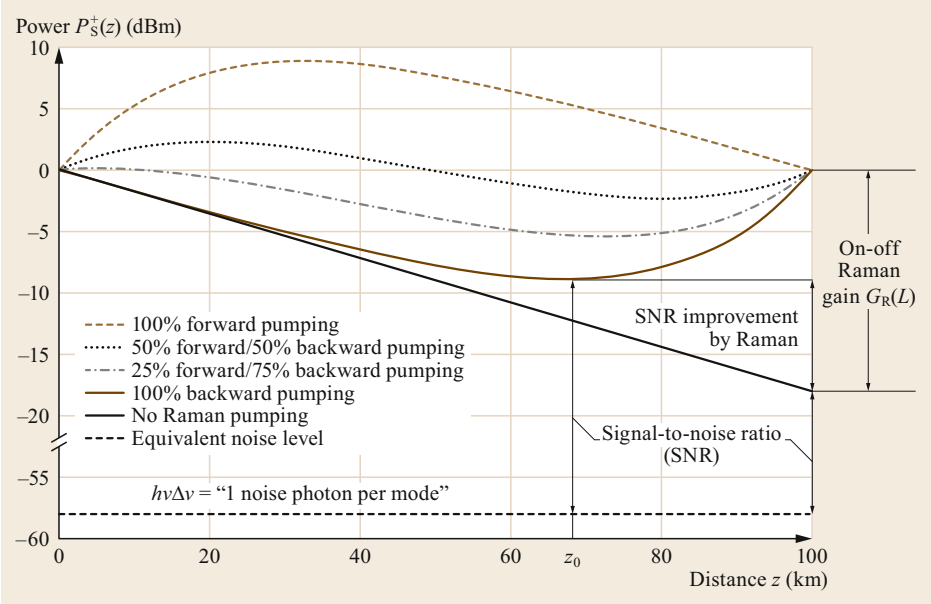

Fig. 3.18 Evolution of signal power over $L = 100$ km span of an SSMF fiber with $\alpha_S = 0.18$ dB/km, $\alpha_P = 0.22$ dB/km, under various Raman pumping configurations. The signal launch power is $P_S^+(0) = 0$ dBm, and the on–off Raman gain $G_R(L)$ of the entire fiber span is set to 18 dB (*transparent* span). The single-photon noise power $h\nu\Delta\nu = -58$ dBm corresponds to $\nu = 193.41$ THz ($\lambda = 1550$ nm) and $\Delta\nu = 12.5$ GHz ($\Delta\lambda = 0.1$ nm). The single-mode SNR at the distributed or lumped amplifier output is related to the ratio between the lowest signal power in the span and the single-photon power level representing the equivalent input noise of the amplifier. The optical signal-to-noise ratio (OSNR) at the amplifier output can be obtained by dividing the single-mode SNR by 2 to account for the ASE in two polarization modes

and $G_R(z)$ is the on–off Raman gain at location z. The on–off gain of the full fiber span is

$$G_R(L) = \exp\left[\frac{g_R(\nu_R)}{A_{\text{eff}}}\int_0^L P_P(z)\,dz\right] = \exp\left[\frac{g_R(\nu_R)}{A_{\text{eff}}}\overline{P_P(z)}L\right], \tag{3.39}$$

where $\overline{P_P(z)} = (1/L)\int_0^L P_P(z)\,dz$ is the path-averaged pump power. To obtain the signal evolution profile in the general case, where the pump depletion term is present in (3.36), one needs to solve (3.35) and (3.36) numerically. However, most frequently, one can neglect the pump depletion term (because the launched pump power is usually much higher than the amplified signal power), which yields

$$P_P(z) = P_{\text{in,P}}[x e^{-\alpha_P z} + (1-x)e^{-\alpha_P(L-z)}] \tag{3.40}$$

and reduces (3.38) to the analytical expression

$$G_R(z) = \exp\left\{\left[x(1-e^{-\alpha_P z}) + (1-x)(e^{\alpha_P z}-1)e^{-\alpha_P L}\right] \times \frac{g_R(\nu_R)P_{\text{in,P}}}{\alpha_P A_{\text{eff}}}\right\}, \tag{3.41}$$

where $P_{\text{in,P}} = P_P^+(0) + P_P^-(L)$ is the total launched pump power, and $x = P_P^+(0)/P_{\text{in,P}}$ and $(1-x) = P_P^-(L)/P_{\text{in,P}}$ are the forward- and backward-propagating fractions of it, respectively. The on–off Raman gain of the entire span in this undepleted pump approximation is given by

$$G_R(L) = \exp\left[\frac{g_R(\nu_R)}{A_{\text{eff}}}P_{\text{in,P}}L_{\text{eff,P}}\right], \tag{3.42}$$

where $L_{\text{eff,P}} = (1-e^{-\alpha_P L})/\alpha_P$ is the effective fiber length for the Raman interaction, and

$$G_R(L)[\text{dB}] = 4.343\frac{g_R(\nu_R)}{A_{\text{eff}}}P_{\text{in,P}}L_{\text{eff,P}}\,. \tag{3.43}$$

Fig. 3.18 shows the evolution of the signal power $P_S^+(z) = P_S^+(0)g(z)$ in a standard single-mode fiber (SSMF) for several values of x at $G_R(L) = 18$ dB.

Raman ASE

As can be seen from Fig. 3.18, the distributed Raman amplification reduces the signal power excursion along the transmission fiber span, and the minimum signal power in the span is increased compared with

that in a fiber with no Raman gain. As a result, one would expect the distributed Raman amplification to yield an improvement in the optical signal-to-noise ratio (OSNR) over lumped amplification. To quantify this improvement, one can compute the Raman ASE noise power from (3.35) by considering it to be a small perturbation of the first-order signal solution of (3.37), (3.38). This yields

$$P^{+}_{\mathrm{ASE}} = 2n_{\mathrm{sp}}h\nu\Delta\nu\left[g(L) - 1 + \int_0^L \frac{g(L)}{g(z)}\alpha_{\mathrm{S}}\,\mathrm{d}z\right], \tag{3.44}$$

which has an analytical solution in the undepleted pump approximation for the backward-pumped case [3.34]. For $\alpha_{\mathrm{P}}L \gg 1$, $G_{\mathrm{R}}(L) \gg 1$, and $\alpha_{\mathrm{S}} = \alpha_{\mathrm{P}}$, this solution for the number of ASE photons per mode reduces to [3.35]

$$N_{\mathrm{ASE}} = \frac{P^{+}_{\mathrm{ASE}}}{2h\nu\Delta\nu} \approx n_{\mathrm{sp}}\frac{G_{\mathrm{R}}(L)}{\ln G_{\mathrm{R}}(L)} \approx n_{\mathrm{sp}}\frac{\mathrm{e}^{\kappa}}{\kappa}\,, \tag{3.45}$$

where $\kappa = g_{\mathrm{R}}(\nu_{\mathrm{R}})P_{\mathrm{in}}/(A_{\mathrm{eff}}\alpha_{\mathrm{P}})$. Equation (3.45) is (up to a constant ≈ 1) equal to the ratio between the signal power at the span output and the lowest signal power in the span, which occurs at a distance $z = z_0 = L - \alpha_{\mathrm{P}}^{-1}\ln(\kappa\alpha_{\mathrm{P}}/\alpha_{\mathrm{S}})$. This leads to a simple physical interpretation of (3.45) as follows: "the generation of Raman ASE noise is equivalent to injecting one noise photon per mode at the point z_0, where the signal power is lowest in the span" [3.35]. (To be more precise, according to (3.45), the generation of Raman ASE noise is equivalent to injecting $en_{\mathrm{sp}} = 3.1$ noise photons per mode at point z_0.) Since the ASE of an ideal (quantum-limited) lumped amplifier at high gain ($N_{\mathrm{ASE}} = G - 1 \approx G$) is equivalent to injecting a single noise photon at its input (i.e., at the $z = L$ end of an unamplified fiber span), then the improvement of the signal-to-noise ratio (SNR) by using the distributed Raman amplifier instead of the ideal lumped one is proportional to the increase in the minimum signal power in the span (Fig. 3.18).

In the forward or bidirectional pumping cases, (3.45) is no longer valid so the ASE power, in general, must be obtained by numerical integration of (3.44). However, even in these cases, qualitative insight into the relative noise performance of various WDM channels or various pumping arrangements can still be obtained by comparing the lowest levels of the signal power in the span (the lower the lowest signal power, the lower the OSNR after the amplifier).

Trade-Off Between Noise Figure and Nonlinearity

From the system performance point of view, when analyzing the unit cell of an optical communication link (i.e., an amplifier and a transmission fiber span), one has to consider the trade-off between its total noise figure and the path-averaged signal power

$$\overline{P_{\mathrm{S}}(z)} = \frac{1}{L}\int_0^L P^{+}_{\mathrm{S}}(z)\,\mathrm{d}z$$

that is responsible for nonlinear impairments [3.36]. Indeed, there are three main possibilities of arranging the gain within the unit cell (i.e., within the amplified span): (a) having a lumped amplifier before the fiber span, (b) having a lumped amplifier after the fiber span, and (c) having the gain distributed within the fiber span. Assuming a transparent unit cell (where the amplifier gain G is equal to the fiber attenuation $\mathrm{e}^{\alpha_{\mathrm{S}}L}$) with input power $P^{+}_{\mathrm{S}}(0)$, one can obtain the noise figures (NFs) and path-averaged powers for these unit cell types, as given in Table 3.1. The lowest NF of the total span in case (a) comes at the expense of the highest path-averaged power (a high-power amplified signal is launched into the fiber). The distributed amplifier's NF and path-averaged power will lie somewhere between

Table 3.1 Performance comparison of types (a), (b), and (c) of amplified fiber spans described in the text. For each type, the total span noise figure, path-averaged signal power, and OSNR factor X from (3.46), (3.47) (as a function of either L or G) are provided, assuming $G = \mathrm{e}^{\alpha_{\mathrm{S}}L}$. For type (c), only the results for ideally distributed gain are given

Amplified span type	NF	$\overline{P_{\mathrm{S}}(z)}$	$X(L)$	$X(G)$
(a) $P^{+}_{\mathrm{S}}(0)$ — G — $1/G$	$3 - 2n_{\mathrm{sp}}(1 - 1/G)$	$P^{+}_{\mathrm{S}}(0)GL^{\mathrm{eff}}_{\mathrm{S}}/L$	$\mathrm{e}^{-\alpha_{\mathrm{S}}L}/(L^{\mathrm{eff}}_{\mathrm{S}})^2$	$1/[G(L^{\mathrm{eff}}_{\mathrm{S}})^2]$
(b) $P^{+}_{\mathrm{S}}(0)$ — $1/G$ — G	$1 + 2n_{\mathrm{sp}}(G - 1)$	$P^{+}_{\mathrm{S}}(0)L^{\mathrm{eff}}_{\mathrm{S}}/L$	$\mathrm{e}^{-\alpha_{\mathrm{S}}L}/(L^{\mathrm{eff}}_{\mathrm{S}})^2$	$1/[G(L^{\mathrm{eff}}_{\mathrm{S}})^2]$
(c) $P^{+}_{\mathrm{S}}(0)$ — $1/G$ — Ideally distributed gain G	$1 + 2n_{\mathrm{sp}}\ln G$	$P^{+}_{\mathrm{S}}(0)$	$1/L^2$	$\alpha_{\mathrm{S}}^2/(\ln G)^2$

the two extreme cases (a) and (b), depending on the signal evolution profile $g(z)$. To compare all of these cases properly, one should consider their OSNR at a fixed path-averaged power, i.e., at a fixed value of the nonlinear phase shift in the span $\Phi_{\mathrm{NL}} = \gamma \overline{P_{\mathrm{S}}(z)} L$, where γ is the nonlinear constant of the fiber. For the general distributed amplifier case (c), this OSNR can be obtained from (3.44) after setting $g(0) = g(L) = 1$

$$\mathrm{OSNR} = \frac{P_{\mathrm{S}}^{+}(0)}{P_{\mathrm{ASE}}} = \frac{\Phi_{\mathrm{NL}}}{2 n_{\mathrm{sp}} h \nu \Delta\nu \gamma \alpha_{\mathrm{S}}} \times X \,, \tag{3.46}$$

where

$$X = \frac{1}{\int_0^L \int_0^L \frac{g(z)}{g(z')} \,\mathrm{d}z \,\mathrm{d}z'} \tag{3.47}$$

is a functional whose value is determined by the signal evolution profile $g(z)$. By setting the functional derivative of (3.47) to zero, it is easy to find that the global maximum of the OSNR for a given value of the nonlinear phase shift corresponds to the signal evolution profile satisfying $g(z) = 1$ for all z, i.e., an *ideal* distributed amplifier (described by row (c) in Table 3.1), in which the fiber loss is compensated by the gain at each point in the span [3.37]. It is worth noting that (3.46), (3.47) also cover cases (a) and (b) when using $g(z) = \mathrm{e}^{\alpha_{\mathrm{S}}(L-z)}$ and $g(z) = \mathrm{e}^{-\alpha_{\mathrm{S}} z}$, respectively. For both of these cases, the OSNR factor X has identical values of $\mathrm{e}^{-\alpha_{\mathrm{S}} L}/(L_{\mathrm{S}}^{\mathrm{eff}})^2$, where $L_{\mathrm{S}}^{\mathrm{eff}} = (1 - \mathrm{e}^{-\alpha_{\mathrm{S}} L})/\alpha_{\mathrm{S}}$. This means that spans with lumped amplification do not result in optimum OSNR performance for a given Φ_{NL}, as illustrated by the fast exponential decay of the OSNR versus their span length L. In contrast, the ideal distributed amplifier exhibits an OSNR with a much slower $1/L^2$ dependence on the span length.

The NF of the distributed amplifier is the total NF of the amplified fiber span, which is subject to the quantum NF limit of $2 - 1/G$. For practical considerations of comparing the distributed and lumped amplified spans, however, it is convenient to separate the passive loss of the fiber and describe the distributed amplifier by a so-called "effective NF" [3.30], which is the noise figure of a fictitious lumped amplifier at the end of the passive fiber span, which provides the same gain and same number of ASE photons as the distributed amplifier. In the general case of a not necessarily transparent span, the total span noise figure is $\mathrm{NF} = (1 + 2N_{\mathrm{ASE}})/g(L)$, whereas the effective Raman NF is

$$\mathrm{NF}_{\mathrm{eff}} = \frac{1 + 2N_{\mathrm{ASE}}}{G_{\mathrm{R}}(L)} \,, \tag{3.48}$$

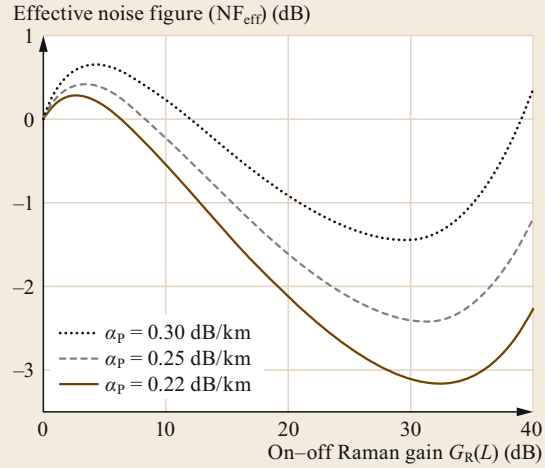

Fig. 3.19 Effective Raman noise figure $\mathrm{NF}_{\mathrm{eff}}$ for a 100-km-long SSMF with $\alpha_{\mathrm{S}} = 0.18\,\mathrm{dB/km}$ and $\alpha_{\mathrm{RBS}} = 5.5 \times 10^{-5}\,1/\mathrm{km}$ (i.e., $R = -31.8\,\mathrm{dB}$) for several values of α_{P}. The increase of $\mathrm{NF}_{\mathrm{eff}}$ at high Raman gains occurs due to Rayleigh backscattered ASE

which is smaller than the total span NF by a factor $g(z)/G_{\mathrm{R}}(L) = \mathrm{e}^{-\alpha_{\mathrm{S}} L}$, i.e., by the transmittance of an unamplified fiber span. The effective NF for a 100-km span of SSMF is shown in Fig. 3.19 as a function of the on–off Raman gain. One can see that $\mathrm{NF}_{\mathrm{eff}}$ can be less than 2 and even less than 1 (i.e., $< 0\,\mathrm{dB}$) at large Raman gains, and the fact that it is below the quantum NF limit simply means that such a fictitious lumped amplifier with the same noise and gain as the distributed Raman amplifier is not physically realizable. The benefit of using $\mathrm{NF}_{\mathrm{eff}}$ is that it permits quick estimation of the OSNR advantage of the distributed amplified span over its lumped counterpart by directly comparing the $\mathrm{NF}_{\mathrm{eff}}$ of the distributed and the NF of the lumped amplifier (in the standard formula $\mathrm{OSNR} = P_{\mathrm{S}}(0)/[h\nu\Delta\nu N(G\,\mathrm{NF} - 1)]$, the lumped NF is simply replaced by $\mathrm{NF}_{\mathrm{eff}}$). From Fig. 3.19, one can also see that this advantage decreases for larger values of α_{P}, because the higher pump attenuation reduces the length of pump penetration into the fiber span and makes the amplifier less distributed.

Impairments due to Rayleigh Scattering

The effect of Rayleigh scattering on the ASE noise and signal can be estimated from (3.35) by treating the Rayleigh terms as small perturbations around the solutions given by (3.44) and (3.37), respectively [3.30]. The first of these effects occurs when the Raman ASE propagating in the $-z$-direction is Rayleigh backscattered in the $+z$-direction, which gives rise to an

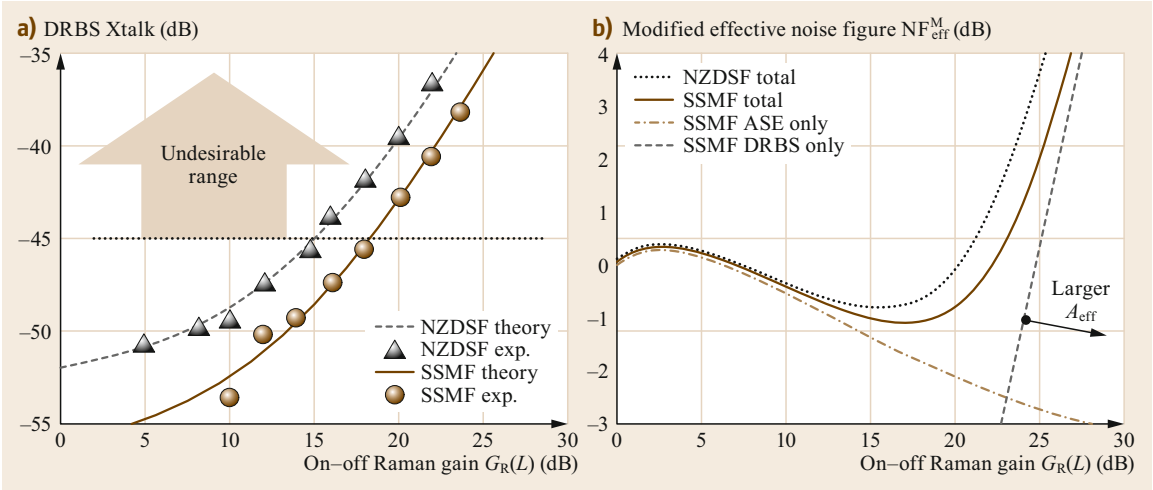

Fig. 3.20 **(a)** DRBS crosstalk, both experimentally measured and theoretically predicted by (3.50), and **(b)** effective Raman noise figure, modified to account for DRBS as in (3.51), for SSMF fiber with $\alpha_S = 0.18\,\mathrm{dB/km}$, $\alpha_P = 0.22\,\mathrm{dB/km}$, $\alpha_{RBS} = 5.5\times10^{-5}\ 1/\mathrm{km}$ ($R = -31.8\,\mathrm{dB}$), $A_{eff} = 80\,\mu\mathrm{m}^2$ and NZDSF fiber with $\alpha_S = 0.19\,\mathrm{dB/km}$, $\alpha_P = 0.23\,\mathrm{dB/km}$, $\alpha_{RBS} = 8.5\times10^{-5}\ 1/\mathrm{km}$ ($R = -30.1\,\mathrm{dB}$), $A_{eff} = 55\,\mu\mathrm{m}^2$, with 100% backward pumping. In **(a)** the length is 80 km for the SSMF and 87 km for the NZDSF, while in **(b)** both fibers have 100 km length. In **(b)**, the NF asymptotes corresponding to ASE-only and DRBS-only contributions are also shown for the SSMF case. To compute the DRBS contribution to the NF, receiver electrical bandwidth $B_{el} = 8\,\mathrm{GHz}$, signal launch power into the fiber $P_S^+(0) = -3\,\mathrm{dBm}$, and signal wavelength $\lambda = 1550\,\mathrm{nm}$ are assumed

additional ASE term referred to as "backscattered ASE" [3.33]

$$P_{\mathrm{ASE}}^{\mathrm{backscatt.}} = 2n_{\mathrm{sp}}h\nu\Delta\nu \times \int_0^L \left(\frac{g^2(L)}{g^2(z)} - \frac{g(L)}{g(z)} + \int_z^L \frac{g(L)g(z')}{g^2(z)}\alpha_S \mathrm{d}z' \right) \times \alpha_{RBS}\mathrm{d}z\,. \tag{3.49}$$

In Fig. 3.19, the backscattered ASE of (3.49) has been added to the original ASE of (3.44) to compute NF_{eff}. The backscattered ASE rises rapidly and monotonically with the on–off Raman gain, and its effect is clearly manifested in Fig. 3.19 by the rise of the NF at high gain values.

The second effect takes place when the forward-propagating signal is backscattered in the $-z$-direction, and this backscattered signal is subsequently backscattered again, now in the $+z$-direction. This double Rayleigh backscattered signal (DRBS) P_{DRBS}^+ represents a crosstalk term that can cause undesirable multiple-path interference with the original signal; this crosstalk is given by [3.38]

$$\mathrm{Xtalk} = \frac{P_{\mathrm{DRBS}}^+(L)}{P_S^+(L)} = \int_0^L \int_z^L \frac{g^2(z')}{g^2(z)}\alpha_{RBS}^2\,\mathrm{d}z\,\mathrm{d}z'\,. \tag{3.50}$$

Since the DRBS makes two passes through the Raman gain region, while the signal only makes one, the DRBS grows much faster with the Raman on–off gain than the signal and, as a result, becomes the main limitation on the Raman gain in the fiber span. Although DRBS cannot be spectrally distinguished from the signal, its crosstalk can be measured either directly in the electrical domain [3.39] or by a time-domain extinction method in the optical domain [3.40], and is shown in Fig. 3.20a for a backward-pumped SSMF and nonzero dispersion-shifted fiber (NZDSF). The higher DRBS crosstalk in the NZDSF is due to this fiber's higher Rayleigh backscattering coefficient α_{RBS}. This coefficient is given by $\alpha_{RBS} = 2R\alpha_S$, where R is the fraction of the light returned (backscattered) by an infinite fiber. R is proportional to $\mathrm{NA}^2 \propto \lambda^2/A_{eff}$ (smaller effective area translates into a larger acceptance angle of the mode, leading to a larger fraction of the Rayleigh scattering being recaptured into the fiber mode). As the DRBS crosstalk keeps increasing with the Raman gain, at some point it enters the range labeled *undesirable* in Fig. 3.20a, where it becomes comparable to the inverse OSNR, i.e., starts causing noticeable performance degradations that limit the maximum usable Raman gain. For the purpose of finding the optimum Raman gain, it is helpful to include the effect of the DRBS crosstalk into a modified effective NF of the Raman amplifier

as [3.33, 41, 42]

$$\mathrm{NF}_{\mathrm{eff}}^{\mathrm{M}} = \mathrm{NF}_{\mathrm{eff}} + \frac{5}{9}\frac{P_{\mathrm{S}}^{+}(L)}{h\nu B_{\mathrm{el}}}\frac{\mathrm{XTalk}}{G_{\mathrm{R}}(L)}\,, \tag{3.51}$$

where the factor 5/9 is the DRBS fraction copolarized with the signal [3.43] and B_{el} is the electrical bandwidth of the receiver ([3.42] provides a more accurate bandwidth expression, suitable for various modulation formats).

The modified noise figure $\mathrm{NF}_{\mathrm{eff}}^{\mathrm{M}}$ is plotted in Fig. 3.20b for backward-pumped NZDSF and SSMF fibers. The presence of DRBS leads to a rapid rise of the NF at high Raman gains that are well below those leading to turnaround in Fig. 3.19. The optimum operation is achieved at the on–off Raman gain at which the modified NF has the lowest value. It can be seen from Fig. 3.20b that the larger effective area of the SSMF pushes the NF of the SSMF toward a later turnaround and lower values than the NF of the NZDSF.

3.2.3 Design Considerations

In the design of practical Raman amplifiers, one needs to consider the following main issues:

- Choosing between a lumped and distributed Raman amplifier, as well as between a Raman-only and hybrid Raman–EDFA amplified span; this choice also sets the target Raman gain.
- Designing a flat gain spectrum for WDM signals by using WDM pumping.
- Flattening and optimizing the NF of the amplifier, including the noise–nonlinearity trade-off.
- Minimizing the potential impact of pump relative intensity noise (RIN).

The rest of this section elaborates on these design steps. The semianalytical theory described in Sect. 3.2.2 provides the necessary insights into these procedures. For accurate quantitative predictions, however, a more complete Raman amplifier model is described at the end of the section, which is typically solved numerically using either home-made or commercial modeling software.

Choosing the Type of Raman Amplifier

The type of Raman amplifier to use is primarily determined by its intended application. Let us first distinguish between distributed and lumped (also known as discrete) Raman amplifiers. Although both types of amplifier use substantial (kilometer-scale) lengths of optical fiber, distributed amplification takes place within the transmission fiber span, whereas discrete amplification uses a piece of fiber specifically designated as the gain medium, so that all the gain occurs within a discrete amplifier box. The primary applications of distributed Raman amplification include SNR improvement by distributed gain, extending the span length between lumped amplifiers, and building communication links in wavelength ranges lying outside conventional EDFA bands. Since a discrete amplifier does not offer the NF advantages of a distributed amplifier, to justify its use instead of a more pump-power-efficient EDFA the application would typically either involve operation outside of the EDFA band or require gain control (e.g., ultraflat gain) beyond what is achievable with an EDFA, or employ a gain medium that has some additional functionality (e.g., a dispersion-compensating fiber). On the other hand, the discrete amplifier has greater design flexibility than the distributed one: it can use specialty fiber with high Raman gain coefficient, split the gain among multiple stages, employ optical isolators to reduce DRBS and backscattered ASE, etc. In what follows, we focus on the design issues that are common to both distributed and discrete amplifiers. More details specific to the discrete amplifier design can be found in [3.44].

The second distinction worth mentioning is whether the distributed Raman amplifiers are designed to compensate the loss of the fiber span on their own (all-Raman communication links) or as low-noise preamplifiers working in combination with EDFA boosters (hybrid Raman–EDFA links). The high gain required for all-Raman links comes at the price of having to deal with DRBS crosstalk, pump depletion, higher path-averaged signal power, etc. All-Raman systems might require higher pump power, but they use fewer optical components in the signal path than hybrid Raman–EDFA systems, which reduces PMD, PDL, PDG, etc. On the other hand, by splitting the gain between the distributed Raman and lumped EDFA stages in hybrid Raman–EDFA systems, one can realize almost the entire NF advantage of distributed Raman amplification without suffering from the aforementioned impairments (DRBS, pump depletion, etc.) associated with high Raman gain. This is because, in such a two-stage amplifier design, the total noise figure $\mathrm{NF}_{\mathrm{total}} = \mathrm{NF}_1 + (\mathrm{NF}_2 - 1)/G_1$ is mostly determined by the NF of the distributed Raman preamplifier (the first stage with $\mathrm{NF}_1 = \mathrm{NF}_{\mathrm{eff}}$ and gain $G_1 = G_{\mathrm{R}}(L)$). The hybrid Raman–EDFA combination is also a simple way to accommodate a longer-than-typical fiber span in an otherwise EDFA-only system. For optimum hybrid Raman–EDFA performance, however, it is important to have an EDFA power amplifier (booster) stage that is designed to handle the higher input signal powers coming from the Raman-amplified span compared with an unamplified span. For example, simple addition of distributed Raman preamplifiers to standard in-line ED-

FAs in an attempt to improve the OSNR in an existing EDFA-only link is of very limited benefit: the reduction of gain in the in-line EDFA, needed to accommodate the higher input signal power, comes with a large increase in the EDFA NF (because the gain adjustment is typically done by a variable optical attenuator inside the EDFA, if the gain flatness is to be preserved), which could considerably reduce the distributed Raman NF advantage while not offering any cost savings. On the other hand, replacing a high-gain in-line EDFA with a low-gain EDFA booster stage permits its operation with the higher input signal power coming from the Raman-amplified span without major degradation of the EDFA NF, while at the same time eliminating the cost of an EDFA preamplifier stage.

Once the application scenario for the Raman amplifier is known, the considerations above lead to the choice between a lumped or distributed, as well as all-Raman or hybrid Raman–EDFA, amplifier. For an all-Raman system, the required Raman gain is determined by the span loss (plus, possibly, the loss of any lumped end-of-span components, e.g., pump-signal WDM multiplexer and isolator). For a hybrid Raman–EDFA system, the Raman gain can be varied over a wide range. If the EDFA stage has been designed to accommodate the higher power of the Raman-amplified signal, then the optimum value of the Raman gain can be found from the trade-off among $\mathrm{NF}_{\mathrm{eff}}$, DRBS, and the nonlinearity of the Raman amplifier, as discussed below. Otherwise, i.e., if the EDFA stage exhibits strong NF dependence on the input signal power, a trade-off among $\mathrm{NF}_{\mathrm{total}}$, DRBS, and nonlinearity is required.

Shaping the Gain Spectrum by WDM Pumping

One of the advantages of Raman amplification is its flexibility in shaping the gain spectrum by the use of multiple pump wavelengths (WDM pumping), which can yield wideband amplification with very low gain ripple [3.31, 45]. Indeed, in the presence of multiple pump wavelengths, (3.35) takes the form

$$\frac{\mathrm{d}P_{\mathrm{S}}^{\pm}}{\mathrm{d}z} = \pm\left[-\alpha_{\mathrm{S}} + \sum_i \frac{g_{\mathrm{R}}(\nu_{\mathrm{P}}^i - \nu_{\mathrm{S}})}{A_{\mathrm{eff}}} P_{\mathrm{P}}^i\right] P_{\mathrm{S}}^{\pm} , \quad (3.52)$$

where ν_{P}^i, $i = 1, \ldots, N$ are the center frequencies of the individual pump lasers. The on–off Raman gain is given by

$$G_{\mathrm{R}}(L) = \mathrm{e}^{\sum_i \frac{g_{\mathrm{R}}(\nu_{\mathrm{P}}^i - \nu_{\mathrm{S}})}{A_{\mathrm{eff}}} \int_0^L P_{\mathrm{P}}^i(z)\mathrm{d}z} , \quad (3.53)$$

which can be conveniently rewritten on a decibel scale as

$$G_{\mathrm{R}}(L)[\mathrm{dB}] = 4.343 \sum_i \frac{g_{\mathrm{R}}(\nu_{\mathrm{P}}^i - \nu_{\mathrm{S}})}{A_{\mathrm{eff}}} \overline{P_{\mathrm{P}}^i(z)} L , \quad (3.54)$$

where $\overline{P_{\mathrm{P}}^i(z)}$ is the path-averaged power of the i-th pump. Equation (3.54) enables synthesis of the desired gain spectrum from the gain spectra $g_{\mathrm{R}}(\nu_{\mathrm{P}}^i - \nu_{\mathrm{S}})$ contributed by the individual pump wavelengths. A typical design procedure starts with the definition of constraints (fiber type, number of pump lasers, and maximum power of each) and desired specifications (gain bandwidth and flatness). Then, design parameters such as the wavelengths and powers of the individual pumps, are varied to achieve the target specifications as close as possible. For rough initial estimates, (3.54) can be used, but for the final amplifier design, the full amplifier model including pump depletion and pump–pump interactions (described below) should be employed. Figure 3.21, adapted from [3.31], presents the results of such synthesis for a >80-nm-wide gain spectrum in an SSMF fiber from five pump wavelengths, yielding gain ripple of 0.3 dB.

Since the Raman gain spectrum is easily shifted by shifting the pump wavelength, the conventional Fabry–Pérot laser-diode pumps used for EDFAs are not well suited for Raman pumping. To stabilize the central wavelengths of the pump lasers, fiber Bragg gratings (FBGs) are frequently used, and such a combination is referred to as FBG-stabilized laser diodes. Various pump wavelengths can be combined (multiplexed) using either cascaded Mach–Zehnder interferometer couplers on a planar lightwave circuit platform, or thin-film-based couplers, or fused fiber couplers, with the latter type being most popular owing to their high power-handling capabilities. For a given pump wavelength, a polarization beam combiner is often used to multiplex two orthogonally polarized lasers, which simultaneously doubles and depolarizes the pump power at this wavelength. If a single-diode pump power is sufficient, then an alternative depolarizing solution can be used, such as coupling the laser equally into the two axes of a polarization-maintaining fiber of sufficient length to introduce a delay between the two polarizations that is greater than one coherence length of the laser. Commercial Raman amplifier modules are usually available in the form of Raman pump units (RPUs), an example of which is shown in Fig. 3.22, and are capable of operating in both backward and forward pumping configurations.

Flattening and Improving the NF

Although WDM pumping can arbitrarily flatten the Raman gain spectrum, the spectrum of the Raman NF is not flat, with short-wavelength signals accumulating larger amounts of noise than longer-wavelength signals. This tilt in the NF spectrum originates from several factors:

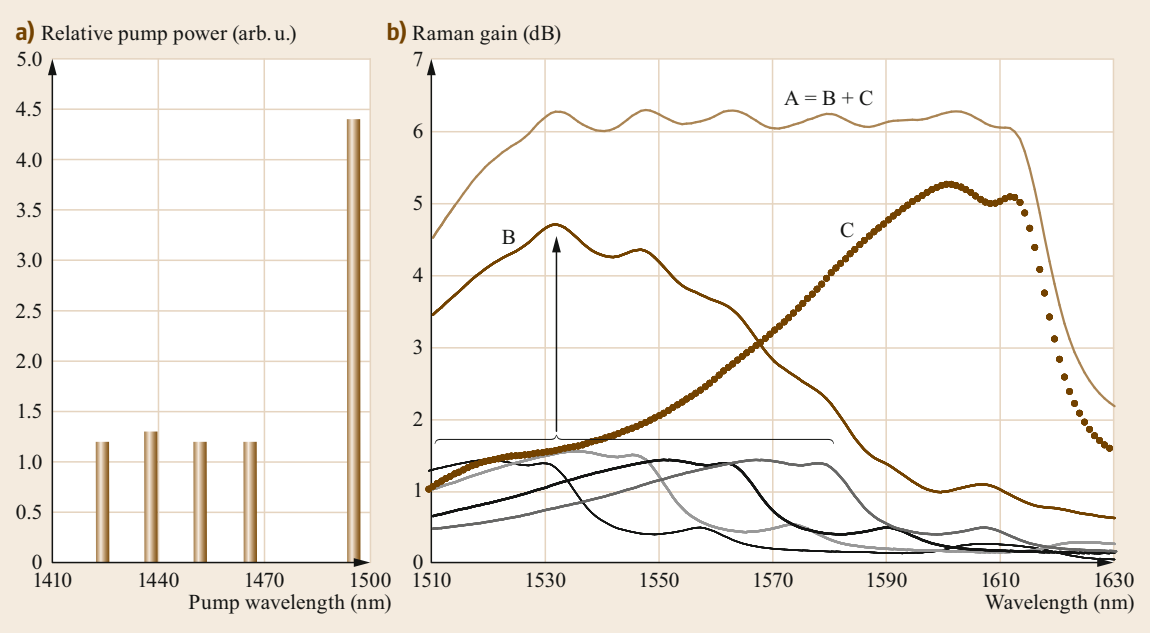

Fig. 3.21a,b Synthesis of broadband and flat Raman gain spectra by WDM pumping in SSMF fiber. **(a)** Relative powers of five WDM pumps. **(b)** Gain spectra contributed by the first four pumps (*lower traces, adding up to trace B*) and the last pump (C), adding up to the flattened net gain spectrum A. (© 2001 IEEE. Adapted, with permission, from [3.31])

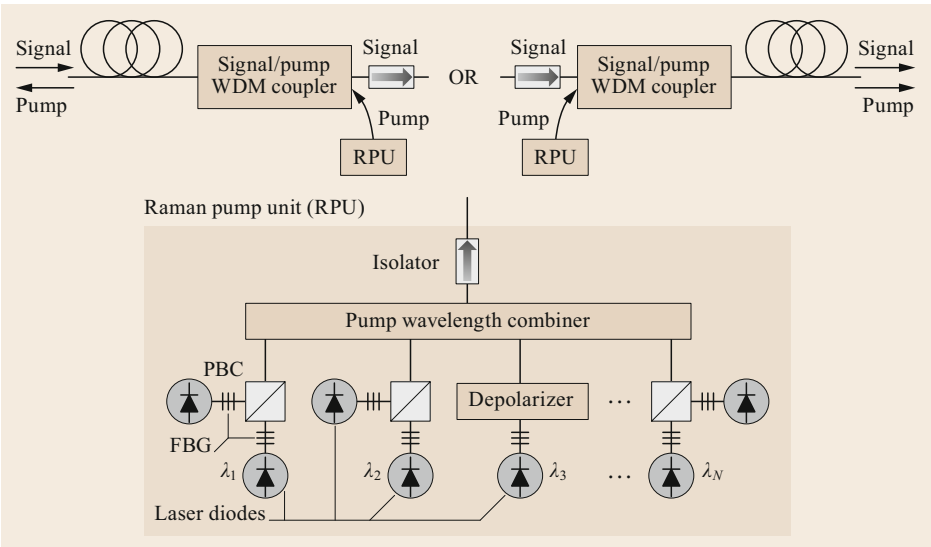

Fig. 3.22 Typical Raman pump unit with *N* pump wavelengths, which can be used in either counterpropagating (backward pumping) or copropagating (forward pumping) signal–pump configuration (PBC – polarization beam combiner; FBG – fiber Bragg grating)

(a) Shorter-wavelength signals are pumped primarily by shorter-wavelength pumps that have higher attenuation coefficients, i.e., do not penetrate as deep into the fiber span as longer-wavelength pumps.
(b) Shorter-wavelength pumps also lose some power to the longer-wavelength ones through pump–pump Raman interactions.
(c) Similar signal–signal Raman interaction leads to additional power loss of short-wavelength signals (SRS tilt).

Thus, the gain for shorter-wavelength signals is less distributed, permitting the signal power to drop to lower levels, which in turn leads to worse NF performance than that of longer-wavelength signals.

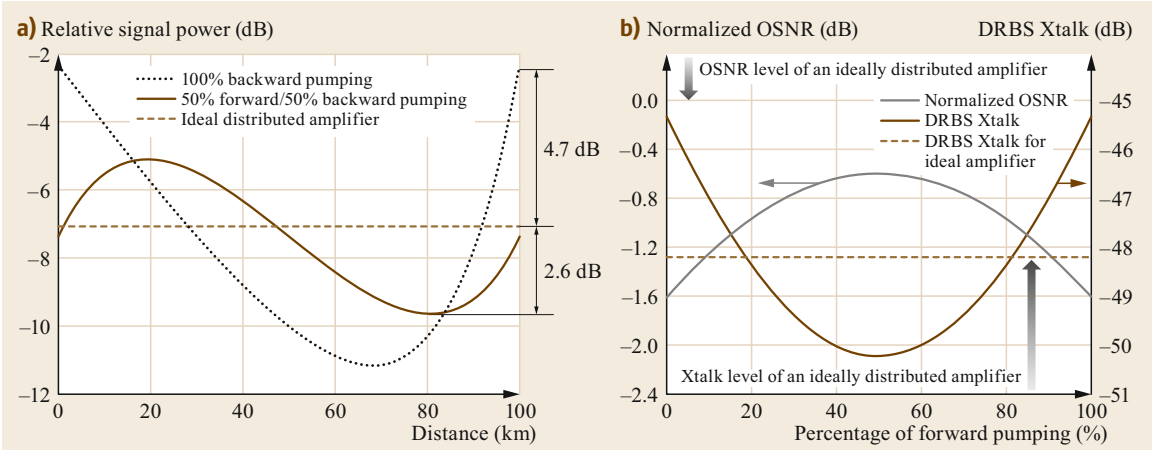

Fig. 3.23 **(a)** Evolution profiles of Fig. 3.18, normalized to yield the same path-averaged power as an unamplified fiber span. **(b)** OSNR, normalized by the OSNR of an ideally distributed amplifier (*left scale*), and DRBS crosstalk (*right scale*) of different pumping configurations for an SSMF span with parameters of Fig. 3.18

To counter this effect, one needs to make the Raman gain more distributed over the fiber span for these short-wavelength signal channels. In this section, three techniques for making the Raman gain more uniformly distributed are considered: (a) bidirectional (i.e., combination of forward and backward) pumping, (b) effective-area management in the span, and (c) second- and higher-order Raman pumping.

Although complementing the backward pumping of all signal channels with forward pumping of shorter-wavelength ones appears to be quite a simple solution, it needs to be accompanied by a significant reduction of the signal launch power into the span. Indeed the signal evolution profiles of Fig. 3.18, corresponding to different forward/backward pumping configurations, have very different path-averaged powers. The proper way to compare their performance is to adjust their signal launch power in such a way that all of these configurations yield the same path-averaged power (Fig. 3.23a). Under these conditions, the best performance is achieved for the 50/50 backward/forward combination, whose evolution profile over a 100-km-long SSMF deviates by no more than 2.6 dB from the ideally distributed amplifier profile, whereas the backward-pumped signal deviates by 4.7 dB. The resulting OSNR of the 50/50 combination is within 0.6 dB of that of an ideally distributed amplifier (Fig. 3.23b). It has also been shown that the 50/50 case is optimum for reduction of the DRBS crosstalk [3.38]. This can be understood by noting that (3.50) implies that, to minimize the DRBS, one needs to avoid generating large amounts of Raman gain in any particular section of the fiber. Indeed, 50/50 pumping splits the Raman gain between the two end regions of the span, with the loss in the middle effectively serving as an isolator to prevent circulation of DRBS between them. The DRBS performance of the 50/50 configuration even outshines that of the ideally distributed amplifier, whose distributed gain yields better DRBS than either backward-only or forward-only pumping, but is still about 2 dB worse than the DRBS of the 50/50 case.

However, since forward pumping has a number of drawbacks as outlined in the next section, alternative approaches have been found and explored. One particularly attractive method uses spans consisting of multiple fibers with judiciously chosen effective areas. The pump initially enters a fiber with large effective area (usually a silica-core fiber with large positive dispersion) and, after experiencing attenuation, subsequently enters a smaller-effective-area fiber (usually with large negative dispersion), so that the pump intensity again reaches high enough values to provide gain deeply into the fiber span (Fig. 3.24a). Spans consisting of $+D$ and $-D$ fibers are frequently used to perform accurate and temperature-independent dispersion and dispersion-slope compensation right within the fiber span, and such dispersion-managed fibers (DMFs) are ideal candidates for effective-area-managed Raman amplification [3.46, 47]. For maximum performance, the large-effective-area $+D$ fiber sections need to be positioned near the ends of the span, with small-effective-area $-D$ fiber in the middle ($+D/-D/+D$, or *symmetric DMF*). A DMF can employ a $-D$ fiber with one of several types of $x:1$ dispersion compensation ratios (x km of $+D$ fiber compensated by 1 km of $-D$ fiber). Figure 3.24b shows that, even with backward-only pumping, the NFs of both 1 : 1 and 2 : 1 DMFs outperform the NF of NZDSF by more than 2.5 dB [3.33, 46],

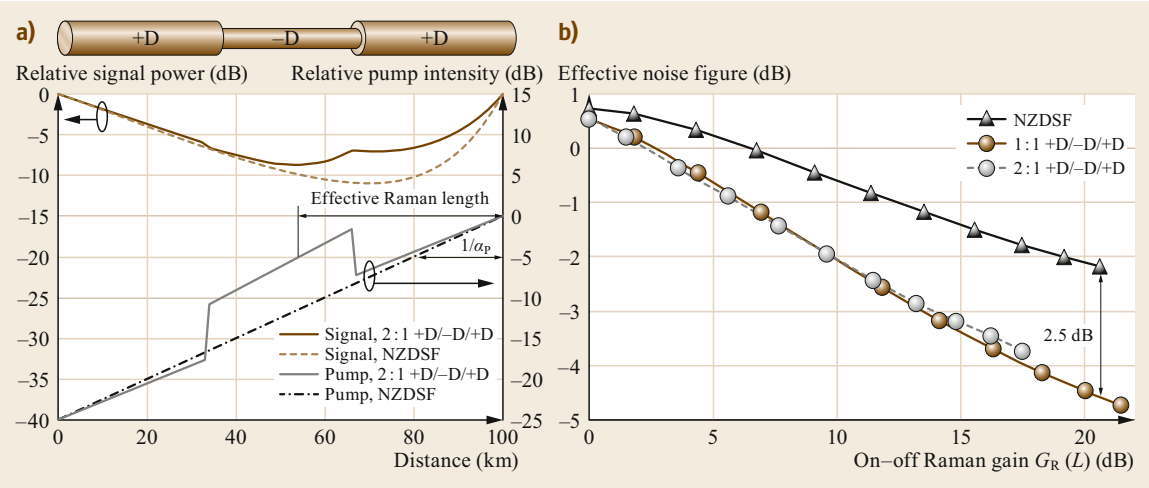

Fig. 3.24 **(a)** Comparison of signal and pump evolutions in 100-km-long NZDSF ($A_{eff} = 72\,\mu m^2$, $\alpha_S = 0.21\,dB/km$, $\alpha_P = 0.25\,dB/km$) and 2 : 1 DMF; $+D$ fiber of the DMF has $A_{eff} = 110\,\mu m^2$, $\alpha_S = 0.19\,dB/km$, $\alpha_P = 0.22\,dB/km$, and $-D$ fiber has $A_{eff} = 27.5\,\mu m^2$, $\alpha_S = 0.25\,dB/km$, $\alpha_P = 0.29\,dB/km$. **(b)** Comparison of experimentally measured effective Raman noise figures NF_{eff} between NZDSF ($L = 100\,km$) and two DMFs, with dispersion ratios 1 : 1 ($25\,km + 50\,km + 25\,km = 100\,km$) and 2 : 1 ($30\,km + 27\,km + 25\,km = 82\,km$). (After [3.33])

which has enabled all-backward-pumped Raman system demonstrations [3.48, 49]. It has been shown [3.50] that the normalized OSNR of the backward-pumped symmetric DMF is within 0.7 dB of the ideal distributed amplifier, and with optimum 30% forward pumping, it can be within 0.3 dB from the ideal. Equations (3.44), (3.49), and (3.50) are written in a form suitable for multiple-fiber spans, if one assumes α_S and α_{RBS} to be functions of distance (and in (3.50) one α_{RBS} should be a function of z, and the other of $-z'$) [3.33, 51–53].

Another approach that similarly achieves deeper penetration of the Raman gain into the fiber span is to use second- or higher-order Raman pumping [3.54, 56]. The second-order pump is placed one anti-Stokes shift higher in frequency from the conventional first-order pump and serves as a pump wave that provides gain for the first-order Raman pump. Third- and even higher-order pumps can be placed at additional anti-Stokes shifts away. As the first-order pump enters the fiber span, it starts being amplified by the second-order pump and reaches its peak power some distance away from the span's end. This pushes the Raman gain deeper into the span, i.e., makes it more distributed and closer to ideal. Figure 3.25, adopted from [3.54], shows that the combination of second-order and bidirectional pumping can yield very small (±0.4 dB) signal power excursions over the length of an 80-km SSMF span. Figure 3.25b shows a typical NF_{eff} tilt for first-order backward pumping, which is flattened by combining it with forward pumping, and further flattened and reduced by second-order pumping.

Challenges of Forward Pumping and Effects of Pump RIN

Forward pumping brings about a new challenge, as the copropagation of the pump and signal makes it necessary to consider time-domain effects such as the transfer of relative intensity noise (RIN) from the pump to signal and interchannel crosstalk mediated by cross-gain modulation (pump depletion). Indeed, pump RIN causes temporal variations of the Raman gain per unit length, which can accumulate exponentially and lead to signal RIN greatly exceeding that of the pump. Fortunately, this degradation is limited by the dispersive walk-off between the signal and pump, which averages the pump fluctuations and effectively acts as a low-pass filter of the pump noise. Figure 3.26 shows the RIN transfer function from the pump to signal in NZDSF and DCF fibers [3.55], demonstrating the much narrower bandwidth of the transferred noise in the more-dispersive DCF. In the counterpumped (backward-pumped) configuration, the averaging takes place over the time of flight over $2L_{eff}$, regardless of the fiber dispersion, which reduces the transferred RIN bandwidth to less than 100 kHz. To avoid Q-factor degradations due to the signal RIN, the total RIN from pump lasers in a chain of amplified spans should be under −120 dB/Hz for forward pumping and under −70 dB/Hz for backward pumping [3.55], which translates into individual pump laser RIN requirements of roughly less than −140 dB/Hz and less than −90 dB/Hz, respectively.

While common FBG-stabilized laser diodes with RIN of about −120 dB/Hz are quite adequate for

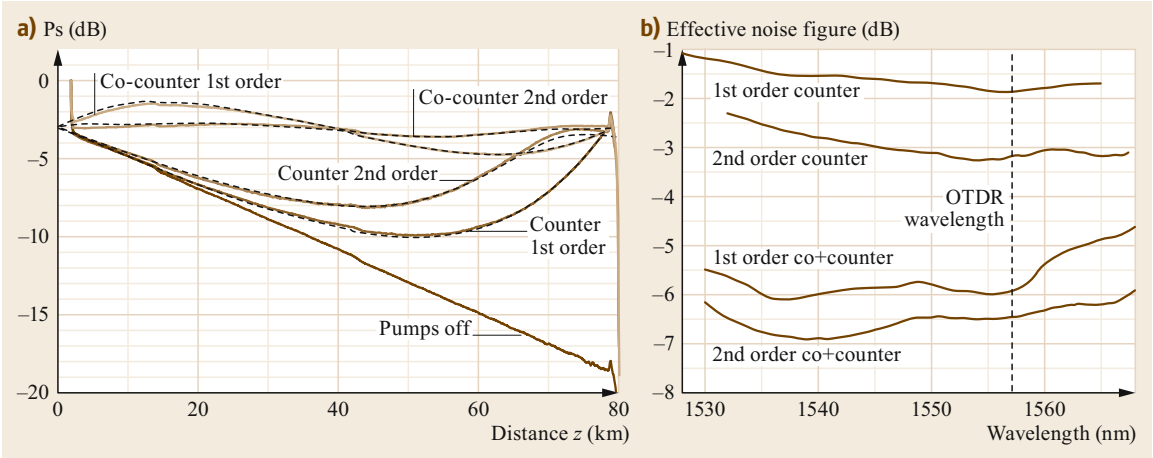

Fig. 3.25 **(a)** Signal evolution profiles measured by optical time-domain reflectometer (*solid lines*) and simulated (*dashed lines*). **(b)** Effective NFs measured for four Raman pumping configurations. (© 2002 IEEE. Adapted, with permission, from [3.54])

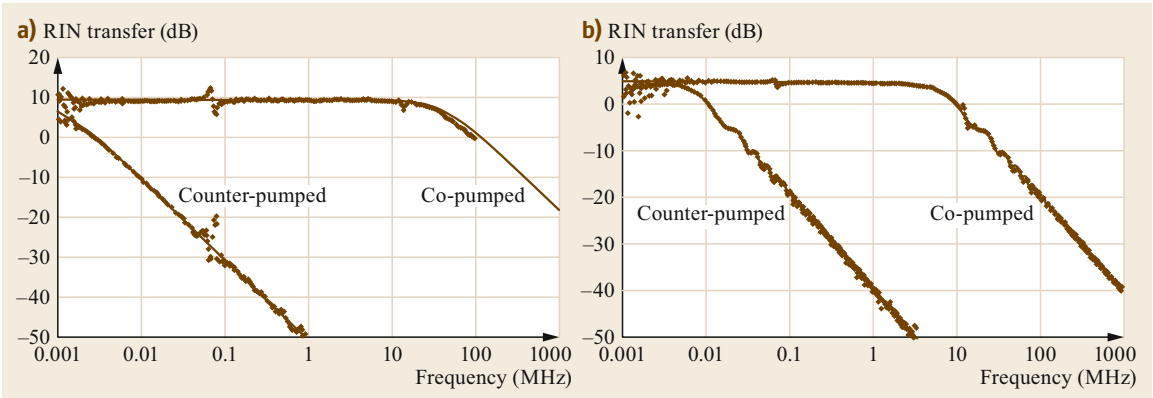

Fig. 3.26a,b RIN transfer characteristic for **(a)** 81 km of TrueWave-RS™ NZDSF ($\alpha_P = 0.25\,dB/km$ at 1455 nm, $D = 2.3\,(ps/nm)/km$ at 1500 nm, and on–off Raman gain = 12.6 dB) and **(b)** 6.8 km long dispersion-compensating fiber (DCF, $\alpha_P = 1.52\,dB/km$ at 1455 nm, $D = -97.6\,(ps/nm)/km$ at 1500 nm, and on–off Raman gain = 7.4 dB). *Dots* indicate measurements; *solid lines* are theoretical calculations. Pump wavelength is 1455 nm, signal wavelength is 1550 nm. (© 2001 IEEE. Adapted, with permission, from [3.55])

backward pumping, their RIN is too high for forward pumping. Fabry–Pérot lasers have lower high-frequency noise, but still unacceptably high low-frequency RIN (below 10–100 MHz). DFB lasers offer the best noise performance ($< -160\,dB/Hz$), but their narrow linewidths make them highly susceptible to stimulated Brillouin scattering (SBS). For forward-pumping applications, special versions of a DFB laser with a modified on-chip grating have been developed to allow multiple longitudinal modes to lase, resulting in significant suppression of SBS while retaining an RIN level close to $-160\,dB/Hz$ [3.57, 58]. Another type of low-RIN pump source for forward pumping is based on broadband ASE noise.

Further complications may occur if the zero-dispersion wavelength of the fiber λ_0 is located either within the pump band or between the pump and signal bands [3.59–62]. In the former case, significant pump–pump four-wave mixing needs to be considered. In the latter case, the pump and signal symmetrically located on the opposite sides of λ_0 copropagate with the same group velocity, and averaging of pump RIN does not take place. This leads to very strong Raman gain modulation and cross-phase modulation of the signal by the pump RIN, making forward pumping highly undesirable. Even in backward pumping, the backscattered ASE might experience gain enhanced by large pump RIN and become noticeable at RIN val-

ues of −115 dB/Hz and higher [3.61]. On the other hand, the same gain and cross-phase modulation by the pump RIN can have the beneficial effect of reducing the impact of DRBS crosstalk in the backward-pumped configuration: the modulation by the pump RIN dramatically broadens the DRBS spectrum and reduces its overlap with the signal [3.62].

Another type of impairment that is particularly important in forward-pumping schemes is the interchannel crosstalk mediated by the pump depletion. This happens when a fluctuation increasing intensity of one WDM channel depletes the pump and reduces the gain for another channel, causing crosstalk. This crosstalk is greatly reduced by the signal–pump walk-off and by increasing the number of WDM channels, which effectively perform temporal and ensemble averaging of the signal intensity fluctuations.

Modeling

Accurate modeling of wideband Raman amplifiers employing multiple WDM signals and WDM pumps requires taking into account not only the Raman gain of the signal, but also pump depletion and pump–pump and signal–signal Raman interactions. The evolution of the pumps, signals, and noise in such a Raman amplifier is described by the following equations [3.31]:

$$\pm\frac{\mathrm{d}P_\nu^\pm}{\mathrm{d}z} = \overbrace{-\alpha_\nu P_\nu^\pm + \alpha_{\mathrm{RBS}_\nu} P_\nu^\mp}^{\text{Fiber loss and Rayleigh backscattering}} + \overbrace{P_\nu^\pm \sum_{\mu>\nu} \frac{g_{\mu\nu}}{A_{\mu\nu}}(P_\mu^+ + P_\mu^-)}^{\text{Raman gain from shorter wavelengths}} + \overbrace{2h\nu\Delta\nu \sum_{\mu>\nu} \frac{g_{\mu\nu}}{A_{\mu\nu}}(P_\mu^+ + P_\mu^-)n_{\mu\nu}}^{\text{ASE noise}} - \overbrace{P_\nu^\pm \sum_{\mu<\nu} \frac{\nu}{\mu}\frac{g_{\nu\mu}}{A_{\nu\mu}}(P_\mu^+ + P_\mu^-)}^{\text{Raman loss to longer wavelengths}} - \overbrace{4h\nu P_\nu^\pm \sum_{\mu<\nu} \frac{g_{\nu\mu}}{A_{\nu\mu}} n_{\nu\mu}\Delta\mu}^{\text{Raman loss due to noise emission}} , \tag{3.55}$$

where the superscripts + and − denote forward- and backward-propagating (propagating in $+z$- and $-z$-direction) waves, respectively, $n_{\mu\nu} = \{1 - \exp[-h(\mu - \nu)/(k_\mathrm{B}T)]\}^{-1}$ is the spontaneous emission factor n_sp dependent on the Stokes shift $(\mu - \nu)$, and the subscripts μ and ν refer to two different frequencies of light. Equation (3.55) treats the signals and pumps in the same way: the wave at frequency ν is amplified by waves at frequencies $\mu > \nu$ and serves as a pump for waves with frequencies $\mu < \nu$. One should note that, in the design of wideband (> 100 nm wide) Raman amplifiers, one needs to consider that the Raman gain coefficient $g_{\mu\nu}$ not only depends on the Stokes shift $(\mu - \nu)$ but also varies slowly with the pump frequency μ. The scaling of $g_{\mu\nu}$ and the effective area $A_{\mu\nu}$ with μ is described in [3.63], but from a practical perspective, it is easier to measure the gain spectrum $g_{\mu\nu}/A_{\mu\nu}$ in a given fiber for several pump wavelengths across the desired wavelength range and then interpolate the results.

The system of coupled ordinary differential equations (3.55) describes a boundary-value problem with initial values known at $z = 0$ for forward- and at $z = L$ for backward-propagating waves. It can be solved numerically, e.g., by implementing algorithms from [3.64–66] or by using commercial software [3.67, 68]. The main challenges that require the numerical solution of (3.55) are the effects of pump depletion, pump–pump interactions, and signal–signal interactions. On the other hand, Rayleigh scattering and ASE noise can usually still be accounted for semianalytically as small perturbations around the evolution profile $g(z)$ of the signal at frequency ν. Such a semianalytical approach is helpful when using some numerical packages that do not otherwise compute the Rayleigh scattering and ASE noise terms. In that case, the DRBS crosstalk is still given by (3.50), whereas the ASE power needs to be rewritten to account for the varying Raman gain coefficients of the multiple pumps as follows

$$P_{\mathrm{ASE}_\nu}^+ = 2h\nu\Delta\nu \times \left\{ \int_0^L \frac{g(L)}{g(z)} \sum_{\mu>\nu} n_{\mu\nu}\frac{g_{\mu\nu}}{A_{\mu\nu}}[P_\mu^+(z) + P_\mu^-(z)]\,\mathrm{d}z + g(L)\int_0^L \frac{\alpha_{\mathrm{RBS}_\nu}(z)}{g^2(z)} \int_z^L g(z') \sum_{\mu>\nu} n_{\mu\nu}\frac{g_{\mu\nu}}{A_{\mu\nu}} \times [P_\mu^+(z') + P_\mu^-(z')]\,\mathrm{d}z'\,\mathrm{d}z \right\} , \tag{3.56}$$

where the first term generalizes the regular ASE of (3.44) and the second term generalizes the backscattered ASE of (3.49). Note also that (3.50), (3.55), and (3.56) are also applicable to multiple-fiber spans [3.33, 51–53], in which case α, α_RBS, $g_{\mu\nu}$, and $A_{\mu\nu}$ become z-dependent (and in (3.50) one α_RBS is a function of z, and the other α_RBS is a function of z').

3.2.4 Summary and Outlook

The low-noise properties of distributed Raman amplification have already made it indispensable for transmission over extralong spans as well as over ultralong-haul links. The extreme OSNR demands of advanced modulation formats, such as high-order quadrature amplitude modulation (QAM), might soon lead to the use of Raman amplifiers even in relatively short-reach systems. Raman amplification can also mitigate the effect of large component losses in fiber-based signal-processing devices and systems [3.69] and lead to the creation of ultralong distributed feedback fiber lasers [3.70].

3.3 Alternative Amplification Technologies

While EDFAs and Raman amplifiers clearly dominate the communication field today and are expected to retain this role in the foreseeable future, it is of interest to note the existence of alternative amplification technologies. These primarily include devices based on parametric optical interaction in nonlinear waveguides and semiconductor optical amplifiers (SOAs). The latter class of amplifiers has a long history that exceeds that of either EDFA and Raman development, dating back to the early 1960s [3.71–74]. One can also regard a semiconductor optical amplifier as a laser device with removed reflective facets, allowing for subthreshold operation. Indeed, it is natural that SOA technology had to be developed before the onset of EDFA and Raman technologies, since semiconductor pumps, which underlie both of these, inherently incorporate semiconductor gain. Depending on the facet reflectivity, an SOA represents either a pure traveling-wave device [3.75, 76] or a bandwidth-limited amplifier, often referred to as Fabry–Pérot SOA types [3.77, 78]. The underlying SOA gain mechanism rests on electron–hole recombination that provides the energy for optical emission. While SOAs can match multiple EDFA operational properties, an important set of differences distinguish the two types and are readily recognized in deployment. In contrast to an EDFA or Raman amplifier, an SOA is pumped electrically and is more efficient. the gain characteristics of SOA material platforms allow for amplification not only within the standard telecommunications bands (1550 and 1300 nm) but also in distant spectral windows.

Despite their long development history, SOAs are not regarded as viable gain elements in conventional lightwave communication links. The incompatibility of SOAs with WDM transmission schemes is the greatest reason for the distinctively niche role that these devices still play. The SOA excited state is orders of magnitude shorter than that of EDFA, resulting in gain that can change rapidly with the signal level. While tolerable in single-channel amplification, in the presence of multiple (independently modulated) channels, this fast SOA dynamics leads to significant impairments that need to be carefully mitigated [3.79, 80]. However, this ultrafast response, which is undesirable in the case of WDM gain elements, has been successfully leveraged in a host of signal processing devices, providing an efficient means for wavelength conversion, signal regeneration, and switching [3.81, 82].

Parametric amplification is the second class of optical amplification that has been widely investigated in multiple material platforms. Similar to Raman amplification, the parametric interaction in silica fiber is not limited to a specific, ion-defined spectral band. This feature was recognized early [3.83, 84] and has justified significant effort on the development of specialty fiber types specifically designed to maximize the parametric gain [3.85, 86]. Parametric devices are also capable of selective quadrature amplification, a unique feature that has been successfully used in signal processing and quantum field manipulation [3.87]. While parametric amplifiers can provide gain–bandwidth products that cannot be matched by any comparable technology [3.88], their use in WDM transport is also limited by interchange crosstalk that must be strictly managed. Consequently, it is expected that parametric devices will find much wider use in signal processing roles [3.84, 89] than in ordinary amplification applications.

Michael Vasilyev

Dept. of Electrical Engineering
University of Texas at Arlington
Arlington, TX, USA
vasilyev@uta.edu

Michael Vasilyev received his PhD from Northwestern University (Evanston, IL) in 1999. After working at Corning Inc. (Somerset, NJ), he joined the University of Texas at Arlington in 2003, where he is currently a professor. He works on nonlinear optical signal processing for classical and quantum communications. He is a Fellow of the OSA and SPIE, and a 2008 DARPA Young Faculty Award recipient.

Stojan Radic

Qualcomm Institute
University of California San Diego
La Jolla, CA, USA
sradic@ucsd.edu

S. Radic graduated from The Institute of Optics (Rochester) in 1995 and subsequently served in Corning and Bell Laboratories. He holds a BSE in electrical engineering, an MA in physics, and a PhD in optical engineering. He is chaired Professor of Electrical Engineering and Director of the Photonics System Laboratory at Qualcomm Institute. He is a Fellow of the Optical Society of America and IEEE.

4. Optical Transponders

Gabriella Bosco, Jörg-Peter Elbers

The first commercial 10-Gb/s transponders, deployed in the mid 1990s, were based on a very simple modulation technique, i.e., a binary light intensity modulation with envelope detection by a single photodiode. To extend the fiber capacity, bandwidth-efficient modulation techniques such as duobinary line coding and multilevel intensity-modulation formats gained popularity in optical communications in the late 1990s. In the following years, the use of differential phase modulation in combination with interferometric detection allowed the transponder data rates to be increased up to 40 Gb/s. However, despite all improvements, the system performance of these 40-Gb/s solutions was still not on par with state-of-the art 10-Gb/s systems at that time. With the advent of coherent detection, things suddenly changed and transmission rates of 100 Gb/s and beyond could soon be achieved, thanks to the use of high-order modulation formats and advanced digital signal-processing techniques.

In this chapter, the configuration and performance of the most common transmitter and receiver combinations that are currently used in optical transmission systems will be described, including an overview of transponder types and their hardware architectures. Finally, relevant standards will be discussed and pluggable optical transceiver modules used in modern transponder implementations will be explained.

Transponders are essential building blocks in any optical communication system. The term *transponder* stems from an amalgamation of two words *trans(mitter)* and *(res)ponder*, first coined in about 1940 to describe radio and radar systems [4.1]. In optical communications, a transponder is a receiver-transmitter combination, which translates an optical signal from one wavelength into another optical signal at a different wavelength by means of optical-electrical-optical (O/E/O) conversion [4.2]. During the conversion process, the received signal is reamplified and normally also reshaped and retimed, i.e., 3R regenerated. Optical transponders commonly operate in full-duplex mode and comprise transmitter and receiver functions on each of their ports. The ports can support different optical interface classes, which are characterized by properties such as the fiber medium, link distance, wavelength range, signaling rate, modulation format, forward error correction, line coding, and/or signal type.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_4

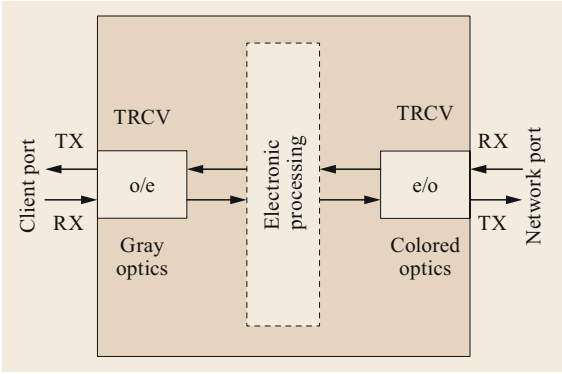

Fig. 4.1 Basic block diagram of an optical transponder (TX: transmitter, RX: receiver, o/e: opto-electric conversion, e/o: electro-optic conversion, TRCV: transceiver)

Network (or line) ports are connected to a multichannel wavelength-division multiplexing (WDM) networks. They are also called *colored interfaces*, as they are available in or can be tuned to multiple WDM colors. Client ports typically connect to subtended equipment such as routers or switches which act as clients of the optical transport network. These ports are termed *gray interfaces* if they only support a single channel per fiber (as opposed to colored interfaces, which can be wavelength multiplexed onto the same fiber). Wavelength grids for dense (DWDM) and coarse wavelength-division multiplexing (CWDM) are defined in the ITU-T G.694.1 and G.694.2 recommendations [4.3, 4]. In this chapter, the focus will be on colored DWDM interfaces.

Another very similar device to the transponder, and might be confused with it, is the *transceiver* (TRCV) which is a device that can simultaneously transmit and receive signals. As a portmanteau of *trans(mitter)* (TX) and *(re)ceiver* (RX), the term *transceiver* first appeared in the early 1920s and was used in descriptions of military communication equipment [4.5]. An optical transceiver comprises an optical transmit and receive interface on the so-called line side and a bidirectional electrical interface on the so-called host side. Transceivers can be realized as pluggable optical modules or as fixed host board implementations. An optical transponder can then be split into a client and line side optical transceiver function with an electronic processing block in between (Fig. 4.1).

In most cases, optical transponders are delivered as part of a complete DWDM network solution by one vendor. In other cases, transponders and the corresponding DWDM systems are supplied independently by different vendors. Colored interfaces may also be integrated into third-party switches or routers on the client side, thereby eliminating the need for separate transponders. When colored interfaces are separated from a WDM system and externally provided, then the scenario is referred to as an alien wavelength or black link approach [4.6] and has been used in commercial networks for many years. More recently, WDM systems supporting alien wavelengths have also been termed *open line systems* [4.7]. A line system is not restricted to just a point-to-point link in this context, but also includes optical networks in ring or mesh topologies.

A typical WDM system is depicted in Fig. 4.2. For simplicity, only one direction is shown. Colored interfaces are connected to a WDM multiplexer, which combines all of the WDM transmit channels onto one fiber before they are optically amplified by a booster amplifier and sent over a fiber link. The fiber link comprises one or more fiber spans of between 50 and 120 km in length (80 km is a typical span length in terrestrial systems). Erbium-doped fiber amplifiers (EDFAs) and/or distributed Raman amplifiers periodically compensate the span loss. At the receiving end, the WDM channels are optically preamplified, demultiplexed, and terminated by colored receiver interfaces. If access to the WDM channels is required at intermediate sites then reconfigurable optical add-drop multiplexers (ROADMs) are used on the transmission link. Multidegree ROADMs (MD-ROADMs) can offer additional wavelength-selective cross-connect functionality for dynamic routing of channels across a meshed network.

The colored interface performance is limited by intersymbol interference (ISI), thermal noise (THN), cross-talk (XTK), laser phase noise (LPN), laser sidemode suppression ratio (SMSR), and optical reflections (RFL). Transmission impairments such as amplified spontaneous emission noise (ASE), spectral loss/gain tilt and ripples, polarization-dependent loss/gain (PDL/PDG), group velocity dispersion (GVD), and polarization-mode dispersion (PMD) limit the optical performance of the channels. With higher optical power levels then fiber nonlinearities will be triggered which will limit the transmission performance further. Nonlinearities include stimulated Raman scattering (SRS) leading to Raman tilt and cross-talk, stimulated Brillouin scattering (SBS) which imposes an upper limit on optical channel carrier powers, and the Kerr effect which introduces intrachannel and interchannel nonlinearities. The Kerr nonlinearities are caused by signal–signal or signal–noise interactions and can be separated into a number of manifestations as shown below in Table 4.1. More specifically, the intrachannel nonlinearities are self-phase modulation (SPM)-induced nonlinear phase noise (NLPN), modulation instability (MI), isolated pulse SPM, intrachannel cross-phase modulation (IXPM), and intrachannel four-wave mixing (IFWM). The interchannel nonlinearities can be

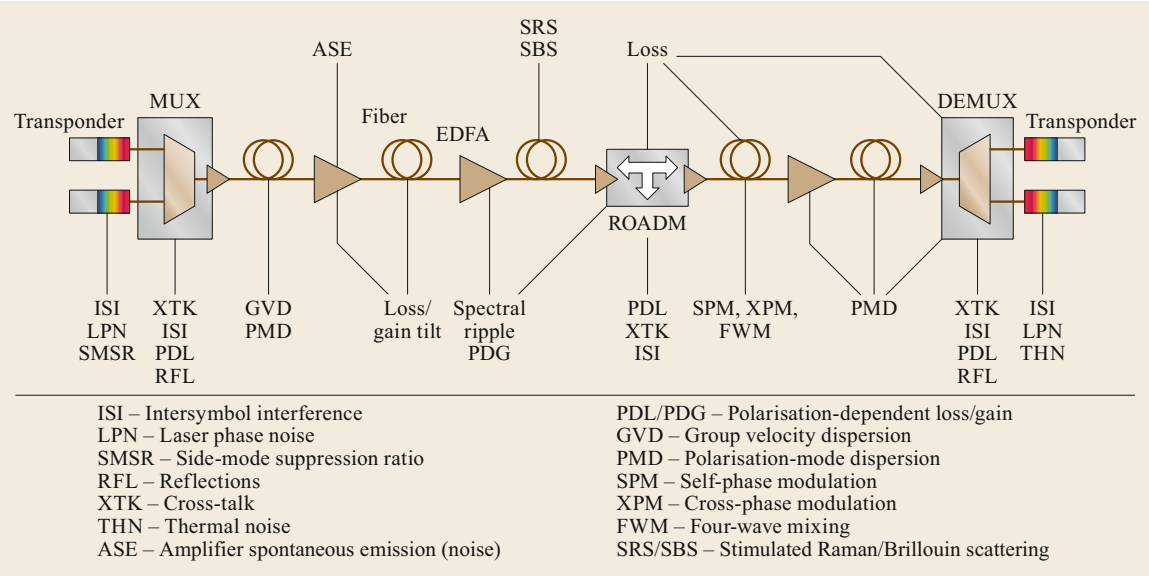

Fig. 4.2 A typical WDM line system and related transmission impairments. MUX: WDM multiplexer, DEMUX: WDM demultiplexer

Table 4.1 Transmission impairments due to fiber Kerr nonlinearity [4.8] (SPM: self-phase modulation, XPM: cross-phase modulation, FWM: four-wave mixing, NLPN: nonlinear phase noise, MI: modulation instability, IXPM: intra-channel cross-phase modulation, IFWM: intrachannel four-wave mixing)

Intrachannel nonlinearities					**Interchannel nonlinearities**		
Signal–noise interaction		Signal–signal interaction			Signal–noise interaction	Signal–signal interaction	
NLPN	Parametric amplification	SPM			NLPN	WDM!nonlinearities	
SPM-induced NLPN	MI	Isolated pulse SPM	IXPM	IFWM	XPM-induced NLPN	XPM	FWM

split into XPM-induced NLPN and interchannel XPM and FWM.

The choice of colored interface technology depends on the network application and is typically determined by such considerations as cost, performance, spectral efficiency, power consumption, and equipment footprint. Point-to-point enterprise and data-center interconnect (DCI) links can be distinguished from ring-based metro-access and metro-core networks as well as meshed regional and long-haul networks on the typical reaches involved, the number of ROADMs and the fiber cost, as shown in (Fig. 4.3). Submarine sys-

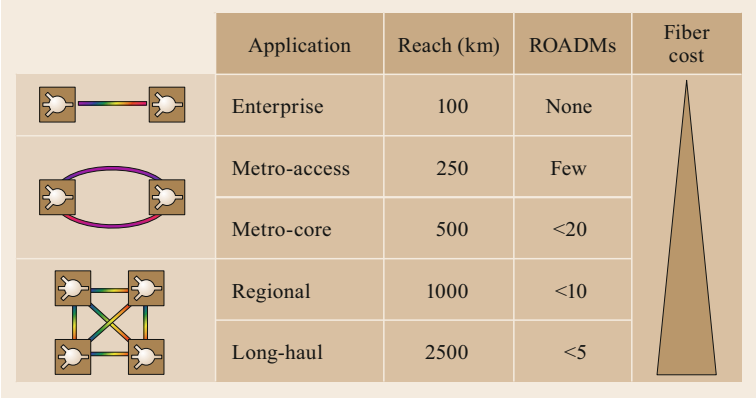

Fig. 4.3 Terrestrial WDM applications and main characteristics

tems can be separated into unrepeated point-to-point systems with passive wet plant over link distances of less than 600 km and repeated ultralong haul systems over link distances of several thousand kilometers. The larger the network reach, the higher is the fiber infrastructure cost and the more important is the spectral efficiency, but the most challenging are the transmission impairments. It is important to note that cascading of ROADMs also causes impairments such as insertions losses, intersymbol interference and cross-talk, so that a metro network with many ROADMs can show a similar performance to a long-haul network with few or no ROADMs despite the difference in network size.

4.1 Evolution of Modulation Formats and Symbol Rates

Because of its simplicity and cost efficiency, nonreturn-to-zero (NRZ) modulation with direct detection has long been the solution of choice for terrestrial DWDM systems. On the basis of a binary light on/off approach, this modulation technique is also known as on–off keying (OOK) [4.9]. OOK signals can be generated using an intensity-modulation (IM) transmitter, in which the intensity of an optical source is modulated by an RF signal, and demodulated using a direct-detection (DD) receiver, which converts the optical power into an electrical signal current using a photodetector. For this reason, optical systems based on OOK modulation are also classified as IMDD systems. Commercial 10-Gb/s NRZ transponders have been available since 1995 and were designed to guarantee a bit error ratio (BER) of 10^{-15} without forward error correction. They were deployed in 32-channel DWDM systems with 100-GHz channel spacing, yielding a total system capacity of 320 Gb/s over distances beyond 500 km of standard single-mode fiber (SSMF) in the C-band (1530−1565 nm) [4.10]. Motivated by the higher tolerance to fiber-nonlinearities, return-to-zero (RZ) modulation was introduced as an alternative to NRZ modulation. RZ modulation was first used in submarine systems [4.11] but also found commercial adoption in ultralong-haul terrestrial networks [4.12]. Aided by forward error correction (FEC) and Raman amplification, terrestrial DWDM systems with 10-Gb/RZ modulation could achieve C-band capacities of 800 Gb/s (80 channels at 50-GHz channel spacing) over distances of more than 3000-km SSMF [4.13]. By adding another 80 channels in the L-band (1565−1625 nm), this capacity could be doubled, albeit with some impact on reach [4.14]. Many terrestrial 10-Gb/s DWDM systems continued to use NRZ modulation, though. As enhanced forward error correction (EFEC) helped to increase the transmission distance up to 1500 km with EDFA-only amplification and more than 2500 km with Raman amplification, this was deemed to be sufficient for most practical applications.

To extend the fiber capacity, more bandwidth-efficient modulation techniques such as duobinary line coding and multilevel IMDD formats gained popularity in optical communications in the late 1990s [4.15]. Duobinary line coding (DB) is a partial-response format [4.9] and was first proposed in the 1960s for radio communications [4.16]. Comprehensive review papers on the advantages and disadvantages of optical duobinary (ODB) modulation have been published [4.17]. It has been pointed out that ODB, besides achieving higher bandwidth efficiency, also features a high resilience to GVD [4.18–21]. Further research has been published showing that improvements in the sensitivity of duobinary receivers is possible through careful optimization of both the electric and optical filter bandwidths in the system [4.22–26]. At 10-Gb/s line rate, ODB found only little commercial adoption apart from single-span transmission over extended link distances (for example 150 km) without optical dispersion compensation. At 40 Gb/s, though, ODB was found to be much more applicable, as it allows transmission of 40-Gb/s channels using 50-GHz filters and therefore a quadrupling of the system capacity compared to 10-Gb/s channels. It then substituted earlier realizations based upon NRZ or RZ modulation. In 2001, ODB modulation was successfully employed to transmit 80 channels at 40 Gb/s over 300-km SSMF [4.27]. Commercial deployments over several hundred kilometers followed in around 2005 [4.28]. Though ODB was by far not the only option for 40-Gb/s transmission.

The use of differential phase-shift keying (DPSK) with interferometric demodulation and direct detection was investigated in the late 1990s. DPSK demonstrated a sensitivity advantage over OOK [4.29, 30] and ODB as well as a high resilience to linear and nonlinear fiber propagation effects [4.25, 31–35]. Both binary (DPSK) and quaternary formats (DQPSK) were extensively studied in the following years, leading to their commercial deployment in around 2006 [4.36, 37]. While 40-Gb/s DQPSK could fit into a 50-GHz channel grid, this proved challenging initially for DPSK. Partial DPSK was able to overcome this limitation by reducing the differential delay of the Mach–Zehnder demodulator [4.38] and was commercially deployed from 2007

onwards under the name adaptive DPSK (ADPSK). Despite all improvements, the system performance of these 40-Gb/s solutions was still not on a par with state-of-the-art 10-Gb/s systems at that time. Stringent requirements on GVD and PMD tolerance required careful network planning and led to operational challenges.

With the advent of coherent detection, the transponder landscape changed dramatically. Earlier work on coherent optical communication systems in the 1980s had been hampered by a lack of digital signal processing (DSP) and large laser linewidths (compared to the Mb/s data rates used at that time). With much higher data rates and advances in CMOS technology now, coherent optical communications suddenly became a very practical option. Polarization-multiplexed quaternary phase-shift keying (PM-QPSK) reduces symbol rates by a factor of four compared to the information bit rate, while at the same time offering a 6-dB sensitivity gain over OOK. Furthermore, powerful DSP performs all the required GVD and polarization mode dispersion compensation, frequency and phase locking, and polarization demultiplexing in the electronic domain [4.39–45]. As a result, coherent transmission can deliver comparable system performance and reach as 10-Gb/s OOK and 40-Gb/s PM-QPSK signals. Furthermore, optical dispersion compensation is no longer required, a major operational advantage. Commercial 40-Gb/s PM-QPSK systems were first introduced in 2007 [4.46].

With the development of the 100-Gb Ethernet, a modulation format for its onward transmission across an optical DWDM network was urgently required. This triggered the development of 100-Gb/s PM-QPSK, which rapidly superseded 40-Gb/s technology. The higher capacity of a 100-Gb/s optical carrier allowed much better cost per bit performance compared to what was achievable at 40 Gb/s. The first commercial single-carrier 100-Gb/s PM-QPSK solutions were introduced in 2010 [4.47]. Competing solutions which achieved 100-Gb/s capacity by bonding two 50-Gb/s PM-QPSK carriers together (2C-PM-QPSK) [4.48, 49] had only limited market success.

Coherent transponder technology was first introduced in long-haul transmission and subsequently penetrated other areas such as metro and submarine networks as well. For shorter metro links and interdata center interconnects, the performance and spectral efficiency of coherent solutions is not always required, where the cost and power consumption of this technology can be prohibitive. As a consequence, alternative solutions based on direct-detect technology have emerged to address this market segment. A 4×25-Gb/s multicarrier ODB metro DWDM solution was introduced in 2011 to fulfill these needs for lower cost and lower power consumption and can operate on a 50 GHz or smaller channel grid to maximize spectral efficiency [4.50]. Using multilevel modulation formats in which each constellation symbol carries more than one bit, the spectral efficiency can be further increased. The transmission bandwidth of an M-ary signal (i.e., a modulation format whose constellation is composed of M points) scales at a factor of $1/\log_2(M)$ compared to a binary signal operating at the same bit rate. Multilevel IMDD systems are based on the use of the pulse-amplitude modulation (PAM), where only the amplitude of the optical field is modulated. Since the constellation points for this modulation format are *unipolar* (i.e., only zero or positive values can be encoded), a non-negligible loss in sensitivity is experienced. For this reason, multilevel IMDD formats have mainly been used in shorter reach applications. Utilizing the PAM4 modulation format to support the IEEE802.3bs and the OIF CEI56 standards, a dual-carrier 25-GBd PAM4 solution (two carriers occupying 100 GHz of bandwidth) was demonstrated in 2016 for DWDM data-center interconnects over 80-km distance [4.7], offering twice the fiber capacity compared to earlier 25-GBd NRZ or ODB OOK implementations.

Higher order modulation has also improved the fiber capacity and cost per bit in coherent communications employing quadrature-amplitude modulation (QAM). Maintaining a symbol rate of about 30 GBd, 200-Gb/s PM-16QAM [4.51] (and 150-Gb/s PM-8QAM [4.52]) was first commercially introduced in 2014 providing 100% (or 50%) more channel and fiber capacity at the cost of roughly 25% (or 50%) of the 100-Gb/s PM-QPSK reach. 200-Gb/s 8QAM [4.53] and 400-Gb/s 32QAM [4.54] have since then been presented as intermediate evolution steps. The next step change, though, is expected to be to 60-GBd technology, which has already been chosen as the basis for the 400G-ZR standard currently under development by the OIF [4.55]. 60-GBd technology doubles the symbol rate per optical carrier and can be used with a variety of modulation formats, for example 200-Gb/s PM-QPSK, 300-Gb/s PM-8QAM, 400-Gb/s 16-QAM, 500-Gb/s 32-QAM, and 600-Gb/s 64 QAM. Real-time 400-Gb/s PM-16QAM was first demonstrated in 2015 [4.56]. While doubling the symbol rate when maintaining the modulation format does not yield spectral efficiency gains for a given link distance, the use of fewer optical carriers results in cost, footprint, and power savings. Moving forwards, future developments will concentrate on (a) increasing the symbol rate even further and (b) providing more flexibility by adapting the modulation format to the requirements and available margins on a given optical path. Figure 4.4 graphically summarizes the historical development of WDM transponder symbol rates and modulation formats in commercial systems.

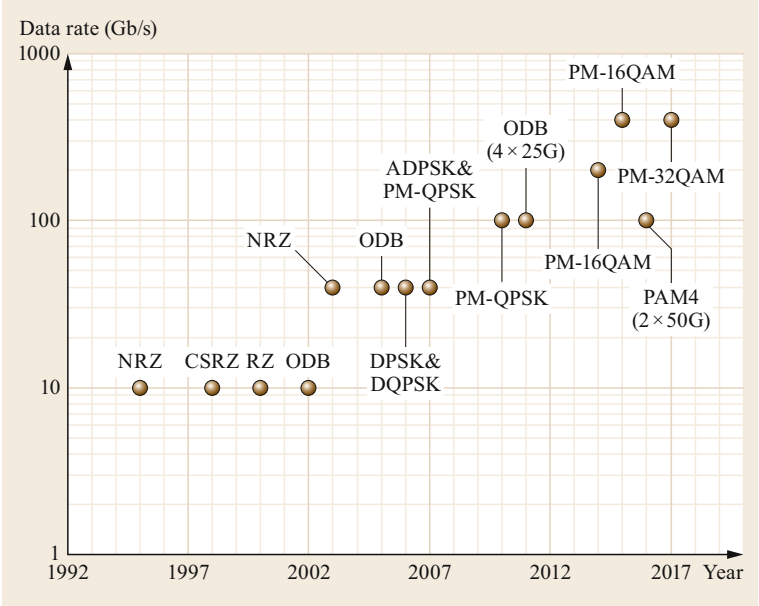

Fig. 4.4 Historical development of WDM transponder symbol rates and modulation formats

In the following sections, the architecture and performance of DWDM transponder line interfaces employing different modulation formats and detection schemes will be discussed. Section 4.2 starts with IMDD, to be followed by ODB in Sect. 4.3, then differential phase modulation in Sect. 4.4 and coherent interfaces in Sect. 4.5. Different transponder types and hardware architectures will then be explained in Sect. 4.6.

4.2 Intensity Modulation with Direct Detection

This section reviews the transmitter and receiver architectures required to generate and detect different types of IMDD optical signals. The intensity-modulation formats are introduced in Sect. 4.2.1, together with the most common line coding techniques used in IMDD transponders. The structures of several types of binary intensity-modulation transmitters are detailed in Sect. 4.2.2, while Sect. 4.2.3 describes the architecture of a receiver based on direct detection (DD). Section 4.2.4 shows the back-to-back performance of binary IMDD systems, including the optimization of the TX and RX filters and the impact of subsystem components implementation. Tolerance to GVD and PMD is also analyzed. Finally, Sect. 4.2.5 discusses multilevel IMDD formats.

4.2.1 Intensity Modulation

The complex envelope of an IM signal at the output of the modulator can be written as [4.9]

$$s_{\mathrm{T}}(t) = \sum_k a_k q_{\mathrm{T}}(t - kT_{\mathrm{s}}) \,, \tag{4.1}$$

where a_k are the symbols carrying the information, T_{s} is the symbol time interval (one symbol is sent every T_{s} seconds) and $q_{\mathrm{T}}(t)$ is the optical pulse shape in the time domain. The symbols a_k may assume $M = 2^{n_{\mathrm{b}}}$ values, where n_{b} is the number of information bits carried by each symbol. The symbol rate R_{s} is defined as the number of symbols that are transmitted in each time unit. It is equal to the inverse of the symbol time ($R_{\mathrm{s}} = 1/T_{\mathrm{s}}$) and is measured in baud or symbols per second. The bit rate R_{b} is defined as the number of bits that are conveyed per unit of time. It is measured in bit per second and is related to the symbol rate by $R_{\mathrm{b}} = n_{\mathrm{b}} R_{\mathrm{s}}$. In the case of binary IM, also known as on-off keying (OOK), $n_{\mathrm{b}} = 1$ and $a_k \in \{0, 1\}$. In each bit slot, one of two alternative waveforms can be transmitted, depending on the value of the information bit: $s_0(t) = 0$, $s_1(t) = q_{\mathrm{T}}(t)$. These two analog waveforms are represented in the signal space [4.9] by the two points shown in Fig. 4.5a. The constellation of quaternary IM, also known as PAM-4 (pulse amplitude modulation), is shown, as well. In practice, a *constellation diagram* shows all the possible symbols that can be transmitted by the system as a *constellation* of points,

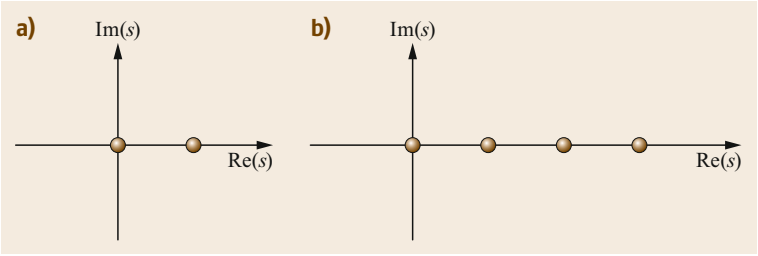

Fig. 4.5 (a) OK and (b) PAM-4 constellations

each characterized by an amplitude (distance from the origin) and a phase. The energy of each symbol is proportional to the square distance of the corresponding constellation point from the origin. For IM signals, only the intensity (amplitude) varies among different symbols, while the phase is constant, thus the constellation points lie on a single straight line.

Depending on the shape of $q_T(t)$ in (4.1), the modulation format is defined as either nonreturn-to-zero (NRZ), when the time duration of $q_T(t)$ is close to the symbol interval T_s, or return-to-zero (RZ), when the duration of the pulse is lower than T_s and the power returns to zero between two successive "1" bits.

The power spectral density of the signal $s_T(t)$ is given by [4.9]

$$G_s(f) = \frac{|Q_T(f)|^2}{T_s}\sigma_a^2 + m_a^2 \sum_n \frac{|Q_T(nR_s)|^2}{T_s^2}\delta(f - nR_s)\,, \qquad (4.2)$$

where $Q_T(f)$ is the Fourier transform of the pulse $q_T(t)$ and m_a and σ_a^2 are the mean and variance of the random variable a_k, respectively. For instance, in case of OOK with equi-probable bits, $m_a = \sigma_a^2 = 1/2$. The power spectrum of IM signals is composed of two terms: a continuous spectrum, which contains the information to be transmitted, and a discrete spectrum, which does not carry any information and whose lines are placed at the harmonics of the bit rate.

Figure 4.6 shows two examples of noiseless spectra of NRZ and RZ signals. The time duration of RZ pulses is shorter, therefore their bandwidth occupation can be significantly larger. The *eye diagram*, i.e., the synchronized superposition of all possible realizations of a signal viewed within a particular signaling interval (equal to $2T_s$ in Fig. 4.6), is also shown in the right upper part of the figures. The eye diagram can be easily displayed on an oscilloscope, and is a useful tool for the evaluation of the combined effects of channel noise and intersymbol interference on the transmitted or received signals [4.9].

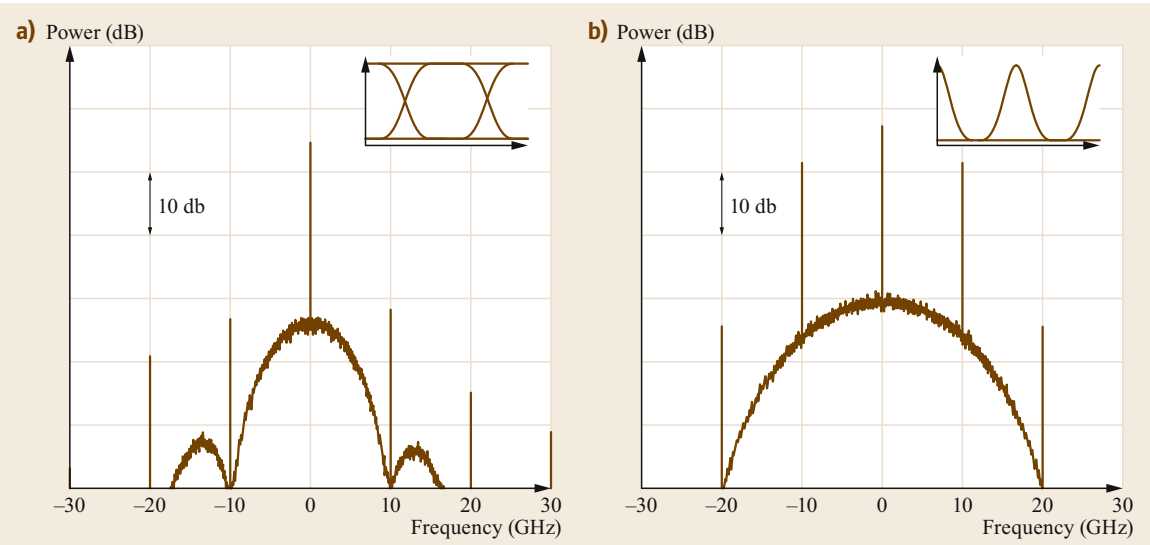

Fig. 4.6a,b Examples of NRZ (a) and RZ (b) optical spectra at 10 GBd. The corresponding eye diagrams are shown in the *insets*

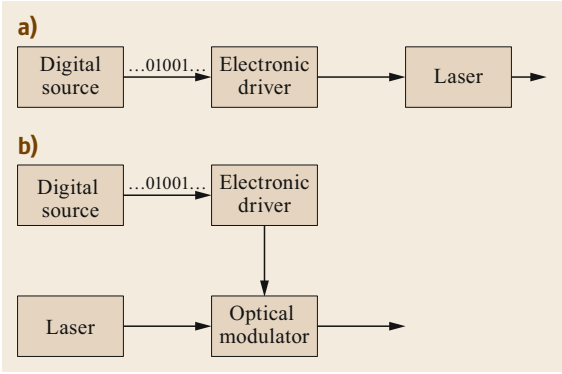

Fig. 4.7a,b Scheme of an OOK transmitter using (a) direct modulation and (b) external modulation

4.2.2 On–Off Keying Optical Transmitter

At the transmitter, there are two alternative ways to convert electrical data into optical form, known as *direct modulation* and *external modulation* [4.57]. In the case of direct modulation, the output power of the light source depends directly on the input drive current (or voltage), e.g., light is emitted from the device when a binary one is being transmitted and no light is emitted when a binary zero is being transmitted. The schematic of an OOK transmitter employing direct modulation is shown in Fig. 4.7a. In the case of external modulation, the light source is always on and an external modulator, driven by the electrical data signal, acts as a switch in order to control the intensity/phase of the generated optical signal. The schematic of an OOK transmitter employing external modulation is shown in Fig. 4.7b.

Since transmitters employing directly modulated lasers (DMLs) do not require the use of external modulators, they are simpler and cheaper, but their transmission performance is strongly limited by the *chirp* phenomenon [4.58, 59] (a residual phase modulation superimposed on the desired intensity modulation). Interacting with chromatic dispersion, chirp may introduce a relevant performance penalty, limiting the application of direct modulation to short-reach transponders [4.60–62]. In this chapter, we focus on external modulation by chirp-free Mach–Zehnder modulators (MZMs).

NRZ-OOK Transmitter

An NRZ-OOK signal can be generated using the transmitter scheme shown in Fig. 4.8, by properly driving an MZM with an RF signal carrying the information bits.

The electrical field and power transmission of an MZM as a function of the applied voltage V_d are,

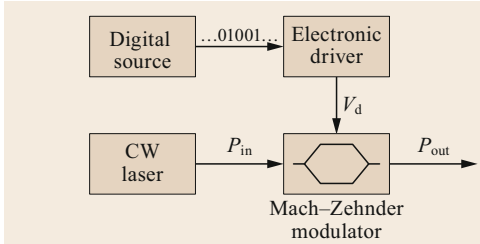

Fig. 4.8 Scheme of an NRZ-OOK transmitter

respectively

$$\frac{E_{out}}{E_{in}} = \sin\left(\frac{\pi}{2}\frac{V_d - V_0}{V_\pi}\right) - j\frac{1}{ER}\cos\left(\frac{\pi}{2}\frac{V_d - V_0}{V_\pi}\right), \quad (4.3a)$$

$$\frac{P_{out}}{P_{in}} = \sin^2\left(\frac{\pi}{2}\frac{V_d - V_0}{V_\pi}\right) + \frac{1}{ER}\cos^2\left(\frac{\pi}{2}\frac{V_d - V_0}{V_\pi}\right), \quad (4.3b)$$

where V_0 is the input voltage corresponding to minimum transmission, V_π is the input voltage difference between maximum and minimum transmission, and ER is the extinction ratio of the MZM, defined as the ratio between the maximum and the minimum output power. A noninfinite value of ER means that the minimum transmission is not zero and a performance penalty can be experienced, as shown in Sect. 4.2.4.

The ideal power transmission of an MZM is shown in Fig. 4.9, where $V_0 = 0$ and $ER = \infty$. The circles indicate the 50% transmission points, also referred to as *quadrature points*. In order to generate OOK pulses,

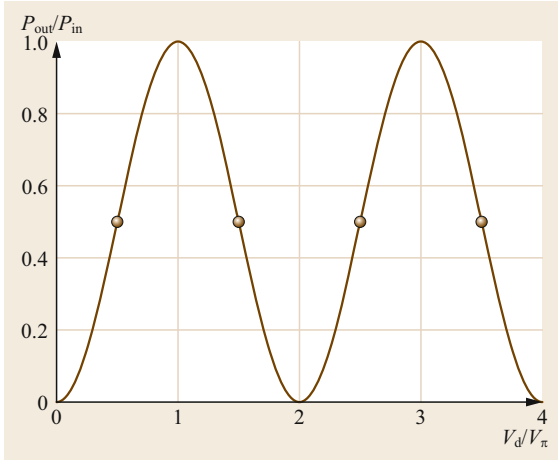

Fig. 4.9 Ideal MZM power transmission. The *circles* indicate the quadrature points

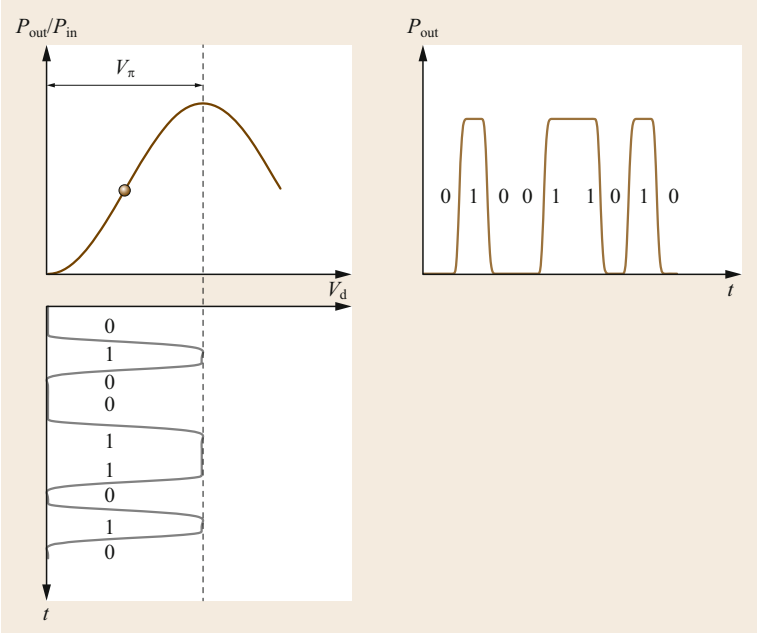

Fig. 4.10 MZM driven by an NRZ drive signal

the MZM needs to be biased at a quadrature point and driven with an input voltage ranging from minimum to maximum transmission, as schematically shown in Fig. 4.10.

RZ Transmitter

RZ transmitters can be implemented either by electronically generating an RZ drive waveform (using the architecture shown in Fig. 4.8) or by carving out pulses from an NRZ signal using an additional modulator, called a pulse carver, as shown in Fig. 4.11. A pulse carver is usually implemented by driving an MZM with a sinusoidal signal. The width of the RZ pulses can be varied by tuning the sinusoidal signal amplitude and frequency. If the sinusoidal signal has a frequency equal to the bit rate and drives the modulator between minimum and maximum transmission, optical pulses with full-width half-maximum of 50% of the bit duration (i.e., with a duty cycle of 50%) are obtained. The pulse width can be reduced by driving the modulator between its transmission minima with a sinusoidal signal whose frequency is equal to half the bit rate. In this case, a duty cycle of 33% can be obtained, as shown in Fig. 4.12.

CSRZ Transmitter

A modification of the RZ line coding, with an increased tolerance to nonlinear propagation effects, was proposed in [4.63]. As for standard OOK formats, the information is encoded on the intensity levels $\{0, 1\}$, but the phase is changed by π every bit, regardless of the data information. Thus, on average, the optical field of half the 1-bits has a positive sign, while the other half has a negative sign, resulting in a zero-mean optical field envelope. As a consequence, the carrier at the optical center frequency vanishes. For this reason, the format is called carrier-suppressed RZ (CSRZ). CSRZ

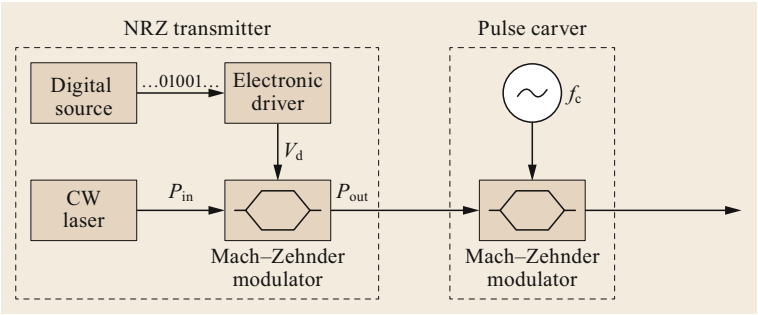

Fig. 4.11 Scheme of an RZ-OOK transmitter

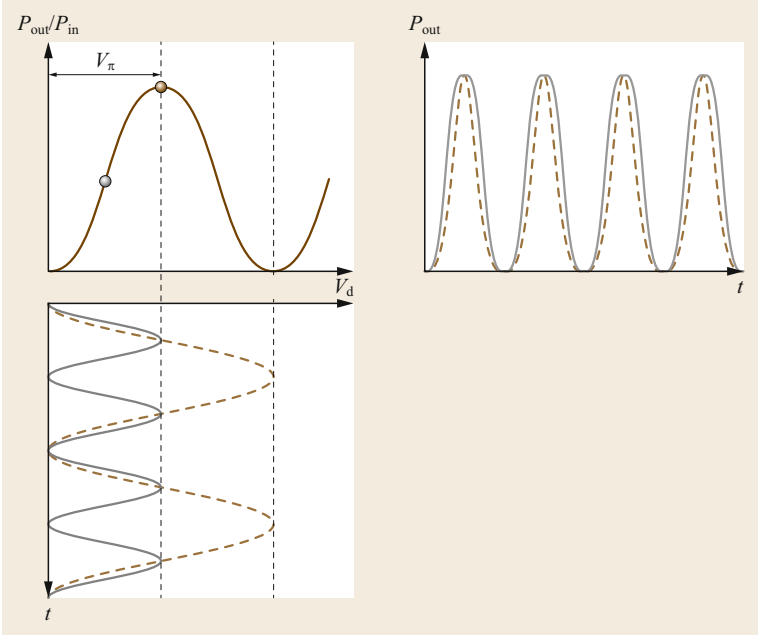

Fig. 4.12 MZM operation as a pulse carver to generate RZ pulses with 33% duty cycle (*dashed lines*) and 50% duty cycle (*solid lines*)

signals can be generated using the same transmitter used for RZ (Fig. 4.11), sinusoidally driving the MZM in the pulse carver at half the data rate between its transmission maxima, as shown in Fig. 4.13. The result is the generation of pulses with 67% duty cycle and alternating phase. Note that the larger duty cycle leads to a lower optical filter penalty (due to either ISI or XTK) with respect to standard RZ pulses.

Chirped Return-To-Zero (CRZ) Transmitter

The chirped-RZ modulation format is obtained by adding a controlled amount of phase modulation to RZ pulses. This can be achieved by inserting a bit-synchronous phase modulator, with an adjustable peak-to-peak level and phase relative to the center of the bit [4.64], after a standard RZ transmitter (just like the one shown in Fig. 4.11). The generated optical phase term is equal to $e^{-jm\cos(2\pi f_0 t)}$, where m is the *phase modulation index* and f_0 is the sinusoidal modulation frequency, which is equal to the data rate. The applied phase modulation reduces the nonlinear propagation distortions [4.65], but it also increases the signal spectrum bandwidth, and consequently the cross-talk between adjacent channels in a WDM system. The optimum amount of phase modulation for CRZ is thus a compromise between tolerance to linear and nonlinear cross-talk. CRZ is typically used in ultralong-haul point-to-point fiber communications, such as submarine systems, with a phase modulation index of approximately 1 rad [4.66].

Alternatively to the three-stage modulation scheme (NRZ modulator, pulse carver, phase modulator), a dual-drive MZM can be used as a chirped pulse carver at various duty cycles by controlling the imbalance of the drive signal amplitudes or their relative phase, as shown in [4.67].

4.2.3 Direct-Detection Optical Receiver

The general scheme of an optically preamplified direct-detection receiver is shown in Fig. 4.14. It is composed of an optical amplifier, followed by an optical filter with impulse response $h_o(t)$, a photodetector, an electrical amplifier, an electrical filter with impulse response $h_e(t)$, and a threshold decision device.

The received optical field at the output of the optical amplifier can be written as

$$y(t) = s_R(t) + n(t)\,, \tag{4.4}$$

where $n(t)$ is the ASE noise introduced by the optical amplifier and $s_R(t)$ is the useful signal component, which is given by

$$s_R(t) = \sum_k a_k q_R(t - kT_s)\,, \tag{4.5}$$

where a_k are the information symbols and $q_R(t)$ is the received optical pulse after propagation in the optical fiber.

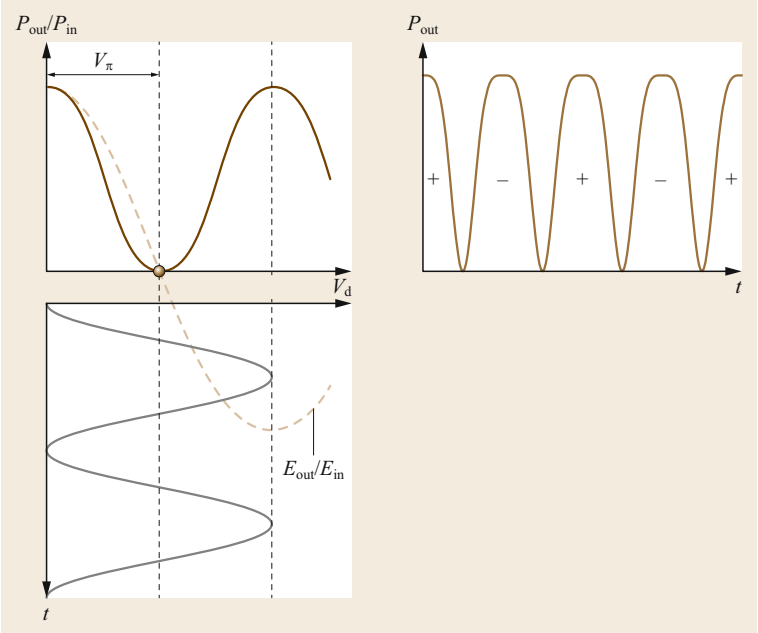

Fig. 4.13 MZM operation as a pulse carver to generate CSRZ pulses with 67% duty cycle

ASE noise is modeled as a white Gaussian noise with spectral density $N_0/2$ [4.57], where

$$N_0 = n_{sp} h\nu (G-1)\,, \tag{4.6}$$

in which n_{sp} is the spontaneous emission factor, h is Plank's constant, ν is the transmission frequency, and G is the amplifier gain. The noise figure F of the optical amplifier, defined as the ratio between the input and output signal-to-noise ratio, is approximately equal to $2n_{sp}$.

The signal at the output of the optical filter can be written as

$$r(t) = s(t) + m(t)\,, \tag{4.7}$$

with

$$\begin{aligned} s(t) &= s_R(t) * h_o(t)\,, \\ m(t) &= n(t) * h_o(t)\,, \end{aligned} \tag{4.8}$$

where the star denotes a convolution and $m(t)$ is a colored Gaussian noise with power spectral density given by

$$G_m(f) = \frac{N_0}{2}|H_o(f)|^2 \tag{4.9}$$

and variance given by

$$\sigma_m^2 = \frac{N_0}{2}\int_{-\infty}^{+\infty}|H_o(f)|^2 \mathrm{d}f = \frac{N_0}{2}\int_{-\infty}^{+\infty}|h_o(t)|^2 \mathrm{d}t\,. \tag{4.10}$$

The detected current is proportional to the incident optical power $P_R(t)$, which is in turn proportional to the squared magnitude of the optical field as shown in (4.7)

$$\begin{aligned} i_R(t) \propto P_R(t) &= |r(t)|^2 = |s(t)+m(t)|^2 \\ &= |s(t)|^2 + |m(t)|^2 + 2\mathrm{Re}\{s(t)m^*(t)\}\,. \end{aligned} \tag{4.11}$$

The first term is the useful signal, the second term is the (noise × noise) beat term, and the third term is the

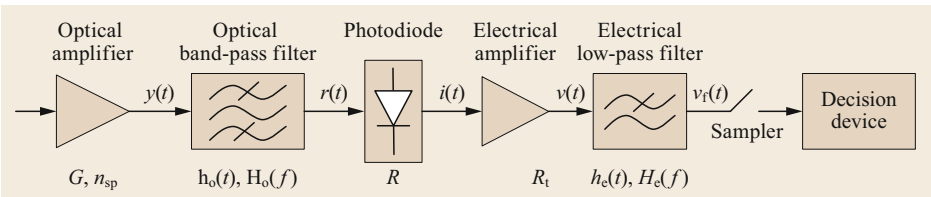

Fig. 4.14 Schematic of an optically preamplified direct-detection receiver

(signal × noise) beat term. The complete photodetection current, including the noise signals generated by the electrical amplifier and the photodetector, can be written as

$$i(t) = i_s(t) + i_{s,ASE}(t) + i_{ASE,ASE}(t) + i_{th}(t) + i_{sh}(t) \,. \tag{4.12}$$

The terms on the right hand side represent the useful signal, the (signal × noise) and (noise × noise) beat terms, the thermal noise and the shot noise respectively [4.57].

The signal after the electrical filter can be written as

$$\begin{aligned} v(t) &= R_t i(t) * h_e(t) \\ &= v_s(t) + v_{s,ASE}(t) + v_{ASE,ASE}(t) \\ &\quad + v_{th}(t) + v_{sh}(t) \,, \end{aligned} \tag{4.13}$$

where R_t accounts for the photodiode and amplifier resistances and $h_e(t)$ is the impulse response of the electrical filter. The signal $v(t)$ is then sampled at the sampling instants $t_k = t_0 + kT$ and compared to a threshold v_{th}. The decision algorithm is then

$$a_k = \begin{cases} 0 & \text{if } v(t_k) < v_{th} \,, \\ 1 & \text{if } v(t_k) > v_{th} \,. \end{cases} \tag{4.14}$$

In general, the system performance is limited by ASE noise, shot noise, and thermal noise. However, in preamplified multispan DWDM systems as addressed in this chapter, shot noise and thermal noise are typically negligible compared to ASE noise. These systems are said to be *ASE limited* and their performance can be characterized by the optical signal-to-noise ratio (OSNR), which is defined as

$$\mathrm{OSNR} = \frac{P_s}{P_N} = \frac{P_s}{2N_0 B_N} \,, \tag{4.15}$$

where P_s is the average power of the optical signal at the input of the receiver optical filter, P_N is the ASE noise power on both polarizations measured over an optical reference bandwidth equal to B_N, and N_0 is the corresponding single-sided ASE noise power spectral density, as shown in (4.6). Often a fixed reference bandwidth B_N of 12.5 GHz is used (corresponding to 0.1-nm wavelength range), which is a standard setting in many optical spectrum analyzers. Alternatively, the symbol rate of the signal R_S can serve as reference bandwidth. In this chapter, we follow the latter approach.

In the 1.55-μm window and with sufficiently high optical amplifier gain, the OSNR (referenced to the symbol rate) can then be rewritten in logarithmic form as

$$\begin{aligned} \mathrm{OSNR_{dB}} &= 58\,\mathrm{dBm} + 10\log\left(\frac{P_s}{1\,\mathrm{mW}}\right) \\ &\quad - 10\log(\mathrm{F}) - 10\log\left(\frac{B_N}{R_S}\right) , \end{aligned} \tag{4.16}$$

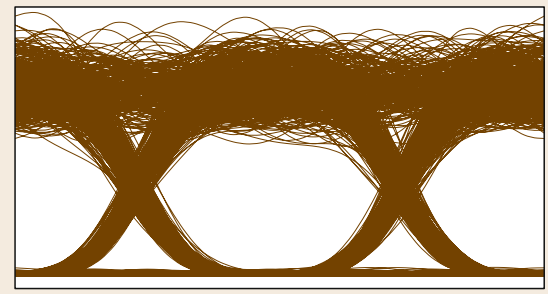

Fig. 4.15 Noisy NRZ-OOK eye diagram after direct detection

where the signal power P_s is given in mW and F is a known amplifier noise figure.

Figure 4.15 shows an example of an eye diagram after direct detection in an NRZ-OOK system limited by ASE noise (where the other noise terms are negligible). Due to the (signal × noise) beat term, the variance of noise is higher on the "1" level and, consequently, the optimum decision threshold v_{th} is closer to the "0" level.

4.2.4 Back-to-Back Performance and Dispersion Tolerance

Ideal Performance of a Binary IMDD System

In ASE-limited systems, for all formats based on intensity modulation and direct detection the optimum receiver is based on the use of an optical filter whose impulse response is matched to the received pulses $q_R(t)$ [4.9]. The optimum achievable performance is independent of the pulse shape, provided that the receiver optical filter is perfectly matched to the electrical field of the input signal. This optimum performance (also known as the *quantum limit* [4.68, 69]) is shown in Fig. 4.16 in terms of bit error rate (BER) versus optical signal-to-noise ratio (OSNR), as defined by (4.16). In Fig. 4.16, the reference noise bandwidth is equal to the symbol rate. This means that the performance curve is valid for any value of the symbol rate (which for binary format is equal to the bit rate).

An analytical derivation of the BER of ASE-noise-limited systems can be found in [4.29]. In the case of a matched optical filter (where $M = 2$ in [4.29])

$$\begin{aligned} \mathrm{BER} &= \frac{1}{2}\Big[\mathrm{e}^{-\varphi}(1+\varphi) + 1 \\ &\quad - Q_2\Big(\sqrt{8\mathrm{OSNR}}, \sqrt{2\varphi}\Big)\Big] \\ \text{with } \varphi &= \frac{v_{th}}{N_0 R_s} \,, \end{aligned} \tag{4.17}$$

where Q_2 is the generalized Marcum Q function of order 2 and φ is the normalized decision threshold that

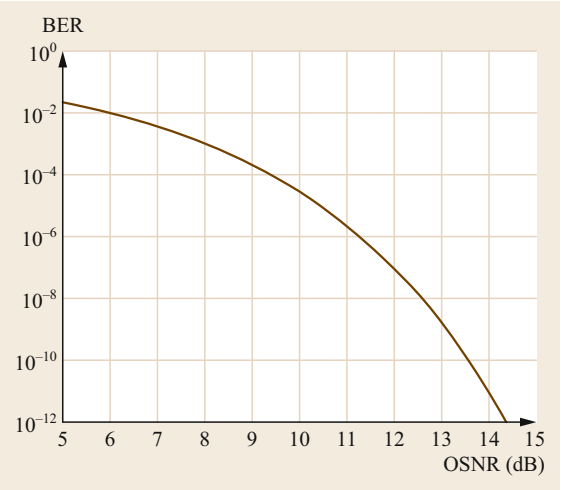

Fig. 4.16 Ideal performance of an IMDD optical system

needs to be optimized in order to minimize the BER. A good approximation of the curve shown in Fig. 4.16 is

$$\mathrm{BER} \cong \frac{1}{2} e^{-0.98\,\mathrm{OSNR}} . \tag{4.18}$$

Optimization of Filter Bandwidths

The ideal performance of IMDD systems is independent of the pulse shape, but only if a perfectly matched optical filter is available, a condition which is difficult to achieve with analog optical filters. This is the reason why a different performance is typically achieved using NRZ and RZ/CSRZ pulses, with the latter showing a better sensitivity in most cases [4.68, 70, 71]. Several research papers have been published on the optimization of the optical and electrical filters in order to achieve system performances as close as is possible to quantum limit [4.69, 72–76]. The final results depend on the filter shapes, but the same general behavior is shown in all papers.

As an example of receiver filter optimization, we report in the following a set of simulation results obtained for NRZ, RZ, and CSRZ transceivers. The transmitter architectures are the ones shown in Figs. 4.8 and 4.11. For NRZ, the bandwidth limitation of the TX is emulated using a 5-pole Bessel low-pass filter with 3 dB bandwidth equal to $0.7R_s$. The FWHM of RZ and CSRZ pulses obtained after the pulse carving operation is 50 and 66%, respectively. At the RX side, the passband optical filter has a 2nd-order super-Gaussian shape with 3 dB bandwidth B_{opt}. An ideal photodetector and a 5-pole Bessel electrical low-pass filter with 3 dB bandwidth B_{el} follow. Since we are considering ASE-noise-limited systems, thermal and shot noise have not been included in the simulations. Noise loading was performed at the receiver input in order to set the OSNR value. The target BER was set to 10^{-3}, which corresponds to the pre-FEC BER value of standard hard-decision EFECs with 7% overhead [4.77]. BER values were evaluated through direct error counting over 2^{18} bit.

The results are shown in Fig. 4.17. The matched filter performance, identical for all systems, is obtained with an OSNR of 8 dB (over a bandwidth equal to R_s). For the NRZ case, the minimum OSNR (with a ≈ 1 dB penalty with respect to the optimum matched filter performance) is achieved for $B_{opt} = 1.2R_s$ and $B_{el} = R_s$. For both the RZ and CSRZ format the penalty with respect to the matched filter performance is lower (≈ 0.5 dB) and the optimum performance is achieved with a larger optical filter bandwidth equal to $B_{opt} = 2R_s$. The reason why the performance of RZ formats is closer to the matched filter limit than NRZ is that there is a greater matching between the RZ pulses and the Super-Gaussian optical filter. The reason why the best performance for NRZ is obtained for a lower B_{opt} value is that NRZ has an intrinsically better bandwidth-efficiency than RZ formats. It's also worth mentioning that RZ/CSRZ contours are less pronounced and therefore low penalty operation can be achieved over a wider (B_{opt},B_{el}) range than for NRZ.

Impact of Finite MZM Extinction Ratio

The extinction ratio ER of a modulator corresponds to the ratio of the power P_1 used to transmit a logic level 1 to the power P_0 used to transmit a logic level 0. Ideally, $P_0 = 0$ and $\mathrm{ER} = \infty$, but in practice $P_0 > 0$ and $\mathrm{ER} < \infty$, because of the presence of spontaneous emission noise and bias errors, as well as the electronic bandwidth limitations in modulator and driver.

A finite value of ER induces a performance penalty, which can be defined as the increase in average power needed to obtain the same bit error rate as an ideal pulse with infinite extinction ratio. In the case of systems limited by additive white Gaussian noise (e.g., IMDD systems limited by thermal noise), the power penalty is given by [4.78]

$$\delta_{\mathrm{ER}} = 10 \log_{10} \left(\frac{\mathrm{ER}+1}{\mathrm{ER}-1} \right) . \tag{4.19}$$

In IMDD systems limited by ASE noise there is an additional penalty due to the increase of ASE noise on the zero level, as shown in [4.79]

$$\delta_{\mathrm{ER}} = 10 \log_{10} \left(\frac{\mathrm{ER}+1}{\mathrm{ER}-1} \right) + 10 \log_{10} \left(\frac{\sqrt{\mathrm{ER}}+1}{\sqrt{\mathrm{ER}}-1} \right) . \tag{4.20}$$

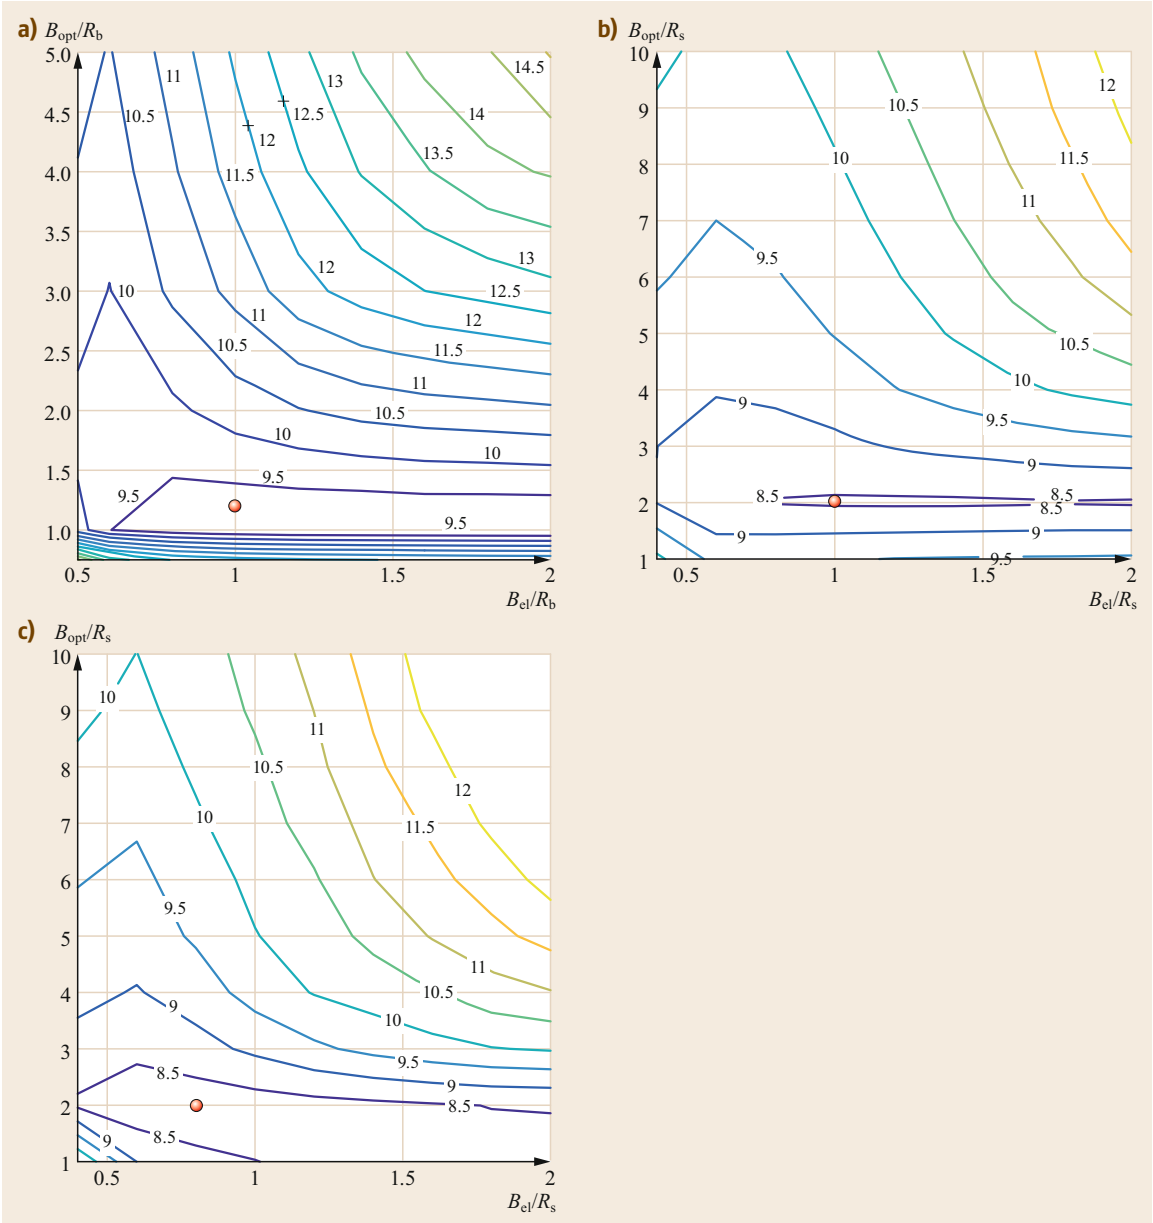

Fig. 4.17a–c Contour plots of the required OSNR to achieve BER $= 10^{-3}$ as a function of the receiver optical and electrical 3-dB bandwidths (B_{opt} and B_{el}) for **(a)** NRZ, **(b,c)** CSRZ pulses. The *red dots* indicate the optimum points (i.e., the points with minimum required OSNR)

Both, (4.19) and (4.20), assume that the eye diagram is perfectly open, i.e., no intersymbol interference (ISI) is present at the sampling instant. Figure 4.18 shows the power penalty as a function of the ER value, for both thermal-noise-limited and ASE-noise-limited receivers. In ASE-noise-limited systems, the power penalty shown in Fig. 4.18 is equivalent to an OSNR penalty. Note that the penalty due to a finite ER might be lower in the presence of ISI and non-perfectly matched receivers, as shown in [4.69, 75]. An approximate estimation of the required OSNR for a certain bit error rate can then be obtained if an effective extinction ratio is calculated from the electrical eye diagram at the receiver and the resulting penalty is added to the reference OSNR at the quantum limit.

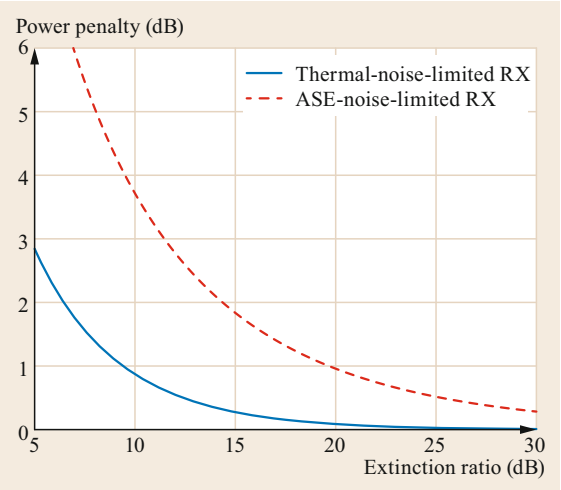

Fig. 4.18 Power penalty due to a finite ER in the absence of ISI

Dispersion Tolerance

Group velocity dispersion (GVD) is the result of the different wavelengths in a light beam arriving at their destination at slightly different times due to the frequency dependence of the refractive index of the fiber. In the literature, the GVD phenomenon is also referred to as chromatic dispersion (CD). Polarization-mode dispersion is a form of modal dispersion where two different polarizations of light in a waveguide travel at different speeds due to random imperfections and asymmetries [4.78]. Both phenomena cause a time spreading of the optical pulses, which in turn induces a performance penalty.

PMD is related to the *differential group delay* (DGD) caused by birefringence in optical fibers. However, birefringence varies along the length of the fiber, with different sections exhibiting a difference birefringence both in terms of levels of refractive index asymmetry and of relative orientation of the slow and fast polarization axis, also known as *principal states of polarization* (PSP). As a result, the instantaneous value of DGD measured at the output of a fiber is a random variable that is well approximated by a Maxwellian distribution [4.80]. The PMD of a fiber is typically described through the parameter δ_{PMD}, which is an estimate of the average value of the statistical distribution of DGD.

The tolerance to GVD and PMD is strongly dependent on the symbol rate of the modulated signal. In particular, the pulse broadening $\Delta\tau_{\mathrm{CD}}$ due to GVD and the average value of DGD between the two principal states of polarizations (normalized to the symbol time $T_{\mathrm{s}} = 1/R_{\mathrm{s}}$) are given by [4.81]

$$\frac{\Delta\tau_{\mathrm{CD}}}{T_{\mathrm{s}}} = 2\pi|\beta_2|kR_{\mathrm{s}}^2 L \times 10^{-6}\,,$$
$$\frac{\langle\Delta\tau_{\mathrm{DGD}}\rangle}{T_{\mathrm{s}}} = \delta_{\mathrm{PMD}}\sqrt{L}R_{\mathrm{s}} \times 10^{-3}\,, \qquad (4.21)$$

where β_2 is the CD coefficient in $\mathrm{ps}^2/\mathrm{km}$, δ_{PMD} is the PMD parameter that can be found in fiber data sheets and is expressed in $\mathrm{ps}/\sqrt{\mathrm{km}}$, R_{s} is the symbol rate in GBd (which for binary formats is identical to the bit rate R_{b}), L is the fiber length in km, and k is a coefficient that depends on the modulation formats, defined as the ratio between the spectral width of the modulated signal and the symbol rate. The coefficient β_2 is related to the dispersion parameter D ($(\mathrm{ps/nm})/\mathrm{km}$) through the relationship $D = -2\pi c\beta_2/\lambda^2$, where c is the speed of light in vacuum and λ is the propagation wavelength.

Equation (4.21) shows that the effect of DGD scales linearly with R_{s}, while the impact of GVD scales quadratically with R_{s}, for example a doubling in the symbol rate reduces the GVD tolerance by approximately a factor of 4. Also, the normalized pulse broadening due to GVD scales linearly with the normalized spectral width of the modulation format, resulting in a higher GVD tolerance (in a linear propagation regime) for NRZ modulation formats. The tolerance to DGD is instead in general higher for RZ modulation formats [4.82].

As an example, Fig. 4.19 shows the performance of NRZ, RZ, and CSRZ modulation formats in the presence of either GVD or a first-order PMD. The simulation setup is the same as described in the first part of this section, with optimized RX filter bandwidth (corresponding to the red dots in Fig. 4.17). Linear fiber propagation was assumed, while first-order PMD was emulated by inserting a deterministic DGD value $\Delta\tau_{\mathrm{DGD}}$ between the two principal states of polarization (PSP) [4.80]. The worst-case of equal power-splitting ratio between the two PSPs was considered [4.83].

In order to make the results symbol-rate independent, the x-axes have been normalized with respect to either R_{s}^2 (in the GVD plot) or R_{s} (in the PMD plot). The value of accumulated dispersion at a given symbol rate ($D\,L$) in ps/nm can be obtained by multiplying the value read on the x-axis of Fig. 4.19a by the coefficient $(2\pi c)/(R_{\mathrm{s}}^2\lambda^2) \times 10^6$, with c expressed in m/s, R_{s} in GBd, and λ in nm. In the 1.55-μm window, this corresponds to a multiplication by a factor $\approx 0.784 \times 10^6/R_{\mathrm{s}}^2$, with R_{s} measured in GBd. As an example, at 10.7 Gb/s the GVD tolerance for a 2-dB penalty is equal to ≈ 550 ps/nm for RZ and to ≈ 750 ps/nm for NRZ and CSRZ. The DGD tolerance for the 2-dB penalty at

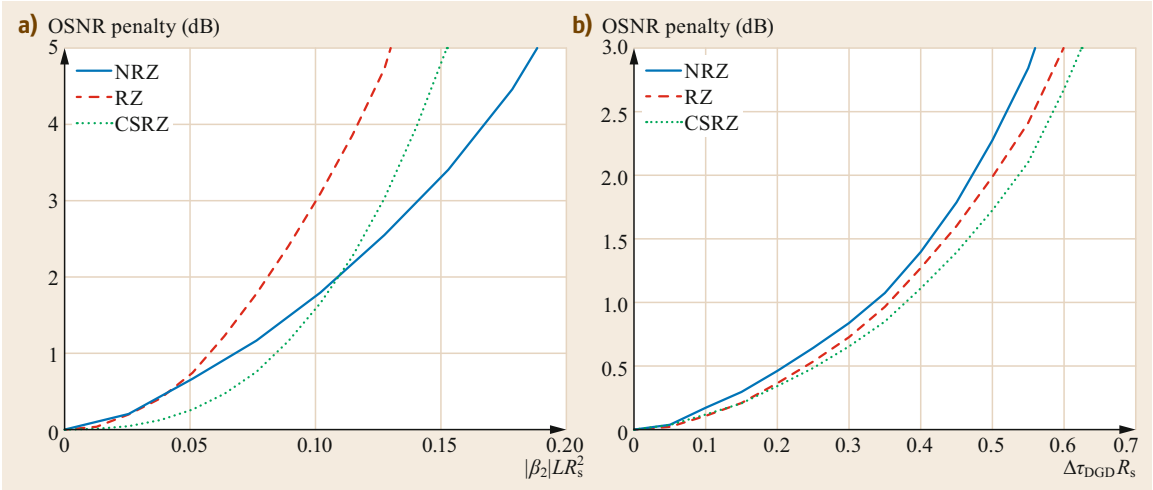

Fig. 4.19a,b GVD and first-order PMD tolerance of NRZ, RZ, and CSRZ in terms of OSNR penalty with respect to back-to-back performance as a function of either **(a)** the normalized accumulated dispersion or **(b)** the normalized DGD in the worst-case power-splitting ratio between the two PSPs. The target BER is 10^{-3} and the value of the reference back-to-back OSNR (over a bandwidth equal to R_s) is 9.0, 8.5, and 8.4 dB for NRZ, RZ, and CSRZ, respectively

10.7 Gb/s is instead equal to 44, 46.5, and 50 ps/nm for NRZ, RZ and CSRZ, respectively. Note that, considering the statistical nature of DGD and allowing a limited outage time, the tolerated PMD (based on the δ_{PMD} parameter) is typically smaller than the tolerable DGD by a factor of ≈ 3 [4.84].

GVD and DGD tolerance, like back-to-back OSNR requirements, can depend in a non-negligible way on pulse and filter shapes used in the system, as well as on other residual distortions [4.35, 85–88]. In general, the impact on a modulation format of various impairments cannot be taken in isolation, but has to be evaluated in the context of the system it is operating in, which might include dispersion maps for nonlinearity mitigation [4.89, 90] and/or advanced digital signal-processing techniques [4.45] that can for instance significantly increase the dispersion tolerance.

4.2.5 Multilevel Intensity Modulation

An M-ary PAM optical signal can be obtained by applying an M-ary electrical signal to an MZM biased at the quadrature point, i.e., half point of its transfer characteristic (Figs. 4.8 and 4.10). The signal bandwidth of an M-ary signal is scaled by a factor $1/\log_2(M)$ compared to a binary signal operating at the same bit rate R_b, where $R_b = R_s \log_2(M)$ and R_s is the symbol rate.

For any optical extinction ratio, it is easy to show that the M levels should be equally spaced (for example $\{0, 1/3, 2/3, 1\}$ for PAM-4) when the noise is stationary, i.e., not signal dependent. This is the case, for example, when receiver thermal noise dominates. Given that the noise in an optically preamplified receiver is strongly signal dependent, it is clear that the lowest probability of error will be achieved when unequal level spacing is used [4.15]. In particular, the photocurrent of each level is approximately Gaussian distributed, with a variance proportional to the intensity. In order to equalize the error probabilities at the M-1 different thresholds, the intensity levels should form a quadratic series, i.e., 0, 1, 4, 9, etc. [4.91]. Under these assumptions, and assuming Gray coding, it can be shown that

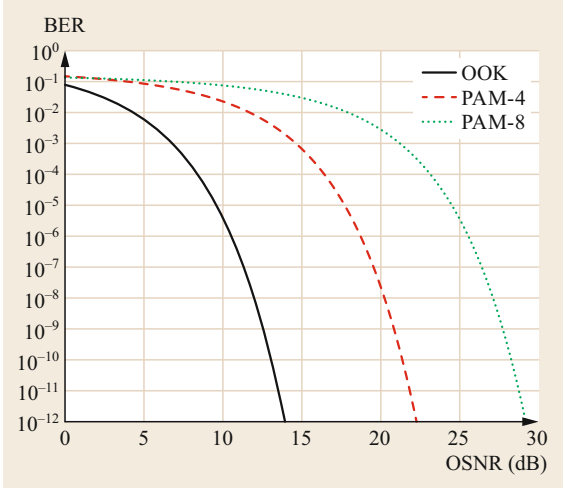

Fig. 4.20 Ideal performance of PAM signals with direct detection in ASE-noise-limited systems (with single-polarization filtering at the RX)

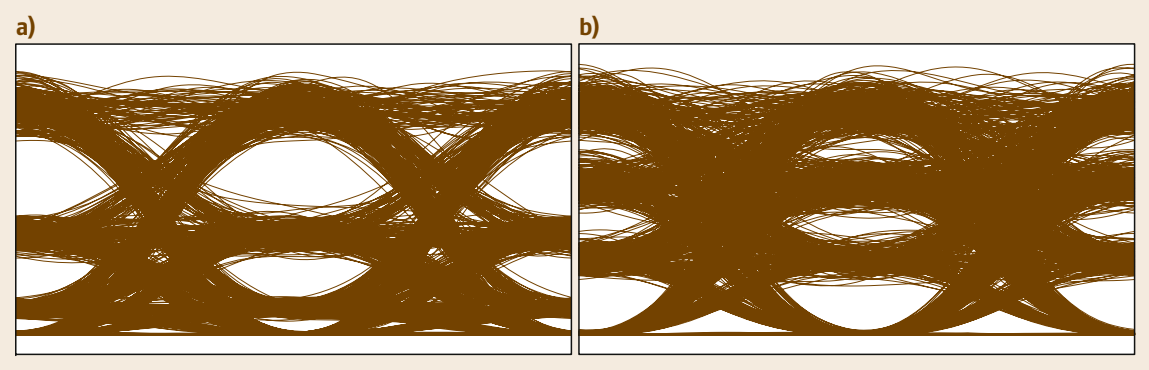

Fig. 4.21a,b Noisy eye diagrams after direct detection of PAM-4 signals with **(a)** quadratic and **(b)** linear level spacing

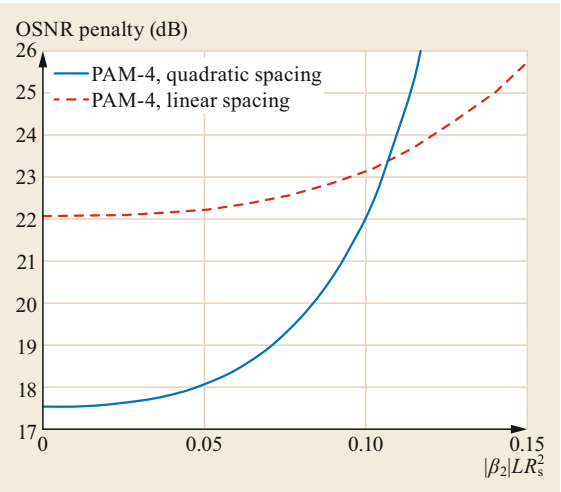

Fig. 4.22 GVD tolerance of PAM-4 in terms of OSNR required to obtain BER $= 10^{-3}$ as a function of the normalized accumulated dispersion

the BER in the optimum matched filter configuration is approximately given by [4.92]

$$\mathrm{BER} \cong \frac{1}{\log_2(M)} \frac{1}{2} \mathrm{erfc}\left(\sqrt{\frac{3\mathrm{OSNR}}{(2M-1)(M-1)}}\right), \tag{4.22}$$

where OSNR is the optical signal-to-noise ratio at the input of the DD receiver, as defined as in (4.15), with $B_\mathrm{N} = R_\mathrm{s}$. Equation (4.22) assumes single polarization filtering at the RX side, i.e., a polarization tracking receiver with a polarization analyzer that blocks the ASE polarized orthogonal to the signal [4.92]. If no polarization filtering is used, the performance is slightly degraded (a fraction of dB of OSNR penalty is typically experienced). Figure 4.20 shows the ideal performance for PAM-2, PAM-4 and PAM-8 constellations, obtained using (4.22). Note that these results hold only at the zero dispersion point. If there is substantial residual dispersion, then a more equidistant level spacing is required. In general, best performance is obtained if the level spacing is optimized. Figure 4.21 shows an example of the back-to-back noisy eye diagrams after the post detection electrical filter with either quadratic or linear level spacing.

Figure 4.22 shows the dispersion tolerance of PAM-4 with either equally spaced or quadratically spaced levels. 5-pole electrical Bessel low-pass filters with 3-dB bandwidth equal to R_s are used both at the TX and at the RX side, and a 2nd-order super-Gaussian passband optical filter with 3-dB bandwidth $2.5R_\mathrm{s}$ is present at the RX input. As expected, while the OSNR sensitivity in back-to-back is significantly better for the quadratic-spacing, the linear-spacing configuration has a higher tolerance to GVD.

4.3 Optical Duobinary with Direct Detection

This section reviews the transmitter and receiver architectures required to generate and detect different types of optical duobinary (ODB) signals. In Sect. 4.3.1, the duobinary modulation concept is introduced. Section 4.3.2 describes the practical implementation of a DB transceiver in an optical system, while Sect. 4.3.3 discusses its back-to-back performance and dispersion tolerance.

4.3.1 Duobinary Line Coding

Figure 4.23 shows the canonical duobinary transmitter structure that can be found in early papers and textbooks [4.9]. It is composed of a precoder, followed by pulse shaping and a duobinary encoder.

The precoder transforms the information bit sequence $a_n \in \{0,1\}$ into a new bit sequence $p_n \in \{0,1\}$ by performing a logical negative exclusive or (XOR) operation between the sequences a_n and p_{n-1}. Then the normalization $b_n = 2p_n - 1$ is applied in order to obtain a bipolar sequence $b_n \in \{-1,+1\}$ [4.17]. Note that the presence of the precoder at the transmitter side allows for easier recovery of the data stream on a bit-by-bit basis and avoids error propagation at the receiver.

The modulated signal after pulse shaping is a standard bipolar ASK signal which can be written as

$$s(t) = \sum_n b_n q_T(t - nT_s)\,, \tag{4.23}$$

where $b_k \in \{-1,+1\}$ are the binary symbols carrying the information, T_s is the symbol time, and $q_T(t)$ is the pulse shape in the time domain. The duobinary coded signal is obtained by adding the data delayed by one symbol period to the present data [4.9, 17], therefore

$$\begin{aligned} s_T(t) &= s(t) + s(t - T_s) \\ &= \sum_n b_n q_T(t - nT_s) + \sum_n b_n q_T(t - nT_s - T_s) \\ &= \sum_n b_n q_{T,DB}(t - nT_s)\,, \end{aligned} \tag{4.24}$$

with $q_{T,DB}(t) = q_T(t) + q_T(t - T_s)$. Note that the signal $s_T(t)$ can be also expressed as

$$s_T(t) = \sum_n 2c_n q_T(t - nT_s)\,, \tag{4.25}$$

with $c_n = b_n + b_{n-1}$. The obtained symbols can thus assume three possible levels ($c_n \in \{-1,0,+1\}$), corresponding to the constellation diagram shown in Fig. 4.24.

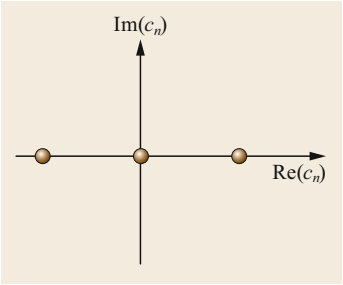

Fig. 4.24 The DB constellation diagram

At the receiver side, the received signal is filtered by a filter with impulse response $h_R(t)$, generating the signal

$$\begin{aligned} s_R(t) &= \sum_n b_n q_{R,DB}(t - nT_s) \\ &= \sum_n 2c_n q_R(t - nT_s)\,, \end{aligned} \tag{4.26}$$

with $q_{R,DB}(t) = q_{T,DB}(t) * h_R(t) = q_R(t) + q_R(t - T_s)$ and $q_R(t) = q(t) * h_R(t)$. The correlated three-level signal is finally demodulated into a binary signal by performing a *modulus* operation which converts -1 and $+1$ to a 1 bit and "0" to a 0 bit. If the precoder shown in Fig. 4.23 is used, $|c_n| = a_n$ and the transmitted sequence is recovered without the need of any further processing. Note that the *modulus* operation is automatically performed by a DD receiver, where the input signal is squared by the photodetector. Figure 4.25 shows an example of the noisy three-level eye diagram before detection and the two-level eye diagram after quadratic detection.

If the pulse $q_R(t)$ satisfies the Nyquist criterion for the absence of ISI, i.e.,

$$q_R(0) \neq 0, q_R(nT_b) = 0, \quad \forall n \neq 0\,,$$

then the duobinary pulse $q_{R,DB}(t)$ has *two* identical nonzero samples T seconds apart [4.9], where

$$\begin{aligned} q_{R,DB}(0) = q_{R,DB}(T_s) \neq 0\,, \\ q_{R,DB}(nT_s) = 0\,, \quad \forall n \neq 0, 1\,. \end{aligned} \tag{4.27}$$

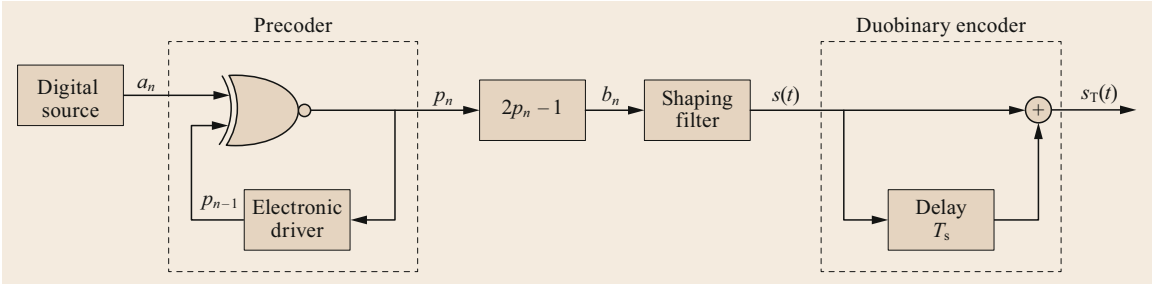

Fig. 4.23 Schematics of a duobinary transmitter

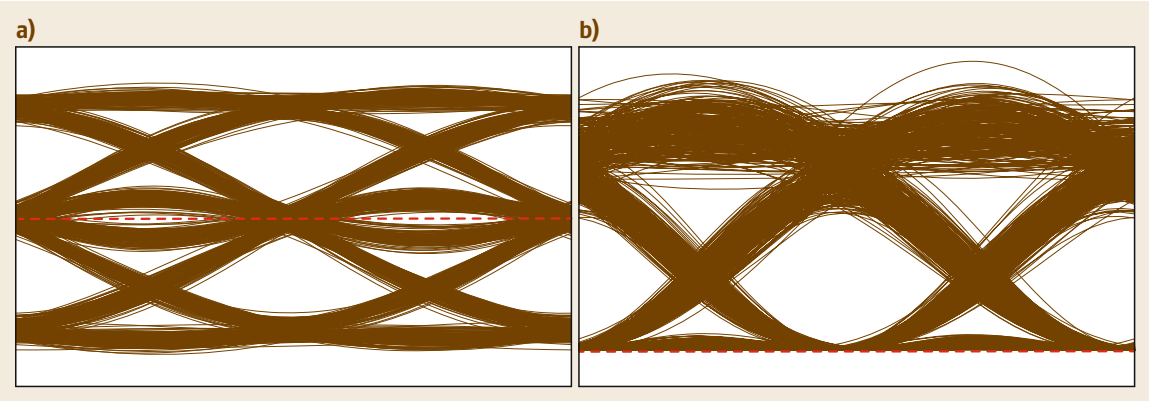

Fig. 4.25a,b The eye diagram of the noisy DB signal before (**a**) and after DD (**b**). The *red dashed lines* indicate the zero power level

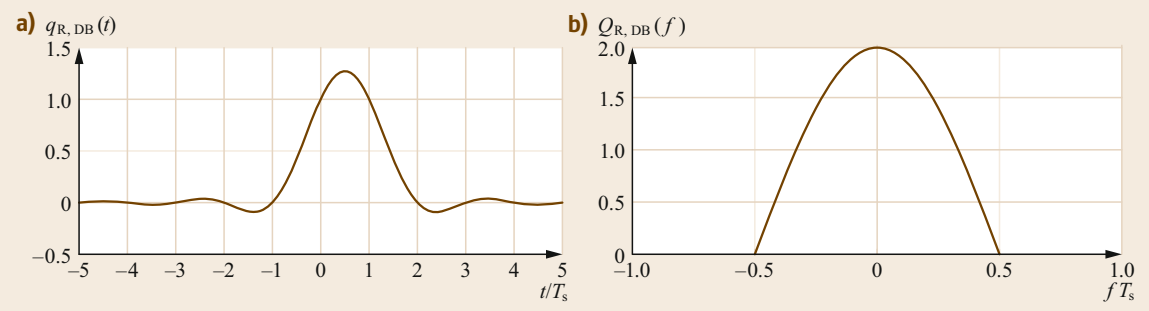

Fig. 4.26 (**a**) The time domain and (**b**) frequency domain characteristics of the minimum bandwidth DB pulse

In practice, DB pulses are defined as pulses that spread over two bit intervals, i.e., pulses that correlate adjacent bits through the introduction of a controlled amount of ISI [4.9].

The DB encoder is equivalent to a filter with transfer function

$$H_{DB}(f) = 1 + e^{-j2\pi f T_s} = 2e^{-j\pi f T_s} \cos(\pi f T_s) \,. \quad (4.28)$$

If an ideal low-pass filter is used for pulse shaping, the minimum bandwidth duobinary signal is obtained [4.9], whose Fourier transform is equal to

$$Q_{R,DB}(f) = \begin{cases} 2e^{-j\pi f T_b} \cos(\pi f T_s) & \text{if } |f| < \frac{1}{2} T_s \\ 0 & \text{if } |f| > \frac{1}{2} T_s \,. \end{cases} \quad (4.29)$$

The time domain and frequency domain characteristics of the minimum bandwidth DB pulse are shown in Fig. 4.26. Note that the spectrum decays to zero smoothly, which means that physically realizable filters can be designed that approximate this spectrum very closely.

In [4.93] a rigorous analysis of the ASE-noise-limited back-to-back sensitivity performance of DB modulation was presented, showing that the quantum limit of DB modulation with DD is 0.91 dB better than that of IMDD (Fig. 4.27). However, as for IMDD, the quantum limit can be reached only using a perfectly matched filter at the receiver (before quadratic detection) [4.94], a condition which is hard to achieve with analog optical filters. In fact, the actual performance of optical systems employing the DB modulation depends on the particular method that is used to perform DB encoding and on the degree of optimization of the system components (for example optical and electrical filters), as shown in the following section.

4.3.2 Optical Duobinary (ODB) Transmitter

The first implementations of optical duobinary (ODB) [4.95] were based on the generation of a three-level electrical signal by tight filtering of a standard electrical binary NRZ signal using a half data-rate raised-cosine filter with roll-off equal to 1. The three-level signal was then applied to a standard MZM to generate a three-level intensity-modulated optical

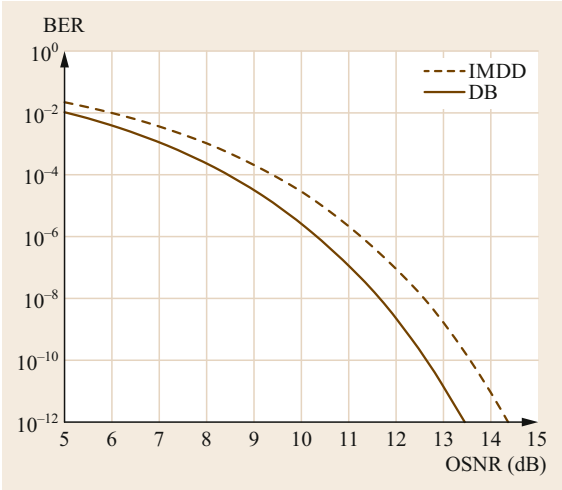

Fig. 4.27 Quantum limit of DB and binary signals with quadratic detection in ASE-noise-limited systems. The quantum limit of binary IMDD is also shown for comparison

signal. A conventional preamplified receiver was used, with an appropriately configured logic circuit to perform a dual threshold detection. The sensitivity penalty of this scheme with respect to binary NRZ was very high (≈ 4 dB at BER $= 10^{-9}$). One of the reasons for this penalty was the use of a pure intensity modulation, allowing transmission and detection of only positive values for the signal levels.

In order to reduce the sensitivity penalty, the use of mixed amplitude and phase modulation was proposed [4.96], which allows the use of a symmetric DB constellation. The transmitter schematic is shown in Fig. 4.28. The ODB signal is obtained by applying a duobinary-encoded three-level electrical signal to a dual-drive MZM driven between its transmission minima (i.e., in a $2V_\pi$ range), as shown in Fig. 4.29. The signal is then decoded using a standard DD receiver. In [4.97] a similar approach was proposed, approximating the delay-and-add operation needed to obtain the DB encoding using a narrow electrical filter. In practice, the effect of this modulation scheme is the generation of an optical signal with two intensity levels (corresponding to the "0" or "1" transmitted bits), but the optical phase of the "1" levels may be equal to either 0 or π, depending on the level ("+1" or "−1") of the three-level driving signal.

These kinds of modulation techniques (based on a binary intensity signal with phase shifts at the higher levels) have subsequently been named phase-shaped binary transmission (PSBT) by *Pennincks* et al. in [4.98], where a similar but simpler approach was proposed, using a conventional low-pass Bessel filter and a single-drive MZM driven between its transmission maxima (Fig. 4.29). The schematic of the PSBT transmitter proposed in [4.21, 98] is shown in Fig. 4.30, where the precoder is followed by a 5-pole Bessel electrical low-pass filter with 3-dB bandwidth $B_{\mathrm{TX,el}} \approx 0.25R_\mathrm{b}$, which is a good approximation of the first arch of an ideal duobinary filter (a cosine-shaped filter). The modulator can be optionally followed by an optical transmitter filter for further pulse shaping [4.23]. Note that Fig. 4.30 shows a transmitter setup with single-ended driver configuration and single ODB filter. In practice, an implementation is sometimes preferred in which both arms of the MZM are driven differentially instead. While such a set-up requires two ODB filters (one for each MZM arm), each driver only needs to drive a swing of V_π instead of $2V_\pi$ which can lead to lower power dissipation and cost.

Figure 4.31 shows an example of the power spectrum of a PSBT signal, compared with a standard

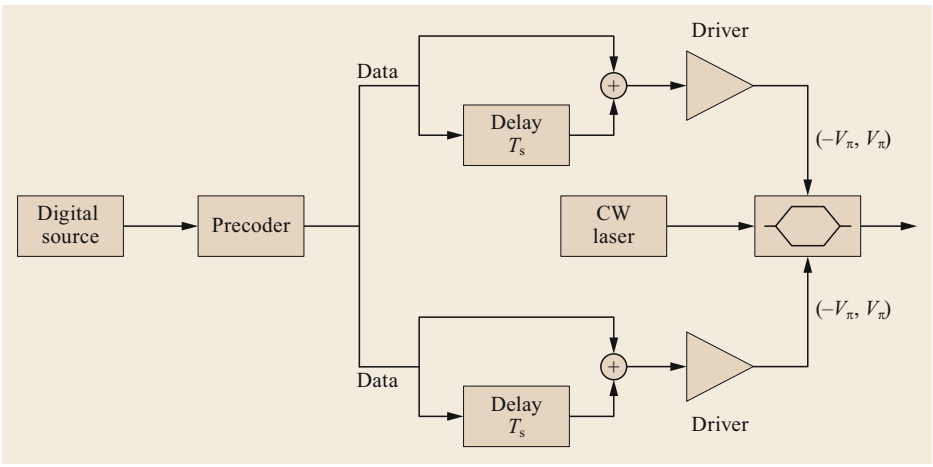

Fig. 4.28 Schematic of the AM/PM ODB transmitter

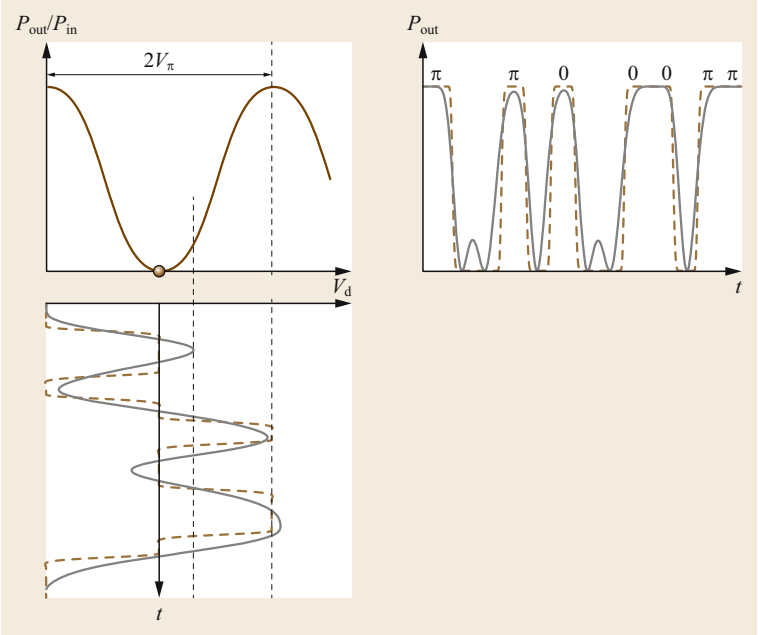

Fig. 4.29 MZM driven by a three-level signal generated as in [4.96] (*dashed lines*) or [4.21] (*solid lines*)

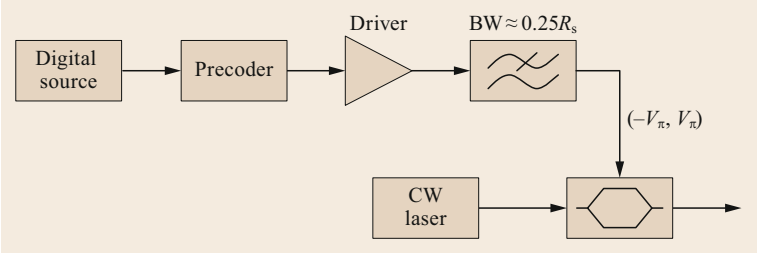

Fig. 4.30 Schematic of the PSBT transmitter

NRZ signal spectrum. Besides its higher resilience to chromatic dispersion [4.18, 19, 98], the narrow optical spectrum of PSBT signals reduces the cross-talk between adjacent channels in ultradense WDM systems [4.17], allowing a higher spectral efficiency than IMDD systems to be achieved.

Among all ODB generation techniques, the PSBT is the one that has become the most popular in optical transmission research because of its simple implementation and good performance. The next subsection is devoted to a performance analysis of ODB transmission implemented through PSBT.

4.3.3 Back-to-Back Performance and Dispersion Tolerance

Several studies have been published on the optimization of electrical and optical filter bandwidths at the transmitter and/or the receiver side [4.22–24, 26, 99], in order to improve the back-to-back performance of PSBT transceivers and approach the theoretical curve shown in Fig. 4.27. All these studies yielded similar results, which are summarized here:

- The optimum electrical filter bandwidth at the transmitter is in the range $0.25-0.35R_s$.
- The use of an optical filter at the transmitter with optimized bandwidth (around $0.75R_s$) can slightly improve the performance.
- The sensitivity can be significantly improved by using a tight optical filter at the receiver (with bandwidth around $0.75R_s$), and the use of the typical bandwidth of MUX/DEMUX in optical systems can significantly degrade the back-to-back performance.
- The optimum electrical bandwidth of the receiver is typically higher than $2R_s$ and the use of the typical bandwidth values around $0.75R_s$ can significantly degrade the performance.

Note, however, that the parameters and results are not all independent. In fact, optical and electrical filter

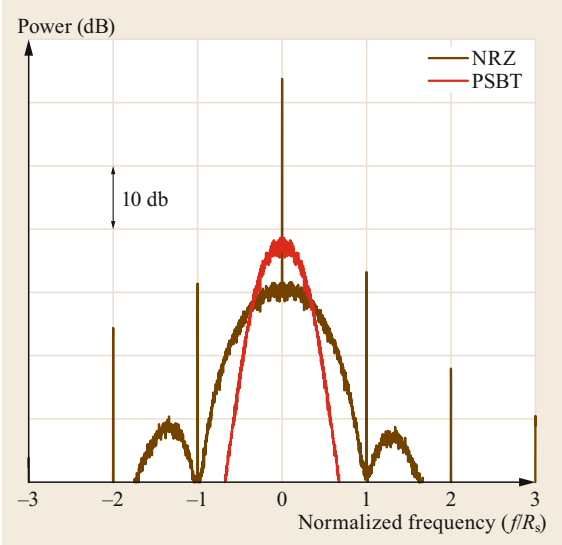

Fig. 4.31 A comparison between the power spectrum of NRZ- and PSBT-modulated signals

bandwidth can be traded-off to some extent. As an example, a narrow optical and wide electrical RX filter can produce similar results to a wider optical filter and a narrower electrical one, as also shown in the following analysis.

Figure 4.32 shows an example of back-to-back performance of PSBT, which compares three different system scenarios at the quantum limit in ASE-noise-limited systems:

- System 1 (an optimized system): 5-pole Bessel electrical low-pass filters with 3-dB bandwidth $0.32R_s$ at the TX and $3.5R_s$ at the RX; second-order super-Gaussian RX optical passband filter with 3-dB bandwidth $0.69R_s$.
- System 2 (a realistic PIN RX, with 7.5-GHz bandwidth at 10 GBd or 30-GHz bandwidth at 40 GBd): 5-pole Bessel electrical low-pass filters with 3-dB bandwidth $0.29R_s$ at the TX and $0.75R_s$ at the RX; second-order super-Gaussian RX optical passband filter with 3-dB bandwidth $0.7R_s$.
- System 3 (standard filter bandwidths at the RX for both electrical and optical filters, for example $B_{RX,el} = 7.5$ GHz and $B_{RX,opt} = 35$ GHz at 10 GBd, with a channel spacing equal to 50 GHz, typical for WDM systems): 5-pole Bessel electrical low-pass filters with 3-dB bandwidth $0.24R_s$ at the TX and $0.75R_s$ at the RX; second-order super-Gaussian RX optical passband filter with 3-dB bandwidth $3.5R_s$.

The optimized PSBT (system 1) has ≈ 0.4 dB penalty with respect to the quantum limit curve both

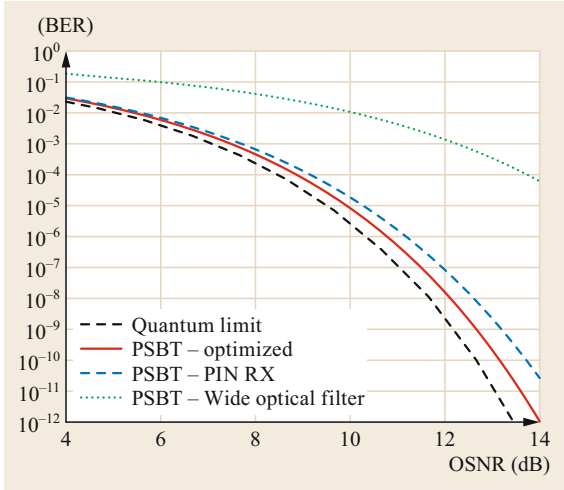

Fig. 4.32 BER versus OSNR characteristics for three configurations of PSBT. The theoretical limit curve is also shown for comparison

at BER $= 10^{-3}$ and BER $= 10^{-9}$. In the more realistic scenario using a standard PIN RX (system 2), the penalty is higher, slightly exceeding 0.6 dB at BER $= 10^{-3}$ and 1 dB at BER $= 10^{-9}$. Note that the use of a wide optical filter at the RX (system 3) yields a much worse performance, i.e., ≈ 5 dB OSNR penalty at a BER of 10^{-3} with respect to the theoretical limit [4.24].

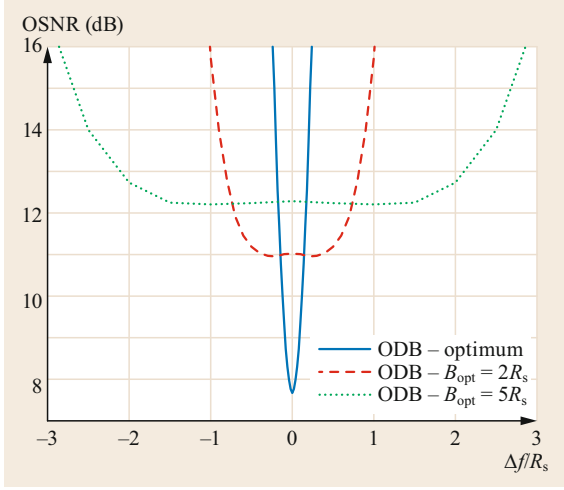

Fig. 4.33 Impact of frequency offset between carrier and optical filter for ODB with optimized RX optical filter bandwidth ($0.69R_s$) and with larger RX filter bandwidths ($2R_s$ and $5R_s$), in terms of required OSNR to obtain a BER equal to 10^{-3}. The electrical filter bandwidths have been optimized in each case

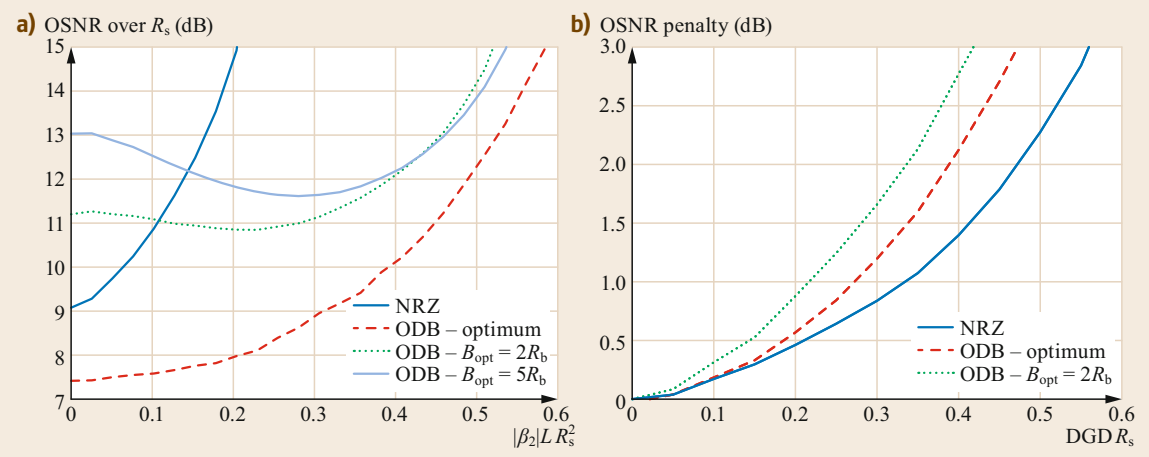

Fig. 4.34 **(a)** GVD tolerance of NRZ and three configurations of ODB in terms of required OSNR (over a bandwidth equal to R_s) to obtain BER $= 10^{-3}$ as a function of the normalized accumulated dispersion. **(b)** First-order PMD tolerance of NRZ and three configurations of ODB in terms of OSNR penalty as a function of the normalized DGD in the worst-case power-splitting ratio between the two PSPs

Impact of RX Optical Filter Detuning

One possible drawback of using narrow-bandwidth optical filtering to tailor the optimum DB pulse shape is the penalty that may be incurred when the carrier frequency drifts away from the filter center frequency [4.23]. Figure 4.33 shows the impact of a frequency detuning Δf between the center frequency of the optical RX filter and the TX laser, in terms of OSNR required to achieve a BER $= 10^{-3}$ as a function of the normalized detuning $\Delta f / R_s$. Because of the narrow bandwidth of the optical filter, the performance of the optimized ODB system is extremely sensitive to the frequency offset. The results shown in Fig. 4.33 demonstrate that the center of the optical filter should be aligned to the carrier frequency within $\pm 0.15 R_s$ in order to maintain the sensitivity advantage over the wide-filter ODB.

Dispersion Tolerance

Because of its narrower spectral width, ODB modulation has a significantly higher tolerance to GVD than binary IMDD. The behavior of ODB in the presence of GVD, though, is strongly dependent on the optical filter bandwidth, as shown in Fig. 4.34a, where the performance of the IMDD-NRZ format is also shown for comparison. The tolerance to PMD is however in general lower for ODB formats [4.35], as shown in Fig. 4.34b. In all cases, the TX and RX electrical filter bandwidths have been optimized in the back-to-back configuration.

4.4 Differential Phase Modulation with Interferometric Detection

This section reviews the transmitter and receiver architectures required to generate and detect different types of optical signals based on differential phase modulation. In Sect. 4.4.1, the concept of differential phase modulation is introduced. Section 4.4.2 describes the optical transmitter structure for the generation of binary and quaternary formats with differential phase modulation, named differential phase-shift keying (DPSK) and differential quadrature phase-shift keying (DQPSK), respectively. Note that DPSK is also referred to as DBPSK in the literature. In Sect. 4.4.3, the interferometric receivers used to extract the phase difference between DPSK and DQPSK symbols are described, while Sect. 4.4.4 shows the back-to-back performance of DPSK/DQPSK systems, focusing on the impact of realistic implementation penalties at the transmitter and receiver sides.

4.4.1 Differential Phase-Shift Keying

Phase-shift keying (PSK) is a modulation technique that encodes the information in the phase of the constellation symbols, keeping the amplitude constant. For instance, in the binary version of PSK (known as BPSK or 2PSK), a "1" may correspond to the phase value 0 and a "0" to the phase value π. In general, for an

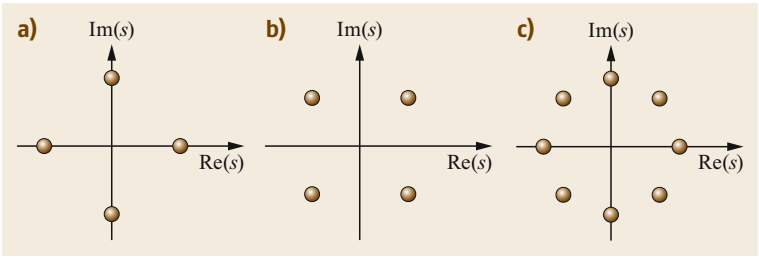

Fig. 4.35a–c Examples of **(a)** 2PSK, **(b)** 4PSK, and **(c)** 8PSK constellations

Table 4.2 The logical operations of the differential precoder for DPSK

Input bit a_k	Phase difference	Output bit p_k
0	π	$\overline{p_{k-1}}$
1	0	p_{k-1}

Table 4.3 The logical operations of the differential precoder for DQPSK [4.101]

Input bits		Phase difference	Output bits	
a_k	b_k		p_k	q_k
0	0	π	$\overline{p_{k-1}}$	$\overline{q_{k-1}}$
0	1	π/2	q_{k-1}	$\overline{p_{k-1}}$
1	0	3π/2	$\overline{q_{k-1}}$	p_{k-1}
1	1	0	p_{k-1}	q_{k-1}

M-level PSK constellation (MPSK), the M information symbols are encoded into M phase values, i.e., $\varphi_n = 2n\pi/M$ with $n = 0, 1, \ldots, M-1$. The complex envelope of PSK-modulated signals can be written as (4.1), with $a_k = e^{j\varphi_k}$ and $\varphi_k \in \{\varphi | \varphi = (2\pi n)/M$, with $n = 0, 1, \ldots, M-1\}$. Figure 4.35 shows examples of PSK constellations with $M = 2$, 4, and 8.

In order to decode a phase-modulated signal, the estimate of the absolute carrier phase is required [4.9]. In practice, however, the carrier phase is extracted from the received signal by performing some nonlinear operation that introduces a phase ambiguity. For instance, the widely used Viterbi&Viterbi phase estimation algorithm [4.100], which raises the signal to the power of M in order to remove the modulation, generates a phase ambiguity equal to $2\pi/M$. Consequently, an absolute estimate of the carrier phase is typically not available for demodulation.

A possible solution to this problem consists in encoding the information in the phase difference between two consecutive symbols. For example, in binary PSK an information bit "1" is transmitted by shifting the phase of the carrier by π with respect to the previous signaling interval, while an information bit "0" is transmitted by applying a zero phase shift relative to the previous signaling interval. In 4PSK the relative phase shifts between successive intervals are 0, π/2, π, and 3π/2, corresponding to the four possible transmitted bit pairs (00, 01, 11, and 10, respectively). Differentially encoded binary ($M = 2$) and quaternary ($M = 4$) modulation formats are often referred to as differential PSK (DPSK) and differential quadrature phase-shift keying (DQPSK).

Tables 4.2 and 4.3 show the logical operations of the differential precoder that is used to encode the information bits on the phase difference of the carrier between two consecutive signal intervals for DPSK and DQPSK, respectively [4.101]. For DPSK, the input bit sequence a_k is encoded onto the output sequence p_k that is used to generate the DSPK waveforms transmitted over the channel. For DQPSK, pairs of input bits (a_k and b_k) are encoded onto two output bit sequences p_k and q_k, corresponding to the in-phase and quadrature components of the DQPSK symbols to be transmitted over the channel.

The optimum detector for PSK signals is based on coherent detection, i.e., the received signal is multiplied by a carrier with the same frequency and phase of the transmitted signal and then goes through a low-pass matched filter [4.9]. Using the optimum demodulator, the bit error probability of both BPSK and QPSK modulations is given by

$$\mathrm{BER} = \frac{1}{2}\mathrm{erfc}\left(\frac{E_\mathrm{b}}{N_0}\right). \tag{4.30}$$

If differential encoding is applied at the transmitter, the same coherent demodulator can be used, followed by a phase comparator that compares the phases of the demodulated signal over two consecutive intervals in order to extract the information. Coherent demodulation of differentially encoded PSK results in a higher BER than standard PSK modulations. In particular, with differentially encoded PSK an error in the demodulated phase of the signal in any given interval will usually result in decoding errors over two consecutive symbols. Consequently, the symbol error rate (SER) of differentially encoded MPSK is approximately twice the SER of MPSK with absolute phase encoding.

As will be shown in Sect. 4.4.3, differentially encoded PSK signals can also be demodulated by a direct-detection optical receiver, composed of a pair of conventional photodetectors, through the use of an

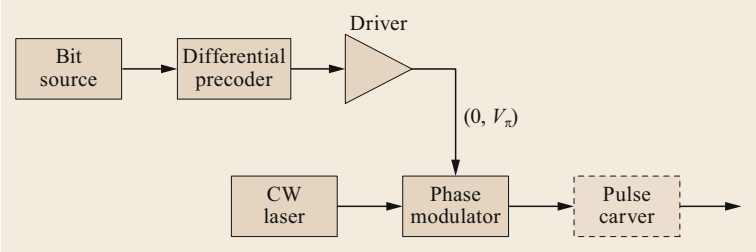

Fig. 4.36 A schematic of a DPSK transmitter using a phase modulator

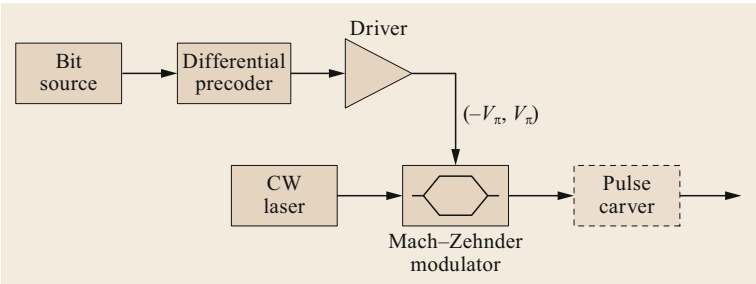

Fig. 4.37 A schematic of a DPSK TX using an MZ amplitude modulator

optical device called the asymmetric MZ interferometer (AMZI) which is able to convert the phase-coded signal into an intensity-coded signal before quadratic detection. The price to pay to avoid the use of standard coherent detection is a performance penalty with respect to the theoretical results determined by (4.30).

4.4.2 DPSK and DQPSK Optical Transmitter

Two possible structures of the DPSK optical transmitter are shown in Figs. 4.36 and 4.37. The first one is based on the use of a phase modulator, driven in the $[0,V_\pi]$ range. The second and most common one employs an MZM, biased at zero power transmission and driven between its transmission maxima. A pulse carver such as the one shown in Fig. 4.11 can be added to generate RZ pulses.

Figure 4.38 shows the schematic of a DQPSK transmitter, which employs an IQ transmitter composed of two MZMs, one for each quadrature of the QPSK modulation. Each MZM is biased at zero power transmission and driven between its transmission maxima. A phase shift of $\pi/2$ is introduced between the two arms before recombining the signals. A pulse carver such as the one shown in Fig. 4.11 can be added to generate RZ pulses.

4.4.3 Interferometric Receiver

The DPSK RX structure is shown in Fig. 4.39. The optical preamplifier is followed by an optical filter and an AMZI with differential delay $T_d = 1/R_s$, where R_s is the symbol rate. Within the AMZI, the input signal is split onto two paths and combined after a path differ-

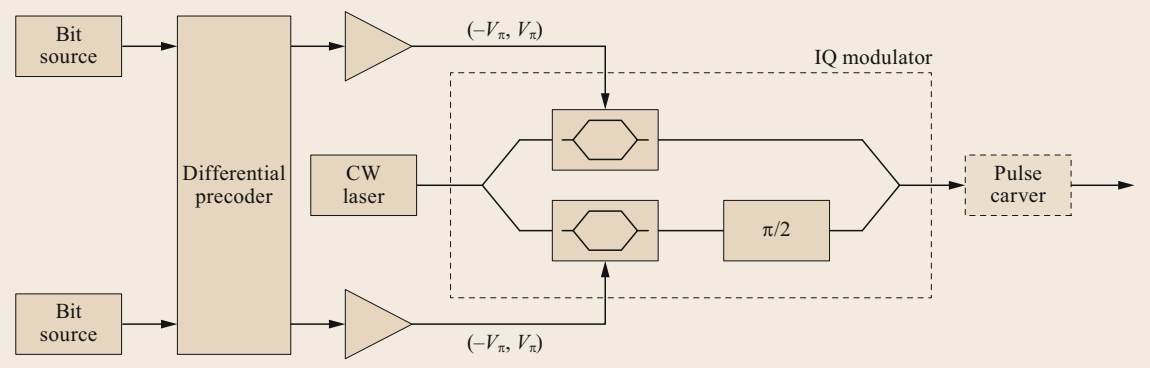

Fig. 4.38 A schematic of a DQPSK TX

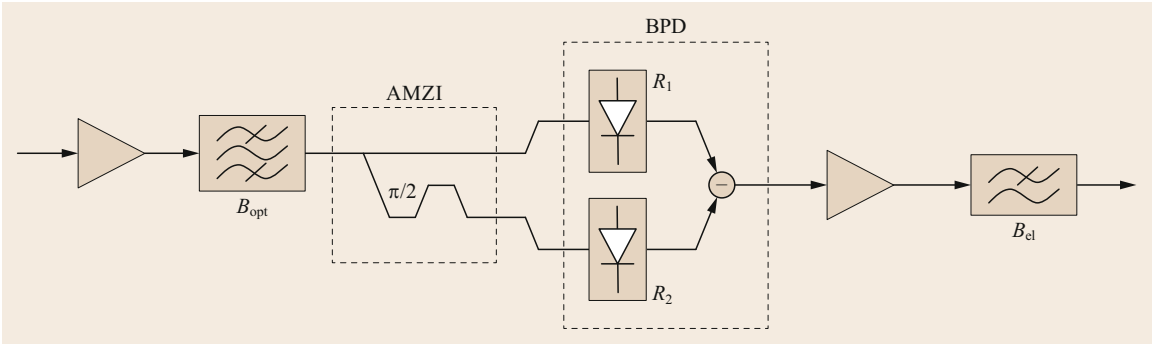

Fig. 4.39 A schematic of a DPSK RX

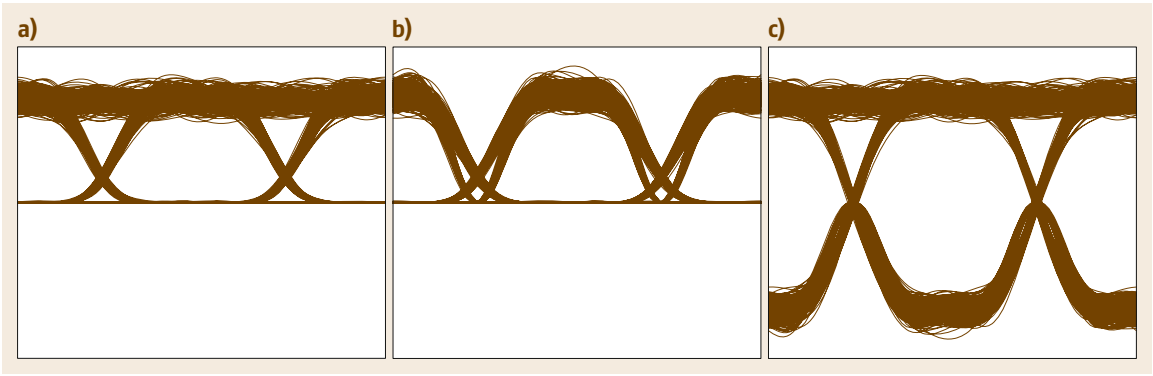

Fig. 4.40a–c Electrical eye diagrams generated at the output of the upper **(a)** and lower arms of the AMZI **(b)** and at the output of the balanced photodetector **(c)**

ence corresponding to one bit delay. If $E(t)$ is the optical field at the input of the AMZI, then the signals at the output of the two arms can be written as

$$E_1(t) = \frac{1}{2}[E(t) + E(t-T_d)e^{j\delta\varphi}], \quad (4.31a)$$

$$E_2(t) = \frac{1}{2}[E(t) - E(t-T_d)e^{j\delta\varphi}], \quad (4.31b)$$

where $\delta\varphi$ is a quantity that should ideally be equal to 0 and that can be controlled, typically by thermal adjustments. A balanced photodetector (BPD) follows, which consists of two photodetectors (one for each output branch of the AMZI), with responsivities R_1 and R_2, connected so as to subtract their currents from each other, and a postdetection electric filter. Ideally, for optimal reception, it should be the case that $R_1 = R_2$ and $\delta\varphi = 0$.

In practice, the AMZI can be viewed as a filter that converts phase modulation into amplitude modulation. The amplitude modulation is then detected by the photodiodes. When two subsequent bits have the same phase then $E_1(t) = E(t)$, $E_2(t) = 0$, while, if they have opposite phase then $E_1(t) = 0$, $E_2(t) = E(t)$. In practice, the AMZI performs a *differential demodulation* of the received signal.

The two ports form slightly different IM signals, which give rise to different *eyes*, as shown in Fig. 4.40, because of the different transfer functions of the two arms of the AMZI (in the absence of phase modulation, the upper and lower branches experience a constructive or destructive interference, respectively). The BPD sums the eyes reinforcing each other. In principle, DPSK can be detected using only one photodiode, on either Out1 or Out2. However, using detection on only one port, the 2.7-dB sensitivity advantage over IMDD is lost [4.102].

The AMZI can also be viewed as a 3-dB splitter followed by a pair of filters whose transfer functions are given by

$$|H_p(f)|^2 = \cos^2\left[\pi(f-f_0)T_d + \frac{\delta\varphi}{2}\right], \quad (4.32a)$$

$$|H_m(f)|^2 = \sin^2\left[\pi(f-f_0)T_d + \frac{\delta\varphi}{2}\right]. \quad (4.32b)$$

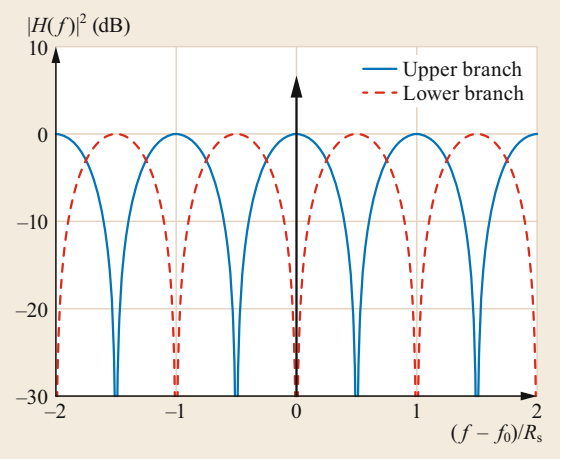

Fig. 4.41 Ideal AMZI transfer functions (given by (4.32), with $\delta\varphi = 0$). The *thick black line* corresponds to the center frequency of the signal at the input of the AMZI

Assuming that DPSK is transmitted at an optical frequency f_0, the optimum demodulation requires that $|H_p(f_0)| = 1$ and $|H_m(f_0)| = 0$. The phase error $\delta\varphi$ can thus be seen as an incorrect tuning of the AMZ filter, by a quantity $\Delta f = R_s\delta\varphi/(2\pi)$. This corresponds to a shift by Δf of the optical frequency of the AMZ filter transfer function. Figure 4.41 shows the AMZI transfer functions of (4.32) when $\delta\varphi = 0$.

DQPSK Receiver

The DQPSK RX structure is shown in Fig. 4.42. It consists of an optical filter, a pair of AMZIs with a differential delay ideally equal to the time duration of a transmitted symbol, each followed by a BPD consisting of two photodetectors (one for each output branch of the AMZIs), connected so as to subtract their currents from each other, and then followed by a postdetection electric filter. The differential optical phase between the interferometer arms should be set to $\pi/4$ and $-\pi/4$ for the upper and lower branches, respectively.

If $E(t)$ is the optical field at the output of the RX optical filter, the signals at the output of the upper AMZI can be written as

$$E_1(t) = \frac{1}{2}[E(t) + E(t - T_d)e^{j\frac{\pi}{4}}e^{j\delta\varphi}], \tag{4.33a}$$

$$E_2(t) = \frac{1}{2}[E(t) - E(t - T_d)e^{j\frac{\pi}{4}}e^{j\delta\varphi}], \tag{4.33b}$$

where $\delta\varphi$ is a quantity that can be controlled, typically by thermal adjustments of the AMZ; $\delta\varphi$ can be transformed into a frequency-detuning parameter Δf of the AMZI transfer function through the relation $\Delta f = R_s\delta\varphi/(2\pi)$. The value $\Delta f = 0$ corresponds to perfect tuning of the AMZI.

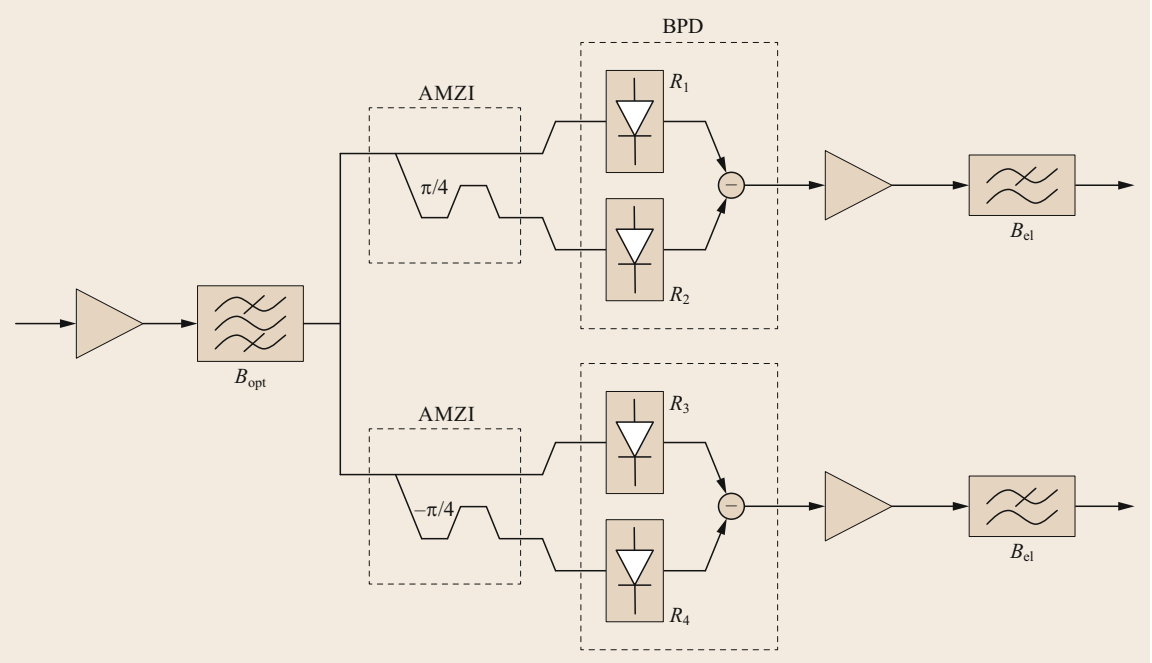

Fig. 4.42 A schematic of a DQPSK RX

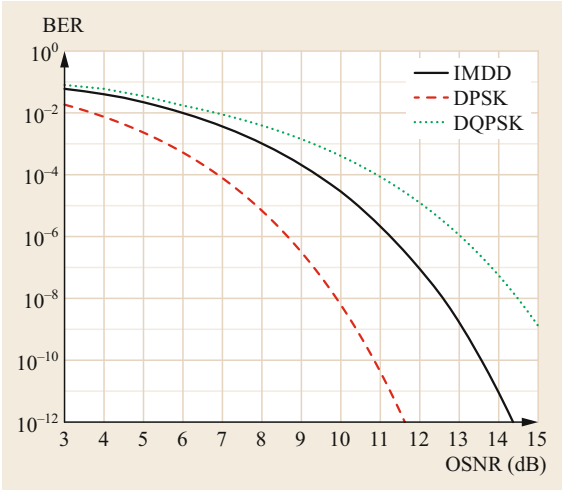

Fig. 4.43 Ideal performance of DPSK and DQPSK systems with interferometric detection. The performance of IMDD is also shown for comparison

4.4.4 Back-to-Back Performance and Dispersion Tolerance

The best performance is achieved when the receiver contains an optical filter matched to the received optical signal, ideal photodetectors, and no postdetection electrical filters. In this ideal case, and in the absence of any TX or RX impairment, the BER achievable with the DPSK modulation is equal to [4.29, 103]

$$\mathrm{BER} = \frac{1}{2}\mathrm{e}^{-2\mathrm{OSNR}}\left(1+\frac{1}{2}\mathrm{OSNR}\right), \qquad (4.34)$$

where OSNR is defined by (4.15) over a bandwidth equal to the symbol-rate R_s. The BER versus OSNR curve for DPSK is shown in Fig. 4.43 as a dashed red line. Comparing it to the optimum matched filter performance of OOK-IMDD (solid black line), an OSNR gain of approximately 3 dB is achieved by DPSK. The performance curve of DQPSK is shown in Fig. 4.43 as a dotted green line. It has been estimated using the semianalytical technique described in [4.104], since a closed-form formula for performance evaluation is not available for DQPSK. The reference bandwidth for the OSNR is equal to R_s, thus the reported curves give a direct comparison of systems operating at the same symbol rate. DQPSK allows transmitting information at a double rate with respect to the binary formats, at the expense of an OSNR penalty of ≈ 1 dB with respect to IMDD and ≈ 3.5 dB with respect to DPSK, at a reference BER of 10^{-3}.

The sensitivity gain of DPSK and DQPSK with respect to IMDD depends on the practical implementation of the transceiver (for example on the electrical and optical filter bandwidths). In [4.34, 102, 104] it was shown that, like for OOK formats, a careful optimization of the filter bandwidths can yield a performance very close to the theoretical matched filter limits, provided that a narrowband optical filter is available at the receiver. If the optical filter bandwidth is wide, the performance penalty with respect to the ideal performance can be kept below 1 dB by optimizing the TX and RX electrical bandwidths [4.104].

Table 4.4 shows an example of optimized 3-dB filter bandwidths when a second-order super-Gaussian optical passband filter and a 5-pole Bessel electrical low-pass filter are used at the RX. Six different cases have been considered, i.e., IMDD, DPSK, and DQPSK all with either NRZ or RZ modulation. In the case of NRZ modulations, the transmitted pulses are shaped by a 5-pole Bessel low-pass filter with 3-dB bandwidths equal to $0.75R_s$ for IMDD, $0.9R_s$ for DPSK, and $0.45R_s$ for DQPSK. The OSNR (over a bandwidth equal to R_s) required to achieve BER $= 10^{-3}$ is also shown, together with the penalty with respect to the matched filter case.

Interferometric Receiver Implementation Impairments

The receiver architecture used for both DPSK and DQPSK is more complex than a standard DD receiver, requiring the additional use of an AMZI and a pair of BPDs for each quadrature. The performance of the system can thus be affected by imperfections in the AMZI or in the BPD:

Table 4.4 Optimized RX filter bandwidths in different configurations and corresponding system performance and OSNR penalty with respect to the ideal matched filter receiver

Case	B_{opt}/R_s	$B_{el,RX}/R_s$	OSNR@BER $= 10^{-3}$ (dB)	OSNR penalty (dB)
IMDD-NRZ	1.2	0.8	9.0	1.0
IMDD-RZ	2.0	1.0	8.5	0.5
DPSK-NRZ	1.2	1.6	5.9	0.3
DPSK-RZ	2.0	1.2	5.7	0.1
DQPSK-NRZ	1.2	1.6	9.7	0.4
DQPSK-RZ	2.0	1.2	9.5	0.2

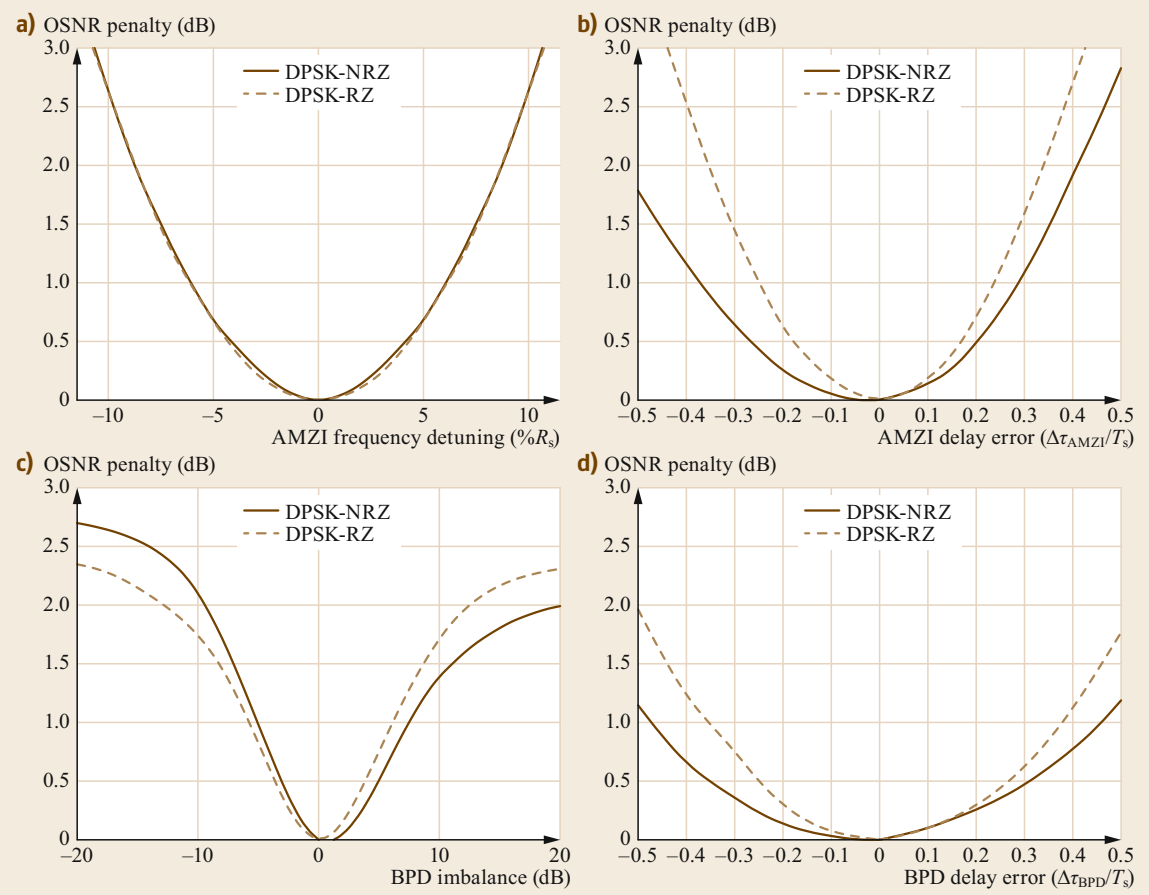

Fig. 4.44a–d Impact of interferometric RX implementation impairments on DPSK-NRZ and DPSK-RZ in terms of OSNR penalty. The target BER is 10^{-3}, and the values of reference OSNR (over a bandwidth equal to R_s) in the absence of impairments are shown in Table 4.4

- AMZI frequency-detuning Δf with respect to the transmit laser, due to a nonzero phase mismatch $\delta\varphi$ between the two branches of the AMZI ((4.32) and (4.33)): $\Delta f/R_s = \delta\varphi/(2\pi)$.
- AMZI delay error $\Delta\tau_{AMZI}$, due to a mismatch between the delay T_d between the two arms of the AMZI and the symbol time T_s: $\Delta\tau_{AMZI} = T_d - T_s$.
- BPD delay imbalance $\Delta\tau_{BPD}$, due to a time mismatch in the propagation paths in the two arms of the BPD.
- BPD gain imbalance K, due to a mismatch between the responsivities R_1 and R_2 of the photodiodes in the two arms of the BPD defined as $K = R_1/R_2$.

In the following, the impact of such impairments on the performance is estimated for both DPSK and DQPSK, in terms of OSNR penalty with respect to the ideal case with no imperfections at a reference BER equal to 10^{-3} (which assumes the use of a hard-decision FEC scheme). The filter parameters used in simulations are those shown in Table 4.4. The results, shown in Fig. 4.44 for DPSK and Fig. 4.45 for DQPSK, indicate that the tolerance to AMZI and BPD imperfections is in general higher for DPSK than for DQPSK, when operating at the same symbol rate (note that all time and frequency errors in the x-axes of Figs. 4.44 and 4.45 are normalized with respect to symbol time/symbol rate). RZ-DPSK is less tolerant that NRZ-DPSK to delay errors (both in the AMZI and in the BPD), whilst the impact is almost the same for RZ-DQPSK and NRZ-DQPSK. The most critical parameter is the frequency detuning between the AMZI and the transmit laser: an offset of only 6% of the symbol rate induces a 1-dB penalty on DPSK and more than 3-dB penalty on DQPSK. Note that this frequency offset could fully be compensated for by proper tuning of the path length difference within the AMZI on an optical wavelength scale, by inserting a phase shifter in

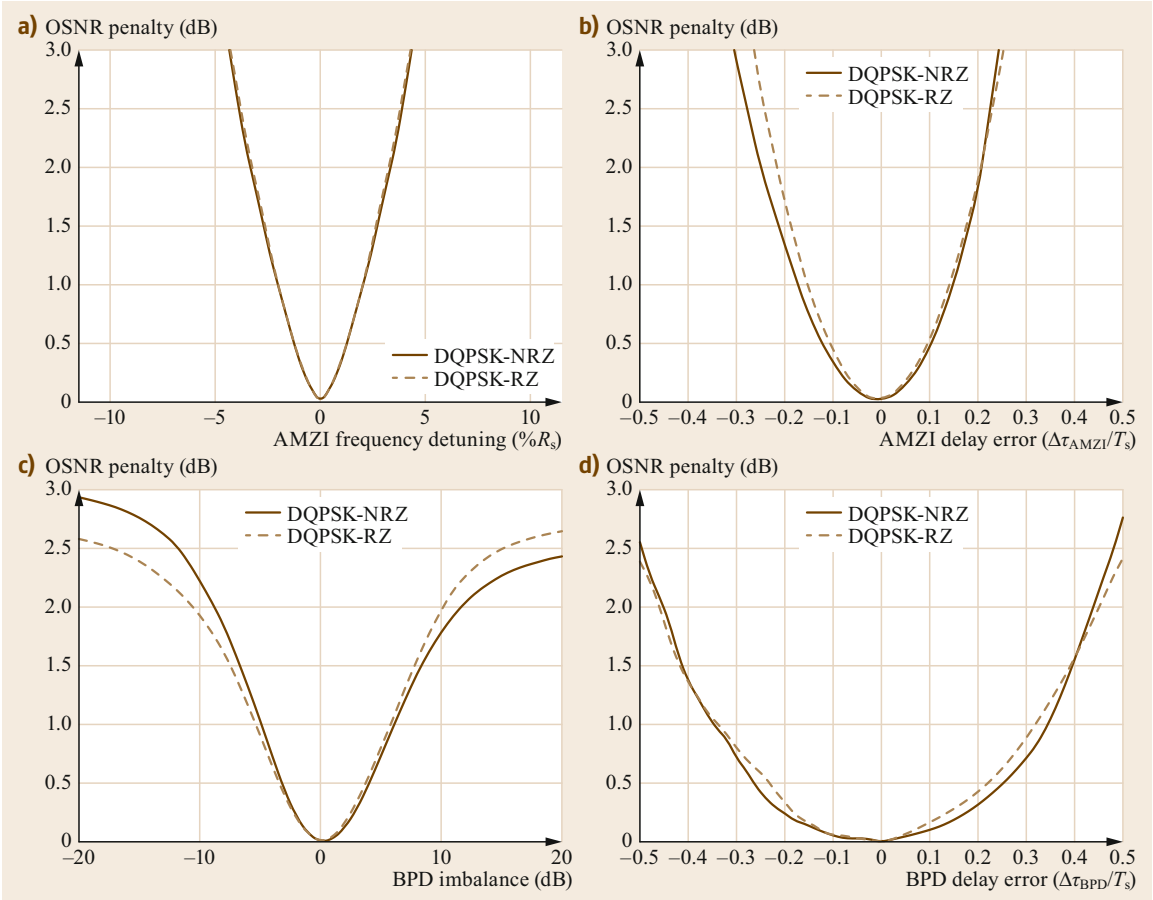

Fig. 4.45a–d Impact of interferometric RX implementation impairments on DQPSK-NRZ and DQPSK-RZ in terms of OSNR penalty. The target BER is 10^{-3}, and the values of reference OSNR (over a bandwidth equal to R_s) in the absence of impairments are shown in Table 4.4

one of the AMZI paths [4.105]. However, the results shown in Figs. 4.44a and 4.45a may set stringent requirements to the wavelength stability of the transmit laser. Similar analyses can be found in [4.104–108], where much lower values of reference BER (10^{-9} or 10^{-10}) were used, which imply a slightly lower tolerance to the imperfections than the one observed at BER $= 10^{-3}$.

Dispersion Tolerance

Figure 4.46 shows the performance of DPSK and DQPSK modulation formats (with either RZ or NRZ line coding) in the presence of either GVD or a first-order PMD. The simulation setup is the same as described in Sect. 4.2.4, with optimized RX filter bandwidth (as shown in Table 4.4). Linear fiber propagation was assumed, while first-order PMD was emulated by inserting a deterministic DGD value $\Delta\tau_{DGD}$ between the two principal states of polarization. The worst-case of equal power-splitting ratio between the two PSPs was considered. The curve for IMDD-NRZ is also shown for comparison.

For the system configurations considered in Fig. 4.46, the highest GVD tolerance is achieved by DPSK-NRZ, while the other formats have a much lower GVD tolerance. However, it must be noted that the comparison is performed at the same symbol rate, i.e., DQPSK has double bit rate with respect to DPSK and IMDD. The tolerance to GVD for DQPSK operating at the same bit rate would thus be increased by a factor of 4, achieving a higher tolerance than the binary formats, thanks to its narrower spectral width. The DGD tolerance is instead similar for all formats (at the same symbol rate).

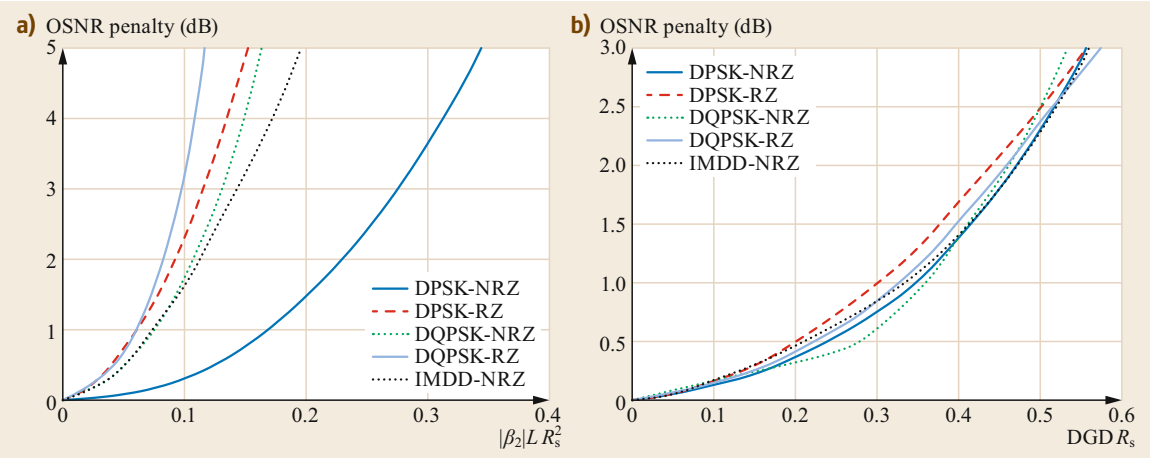

Fig. 4.46a,b GVD and first-order PMD tolerance of DPSK and DQPSK in terms of OSNR penalty with respect to back-to-back performance as a function of either **(a)** the normalized accumulated dispersion or **(b)** the normalized DGD in the worst-case power-splitting ratio between the two PSPs. The performance of IMDD-NRZ is also shown for comparison. The target BER is 10^{-3} and the values of reference back-to-back OSNR (over a bandwidth equal to R_s) are shown in Table 4.4

4.5 IQ Modulation with Coherent Detection

This section reviews the transmitter and receiver architectures required to generate and detect different types of high-order modulation formats employing coherent detection. Section 4.5.1 reviews the architecture of an IQ transmitter, which can be used to generate arbitrary two-dimensional (2D) constellations or four-dimensional (4D) constellations if polarization multiplexing is employed. The architecture of a coherent-detection optical receiver is described in Sect. 4.5.2, while Sect. 4.5.3 introduces the Nyquist-WDM multiplexing technique, highlighting the compromise between spectral efficiency and performance. Finally, Sect. 4.5.4 focuses on flexible transponders, designed to dynamically adapt the transmission speed and modulation format to the channel conditions.

4.5.1 IQ Transmitter

Combining amplitude modulation and phase modulation, the class of modulation formats known as QAM (quadrature amplitude modulation) is obtained. The complex envelope of QAM modulated signals can be written as [4.9]

$$s_T(t) = \sum_k (p_k + \mathrm{j}q_k) g_T(t - kT_s)\,, \qquad (4.35)$$

where p_k and q_k are the coordinates of the constellation points on the in-phase and quadrature axes, respectively, T_s is the symbol time, and $g_T(t)$ is the optical pulse shape in the time domain. For each symbol slot, M alternative waveforms can be transmitted, depending on the value of the information bits; M is called the cardinality of the constellation. The maximum number of bits n_b that can be carried by each constellation symbol is equal to $\log_2(M)$. The transmission speed, i.e., the bit rate, is given by $R_b = n_b/T_s$. Figure 4.47 shows a few examples of QAM constellations (for $M = 4, 16, 32, 64$).

Any optical QAM signal could be in principle generated by using a single dual-drive MZM [4.109]. However, the required number of levels of the electrical driving signals would be quite high (for example for a 16-ary driving signals are needed for 16QAM), trading the simplicity of the optical part for a big electrical effort. Another method to generate arbitrary QAM constellations is based on the use of two consecutive optical modulators: an MZM for amplitude modulation and a phase modulator to set the phase. Also in this case, the simplicity of the optical TX part implies the use of a complex electrical level generator which cannot be easily implemented for high data rates [4.110].

The most commonly used TX configuration to generate QAM signals is based on an IQ modulator, like the one used in the generation of DQPSK signals (Fig. 4.38). This configuration exploits the fact that each constellation point can be projected on the in-phase and

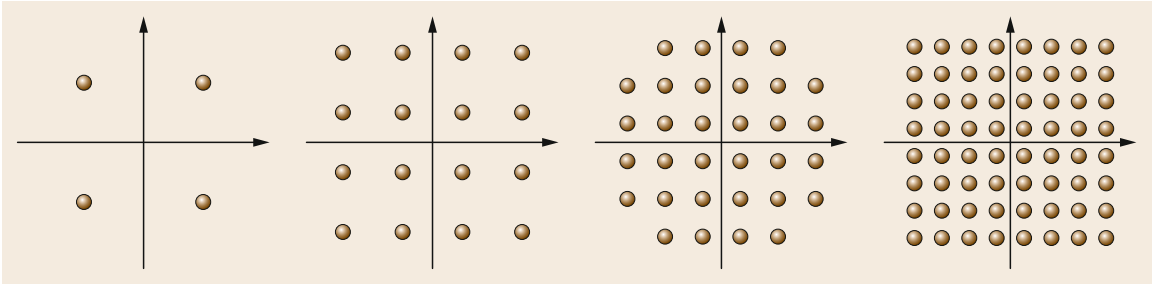

Fig. 4.47 High-order square QAM modulation format constellations (for $M = 4, 16, 32, 64$)

quadrature axes, in order to reduce the number of required levels for the driving signal (which is equal to $\log_2(M)$ for M-QAM). The scheme of the conventional IQ transmitter is shown in Fig. 4.48. Two multilevel electrical driving signals are generated (one for the in-phase and the other for the quadrature component of the QAM signal), each of them driving one of the two MZMs in the IQ modulator. In general, an adaptive and precise bias control algorithm for the IQ modulator is essential to minimize transmitter impairments and to maintain long-term stable operation [4.111–115].

Combining two IQ transmitters using a polarization beam splitter/combiner, polarization-multiplexed QAM (PM-QAM) signals can be generated, as shown in Fig. 4.49. The light from a single laser signal is split and sent into four separate Mach–Zehnder modulators. The upper and lower portions of this super-MZM structure each generate an M-QAM signal. The signals are then sent into a polarization beam combiner (PBC), after applying a polarization rotation to the lower branch, so that the signal from the upper half of the circuit becomes X-polarized, while the signal from the lower half of the circuit becomes Y-polarized.

Generation of the Multilevel Driving Signals

Multilevel driving signals with a desired pulse shape can be efficiently generated using a digital signal processing (DSP) block, followed by a digital-to-analog converter (DAC) which generates the driving electrical signal. Any DAC device is characterized by two main parameters, which set a limit to its performance. These are:

- The sampling speed f_{DAC}, which limits the achievable symbol rate $R_{\mathrm{s}} = f_{\mathrm{DAC}}/N_{\mathrm{SpS}}$, where N_{SpS} is the number of samples per symbol (SpS), also indicated as the *oversampling factor*.
- The number of resolution bits N_{DAC}, which limits the cardinality of the modulation format. In fact, the higher the order of the modulation format, the higher is the required value of N_{DAC}.

Typically, if f_{DAC} increases, N_{DAC} decreases. The achievable symbol rate can clearly be increased by decreasing the oversampling factor. In doing so, penalties could be incurred due to interference produced by spectral replica of the useful spectrum in the DAC process. In [4.116], a 1.5 SpS DAC-supported Nyquist-WDM PM-16QAM experiment was reported, using a DAC with $f_{\mathrm{DAC}} = 23.4$ GHz and thus achieving a symbol rate $R_{\mathrm{s}} = 15.6$ GBd. In [4.117], 1.33 SpS were employed in a 100-km PM-64QAM single-channel transmission at 252 Gb/s. In [4.118], an oversampling factor as low as 1.15 was used, limiting the penalty due to spectrum replica thanks to the use of antialiasing electrical

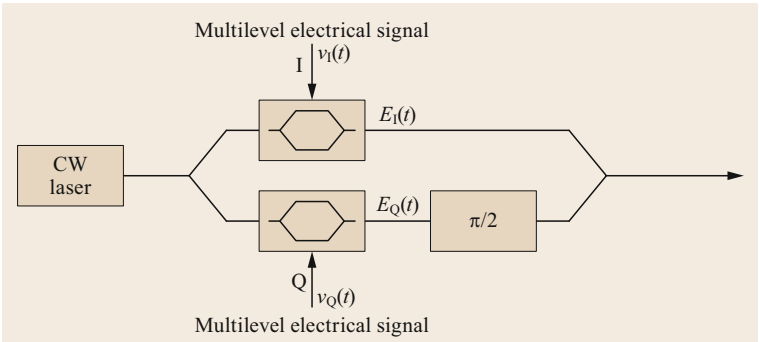

Fig. 4.48 A single polarization IQ transmitter

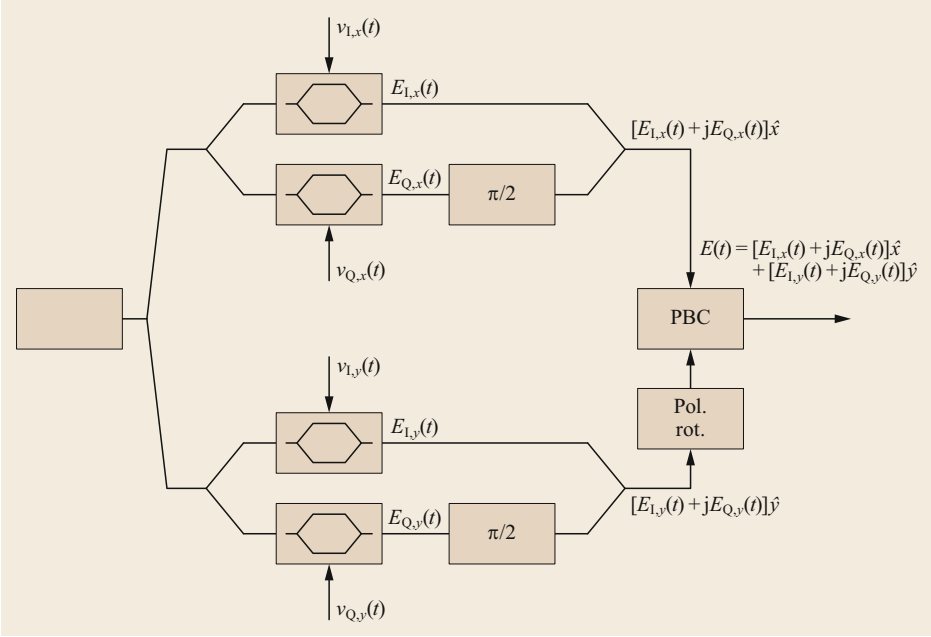

Fig. 4.49 A dual polarization IQ transmitter (PBC: polarization beam combiner)

filters. The distortions on the useful signal introduced by the bandwidth limitations of the TX can be compensated for in the digital domain using a properly designed pre-equalizer in the DSP block before the DAC [4.119].

4.5.2 Coherent Optical Receiver

The basic structure of the most commonly used coherent optical receiver is shown in Fig. 4.50. It is a phase-diversity RX [4.39, 120] which is able to retrieve the in-phase and quadrature components of the complex amplitude of an optical signal without locking the frequency and phase of the local oscillator (LO). The only requirement is that the frequency offset between the TX laser and the LO is limited to a fraction of the symbol rate. This type of coherent detection without active optical phase lock loop is also known as *intradyne* coherent detection.

In the schematic shown in Fig. 4.50, the optical data signal is mixed with a signal generated by an LO through a six-port optical device called a 90° *hybrid* [4.121], which consists of a two-by-two optical coupler with a 90° phase delay function implemented in one arm of the coupler. The input/output characteristic of a 90° hybrid is given by

$$\begin{pmatrix} E_1(t) \\ E_2(t) \\ E_3(t) \\ E_4(t) \end{pmatrix} \begin{pmatrix} +1 & +1 \\ +1 & -1 \\ +1 & -\mathrm{j} \\ +1 & +\mathrm{j} \end{pmatrix} \begin{pmatrix} E_S(t) \\ E_{LO}(t) \end{pmatrix} , \tag{4.36}$$

with

$$E_S(t) = \sqrt{P_S(t)}\,\mathrm{e}^{\mathrm{j}[2\pi f_S t+\varphi_D(t)]} , \tag{4.37a}$$

$$E_{LO}(t) = \sqrt{P_{LO}}\,\mathrm{e}^{\mathrm{j}[2\pi f_{LO} t+\varphi_{LO}(t)]} . \tag{4.37b}$$

The output signals are then converted from the optical domain into the electronic domain with a pair of balanced photodetectors, whose output currents are given by

$$I_I(t) = R\left(|E_1(t)|^2 - |E_2(t)|^2\right) , \tag{4.38a}$$

$$I_Q(t) = R\left(|E_3(t)|^2 - |E_4(t)|^2\right) , \tag{4.38b}$$

where R is the responsivity of the photodiode (which is ideally the same for all four photodetectors). Substituting (4.36) and (4.37) into (4.38), gives

$$\begin{aligned} I_I(t) &= 4R\,\mathrm{Re}(E_S(t)E_{LO}^*(t)) \\ &= 4R\sqrt{P_S(t)P_{LO}^*}\cos\left[2\pi\delta f t+\varphi_D(t)-\varphi_{LO}(t)\right] , \end{aligned} \tag{4.39}$$

$$\begin{aligned} I_Q(t) &= 4R\,\mathrm{Im}(E_S(t)E_{LO}^*(t)) \\ &= 4R\sqrt{P_S(t)P_{LO}^*}\sin\left[2\pi\delta f t+\varphi_D(t)-\varphi_{LO}(t)\right] , \end{aligned} \tag{4.40}$$

where $\delta f = f_S - f_{LO}$ is the frequency offset between the TX laser and the LO. Combining the two photocurrents

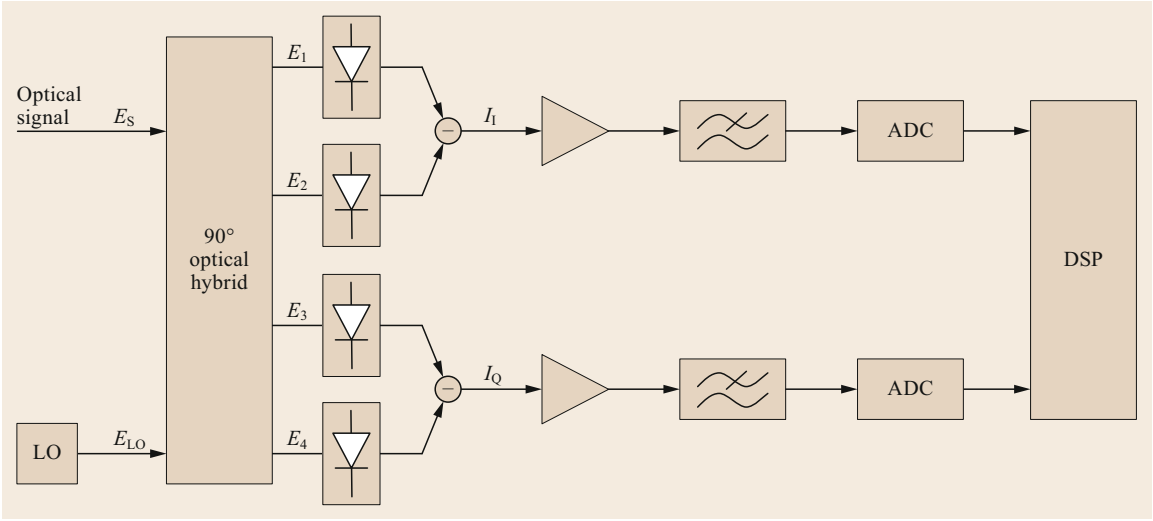

Fig. 4.50 A coherent intradyne receiver based on phase-diversity detection (ADC: analog-to-digital converter, LO: local oscillator; DSP: digital signal processing)

into a complex signal format gives

$$I_{IQ}(t) = I_I(t) + jI_Q(t) = 4R\sqrt{P_S(t)P_{LO}^*}\,e^{j[2\pi\delta ft+\varphi_D(t)-\varphi_{LO}(t)]}\,, \quad (4.41)$$

which has the same phase as the data signal $E_s(t)$ except for the frequency offset and the additional phase noise introduced by the LO. Both, phase noise and frequency offset, can be compensated for using properly designed DSP algorithms that can be applied to the received samples after the analog-to-digital conversion process, together with the compensation of the propagation effects. Note that, if a single photodetector was used instead of a balanced one, it would be necessary to employ a local oscillator laser with 20–25 dB more power than the incoming signal in order for the resulting coherent signal term to dominate [4.121]. By using a balanced photodetector it is possible to employ a much less powerful local oscillator.

The electrical low-pass filters (LPFs) shown in Fig. 4.50 represent the cascade of all band-limiting components in the RX. An additional antialiasing electrical filter may be needed before the ADCs in order to reduce the bandwidth of the input signal, thus relaxing the requirements for the ADC sampling frequency f_{ADC}, which, in order to avoid a performance degradation due to *aliasing* [4.9], has to be higher than twice the bandwidth of the input signal. The distortions introduced on the useful signal by the bandwidth limitations of the RX can be compensated for in the digital domain by the adaptive or static equalizers present in the DSP chain (refer to Chap. 6 for further details).

A polarization controller is needed at the input of the receiver in Fig. 4.50 in order to align the polarization states of the LO and the data signal. However, in practical systems, the polarization of the incoming signal is unlikely to remain aligned to the SOP of the LO because of random changes in the birefringence of transmission fibers [4.122]. To deal with this problem, polarization-diversity detection has been introduced into the coherent receiver. The schematic of the dual-polarization coherent receiver, based on polarization diversity, is shown in Fig. 4.51. The incoming optical signal passes through a polarization beam splitter (PBS), which divides the signal into two orthogonal polarization signal components. Each component is combined with an LO through an independent 90° optical hybrid circuit. The eight signals are then converted from the optical domain into the electronic domain using four balanced photodetectors. In the case of the polarization-multiplexed system, the polarization tributaries can be demultiplexed from the four outputs of the receiver using DSP algorithms [4.45].

Customarily, the performance of optical coherent systems is estimated by means of the OSNR, defined by (4.15). To find the BER, the OSNR is inserted into a suitable formula, which depends on the transmission format. For instance, the ideal BER performance of square PM-QAM formats with M constellation points is given by [4.9]

$$\mathrm{BER}_{\mathrm{PM-MQAM}} = \frac{2(1-1/\sqrt{M})}{\log_2 M} \times \mathrm{erfc}\left(\sqrt{\frac{3\mathrm{OSNR}}{2\,(M-1)}}\right), \quad (4.42)$$

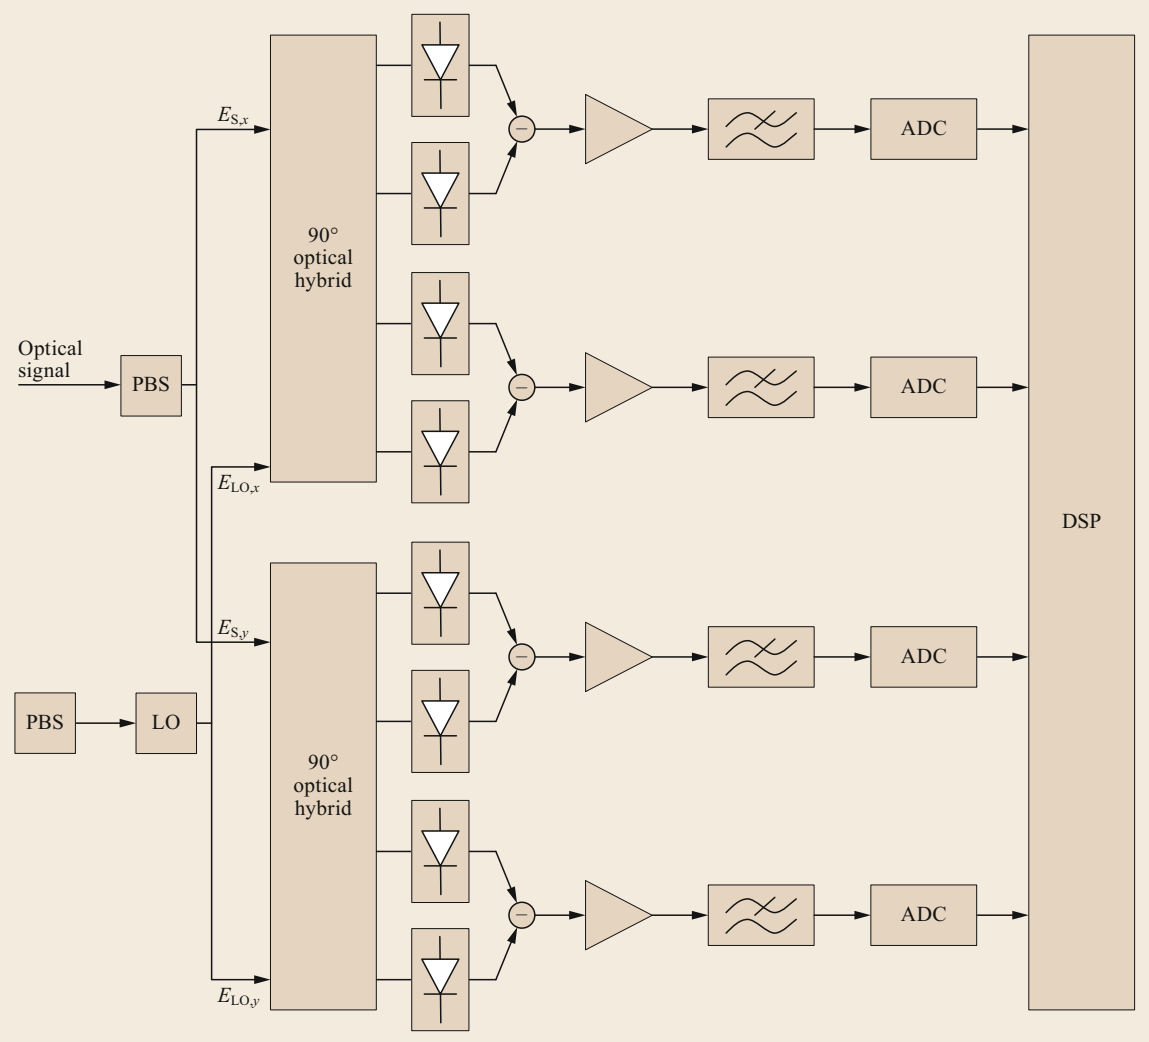

Fig. 4.51 A dual-polarization coherent intradyne receiver based on phase- and polarization-diversity detection (ADC: analog-to-digital converter, LO: local oscillator; DSP: digital signal processing; PBS: polarization beam splitter)

where OSNR is measured over a bandwidth equal to the symbol rate. Equation (4.42), as well as textbook formulas addressing other formats, assume that the RX operates by filtering the incoming signal through a baseband transfer function $H_{RX}(f)$ that is matched to the transmitted signal baseband pulse. It is also assumed that the ISI be absent. Otherwise, they are no longer valid, in the sense that there is a penalty with respect to what they predict. Note that in modern coherent systems, the DSP adaptive equalizer tends to make $H_{RX}(f)$ converge to a matched shape, so that this condition is typically well satisfied.

Under the mentioned assumptions of a matched $H_{RX}(f)$ and no ISI, the OSNR in (4.15) also corresponds exactly to the signal-to-noise ratio SNR that can be directly measured on the RX electrical signal constellation, at the input of the decision stage. In addition, such SNR also coincides with the communications theory widely used parameter *energy-per-symbol versus noise spectral density* [4.9], that is SNR $= E_s/N_0$.

4.5.3 Nyquist-WDM

Today, transmission at 100 Gb/s, enabled by the use of quadrature phase-shift keying (QPSK) at 32 GBd with polarization multiplexing (PM), has reached maturity and widespread deployment, and 200-Gb/s PM-16QAM coherent transceivers are already commer-

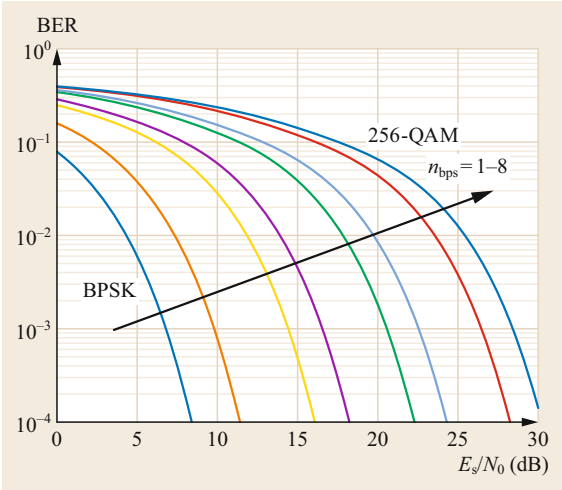

Fig. 4.52 Ideal back-to-back performance of high-order QAM formats with coherent detection

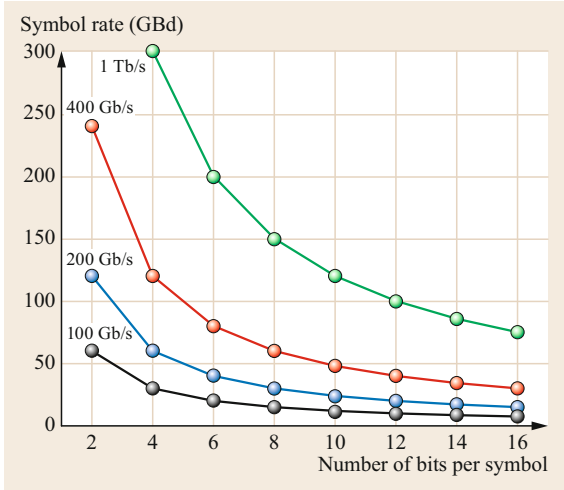

Fig. 4.53 Symbol rate versus number of bits per symbol needed to achieve a target net transmission speed of 100, 200, 400 Gb/s, or 1 Tb/s (assuming that an FEC with 20% overhead is used) (after [4.127])

cially available. Industry efforts are currently devoted to the ASIC development for transceivers for 400 Gb/s and soon they will move to 1 Tb/s. Since the transmission speed R_b is given by the product of the symbol rate R_s and the number of bits per symbol n_{bps} ($R_b = R_s n_{bps}$), higher values of R_b can be obtained by increasing either R_s or n_{bps} (i.e., the order of the modulation format). Note that the first solution would have a strong impact on the hardware complexity, whilst the second one would mainly impact the DSP complexity. As an example, a raw transmission rate of 480 Gb/s can be achieved either with 120-GBd PM-QPSK ($n_{bps} = 4$) or 30-GBd PM-256QAM ($n_{bps} = 16$). Figure 4.52 shows the theoretical back-to-back performance of high-order modulation formats, which highlights the fact that an increase in the n_{bps} introduces a higher requirement in terms of SNR, which in turn results in a significantly reduced achievable transmission distance [4.123].

Figure 4.53 shows the values of symbol rate and number of bits per symbol needed to achieve a target net transmission speed of 100, 200, 400 Gb/s, or 1 Tb/s, assuming that an FEC with 20% overhead is used. The curves in Fig. 4.53 highlight the fact that serial interface rates well beyond those provided by state-of-the-art components (such as electro-optic (E/O) converters, O/E converters, DACs, and ADCs) are needed to achieve transmission speeds beyond 200 Gb/s. This electronic bottleneck can be efficiently circumvented through the use of superchannels, which exploit optical parallelism to provide high per-channel data rates and better spectral utilization [4.124]. A superchannel is a collection of optical signals that are modulated and multiplexed together with high spectral efficiency (SE) at a common originating site, transmitted and routed over a common optical link as a single entity and received at a common destination site. Typically, the superchannels use spectrally efficient advanced modulation formats in combination with advanced multiplexing schemes such as orthogonal frequency-division multiplexing (OFDM) [4.125] or Nyquist-WDM [4.123]. In [4.126] it was shown that both techniques have potentially the same performance, but Nyquist-WDM is much more robust to practical implementation RX constraints, such as limited analog bandwidth and limited ADC speed. In the following, we focus on the use of the Nyquist-WDM technique, briefly describing its generation and detection processes.

Generation of a Nyquist-WDM Signal

Nyquist-WDM signal generation and transmission have been demonstrated using either optical filters or DSP-based electrical filters [4.128–130]. Compared to the optical filter solution, the DSP-based approach is more flexible as the same hardware can be used to generate different filter shapes and modulation formats [4.131, 132]. In practice, the system cost is limited by the complexity, speed, and power consumption. Therefore, it is necessary to optimize the digital Nyquist design for the required signal in order to minimize complexity and speed [4.133–135].

In order to satisfy the Nyquist criterion for the absence of ISI among adjacent pulses [4.9], a raised-cosine (RC) spectral shape is typically used. The RC

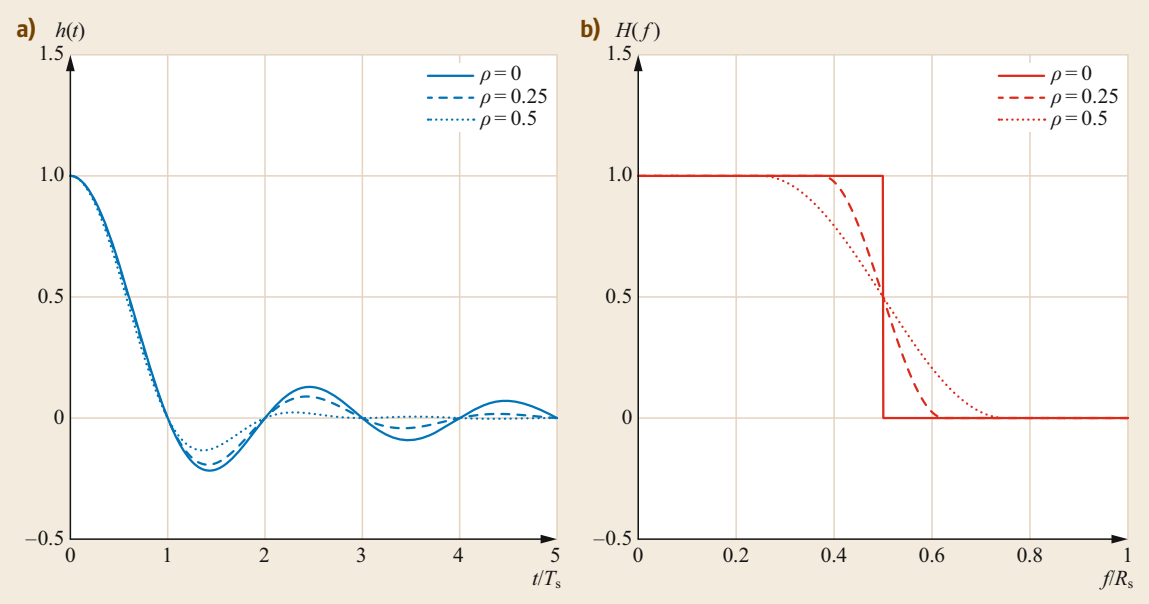

Fig. 4.54a,b RC pulses in the time domain **(a)** and frequency domain **(b)**

transfer function is defined as follows

$$H_{\mathrm{RC}}(f) = \begin{cases} T_\mathrm{s}, & \text{if } |f| \le \frac{1-\rho}{2T_\mathrm{s}} \\ \frac{T_\mathrm{s}}{2}\left\{1-\cos\left[\frac{\pi T_\mathrm{s}}{\rho}\left(f-\frac{1+\rho}{2T_\mathrm{s}}\right)\right]\right\}, & \text{if } \frac{1-\rho}{2T_\mathrm{s}} \le |f| \le \frac{1+\rho}{2T_\mathrm{s}} \\ 0, & \text{if } |f| \ge \frac{1+\rho}{2T_\mathrm{s}} \end{cases}, \tag{4.43}$$

where T_s is the symbol time (reciprocal of the symbol rate) and ρ is the *roll-off* factor, that can take values in the range $[0, 1]$. The impulse response corresponding to an RC spectrum is

$$h_{\mathrm{RC}}(t) = \frac{\sin(\pi t/T_\mathrm{s})}{\pi t/T_\mathrm{s}} \frac{\cos(\rho\pi t/T_\mathrm{s})}{1-(2\pi t/T_\mathrm{s})^2}. \tag{4.44}$$

In the case in which the channel has a flat frequency response, the optimum receiver filter is matched to the transmit one and both assume a square-root raised cosine (SRRC) shape: $H(f) = \sqrt{H_{\mathrm{RC}}(f)}$. Figure 4.54 shows examples of RC pulses in the time and frequency domain, for different values of ρ.

In Nyquist-WDM transmission with RC or SRRC spectra and frequency spacing equal to Δf, ideally no cross-talk is present between adjacent WDM channels if $\Delta f > (1+\rho)R_\mathrm{s}$. As an example, if $\rho = 0.1$, the penalty due to linear cross-talk is negligible if the channel spacing is larger than $1.1R_\mathrm{s}$, i.e., if the normalized spacing $\Delta f/R_\mathrm{s}$ exceeds 1.1. For lower values of channel spacing, a cross-talk penalty is present, as shown in Fig. 4.55 for three different modulation formats (QPSK, 16QAM, and 64QAM). If $\Delta f/R_\mathrm{s} > 1.1$, the performance of all three formats converges to the theoretical value, whilst for lower spacing values an SNR penalty is present, which is higher for higher cardinality modulation formats.

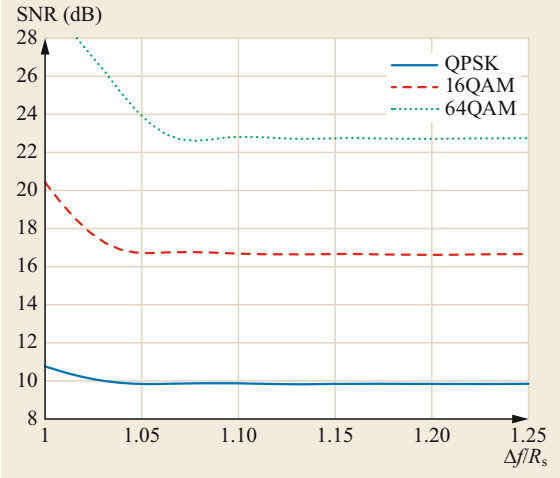

Fig. 4.55 The SNR needed to achieve a target bit error rate of 10^{-3} as a function of the normalized frequency spacing $\Delta f/R_\mathrm{s}$. SRRC filters with roll-off equal to 0.1 when used both at the TX and RX sides [4.137]

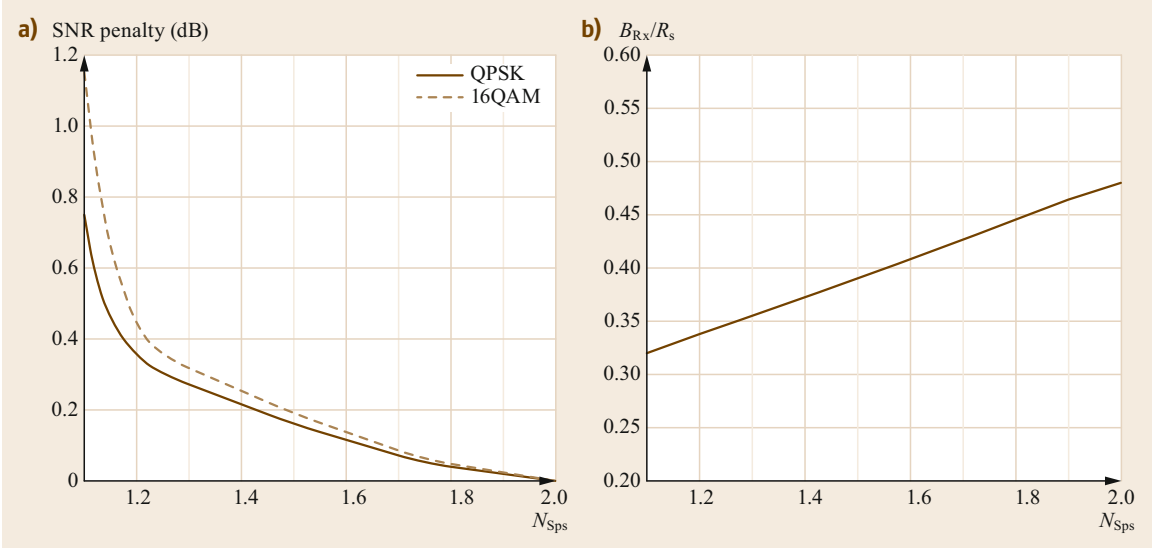

Fig. 4.56a,b The SNR penalty **(a)** and optimum RX bandwidth **(b)** as a function of the number of samples per symbol at the output of the ADC. The reference BER is 10^{-3}

Typically, Nyquist pulse shaping is performed in the digital domain using FIR filters. The required length of the digital filters that generate SRRC or RC pulses depends on the roll-off factor: For low values of ρ, the length of the pulse in time domain increases (as shown in Fig. 4.54a), thus a larger number of FIR filter taps is needed to properly approximate it. Complexity and performance of digital pulse shaping was investigated in [4.138], showing that the use of FIR filters with 17 taps allows for a reduction in channel spacing to 1.1 times the symbol rate with a 1-dB penalty. If the channel spacing is tighter, a higher number of FIR filter taps are needed, as shown in [4.139], where a 32-tap FIR filter was used to shape 14-GBd PM-16QAM Nyquist-like pulses with frequency spacing equal to $1.06R_s$ without substantial cross-talk penalty.

The achievable symbol rate and cardinality of the modulation format are limited by the DAC characteristics, as discussed in Sect. 4.5.1.

Detection of a Nyquist-WDM Signal

Nyquist-WDM signals can be efficiently detected using the standard coherent optical receiver described in Sect. 4.5.2. The single WDM channel is selected by tuning the local oscillator (LO) to its center frequency and the sharp filter shapes needed to cut out the adjacent channels are efficiently implemented in the digital domain. This enables the detection of single WDM channels without the need of any tight optical filtering at the RX. However, the use of antialiasing electrical filters before the ADCs might be beneficial, since they would reduce the signal bandwidth and thus relax the requirements for the ADC sampling frequency f_{ADC} (which, in order to satisfy the Nyquist sampling theorem, needs to be larger than twice the absolute bandwidth of the input signal [4.9]). The ratio between the ADC sampling frequency f_{ADC} and the symbol rate R_s determines the number of samples per symbol N_{SpS} at the output of the ADC. Typically, $f_{ADC} = 2R_s$, which corresponds to $N_{SpS} = 2$, but lower values can be used without incurring any substantial penalties [4.126, 137, 140].

Figure 4.56a shows an example of back-to-back SNR penalty as a function of the number of samples per symbol N_{SpS} at the output of the ADC. The reference BER was 10^{-3} and the penalty was evaluated with respect to the two samples per symbol case. The results were obtained through numerical simulations [4.137], where Nyquist-WDM signals were generated with an SRRC shape and $\rho = 0.1$. A fifth-order electrical Bessel low-pass filter with 3-dB bandwidth B_{RX} was used at the RX. The value of B_{RX} was optimized for each value of N_{SpS}, obtaining the optimum values as shown in Fig. 4.56b (normalized with respect to the symbol rate). Since a low value of N_{SpS} corresponds to a low value of f_{ADC}/R_s, the RX bandwidth has to be decreased accordingly in order to avoid aliasing. This, however, causes a distortion on the useful signal, which in turn induces an SNR penalty, which is greater for higher order modulation formats, as shown in Fig. 4.56a.

In [4.133] it was shown that the complexity of the blind equalizer can be significantly reduced by incorporating the matched SRRC filter in the bulk CD equalizer. It was also pointed out that Nyquist-WDM systems with matched filtering can be extremely sensi-

tive to the frequency offset between the transmitter laser and the local oscillator, and that the induced penalty is higher for low values of the SRRC roll-off factor.

Another critical point of Nyquist-WDM signals that has to be taken into account is related to the difficulty in performing clock recovery, i.e., in extracting the timing information from the incoming signal so that the frequency and phase of the local clock is adjusted, and the transmitted symbols may be correctly recovered. In fact, modern optical transceivers have demanding jitter tolerance and generation requirements [4.141], and must operate under high noise-loading conditions with signals that are distorted by GVD, PMD, optical filtering, and nonlinear phase noise. Whilst Nyquist pulse shaping does not result in ISI in the center of the eye, significant horizontal eye closure is introduced, presenting further difficulties for clock recovery and requiring the use of advanced DSP algorithms to minimize the penalty, as discussed in [4.142].

4.5.4 Flexible Transceivers

The key design parameters to optimally exploit all available resources in long-haul and high-capacity optical transmission systems with coherent detection are the spectral efficiency (SE) and the maximum transmission reach. Nonbinary modulation with coherent detection maximizes SE and improves tolerance to transmission impairments, while enabling effective, low-complexity electrical compensation of these impairments [4.143]. SE can be increased by minimizing the frequency spacing between WDM channels (e.g., using the *Nyquist-WDM* technique), using FEC codes with low overhead or increasing the modulation cardinality. In turn, the maximum transmission reach can be increased by using energy-efficient modulation formats (e.g., low-cardinality QAM) which reduce the SNR requirements at the receiver, using FEC codes with high overhead to ensure reliable transmission or applying proper techniques to mitigate the nonlinear propagation effects in the optical fiber. In practice, a compromise has to be made between SE and achievable reach. For example, a transceiver that operates on a short network segment with high SNR can achieve a high SE to maximize the net data rate. Similarly, a transceiver operating on a long network segment with low SNR should use either a lower order modulation format or an FEC code with high overhead to ensure reliable transmission, at the expense of a loss in SE.

Since the huge amount of traffic foreseen for the near future cannot be efficiently supported by static increases in network capacity, optical transport networks are currently migrating from a static configuration with little flexibility to the concept of software-defined optical networks [4.144]. In the scenario of next-generation optical networks, a key role will be played by flexible and scalable optical transceivers, able to dynamically adapt the modulation format and the transmission rate to the network conditions [4.145].

For flexibility, today's coherent optical transceivers typically use a set of different modulation formats based on standard QAM constellations, generated through the combination of two PAM formats in the in-phase and quadrature components. For these standard QAM formats, a gap to Shannon capacity remains, which can be expressed in terms of a penalty in SNR. Also, the standard QAM formats only offer a coarse granularity in spectral efficiency and hence also a coarse granularity in the achievable transmission reach.

To overcome the lack in granularity, several techniques are currently under study, which take advantage of the high flexibility provided by commercially available high-speed digital-to-analog converters (DACs), allowing the transmitted signal in the digital/electrical domain to be fully designed. This means that, using the same hardware, different modulation formats can be generated and different transmission rates can be achieved. Examples of techniques used to increase the flexibility of optical transceivers are: subcarrier multiplexing (SCM), implemented as either Nyquist frequency-division multiplexing (Nyquist-FDM) [4.146] or orthogonal frequency-division multiplexing (OFDM) [4.147], time-domain hybrid formats (TDHF) [4.148], and probabilistic shaping (PS) [4.149]. The great advantage of all these methods is that the flexibility is achieved without requiring any additional hardware, thus allowing currently available single-carrier transceivers to be reused by simply reprogramming the transmitted signal. The general schematics of the TX/RX pair that can be used to generate SCM, TDHF, or PS signals, as well as standard QAM signals, is shown in Fig. 4.57: the same hardware is used in all cases, the difference is in the DSP algorithms implemented at the TX and RX side. In the following, the above-mentioned techniques are briefly reviewed.

Orthogonal Frequency-Division Multiplexing (OFDM)

Orthogonal frequency-division multiplexing (OFDM) has been widely researched in optical communications due to its high spectral efficiency, resistance to chromatic dispersion, simplicity of one-tap equalization, and flexibility in modulation format [4.147, 150, 151]. This technique is based on the use of electrical subcarriers, each carrying symbols of a QAM constellation, with a sinc-function spectrum to achieve subchannel orthogonality.

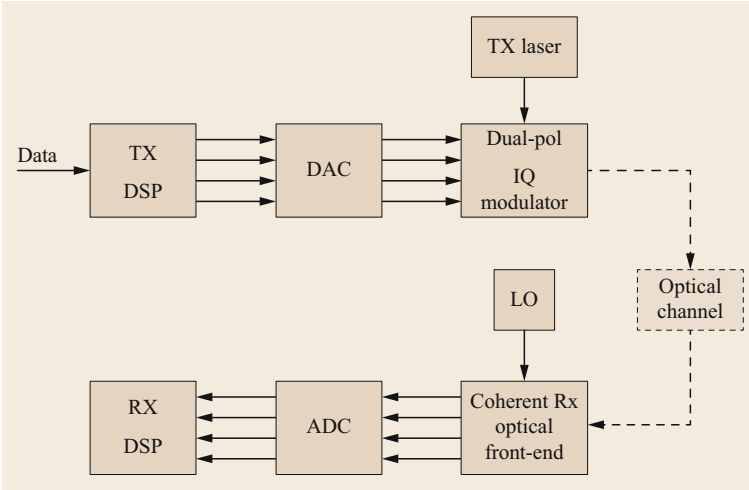

Fig. 4.57 Block diagram of a DSP-based optical TX/RX pair that can be used to generate/detect signals employing SCM, TDHF, or PS techniques, as well as standard single-carrier QAM modulation formats (DAC: digital-to-analog converter; ADC: analog-to-digital converter; DSP: digital signal processing; LO: local oscillator)

Recently, the real-valued OFDM signal (i.e., discrete multitone, DMT) has been the subject of intense investigations for intensity-modulation and direct-detection (IM/DD) optical systems, as an alternative to multilevel PAM formats for the optical interconnects such as passive optical networks, data centers, and system-on-chip interconnects [4.152–154]. However, OFDM signals show relatively high peak-to-average power ratio (PAPR) and high computational complexity, which hinder its practical application in the cost-sensitive and power-sensitive optical interconnects [4.155].

Nyquist-FDM

Like OFDM, this technique consists in electrically decomposing a high symbol-rate signal into a given number of electrical subcarriers, each of which operates at a lower symbol rate [4.156–158]. In Nyquist-FDM signals the cross-talk between adjacent subcarriers is avoided by using Nyquist shaping on the electrical subcarriers. Depending on the optical system being tested, several degrees of freedom can be optimized, such as the number of subcarrier components, the intersubcarrier spacing and the associated modulation format and pulse shaping. The granularity of the subcarriers allows control of the subcarrier symbol duration by keeping a constant overall bandwidth. This ability of optimizing the symbol duration allows the signal for nonlinearity tolerance to be adapted and it can therefore be used to extend the reach of optical transport systems [4.146, 159]. Furthermore, Nyquist-FDM allows the flexible adaption of the bandwidth [4.160] and modulation format [4.161] of each individual subcarrier. This allows for a flexible design of the spectral efficiency and therefore a finer granularity in transmission reach. A disadvantage of the Nyquist-FDM scheme is its larger sensitivity to transmitter impairments, like the IQ-skew which needs a more precise calibration or additional calibration algorithms [4.136, 162].

Time-Domain Hybrid Formats (TDHF)

The TDHF technique consists in transmitting different modulation formats interleaved in the time domain. By changing the ratio of symbols carrying the different modulation formats, the spectral efficiency can be adjusted in fine steps [4.163]. In this way, a high degree of flexibility is achieved, since the transmission rate and, consequently, the SNR performance can be tuned by simply modifying the pattern of the QAM formats. However, even if the composition of hybrid formats is optimized, the SNR performance is still far from that of the optimum Gaussian constellation [4.164–166].

Constellation Shaping (PS)

To overcome the gap to Shannon capacity of QAM constellations, modulation formats that have a Gaussian-like shape can be used [4.167–169]. Two main approaches have been proposed to achieve a Gaussian distribution, i.e., *geometrical shaping* (GS) and *probabilistic shaping* (PS). The first approach (GS) consists in designing nonsquare constellations with a Gaussian-like distribution of points and equal transmission probability for all symbols. The second approach (PS) is based on the use of a standard QAM modulation with a nonuniform distribution of the occurrence probability of the symbols of a given constellation. PS can be implemented either using modified FEC codes [4.169, 170] or using a distribution matcher [4.149]. The main advantages of PS over GS in terms of flexibility are that the net data rate can be adjusted with arbitrary granular-

ity and that the same DSP unit can be used to equalize the signal at different spectral efficiencies. In addition, a sensitivity gain on the order of 1 dB can be achieved with respect to standard QAM constellations [4.149, 171, 172], whilst a more limited gain can be obtained with GS [4.173].

4.6 Transponder Architectures

In the previous subchapters, the concept of a transponder has been introduced and different line interface variants have been presented. In what follows, the transponder concept will be generalized in Sect. 4.6.1. An explanation of which transponder types exist and what their hardware architectures look like will be given in Sect. 4.6.2. In Sect. 4.6.3, the relevant interface standards will be listed and the pluggable optical transceiver modules used in modern transponder implementations will be discussed.

Transponders are realized on printed circuit boards (PCBs) and are therefore often called *transponder cards*. They fit into monolithic or modular WDM transport platforms (Fig. 4.58) and may comprise multiple ports to improve equipment density and to provide additional functionality. Monolithic WDM equipment commonly uses a 1 HU (height unit) chassis which is sometimes referred to as a *pizza box* due to its apparent similarity (1 HU equals 1.75 in or 44.45 mm). Multiples of these shelves can be combined in a rack and stack fashion if more capacity is needed at a particular location. A modular chassis provides multiple slots (4–64 being typical amounts) into which transponders and other cards (for instance amplifier, filter, and ROADM cards) can be inserted. Placed into a 19 (or 21)-in rack with 300- or 600-mm depth, the height of a particular node can vary between 1 and 45 HU depending on the slot configuration and the amount of optical cards required. Modular shelves are typically used for large node configurations. Common equipment functions such as power supplies, fans, management and control, alarm contacts, and system timing can be shared between all cards in the same shelf. An optional high-speed backplane may provide data plane interconnections between cards. This allows the pairing of card slots and the splitting of transponder functions across multiple cards, for example into cards containing only network ports (*line cards*) and cards containing only client ports (*tributary cards*). An electronic switch fabric, typically distributed across two or more cards for redundancy reasons, can turn a transponder shelf into an electronic cross-connect, which can switch at the wavelength, OTN, and/or SDH/SONET traffic levels. Adding packet processing functions converts such equipment into a packet optical transport platform (POTP). Traffic processing at layer 2 or 3 only

effectively turns the platform into a packet switch or router with integrated colored interfaces.

4.6.1 Transponder Types

Generalizing the transponder definition from Sect. 4.1, four basic card types can be distinguished: a transponder, a muxponder, an add-drop multiplexer, and a cross-connect. Line cards can be made configurable to support more than one of these functionalities. Figure 4.59 illustrates the basic card types.

A *transponder* is characterized by a 1-to-1 relationship between client and network ports. There are two basic modes of operation: transparent and mapped, both will be described below.

In *transparent* mode, the transponder performs a 2R (reamplifying and reshaping) or 3R (with additional retiming) regeneration between client and network ports without any intermediate protocol processing. Such a configuration can be attractive because of its low complexity and latency, but only allows limited signal monitoring and conditioning. If the same optical interface types are employed on the network and client side, the transponder acts as a simple regenerator. If different optical interface types are used on both sides, the transponder performs a media conversion and can serve as a demarcation point between different network or equipment domains. A switching function between client and network ports – if available – can be used for signal restoration: in the case of failures on the network side, client ports can be switched to an alternative network port. Depending on the switching capabilities and the number of supported ports then $1+1$, $1:1$ or $1:N$ protection schemes can be supported. If client and line interfaces are realized with pluggable transceivers, only those transceivers need to be equipped which are required for the desired functionality.

In *mapped* mode, the transponder then also performs a protocol conversion between the client and line signals. Multiple services such as local area network (LAN), storage area network (SAN), high-performance computing (HPC), video distribution, passive optical networking, synchronous digital hierarchy (SDH)/synchronous optical network (SONET), optical transport network (OTN) and generic constant bit rate (CBR) or packetized signals on the client side can be mapped into a transport signal on the line side. Please see Chap. 13 for a summary of the most popularly used client signals. While SDH and SONET have been used since the late 1980s, OTN was introduced in 2001 and has since then established itself as the common transport protocol on the network side. Adding a protocol mapper to a transponder allows the monitoring of client and line signals which eases operations, administration, and maintenance (OAM) of the signal and offers increased performance by optional forward error correction (FEC). It can also provide fault and performance management capabilities as well.

A *muxponder* is a combination of a multiplexer and a transponder. It is characterized by an N-to-1 re-

lationship between client and network ports. Several client signals are multiplexed together to obtain a higher speed line signal. 10G and 100G muxponders are the most commonly used today (note that the letters M and G are used to denote the data rate units Mb/s and Gb/s, respectively). The client ports can support different service types and data rates and may require specific mapping processes depending on the selected service. OAM functions allow the integrity of the service to be monitored and to take the necessary actions in case of faults or performance issues. As client ports generally run on independent clocks, an adaptation to the common clock of the line signal is required (for example by bit or byte stuffing). Multiplexing can be done in one or more stages and based on SDH/SONET, OTN, or other technologies. Aggregation of services at a packet level is also possible if the muxponder is equipped with packet processing functions.

An *add/drop multiplexer* is an extension of the muxponder where a second network port is available to enable the support of ring or protected point-to-point applications. The two network ports are often named *east* and *west* ports indicating that they are connected to two diverse fiber routes or ring directions. An add/drop multiplexer can pass traffic between the network ports (called pass-through traffic) and can terminate a portion of the traffic locally (called add/drop traffic) at each network port. A predefined mapping and multiplexing structure as well as a time slot approach is required to be able to isolate the client signals contained within the aggregate line signals. Client signals can be protected against link failures by switching the respective traffic from one to the other network port. In many cases, an add/drop multiplexer can also be operated as two independent muxponders, provided enough client ports are available to match the capacity of the line signal. While add/drop-multiplexers commonly operate on layer 1, adding and dropping of client signals can also be performed at layer 2 or 3, thereby providing oversubscription and statistical multiplexing capabilities.

A *cross-connect* allows a flexible switching between network and client ports, including hair-pinning for client-to-client connections. Multiple colored network ports allows multidegree network nodes to be supported, switching signals between more than two fiber directions. Client ports provide local add/drop access. Depending on the card architecture, the distinction between network and client port can be removed, and any port can serve as network or client port. Switching can be performed on multiple levels and is not restricted to simple port-to-port connectivity only. Higher order SDH and SONET cross-connects operate on a VC-4 (155M) and STS-1 (51M) granularity, respectively. OTN cross-connects can switch on ODU*k* (where if $k = 0$ then the data rate is 1.25G, if $k = 1$ 2.5G, if $k = 2/2e$ 10G, if $k = 3$ 40G, and if $k = 4$ 100G) and ODUflex (supporting multiples of 1.25G) levels. They can operate with tributary slot granularities of 1.25G, 2.5G, or 5G. If a cross-connect supports switching at the packet level, packet flows at Mb/s or lower granularities can also be supported. In principle, SDH/SONET, OTN and packet traffic require dedicated switching matrices. As the size of these matrices needs to be determined upfront, this either limits the flexibility leading to blocking of signals or requires an overprovisioning of switch capacity. A universal switch matrix can alleviate these disadvantages and is of particular interest if cross-connect functions are split across multiple cards [4.174]. In a packet-based universal switch, signals are segmented into packets at ingress, passed over the fabric, and then reassembled at egress. The functional unit performing the packetization is often called a segmentation and reassembly (SAR) block. Typical packet lengths are 128, 256, or 512 byte. However, care needs to be exercised so that client timing (phase and frequency) is maintained and latency as well as latency variations across the fabric are minimized. This can be achieved by variable length packets in which the packet size is slightly varied over time, for instance by lengthening or shortening the packet size by one byte [4.175]. Small cross-connects can be realized on a single line card, whereas large cross-connects can occupy a modular equipment shelf or even require multishelf configurations scaling up to tens of Tb/s of switching capacity.

4.6.2 The Anatomy of a Line Card

WDM platforms often use a generic line card approach. A common base design provides the functions necessary for the operation of any card. Customization is then performed to accommodate specific optical and electronic components for realization, for instance a transponder, an amplifier, or a wavelength-selective switch card. In multislot systems, a backplane is used to connect the line cards with the host platform. It provides power and control to the line cards and may include high-speed data plane connections between line cards or to a central switch fabric.

Common card functions include DC/DC converters, control logic, and the card processor. WDM platforms run off a −48 or +12 V DC (often redundant) power supply which feeds the line cards via the backplane. DC/DC converters on the card then derive all the necessary supply voltages from the base voltage. An onboard microprocessor connects the card to the shelf or network element controller; it is responsible for controlling and managing all card functions as well

as collecting associated fault and performance data. The microprocessor system may contain electronically erasable programmable read-only memory (EEPROM) and flash memory for storing the card calibration data and the card firmware, respectively. Often, the microprocessor is accompanied by additional control logic such as field-programmable gate arrays (FPGAs) which are used for more elaborate control tasks while complex programmable logic devices (CPLDs) are often employed whenever simple logic operations need to be performed in a hard-wired manner (for example laser safety actions).

Figure 4.60 shows the block diagram of a simple OTN transponder line card. In the text, the signal flow only in one direction will be described for clarity, while the other direction passes through the same functional blocks in the reverse order.

A gray transceiver on the client port receives the incoming optical signal, performs an optical to electrical conversion, and passes the signal on to an OTN mapper device. At lower speeds, the electrical interface between the transceiver and the mapper comprises only a single digital lane per direction. At higher speeds, the interface can be implemented over multiple parallel lanes. It then requires a multilane distribution (MLD) algorithm to distribute the transceiver signal over the lanes at one side and to reassemble it at the other side, taking into account the fact that delay differences between the lanes need to be compensated for by appropriate skew management. If enabled, client-side FEC is applied before the signal is passed onto the next step. Often, a non-intrusive monitoring of the client signal is provided to ensure that the incoming signal is of good quality and that the client side network connection is working properly. If the client signal is not already an OTN signal, the client mapper then maps the received signal into an optical payload unit (OPU). The mapping is client specific and can be performed employing a bit-synchronous (BMP), asynchronous (AMP), generic (GMP), or idle (IMP) mapping procedure [4.176]. With BMP, the line clock is phase-locked to the client signal. AMP, GMP, and IMP typically operate with a line clock that is independent from the client clock and therefore require stuffing of bits, bytes, or control characters to compensate for clock rate differences between the line and client clocks. Since its introduction in 2009, GMP has become the preferred mode for all new mappings due to its flexibility and capability to compensate large clock tolerances. Constant bit rate (CBR) signals can directly be mapped into OPU, while packetized signals must first undergo an adaptation step using the generic framing procedure (GFP) [4.177] or IMP. Timing transparent transcoding (TTT) [4.176] may be used as an intermediate step for CBR signals to reduce the data rate of client signals

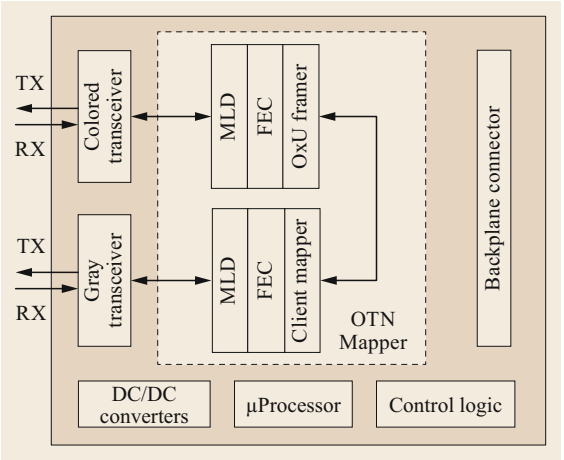

Fig. 4.60 Block diagram of a simple OTN transponder line card

by compressing the employed line coding overhead. In the OxU (OTU/ODU/OPU) framer, the OPU signal is mapped into an optical data unit (ODU) and the ODU is mapped into an optical transport unit (OTU). After adding FEC information, the signal is then sent to the colored transceiver on the line side (using MLD in the case of multiple electrical lanes) where the electrical signal is converted into an optical DWDM signal.

The client- and line-side transceivers may be realized as pluggable modules or discrete implementations on the transponder line card. They may contain clock-and-data recovery as well as basic equalization capabilities to compensate for the PCB trace losses between the transceivers and the mapper device. If the number of optical lanes and electrical lanes is different, they may also incorporate a multiplexer or gearbox IC. For higher data rates and longer reach applications, an enhanced FEC function may also be included. Coherent transceivers typically use a dedicated digital signal processor (DSP). In this case, some OTN mapping and multiplexing functions may be incorporated into the DSP, eliminating the need for a separate OTN mapper device in certain applications.

Extending the functions available to the transponder card described above, Fig. 4.61 shows a universal OTN line card which facilitates access to CBR, packet (for example Ethernet or IP/MPLS flows), TDM traffic (SDH/SONET) and OTN traffic from each of the optical interfaces. The interfaces may be implemented using pluggable transceivers. At data rates up to 10G, colored (line side) and gray (client side) transceivers may use the same pluggable module standard. If the protocol processing capabilities are then the same for each port, a flexible allocation of ports to network- and client-side traffic is possible. The OTN mapper device offers

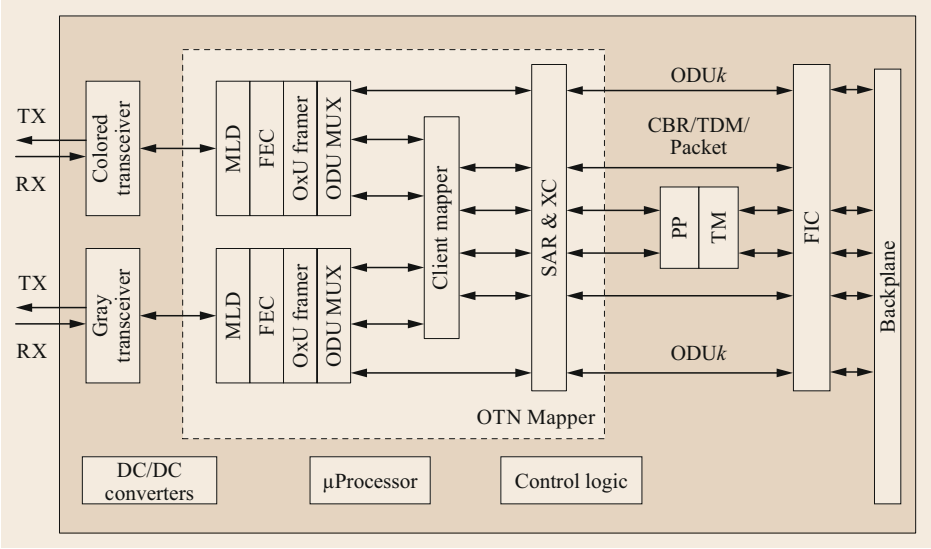

Fig. 4.61 Block diagram of a universal OTN line card (FEC: forward error correction, MLD: multi-lane distribution, TX: transmitter, OxU: OTU/ODU/ OPU, RX: receiver)

configurable protocol processing blocks which can either pass the frames through sequentially or make them accessible via device internal switches which allow individual signal paths for each port to be programmed. Assuming that each of the blocks can be bypassed if it is not required, Fig. 4.61 depicts a sequential arrangement of processing blocks. Incoming OTN signals from the transceivers are passed through the MLD and FEC blocks and then enter the OxU framer, where they are demapped and forwarded to the ODU multiplexer. If the OTN signal comprises a multiplex of lower order ODU*k* signals, then a demultiplexing is performed to access these lower order signals. While an OTN signal in principle may be multiplexed over multiple stages (for example ODU0 to ODU1 to ODU2 to ODU3 to ODU4), practical considerations and hardware constraints often limit the MUX block inside the mapper device to two multiplexing and several mapping stages which can be arbitrarily selected. At this point, multiple processing paths are possible: ODU*k* signals can directly be cross-connected (XC) to other ports of the same mapper device or passed on to a centralized switch matrix. An SAR device packetizes the OTN signals which are delivered to a universal packet-based switch fabric via a fabric interface chip (FIC). Typically, an Interlaken interface is used between the OTN mapper and the FIC. For smaller switch configurations, a direct interconnection of OTN mapper devices between paired cards is also sometimes possible, alleviating the need for an FIC in between. FEC and time stamping may be provided to improve the transmission and timing performance over the fabric. If CBR, packet, or TDM client signals inside an ODU*k* are to be accessed, the signals are passed on to a client mapper which extracts the traffic and cross-connects it either to another transceiver port or to the universal switch matrix via an SAR and an FIC. For advanced processing of packet traffic, an external packet processor (PP) and traffic manager (TM) is often used before the traffic is passed on to the switch matrix via the FIC. Packet traffic does not need to pass through the SAR block, as it is supported natively by the packet fabric. CBR, TDM, or packet traffic entering from a gray transceiver may pass the MLD and FEC blocks and is then directly processed in the client mapper, bypassing the OxU framer and ODU MUX stages. It can then be switched to another transponder port as in the case of the simple transponder of Fig. 4.60, directly fed to the switch fabric, or wrapped into an ODU structure first and then passed through the ODU MUX block.

4.6.3 Interface Standards

Standards are necessary to facilitate a line card design based on interoperable building blocks which can be procured from multiple sources. The most important areas of standardization include transceiver modules as well as their respective optical, electrical, and control interfaces. While transceivers historically were implemented using discrete optics and electronics, multisource agreements (MSA) for transceivers emerged in the late 1990s and allowed the use of integrated transceiver modules instead.

Hot pluggable, front-plate accessible transceiver modules were introduced starting with the gigabit interface converter (GBIC) in 1995, followed by the 10 Gb Ethernet transceiver package (XENPAK) and the small form-factor pluggable (SFP) transceiver in 2001, the 10 Gb small form-factor pluggable (XFP)

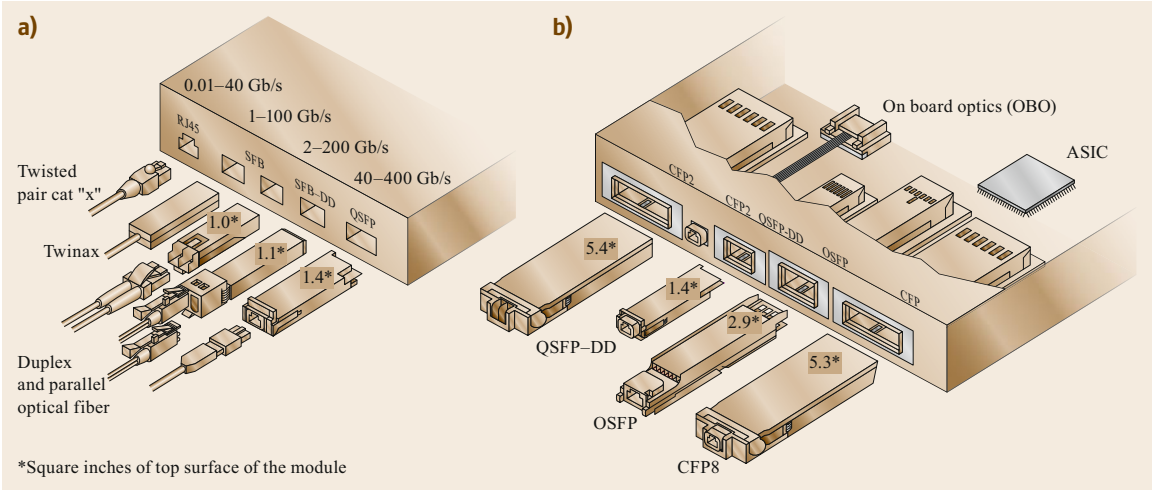

Fig. 4.62a,b Pluggable module form factors: **(a)** current modules, **(b)** modules in development for 400G (Graphics courtesy of Ethernet Alliance [4.178])

module in 2002, the quad small form-factor pluggable (QSFP) transceiver and the $1 \times 10\,\mathrm{Gb/s}$ small form-factor pluggable (SFP+) transceiver in 2006, as well as the $10\,\mathrm{Gb/s}$ 4 × pluggable transceiver (QSFP+) in 2009. SFP+ and QSFP+ modules are available in different speed classes. To distinguish them, the nominal electrical lane speed is often appended instead of the + symbol (for example SFP10 and QSFP10). The MSAs define the mechanics, the electrical connector, the power supply as well as the high- and low-speed signaling along with implementation and measurement descriptions. The specifications are maintained by the Storage Networking Industry Association (SNIA) small form-factor (SFF) Technology Affiliate Technical Work Group [4.179]. New developments include the QSFP double density (QSFP-DD) [4.180] and the octal SFP (OSFP) [4.181] targeting 400G and the SFP double density (SFP-DD) [4.182] targeting 100G applications.

Also the 40G/100G form-factor (CFP) MSA group [4.183] has developed specifications for 100G+ transceivers offering more space for component integration and a higher power dissipation than their SFP and QSFP counterparts. Since formation of the group in 2009, three generations of 100G small form-factor pluggable (CFP) modules (CFP, CFP2 and CFP4) were brought to market, while the CFP8 specification has just been released in 2017.

The most common front pluggable optical modules are illustrated in Fig. 4.62 with a twisted pair RJ45 copper cable connector for comparison, along with new module standards in development for 400G and beyond. QSFP-DD is by many the favored 400G interface standard, although it is the most challenging from an integration and thermal management point of view, as it possesses a smaller module surface area compared to the OSFP and CFP8.

In addition to front pluggable modules, MSAs have been drawn up for PCB mountable optical transceivers (on-board optics – OBO). This development started with 300-pin transceivers for 10G applications in a 5×7-in footprint which were first released in 2001. Subsequently, a smaller form-factor variant (2.2×3 in) and 40G support were added and the first 40G MSA modules became available in 2006. While the primary design target was colored WDM applications, MSA modules for gray interface applications were also offered. For 100G coherent long-haul applications, the OIF published an implementation agreement for a 5×7-in 168-pin transmission module in 2011 [4.184], which was augmented in 2015 by a second release targeting a smaller module footprint (4×5 in). Advances in CMOS technology and photonic integration since then have allowed integrating digital coherent 100G/200G transceivers also into CFP and CFP2 front pluggable modules (digital coherent optics or DCO modules). As an intermediate step to the CFP2-DCO module, a CFP2-ACO analog coherent optics transceiver was released which integrates all optics and RF electronics but not the coherent DSP. Further development directions include the definition of 400G and 800G on-board optical modules as currently being pursued by the Consortium on On-Board Optics (COBO) [4.185] as well as an integration of 400G coherent transceiver technology into next-generation optical modules (QSFP-DD, OSFP, CFP8 or coherent OBO).

Client-side optical interface standards are defined by the industry bodies responsible for the respective protocol specifications. These are Telcordia for SONET, the ITU-T Study Group 15 for SDH, OTN,

Table 4.5 Ethernet interface standards and related nomenclature (after [4.178]). Color code: *black* = IEEE standard, *blue* = non-IEEE standard but complies to IEEE electrical interfaces, *red*: under discussion in standardization

Standard	Electrical interface	MMF	Parallel SMF	2 km SMF	10 km SMF	40 km SMF

and PON, the IEEE 802.3 group for Ethernet and Ethernet-PON, the International Committee for Information Technology Standards (Incits) Task Group 11 (T11) for Fiber Channel, the Infiniband Trade Association (IBTA) for Infiniband, the CPRI group for the Common Public Radio Interface, and the Society of Motion Picture and Television Engineers (SMPTE) for video distribution.

An overview of Ethernet interfaces over single-mode (SMF) and multimode (MMF) fiber along with their electrical host-side interfaces is shown in Table 4.5. Note that the numbers stated after the interface classifier indicate the number of parallel signaling lanes (with exception of the 4WDM interfaces where the numbers indicate the reach in km). NRZ signaling is commonly used up to 25G, and PAM4 signaling above this rate on optical and electrical interfaces.

Optical client-side interfaces for SDH/SONET and OTN signals are defined in the Telcordia GR-253 standard as well as the ITU-T G.957, G.691-693, G.695, and G.959.1 recommendations. Colored line-side interfaces are described in the ITU-T G.698 series of recommendations. Published ITU-T recommendations can be accessed online here [4.186].

The OIF Common Electrical I/O Implementation Agreement (CEI IA) defines electrical and jitter requirements for electrical chip-to-module, chip-to-chip, and backplane interfaces. Currently included are interfaces with 3G, 6G, 11G, and 28G signaling rates [4.187], and new revisions including 56G and 112G are already in development. The CEI forms the basis of the 10 to 400G attachment unit interfaces (AUI) as well as the SFP (SFI) and XFP (XFI) interfaces connecting Ethernet transceivers to the attached host board chip. For the AUI, a change of the speed classes is occurring translating from Arabic to Roman numerals (e.g., from CAUI where *C* denotes 100 to 100GAUI). Protocol-specific aspects such as MLD are defined in the IEEE 802.3 standard. The CEI IA also defines the electrical parameters for SDH/SONET and OTN module-to mapper/framer interfaces. At 10G, these interfaces typically need only a single serial electrical lane (SFI/XFI) and therefore do not require any MLD. At 40G, a group of four synchronous (STL256.4) and optical transport lanes (OTL3.4) as defined in ITU-T G.707 and G.709 are used for SDH/SONET and OTN signals, respectively. 100G OTN signals are transported over a 10 × 10G (OTL4.10) or a 4 × 25G (OTL4.4) interface. Beyond 100G module-to-framer interfaces can use multiple 100G optical transport lane (OTLC) groups or a FlexO interface (FOIC) as described in ITU-T G.Sup58 [4.188]. Future interface standards are expected to increase the signaling rate and reduce the number of lanes further.

Digital control of transceiver modules relies on either a two-wire serial (TWS) or a management data input/output (MDIO) interface as defined in IEEE 802.3. Currently, the management interface specification (MIS) forms part of module MSA documentation and is specifically developed for it. In the future, a common MIS (CMIS) may be created from which a module MIS can be derived.

Jörg-Peter Elbers is Senior Vice President of Advanced Technology, Standards and IPR at ADVA Optical Networking. Before joining ADVA, he was Director of Technology in the Optical Product Unit of Marconi (now Ericsson) and Director of Network Architecture in the Optical Networks Business Unit of Siemens. He received his Dr-Ing degree in electrical engineering from the Technical University Dortmund, Germany.

5. Optical Transponder Components

Xi Chen, Sethumadhavan Chandrasekhar

This chapter introduces the general architecture of an optical transponder and describes the three critical optical components that comprise the transponder, the laser, the optical modulator, and the photodetector. Following this, the subsystem consisting of the optical transmitter and the coherent receiver that are typically used for generating and detecting dual-polarization complex-modulated signals are explained. The typical characteristics of the components used in the transponder are presented both from current-generation products, as well as from more recent research demonstrations.

In this chapter, we focus on the line-side optics, as they are the key to understanding the components in a transponder. The transmitter at the line side consists of a number of high-performance optical components, such as narrow-linewidth lasers, and high-speed modulators with linear driver amplifiers. The receiver at the line side consists of 90° optical hybrids, high-dynamic-range linear balanced photodetectors (BPDs), and high-gain low-noise transimpedance amplifiers (TIAs). The digital electronic functions are in application-specific integrated circuits (ASICs), which include digital-to-analog converters (DACs) for the transmitter to generate optical signals, analog-to-digital converters (ADCs) for the receiver to recover the optical signals. Both ends need digital signal processing (DSP) engines to condition and process the signals. The client side optics, which are not covered in this chapter, are usually a subset or a simpler version of those used in the line-side part of the transponder.

An optical transponder consists of a client side and a line side. The client side collects traffic from various client applications such as text, images, audio, video, etc. The line side connects to the optical core network and has high-speed interfaces. The transponder collects low-speed optical signals from clients, down-converts the optical signals to electrical signals, and multiplexes all the information collected onto one optical carrier that carries the high-speed signal. This high-speed signal will then be sent to the core network. The core network is often referred to as the line system. An optical transponder also performs the reverse function, namely, de-multiplexing the high-speed signal received from the line system to multiple low-speed client optical signals and sends them to the clients. An optical transponder is usually characterized by the information

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_5

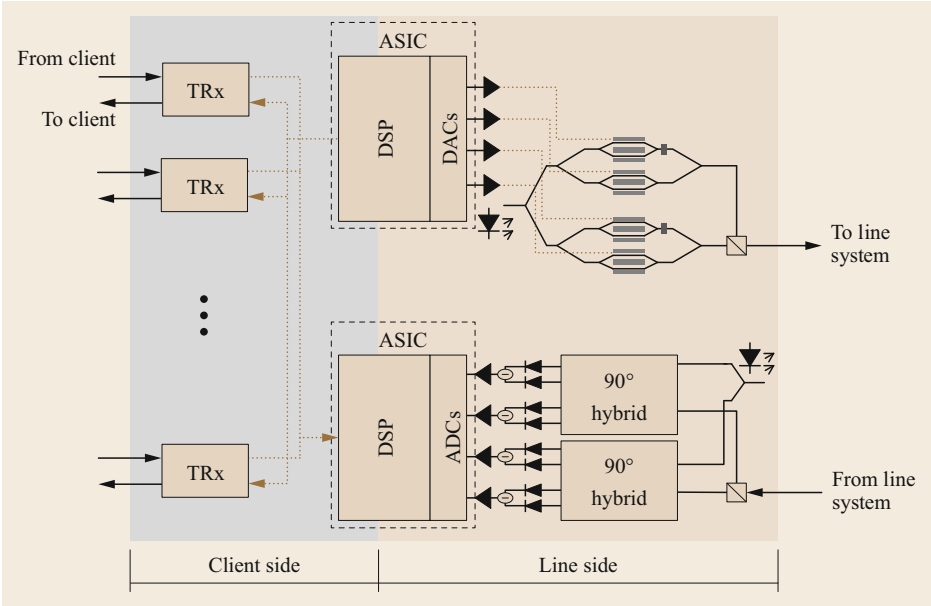

Fig. 5.1 Schematic architecture of an optical transponder (TRx: transceiver)

rate that faces the line side. For instance, a 100 Gb/s transponder could collect either ten 10 Gb/s signals or four 25 Gb/s to form 100 Gb/s and send them to the line system. A schematic hardware architecture of an optical transponder is shown in Fig. 5.1.

In the following sections, we first explain three critical components of an optical transponder, namely, the laser, the optical modulator, and the photodetector. We then describe the architecture of the transmitter and receivers and their other related components.

5.1 Lasers

The word *laser* stands for *light amplification by stimulated emission of radiation*. It is a device that emits light through the process of optical amplification based on stimulated emission of electromagnetic radiation, and the device under this condition is sometimes referred to as *lasing*. A laser, different from other light sources such as light bulbs and light-emitting diodes (LEDs), emits coherent light with a very narrow optical spectrum, which makes it particularly suitable for telecommunication applications.

In order to achieve *lasing*, the laser needs a cavity and a gain medium in the cavity. Depending on the type of gain medium, lasers can be categorized as solid-state lasers, liquid lasers, gas lasers, and semiconductor lasers. The most common type of laser for telecommunications is the semiconductor laser, due to its low cost, compact size, and low power consumption. Semiconductor lasers are also known as *laser diodes*, as a pn junction of a semiconductor diode forms the gain medium. The physics behind the stimulated emission is important for understanding lasers. The stimulated emission is the process that generates coherent photons, resulting in a highly coherent and directional light beam. A semiconductor laser needs a pump current to move the electrons to their higher-energy state so that stimulated emission can occur. The details of these processes are not covered in this chapter but can be found in other textbooks [5.1, 2]. In this chapter, we explain the basics of how lasers work based on different cavity structures. Depending on the cavity structure, lasers can be categorized as Fabry–Pérot (FP) lasers, distributed feedback (DFB) lasers, or external cavity lasers (ECLs).

5.1.1 Fabry–Pérot Laser

The FP laser, though not used in optical transponders, has important features, and by studying these features we can learn about lasers in general. Figure 5.2 shows the schematic structure of an FP laser. An FP resonator forms the cavity with one mirror at each end. A gain medium is placed inside the FP resonator.

The laser starts with some weak spontaneous emission. At this stage, the light is broadband and incoherent. The two mirrors, one with very high reflection

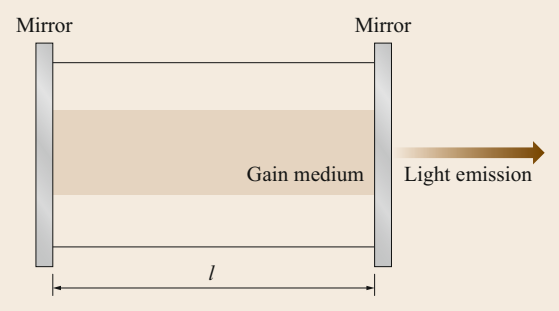

Fig. 5.2 Schematic architecture of an FP laser

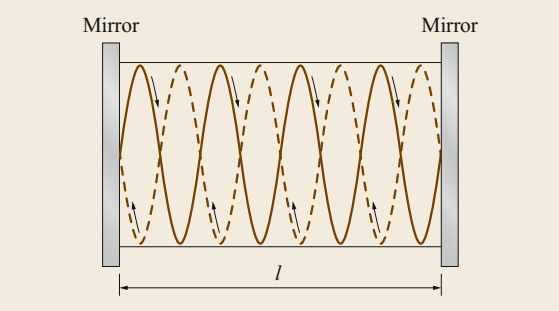

Fig. 5.3 An example of a cavity mode

($\approx 100\%$) and the other with a slightly lower reflectivity ($\approx 99\%$), cause the broadband light to bounce back and forth between the mirrors. One can imagine that each round-trip of the bouncing generates a new wave that can be superimposed on the original wave. The new wave will be constructively added to the old wave when they are in phase. This basically requires the wave to repeat itself after every round trip. An example of such repetition is shown in Fig. 5.3.

To achieve such repetition, the wavelength must equal the cavity round-trip distance divided by an integer number. In other words, assuming the cavity has a length of l, the wavelength λ needs to satisfy

$$N\lambda = 2l\,, \tag{5.1}$$

where N is an integer. From (5.1), it can be seen that only certain frequencies can constructively add and extract the maximum gain from the cavity. These frequencies are also known as longitudinal modes of the cavity, or equivalently, cavity modes. Equation (5.1) suggests that an infinite number of modes can be supported by the cavity. However, the gain medium provides gain over a limited bandwidth (BW), and, therefore, only the modes within the gain medium's bandwidth can achieve *lasing*. A schematic spectrum of the gain profile and its limitation on the cavity modes are shown in Fig. 5.4.

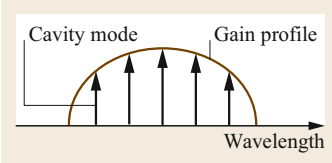

Fig. 5.4 Schematic spectrum of cavity modes and the gain medium's gain profile

From (5.1), one can also note that a change in the laser cavity length l can result in a change in the lasing wavelength(s). This is how lasers, not only FP lasers but essentially all lasers, achieve their wavelength tunability. For instance, in FP lasers, devices with different cavity lengths will have different emission wavelengths.

In a laser cavity, the quantum fluctuations associated with the lasing process affect the phase of the optical field emitted. A change in phase leads to a shift in the lasing frequency. These fluctuations effect the spectral coherence of the emitted light. A measure of this spectral coherence is the laser linewidth. The linewidth is defined as the full width at half maximum (FWHM) of the power spectral density. This is an important figure of merit for lasers. In an optical transponder, the smaller the laser linewidth, the lower the degradation to data modulation and detection. Typical linewidths of telecom lasers will be mentioned later in this section.

5.1.2 Distributed Feedback (DFB) Laser

FP lasers emit multiple wavelengths (as shown in Fig. 5.4), which are not suitable for optical transponders. An optical transponder needs lasers to emit only one wavelength (one cavity mode). One way to achieve this single mode operation is to use a Bragg grating, as depicted in Fig. 5.5. The Bragg grating, with a periodic variation of the refractive index, reflects light along the cavity and functions as a distributed mirror. This type of laser is known as a distributed feedback (DFB) laser. Additionally, as there is typically only one mode that is favored by the grating in terms of loss, the grating also functions as a wavelength selector. In a practical implementation, the mirrors at the two ends are still used, as the grating gives only $\approx 80\%$ reflectivity. The wavelength tunability of a DFB laser is achieved by thermally changing the period of the grating. A typical DFB laser diode can be tuned continuously over a few nanometers by changing the temperature of the device.

As shown in Fig. 5.5, in the DFB laser, the gain region overlaps with the wavelength selection element. This is inconvenient, as the tuning of wavelength affects the lasing process. Additionally, as the cavity length is relatively short, the linewidth of a DFB laser is usu-

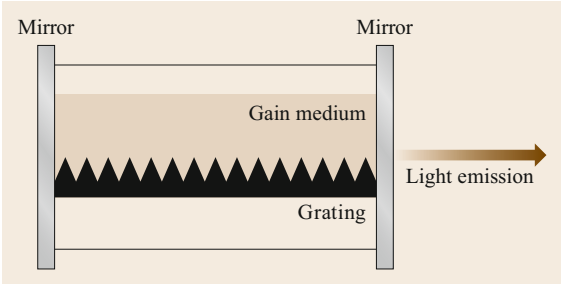

Fig. 5.5 Schematic architecture of a DFB laser

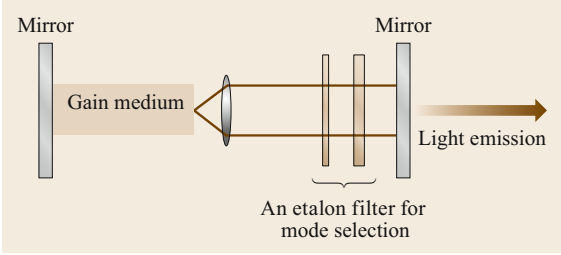

Fig. 5.6 Schematic structure of a free-space etalon filter-based ECL

ally large, e.g., a few MHz. Due to this relatively large linewidth, DFB lasers are used in some of the client-side optics but not in the line-side optics.

5.1.3 External Cavity Laser (ECL)

A better way to achieve a wider range of tunability and a narrower linewidth is to use an external cavity structure. The external cavity means that part of the laser cavity is outside the gain medium. A laser that uses an external cavity is known as an external cavity laser (ECL).

An example of an external cavity laser is shown in Fig. 5.6. The light generated from the gain medium (which consists of multiple cavity modes) is collimated and passed through an etalon filter. The etalon filter is an interference-type filter that usually consists of two thin-film plates. The transmission spectrum of the filter is adjustable by varying the distance between the two plates. This type of filter provides very narrow bandpass feature and is used to select the desired mode/wavelength. Such mode selection is illustrated in Fig. 5.7. The wavelength tunability of this type of ECL is achieved by adjusting the position of the laser cavity mirrors and the transmission spectrum of the etalon filter.

The external-cavity-based wavelength selection can also be achieved with gratings as shown in Fig. 5.8. The ECL can also be made with DFB structures. For instance, sampled Bragg gratings can be added

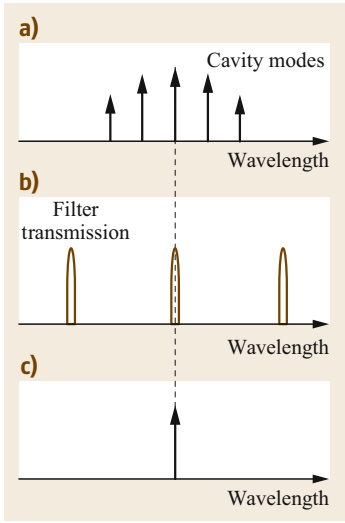

Fig. 5.7a–c Mode selection process in an ECL using an etalon filter. **(a)** Spectrum of laser cavity modes without the etalon filter; **(b)** transmission spectrum of the etalon filter; **(c)** generated laser spectrum

to the two sides of the gain region as depicted in Fig. 5.9 [5.3].

ECLs have much a narrower linewidth than stand-alone laser diodes, because the cavity length in an ECL is much longer than that of a solitary laser diode. The short gain medium in combination with a long cavity causes phase fluctuations to decrease dramatically [5.4]. With the different kinds of free-space or sampled grating ECLs, the laser linewidth is of the order of 100 kHz. The tuning range of such ECLs can be ≈ 40 nm. These ECLs are the most popular lasers used in modern optical transponders. More information about these tunable lasers can be found in [5.5].

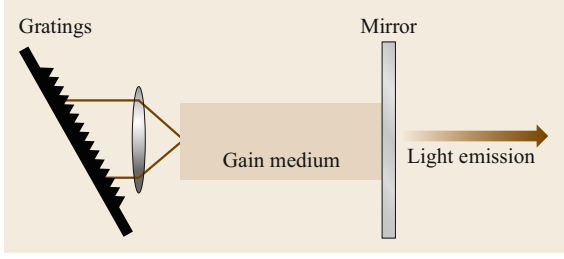

Fig. 5.8 Schematic structure of a free-space and grating-based ECL

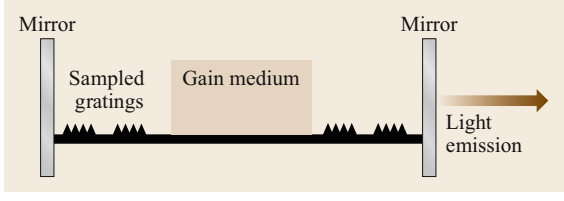

Fig. 5.9 Schematic structure of a sampled grating-based ECL

A further reduction of linewidth can be achieved with fiber lasers, where the cavity is formed by a special fiber Bragg grating. Fiber lasers can have linewidths in the region of several kHz [5.6, 7]. Very advanced fiber lasers may have linewidths of ≈ 100 Hz. Even lower linewidths, e.g., less than 1 Hz, can be achieved via self-injection locking to an optical microresonator. These ultra-low linewidth lasers are usually single frequency and not tunable, and therefore not used in optical transponders. Nevertheless, such narrow linewidth lasers could be useful in the future for generation and detection of ultra-high-order modulation formats (which are sensitive to laser phase noise).

5.1.4 Performance Merits of a Laser

There are a number of important parameters to consider when selecting a laser for optical transponders:

1. Wavelength/frequency. A telecom laser should operate at a wavelength around 1310 or 1550 nm.
2. Tunability. According to the International Telecommunication Union (ITU) standardization sector, lasers for dense wavelength-division multiplexing (DWDM) networks should have a continuous wavelength tunability across the C band (1530–1565 nm) [5.8].
3. Output power. A typical telecom laser should produce 4–40 mW of output power to have enough power for data modulation and fiber transmission.
4. Linewidth. A typical line-side optical transponder laser should have a linewidth of no more than a few hundreds of kHz. Different modulation formats have different tolerances to the laser linewidth. The linewidth's impact on data modulation and detection are rather complex. More information can be found in the literature [5.9, 10].

5.2 Modulators

A modulator is a device that can modulate a beam of light. *Modulate* means manipulating the parameter(s) of the light using an electrical signal. Depending on which parameter is manipulated, modulators can be categorized as phase modulators, amplitude modulators, polarization modulators, etc. Modulators can also be categorized by the mechanism with which the modulation is achieved. For instance, modulation can be done by direct-modulated lasers (DMLs) where the laser itself serves as a modulator; by electro-absorption modulators (EAMs), where the material absorption spectrum is changed by an applied electric field; or by electro-optic modulators where an electro-optic crystal is used, and the phase of the optical field in the crystal can be changed by an electric field. In this section, we explain DML, EAM, and one basic type of electro-optic phase modulator. Based on the phase modulator, we describe the operation of Mach–Zehnder modulators (MZMs), in-phase/quadrature (I/Q) modulators, and dual-polarization I/Q modulators.

5.2.1 Direct-Modulated Laser (DML)

A DML is a device that performs the function of both light emission and data modulation. In a DML, the laser output power is changed by changing the pump current in the laser gain medium. This pump current is controlled via an electrical driving signal, as shown in Fig. 5.10. The DML eliminates the need for coupling light between a laser and a modulator, which reduces the cost of fabrication and packaging. DMLs are suitable for applications requiring compact design and low power consumption.

The output power as a function of pump current for a typical DML is shown in Fig. 5.11. This curve is known as the light–current (L–I) characteristics of a semiconductor laser. One can observe from the L–I curve that there is a threshold current (I_{th}) required to *turn on* the laser (the onset of lasing). With a current that is larger than the threshold, the laser output power increases linearly with the pump current. However, after a certain current level, there is a *kink* on the L–I curve, indicating the existence of transitions to higher-order modes or transitions from TE to TM mode [5.2]. Operation of the DML beyond the kink is generally avoided. Therefore, as shown in Fig. 5.11, the DML has a limited current range available for data modulation. As a result, the ratio between maximum and minimum modulated optical power is limited. This power ratio is known as the modulator's extinction ratio. Typical DMLs have an extinction ratio of the order of several dBs. The ex-

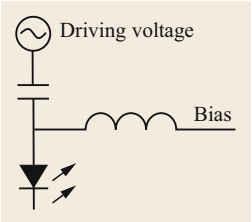

Fig. 5.10 Schematic structure of a DML

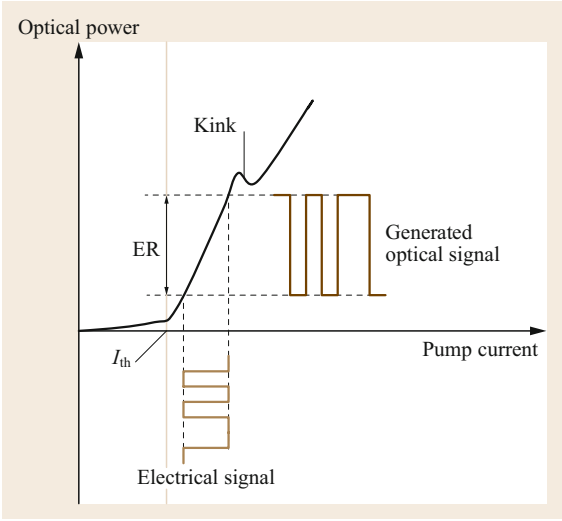

Fig. 5.11 An exemplary light–current curve of a laser. ER: extinction ratio

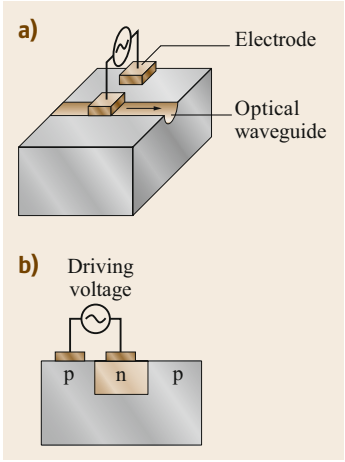

Fig. 5.12 **(a)** Schematic structure of an EAM; **(b)** cross-section of the EAM

tinction ratio is a very important figure of merit for modulators, as the data reception relies on the separation of different optical power/amplitude levels. A small extinction ratio affects the quality of the data detection.

The other characteristic associated with DMLs is the modulation chirp. The chirp of an optical pulse is the time dependence of its instantaneous emission frequency. In a DML, the pump current that modulates the laser introduces a shift in the emission frequency, typically resulting in spectral broadening. The modulation chirp degrades the signal and usually needs to be minimized.

Commercial DMLs typically modulate signals at $\approx 10\,\mathrm{Gb/s}$. Recent research demonstrations have shown DMLs with bandwidths beyond 50 GHz [5.11, 12] and capable of modulating data at $>100\,\mathrm{Gb/s}$ [5.12]. Though high-speed operation can be achieved, due to the limited extinction ratio and other constraints that originate from the fact that the modulation changes the laser properties directly (e.g., the modulation chirp), DMLs are mainly used for short reach transmission ($< 10\,\mathrm{km}$). In other words, they are used in client-side optics or data center interconnections, but are not used in a transponder's line-side optics.

5.2.2 Electro-Absorption Modulator (EAM)

External modulators are needed to achieve a better extinction ratio. An external modulator is a modulator that is independent of a laser. Such a modulator typically has a CW optical input, an RF port for adding the electrical drive signal, and an optical output for coupling the modulated light out.

An EAM is an example of an external modulator and is often made in the form of a semiconductor waveguide (a pn junction) with electrodes for applying an electric field in a direction perpendicular to the propagation direction of the light beam (Fig. 5.12). The semiconductor's optical absorption spectrum is changed by the electric field, known as the Franz–Keldysh effect [5.13]. The length of the EAM device determines the frequency response of the modulator. The device is typically short, in order to achieve high-speed operation. The electrodes that apply the field to an EAM are generally much shorter than the operating electrical wavelength. Such electrodes are referred to as a lumped electrode design.

A modulator based on electro-absorption is usually very efficient. EAMs can operate with drive voltages as low as $\approx 2\,\mathrm{V}$ and can provide bandwidths of more than 100 GHz [5.14]. Another important feature of EAMs is that they can be integrated with DFB laser diodes on the same chip, a device referred to as the electro-absorption modulated laser (EML).

Though EAMs are compact and have a large bandwidth, they can still produce a modulation chirp, and the only parameter they can modulate is the optical power. To have more flexibility in modulation and also to achieve chirp-free modulation, phase modulators and Mach–Zehnder modulators have to be used.

5.2.3 Phase Modulators

A phase modulator is another type of external modulator where the optical phase can be changed according to an applied electric voltage. To change the optical phase, an electro-optic crystal is often used. In electro-optic crystals the refractive index of the crystal can be modified via an electrical voltage, thus the phase delay of the propagating light can be manipulated. This effect

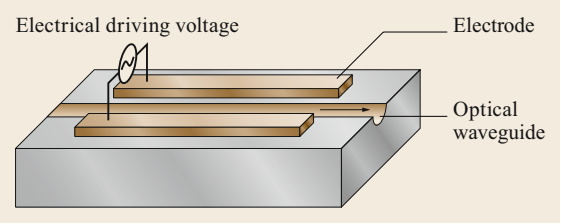

Fig. 5.13 Schematic structure of a phase modulator

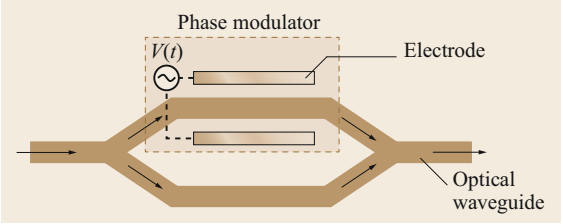

Fig. 5.14 Schematic structure of an MZI

is known as the Pockels effect. Typical crystal materials that exhibit the Pockels effect are lithium niobate ($LiNbO_3$), gallium arsenide (GaAs), and indium phosphide (InP). Devices that make use of the Pockels effect are referred to as Pockels cells.

An important property of a Pockels cell is its half-wave voltage V_π. This is the voltage required for inducing a phase change of π on the light beam. The phase-modulated light C is given by

$$C = A e^{j\omega_c t} e^{j\frac{\pi}{V_\pi}V(t)}, \tag{5.2}$$

where A and ω_c are the amplitude and the angular frequency of the laser beam, and $V(t)$ is the applied electric voltage. For simplicity, the instantaneous phase of the CW light and the waveguide propagation delay and loss are ignored.

Phase modulators may use lumped electrode design as EAMs. However, to modulate the light more efficiently, a traveling-wave configuration is often adopted. In traveling-wave configurations the electrodes are placed along the optical waveguide, and the velocity of the driving electrical wave is designed to match the velocity of the optical wave. This way, the light not only experiences phase change at one local position but accumulates it along the waveguide, and the modulation efficiency can be improved. An exemplary structure of the traveling-wave layout is shown in Fig. 5.13. Traveling-wave phase modulators typically have half-wave voltages of 3–5 V.

5.2.4 Mach–Zehnder Modulator (MZM)

Phase modulators can be used to construct power/amplitude modulators. A very popular type of amplitude modulator is the MZM.

A simple Mach–Zehnder interferometer (MZI) structure is shown in Fig. 5.14. The MZI splits the light into two arms and, after phase modulating one of the arms, recombines the two paths at the output. In this example, the two arms have exactly the same length, and the upper interferometer arm incorporates a phase modulator to add extra phase relative to the other arm. By writing the extra phase term as $e^{j(\pi/V_\pi)V(t)}$, the optical field C at the output can be expressed as

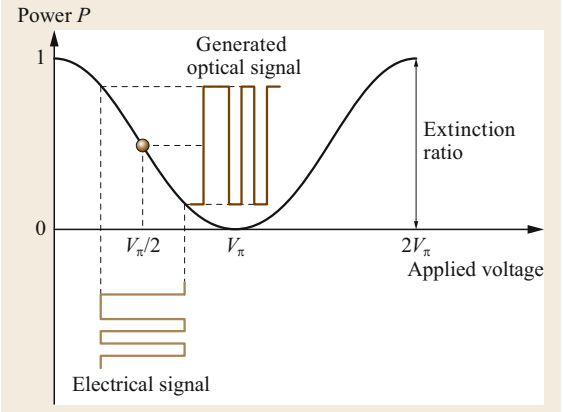

Fig. 5.15 The power transfer function of an MZM. The *vertical axis* is the MZM's output optical power normalized to the input optical power

$$C = \frac{1}{2}Ae^{j\omega_c t}\left(e^{j\frac{\pi}{V_\pi}V(t)} + 1\right) \tag{5.3}$$

and the optical power can be written as

$$P = |C|^2 = \frac{1}{2}A^2\left\{\cos\left[\frac{\pi}{V_\pi}V(t)\right] + 1\right\}. \tag{5.4}$$

It can be seen from (5.4) that the optical power can be modulated by the electrical voltage $V(t)$. The relationship between the optical power P and the electrical voltage $V(t)$ is known as the power transfer function of the modulator. This power transfer function is shown in Fig. 5.15. The power transfer function of an MZM is sinusoidal.

Theoretically, an MZM can have an infinite extinction ratio, as the minimum power should be zero when the two arms of the MZM are perfectly balanced. In practice, the extinction ratio is finite due to factors such as fabrication errors resulting in incomplete extinction. A typical telecommunication MZM has an extinction ratio between 25 and 35 dB.

An important property of an MZM is its operating point. This operating point is the point on the transfer curve around which the modulation signal $V(t)$ is

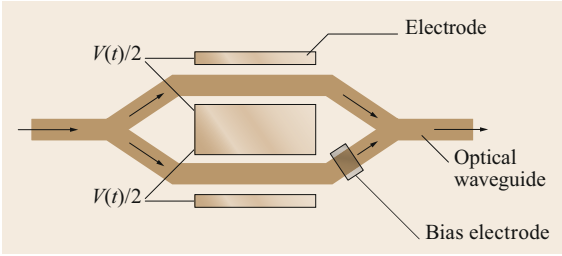

Fig. 5.16 Schematic structure of an MZM

applied and is controlled by a bias voltage. The bias voltage is a DC voltage that is added via an additional pair of lumped electrodes on one of the MZM arms, as shown in Fig. 5.16. The DC voltage induces an extra phase shift φ_{bias} to one of the MZM arms, as described in (5.5), thus shifting the operating point. The purpose of shifting the operating point is to operate the MZM in a desired region within its sinusoidal transfer function. For example, according to the power transfer function shown in Fig. 5.15, operation around $V_\pi/2$ gives the maximum linear power modulation range

$$P = |C|^2 = \frac{1}{2}A^2\left\{\cos\left[\frac{\pi}{V_\pi}V(t) + \varphi_{\text{bias}}\right] + 1\right\}. \tag{5.5}$$

As the $V_\pi/2$ bias voltage induces a 90° (a quarter of 2π rad) relative phase delay between the two arms, this bias point is known as *quadrature bias point*. The quadrature bias point is typical for client-side MZMs used for simple optical power modulation. A different bias point is needed for line-side MZMs for generation of more advanced modulation, as will be explained shortly.

In practice, inserting a phase modulator in only one of two the arms would result in a modulation chirp (this is not explained in this chapter but can be found in [5.15, 16]). In order to avoid this, most practical MZMs have phase modulation on both upper and lower arms. By applying equal voltages on the two phase modulators, the electric field in the two arms undergo phase shifts of equal magnitude. The relative phase offset between the two arms can be controlled by the DC bias, resulting in the sinusoidal transfer function. Operation of the MZM with equal drive voltages but with opposite signs is known as a push–pull operation, an intrinsically chirp-free condition. For example, if $V(t)/2$ and $-V(t)/2$ are the voltages applied to the upper and lower arms, respectively (Fig. 5.16), the optical field generated (normalized to the input CW frequency) can then be expressed as

$$C_{\text{Norm}} = \frac{1}{2}A\left(e^{j\varphi_{\text{bias}}}e^{j\frac{\pi}{V_\pi}\frac{V(t)}{2}} + e^{-j\frac{\pi}{V_\pi}\frac{V(t)}{2}}\right). \tag{5.6}$$

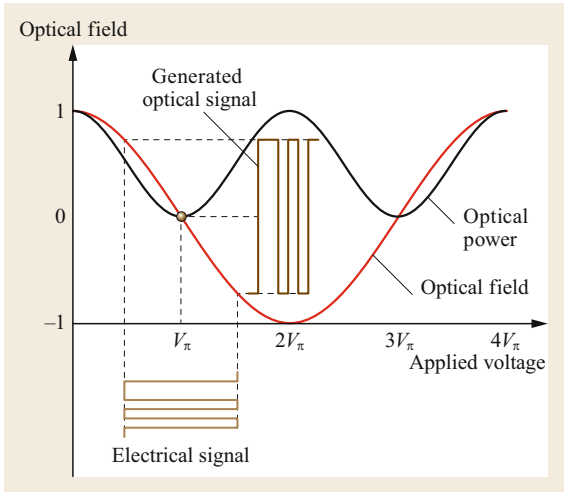

Fig. 5.17 Optical field and power transfer function of an MZM biased at null position. The *vertical axis* is the output optical field normalized to input optical amplitude

For the bias phase φ_{bias}, only the relative phase between the two arms matters, and we can rewrite (5.6) as

$$\begin{aligned} C &= \frac{1}{2}A\left(e^{j\frac{\varphi_{\text{bias}}}{2}}e^{j\frac{\pi}{V_\pi}\frac{V(t)}{2}} + e^{j-\frac{\varphi_{\text{bias}}}{2}}e^{-j\frac{\pi}{V_\pi}\frac{V(t)}{2}}\right) \\ &= A\cos\left(\frac{\pi}{V_\pi}\frac{V(t)}{2} + \frac{\varphi_{\text{bias}}}{2}\right). \end{aligned} \tag{5.7}$$

As the modern optical transmitter modulates the optical field, and the coherent receiver also recovers the field, it is more important to understand the MZM's field transfer function rather than the power transfer function. The field transfer function describes the relationship between the optical field and the electrical driving voltage. For instance, (5.3) (with normalization to input CW frequency) is the field transfer function for the MZM shown in Fig. 5.14. It is a complex-valued function, and its dependence on the driving voltage is difficult to depict in two dimensions. However, with (5.7), the field transfer function becomes real valued and can easily be plotted as shown below (Fig. 5.17). For comparison, the optical power is also plotted in Fig. 5.17.

It can be seen that the best linear range for field modulation is achieved when operating around V_π. This is the bias point that line-side MZMs use. As this bias voltage corresponds to zero optical power when there is no electrical signal, the bias position is also known as the *null bias position*.

Most MZMs used in optical transponders are typically $LiNbO_3$ MZMs. The optical waveguide in those MZMs is made via ion diffusion, and the waveguide is usually bulky (> 5 cm long). The driving electrodes have to be placed far from each other, resulting in less

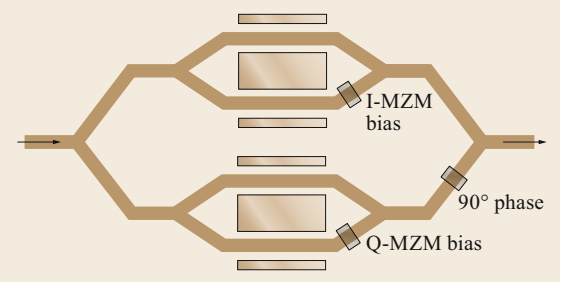

Fig. 5.18 Schematic structure of an I/Q modulator

efficient modulation at high frequencies. Such $LiNbO_3$ MZMs typically have a 3 dB bandwidth of ≈ 35 GHz and a V_π of ≈ 3.5 V [5.17]. There are new MZMs using thin-film $LiNbO_3$ that have a much higher refractive index, and the electrodes can be placed closer, which offers ultra-high modulation bandwidth. Research demonstrations have shown thin-film based $LiNbO_3$ MZMs with 3 dB bandwidths beyond 100 GHz and a V_π voltage of about 4 V [5.18]. Ultra-high speed modulators have also been demonstrated on other platforms such as InP [5.19] and silicon-organic hybrid materials [5.20].

5.2.5 Dual-Polarization I/Q Modulators

So far, we have mostly discussed optical power/amplitude modulators. However, a light wave, like all other electromagnetic waves, is characterized not only by amplitude but also by phase. The amplitude and phase are two orthogonal dimensions and can be multiplexed to encode more information onto one light wave (more information can be found in [5.21–24]). The amplitude and phase can also be represented as the real and imaginary parts of the complex field. The real and imaginary parts are known as sine and cosine components, or alternatively, in-phase and quadrature (I/Q) parts of the optical field.

A modulator that modulates the in-phase and quadrature parts of the optical field is known as an I/Q modulator. (*Nested MZM*, *vector modulator*, and *Cartesian modulator* are some other names used to describe the I/Q modulator.) The I/Q modulator consists of two MZM-based amplitude modulators for modulating the real and imaginary parts, and the modulated light from the two MZMs are combined with a 90° phase difference to form the complex field. The architecture of an I/Q modulator is shown in Fig. 5.18. Besides the two bias electrodes for the two MZMs, there is a third electrode on one of the MZM outputs to adjust the 90° phase for the field.

Like the I and Q parts, the two orthogonal polarizations of an electric field can also be used for information encoding. To modulate the optical field on both polarizations, dual-polarization I/Q modulators are needed. Dual-polarization I/Q modulators are made by splitting the optical carrier and modulating two independent complex streams via two I/Q modulators, and then combining the two modulated fields via a polarization beam combiner (PBC). A schematic architecture of a dual-polarization I/Q modulator is shown in Fig. 5.19. Such dual-polarization I/Q modulators are used in advanced line-side optical transponders.

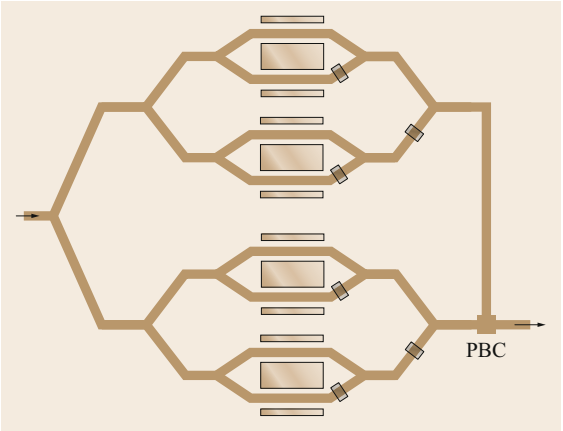

Fig. 5.19 Schematic structure of a dual-polarization I/Q modulator

5.2.6 Figure of Merits of a Modulator

In addition to the bandwidth (BW) and the V_π, the insertion loss (IL) and the footprint are also important figures of merit that characterize modulators for an optical transponder. The IL includes the optical waveguide propagation loss and fiber coupling loss. The insertion loss is measured by comparing the input and output light power when the modulator is biased for maximum transmission. An acceptable insertion loss is ≈ 5 dB.

In traditional commercial line-side optical transmitters, bulk $LiNbO_3$ modulators are used. They have 3 dB bandwidths around 35 GHz and have been used for 100, 200, and 400 Gb/s data modulation. The device length of the such modulators is typically 5−7 cm. To reduce the footprint and to increase the bandwidth, modulators that are fabricated on other platforms or with different materials are being investigated. For instance, thin-film $LiNbO_3$ modulators have been demonstrated with very high bandwidths [5.18]. Modulators made with InP and SiPh technologies offer a very small footprint [5.25, 26], and commercial products are available. A comparison of the characteristics of the different modulator technologies is shown in Table 5.1. The values shown in this table are typical, as quoted from the references, and are constantly being improved.

Table 5.1 Comparison of different technologies for phase modulators and MZMs

	3 dB bandwidth (GHz)	V_π (V)	Insertion loss (dB)	Length (cm)	Reference
$LiNbO_3$	≈ 35	≈ 3.5	≈ 5	≈ 5	[5.27]
Thin-film $LiNbO_3$	≈ 100	≈ 4.4	0.5[a]	0.5	[5.18]
InP	> 70	≈ 1.5	≈ 9	0.8	[5.25]
SiPh	≈ 25	≈ 5	≈ 6[a]	0.4	[5.26]

[a] On-chip insertion loss (fiber coupling loss) is not reported. (The other two insertion losses reported in this table include both fiber coupling loss and in-chip loss.)

5.3 Photodetectors

A photodetector (PD) converts an optical signal into an electrical signal via the process of photon absorption followed by electron–hole pair generation. There are several types of PDs, including the Schottky-barrier (SB) diode, the metal-semiconductor-metal (MSM) photodiode, the p-i-n photodiode, the avalanche photodiode (APD), and the heterojunction phototransistor (HPT). The most commonly used PD in optical transponders is the p-i-n photodiode. Common semiconductor material(s) used to fabricate the p-i-n photodiode are silicon (Si), GaAs, germanium (Ge), InP, and indium gallium arsenide (InGaAs). The material characteristics determine the photodiode's spectral response. Generic performance metrics of a photodiode include responsivity, bandwidth, dark current, and nonlinearity.

The responsivity is an expression that reflects how efficiently the PD can convert the optical power into electrical current. In other words, the responsivity is defined as the ratio of this photocurrent divided by the total incident light power falling upon the PD. The symbol for responsivity is R, and the unit is Ampere/Watt. The responsivity of the PD for each of the different materials listed above is typically a function of the wavelength (of frequency) of the incident optical signal.

The bandwidth of a PD defines how fast it responds to a time-varying incoming optical signal. When a light pulse impinges on a PD, the time needed for the photocurrent to go from 10 to 90% of the final output is defined as the response time. In frequency domain, the frequency at which the detected RF power drops to half its value at zero frequency is termed the 3 dB bandwidth of the PD. The response parameters strongly depend on the physical dimensions of the PD to a first order, as they determine the device parasitics such as capacitance, resistance, and transit time. Higher-bandwidth devices would generally be smaller in size.

As the PD has a junction (a p-n junction in the semiconductor case), the imperfections at the junction result in a leakage current. This current flowing through a PD even in the absence of light is termed dark current. The unit of dark current is A. The dark current manifests itself as noise and degrades the detection process. All well-designed PDs have dark currents in the pA to nA range. The frequency domain representation of the dark current is known as the noise spectrum of the PD.

Nonlinearity is a measure of the response (specifically the responsivity) of the PD as a function of the incident optical power (or incident photons) at a given modulation frequency. When the incident optical power is small, the response is generally linear. However, when the incident power is large, the large number of photon-generated carriers build up a space charge within the PD, resulting in a saturation of the response. The onset of saturation depends on the device structure and the frequency of the modulated signal. Generally, p-i-n photodiodes are more linear than APDs, where the multiplication process introduces nonlinearity in the response.

5.3.1 Normal-Incidence PIN Photodiodes

In Fig. 5.20, the p-i-n photodiode is a p-doped semiconductor and an n-doped semiconductor with an intrinsic

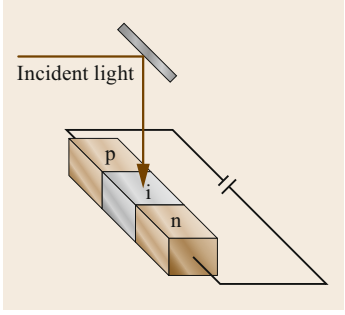

Fig. 5.20 Schematic structure of a normal-incident p-i-n photodiode

layer of the semiconductor sandwiched between them. A reverse bias is applied to the p-n junction, providing an electric field that sweeps out the photo-generated carriers to the contacts, where it appears as photocurrent.

In a conventional PD design, the light enters perpendicular to the semiconductor surface (Fig. 5.20) passing through the substrate. Such light coupling is called normal-incidence coupling. Absorption of light in normal-incidence PDs takes place in the thin intrinsic layer. High-speed response of these PDs is obtained by reducing the thickness of the intrinsic region (so that the carrier transit time can be minimized). However, this comes at the expense of two impairments. The capacitance of the PD increases when the intrinsic layer thickness is reduced, resulting in an RC limited frequency response. In addition, the volume for light absorption is reduced, resulting in a decrease in the responsivity. As a result, normal-incidence PDs have an inherent tradeoff between the responsivity and the bandwidth [5.28]. A responsivity of 0.5 A/W with a 50 GHz bandwidth is typical for such a PD.

5.3.2 Waveguide PIN Photodiodes

A method to circumvent the responsivity-bandwidth tradeoff seen in normal incidence PDs is to partially decouple the responsivity from the device parasitics. This is achieved using waveguide coupled p-i-n PDs. Bandwidths higher than 50 GHz have been demonstrated using such a waveguide coupling structure [5.29–31]. A waveguide PD utilizes an input optical waveguide with embedded absorbing layers, as shown in Fig. 5.21. The light is absorbed when it propagates through the intrinsic layer. The propagating length in such devices can be made much larger than the thickness of the intrinsic layer in a normal incidence PD, resulting in large responsivity. At the same time, the thickness of the waveguide layer can be designed to be small to reduce the transit time of the photon-generated carriers, within some bounds. The combined design approach minimizes the bandwidth-responsivity tradeoff seen in normal incidence PDs, yielding higher bandwidth PDs. Waveguide PDs with 3 dB bandwidths greater than 100 GHz and with responsivity of about 0.5 A/W have been demonstrated.

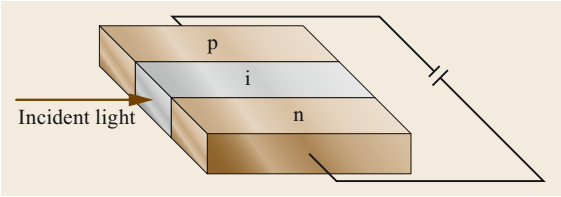

Fig. 5.21 Schematic structure of a waveguide photodiode

5.3.3 Avalanche Photodiodes (APD)

The APD is a special case of the p-i-n PD where one of the photo-generated carriers (usually electrons) is accelerated by a strong electric field to result in a multiplication, leading to an avalanche of carriers. The APD thus provides gain as compared to a simple p-i-n PD through the avalanche multiplication process. An APD is typically operated near its reverse bias break-down voltage (for a high electric field) to realize gains between 5 and 10 (in linear units). APDs are generally used where high receiver sensitivity is needed.

5.4 Transmitter Hardware

An optical transmitter, as shown in Fig. 5.22, comprises a laser that generates a light beam and a dual-polarization I/Q modulator for imprinting the information onto the light beam. The information, before optical modulation, is represented by electrical voltages. The voltages are generated by DACs, which receive the information from the DSP engine. There are linear RF amplifiers between the DACs and the modulator to amplify the DAC output (which is less than 1 V) to the modulator's required voltage (3–5 V). The laser is typically an ECL as described in Sect. 5.1. The dual-polarization I/Q modulator has the same architecture as described in Sect. 5.2.5. In this section, we explain the DACs and their drivers.

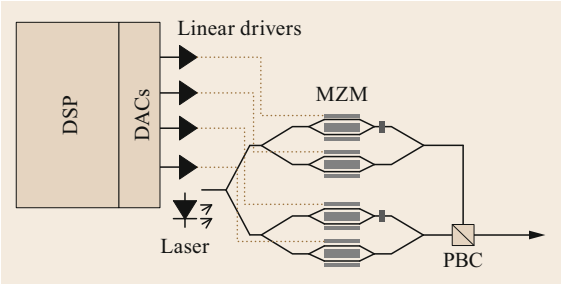

Fig. 5.22 Schematic architecture of an optical transmitter for the line side

5.4.1 Digital to Analog Converters (DAC)

A DAC converts a finite-precision number into a physical quantity. In the telecommunications context, a DAC converts a finite-precision binary series to a continuously time-varying voltage. In modern optical communications, DACs are the key to the generation of arbitrary electrical waveforms that are needed for advanced multilevel modulation formats.

To understand DACs, we start with the simple 2 bit DAC shown in Fig. 5.23a. To represent a ramp signal, e.g., the dashed waveform shown in Fig. 5.23b, we can describe the waveform (at each time instance) as two binary values (Fig. 5.23c). The 2 bit DAC will take two values (D_0 and D_1) at a time and convert them to a voltage. The voltage is generated and held until the next voltage is produced. An example of the 2 bit DAC generated ramp signal is shown as the solid line in Fig. 5.23b. As this DAC uses 2 bit at a time to produce one voltage, it has a digital-to-analog conversion resolution of 2 bit.

Typical DACs in deployed line-side transmitters have resolution from 6 to 8 bit. The more resolution a DAC has, the better it can represent an arbitrary waveform. A limited number of bits results in quantization noise. The quantization noise is a fundamental digital-to-analog conversion noise, representing the information loss when using finite-precision binary numbers to represent an arbitrary waveform. The more quantization bits a DAC has, the lower the quantization noise. Besides the quantization errors, there are other noise and distortions in a DAC that are induced by electronic circuits. Such noise and distortions, along with the fundamental quantization noise, lead to the definition of the effective number of bits (ENOB). The ENOB is the equivalent number of bits for practical DACs that includes quantization noise and electric circuit-induced noise and distortions. Typical ENOB values range between 5 and 6 bit. The ENOB is also frequency dependent, as electronic circuit noise changes with frequencies. In general, ENOB decreases with frequency.

Besides the resolution, the sampling speed is another figure of merit of DACs. The sampling speed tells how fast the DAC can generate a new voltage. In the example shown in Fig. 5.23, the DAC can generate a new voltage every Δt seconds. This means the sampling rate of the DAC is $Sa = 1/\Delta t$ samples/s (Sa/s). According to the sampling theorem [5.32, 33], the sampling rate Sa bounds the highest possible analog bandwidth of the DAC ($Sa/2$ Hz for this example). Quite often, instead of the sampling rate, the electronic circuits are more likely to limit the actual bandwidth. Practical DACs realized from complementary metal oxide semiconductor (CMOS) technologies generally have 3 dB bandwidths that are smaller than $Sa/2$.

DACs with a higher sampling rate usually have lower resolutions due to the challenges in electronic circuit design for higher frequencies. For example, DACs with a sampling speed lower than 10 GSa/s can have more than 10 bit resolution. DACs that are being used in line-side transponders, which operate at $\approx$ 100 GSa/s, usually have a nominal resolution of 8 bit and an ENOB of 5–6 bit. For commercially available CMOS-integrated DACs, the 3 dB bandwidths are usually around 20 GHz. Signals with more than 20 GHz bandwidth can still be generated with such DACs if proper pre-emphasis via digital signal processing is used, at the expense of ENOB. Silicon germanium (SiGe)-based DACs can have a higher speed, e.g., with a 3 dB bandwidth of $\approx$ 40 GHz. In laboratory demonstrations where discrete components (binary sources, electrical multiplexers, etc.) are used, DACs can have sampling rate of up to 204 GSa/s with 1 bit resolution [5.34, 35]. Comparable sampling speeds but higher resolutions can be achieved via electrical frequency multiplexing. With such multiplexing (also referred to as the digital band interleaving technique), DACs with a sampling rate of 240 GSa/s and a bandwidth of 100 GHz with a nominal resolution of 8 bit can be achieved [5.36, 37].

Besides the bandwidth and resolutions, there are other figures of merit associated with DACs, such as the spurious-free dynamic range, signal-to-noise ratio, and

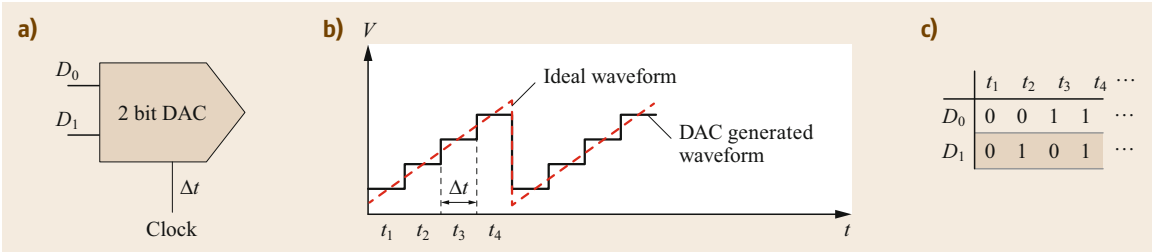

Fig. 5.23a–c An example of a 2 bit DAC. **(a)** Schematic diagram for a 2 bit DAC. **(b)** example of an ideal ramp signal, and a 2 bit DAC generated ramp signal. **(c)** description of the ramp signal in the form 2 binary bits

quantization errors, all of which are extensively treated in textbooks [5.38, 39].

5.4.2 Linear Driver Amplifier

Linear RF amplifiers between the DACs and the optical modulator amplify the DAC output voltage to the voltage required to drive the modulator. The typical gain of these drivers is $\approx 20\,\mathrm{dB}$. Linearity is an important aspect for these drivers, as the waveforms generated from the DACs are arbitrary with many levels, and the amplifiers should preserve the characteristics of the waveforms. Departure from linearity would result in distortions that are passed on to the modulated optical signal. In the case that the amplifiers are not linear enough, mitigation is possible in the DSP engine that precedes the DAC, albeit at the expense of the available DAC resources (dynamic range, ENOB, etc.).

As described in Sect. 5.2.5, the dual-polarization I/Q modulator, typically used for line-side signal generation, has four MZMs and requires four input RF waveforms (namely, Ix, Qx, Iy, and Qy). Therefore, four-in-one linear driver arrays are commonly used for such applications. The quad-drivers must have well-matched characteristics such as gain, analog bandwidth, and noise figure. The ability to control the gain of each driver is also important for the optimization of the symmetry of the I–Q constellations.

5.5 Coherent Receiver Hardware

The modern optical modulator modulates both amplitude and phase of the light, as we learnt in Sect. 5.2.5. This requires the receiver to be capable of recovering both the amplitude and phase. However, one PD with power detection squares the received optical field $C_{\mathrm{SIG}} = A\mathrm{e}^{\mathrm{j}\varphi}\mathrm{e}^{\mathrm{j}\omega_{\mathrm{c}}t}$ as

$$E = |C_{\mathrm{SIG}}|^2 = \left|A\mathrm{e}^{\mathrm{j}\varphi}\mathrm{e}^{\mathrm{j}\omega_{\mathrm{c}}t}\right|^2 = A^2\,, \tag{5.8}$$

where ω_{c} is the angular frequency of the optical carrier; A and φ are, respectively, the amplitude and phase of the modulated light. Both A and φ contain information and need to be recovered at the receiver. It can be seen that single PD power detection captures only the power/amplitude of the light and loses the phase information. To receive the phase information, various receivers can be implemented. For instance, one can encode the signal differentially at the transmitter and use a 1 bit delay receiver at the receiver. One can also use self-coherent receivers where CW light is transmitted with the signal and is used to mix with the signal at the receiver to recover the phase.

More conveniently, for high-speed optical transponders, coherent receivers are used. The coherent receiver uses an optical local oscillator (OLO) $C_{\mathrm{LO}} = R\mathrm{e}^{\mathrm{j}\omega_{\mathrm{LO}}t}$ to mix with the signal. The mixed light is detected by the PD,

$$\begin{aligned} E &= \left|\frac{C_{\mathrm{SIG}} + C_{\mathrm{LO}}}{\sqrt{2}}\right|^2 \\ &= \frac{R^2}{2} + \mathrm{Re}\left(RA\mathrm{e}^{\mathrm{j}\varphi}\mathrm{e}^{\mathrm{j}\Delta\omega t}\right) + \frac{A^2}{2}\,, \end{aligned} \tag{5.9}$$

where R and ω_{LO} are the amplitude and angular frequency of the OLO. The instantaneous phase of the OLO is ignored for simplicity; $\Delta\omega = \omega_{\mathrm{c}} - \omega_{\mathrm{LO}}$ is the angular frequency difference of the signal carrier and the OLO; $\mathrm{Re}(\cdot)$ stands for the real part of a complex number. The factor $1/\sqrt{2}$ is brought by a 3 dB power loss from an optical coupler. In (5.9), the first term is a DC term that is easy to remove using a DC block, and the second term is the signal of interest. The third term is a square of the signal and is an unwanted term. Note that the third term is a broadband distortion and spectrally overlaps with the signal of interest, thus can not be removed by a DC block. Keeping the power of the OLO much larger than the signal, the second term will dominate over the third term.

In this section, we start with the simplest coherent receiver that realizes (5.9). We then describe more complex versions of coherent receivers that can improve the performance. In the end, we will explain coherent receivers being used in most advanced coherent transponders.

5.5.1 2×2-Coupler-Based Coherent Receivers

Combining an OLO with the signal can be realized by a simple 2×2 optical coupler followed by a PD (Fig. 5.24), and is known as a 2×2-coupler-based coherent receiver. A PD placed at one output of the coupler performs the detection, while the second output can be used to provide feedback for phase locking the OLO to the incoming signal.

Adding a second PD at the other output and combining the two PDs outputs in a differential manner, as shown in Fig. 5.25, can remove the first and third term of (5.9), leaving only the second term (with twice the magnitude compared to (5.9)) yielding a better per-

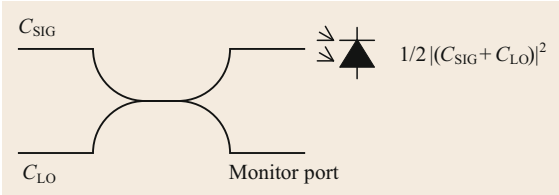

Fig. 5.24 Schematic architecture of a 2×2-coupler-based coherent receiver

formance. With this structure, the power ratio between the OLO and the signal can therefore be reduced compared to the architecture shown in Fig. 5.24. This PD pair is known as a balanced photodetector (BPD). The 2×2 coupler, as it mixes the signal and OLO and produces the second copy of the OLO with a 180° phase shift, can be viewed as a 180° optical hybrid

$$E = \left|\frac{C_{SIG}+C_{LO}}{\sqrt{2}}\right|^2 - \left|\frac{C_{SIG}-C_{LO}}{\sqrt{2}}\right|^2 = 2\mathrm{Re}\left\{RAe^{j\varphi}e^{j\Delta\omega t}\right\}. \quad (5.10)$$

To explain the required number of PDs and ADCs for the received signal, we rewrite the detected signal in (5.10) as $E = 2RAe^{j\varphi}e^{j\Delta\omega t} + 2RAe^{-j\varphi}e^{-j\Delta\omega t}$. From this expression, it can be seen that the detected signal is composed of the down-converted signal and its conjugate. According to the sampling theorem, given only one ADC, the signal and its conjugate should be spectrally separated to avoid loss of information. This means that the $\Delta\omega$ then has to be larger than half the bandwidth of the signal. In other words, this *spectral separation* means the OLO should be placed outside the signal spectrum. (More explanations on the sampling theorem can be found in the literature [5.28, 29].) Such a type of coherent receiver, with the OLO placed outside the signal spectrum, is known as a *heterodyne receiver*. A heterodyne receiver requires the PD and ADC's bandwidths be equal to (or larger than) the optical signal's bandwidth.

5.5.2 90° Optical Hybrid Based Coherent Receivers

The other way to avoid a loss of information is to use a 90° hybrid plus a pair of lower-speed PDs and ADCs. In this setting, the real and imaginary parts (or I and Q parts) of the complex signal can be received by two separate PDs and ADCs. The 90° hybrid is a special type of coupler that has two input ports and four output ports. As shown in Fig. 5.26, the 90° hybrid mixes the incoming signal with the four quadrature states associated with the OLO. The four mixed signals are, respectively, $(C_{SIG}+C_{LO})/2$, $(C_{SIG}-C_{LO})/2$, $(C_{SIG}+jC_{LO})/2$, $(C_{SIG}-jC_{LO})/2$, and they are grouped into two pairs and sent to two BPDs. The output of the two BPDs, E_1 and E_2, can be expressed as the following

$$E_1 = \left|\frac{C_{SIG}+C_{LO}}{2}\right|^2 - \left|\frac{C_{SIG}-C_{LO}}{2}\right|^2 = 2\mathrm{Re}\left\{RAe^{j\varphi}e^{j\Delta\omega t}\right\}, \quad (5.11)$$

$$E_2 = \left|\frac{C_{SIG}+jC_{LO}}{2}\right|^2 - \left|\frac{C_{SIG}-jC_{LO}}{2}\right|^2 = 2\mathrm{Im}\left\{RAe^{j\varphi}e^{j\Delta\omega t}\right\}, \quad (5.12)$$

where $\mathrm{Im}\{\cdot\}$ stands for the imaginary part of a complex value. It can be seen that the two BPDs receive the real and imaginary parts of the optical field. In this case, $\Delta\omega$ is close to zero, and this type of coherent receiver is known as an intradyne receiver. In a very special case, when the $\Delta\omega$ equals zero, the receiver is called the homodyne receiver.

5.5.3 Polarization-Diversity Coherent Receiver

In the approach described earlier, the signal was considered to have one polarization state. For efficient mixing, the OLO's polarization must be aligned with that of the signal. One can use a feedback mechanism to track the signal polarization and tune the OLO accordingly. Such tracking is usually fairly complex. An alternate option is to extend the coherent receiver design to a polarization diversity design, as shown in Fig. 5.27. With this approach, there is no need to track the polarization states. Moreover, such a receiver is even capable of receiving polarization-multiplexed signals.

As shown in Fig. 5.27 in a polarization diversity coherent receiver, a polarization beam splitter (PBS) splits the incoming signal into the two orthogonal polarizations (namely, x and y), while a 3 dB coupler splits the

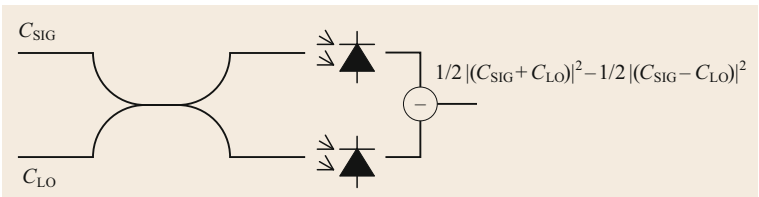

Fig. 5.25 Schematic architecture of a 2×2-coupler-based coherent receiver with a balanced photodetector

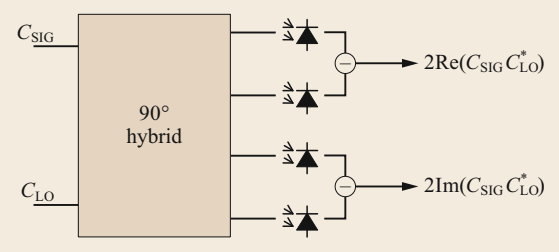

Fig. 5.26 Schematic architecture of a 90° hybrid based coherent receiver

OLO into two copies. Two sets of 90° hybrids are then used to recover the x and y electric fields, respectively. The two sets of the hybrid, the PBS and the OLO power splitter, together are known as the *polarization diversity hybrid*. This hybrid has eight output ports, four for each polarization. A total of four BPDs (eight PDs) in addition to their amplifiers complete the receiver's optical-to-electrical (O/E) front-end.

It is important to mention that this polarization diversity coherent receiver is capable of receiving all four multiplexing dimensions (namely, two quadratures and two polarizations) of an optical signal. This is then the universal coherent receiver that is used to recover any type of information encoding of the optical field.

5.5.4 Transimpedance Amplifier (TIA)

The electrical signal at the output of a BPD (or a PD as the case may be) is typically small. The BPD is usually followed by a low-noise electronic amplifier to raise the electrical signal to a sufficient level for ADCs. This amplifier transfers the detected photocurrent I_{ph} from PDs into a proportionate output voltage V_{pp}, and is known as a transimpedance amplifier (TIA). A TIA is characterized by its transimpedance Z, given by $Z = V_{pp}/I_{ph}$. Typical values for Z are in the range from 1 to 3 MΩ. TIAs also typically have automatic gain control (AGC) to allow for delivering a fixed output voltage independent of the input optical power to the photodiode. Since the PDs are linear in detecting multilevel waveforms (as described in Sect. 5.3), the following electrical amplifiers should also preserve that linearity. TIAs are also characterized by their gain, bandwidth, and electronic circuit noise. Typical TIAs that are used in coherent optical receivers have bandwidth of 30–40 GHz.

5.5.5 Analog to Digital Converter (ADC)

The signal detected by the coherent receiver is an analog signal that needs to be digitized and then digitally processed to recover the encoded information. ADCs are the devices that convert the analog signals to digital signals. This device essentially performs the reverse function of the DAC described in Sect. 5.4.1. It converts a continuous-time and continuous-amplitude analog signal to discrete-time and discrete-amplitude digital samples. Similar to the DACs, the main characteristics of ADCs are the sampling rate, analog bandwidth, and ENOB. For a coherent receiver, four channel ADCs are integrated on a single chip, allowing for synchronized reception.

CMOS-integrated ADCs nowadays typically have ≈ 128 GSa/s sampling rate with 8 bit nominal resolution. Higher speeds have been achieved with other technologies such as InP. For instance, InP-based ADCs in the form of real-time sampling scope can have

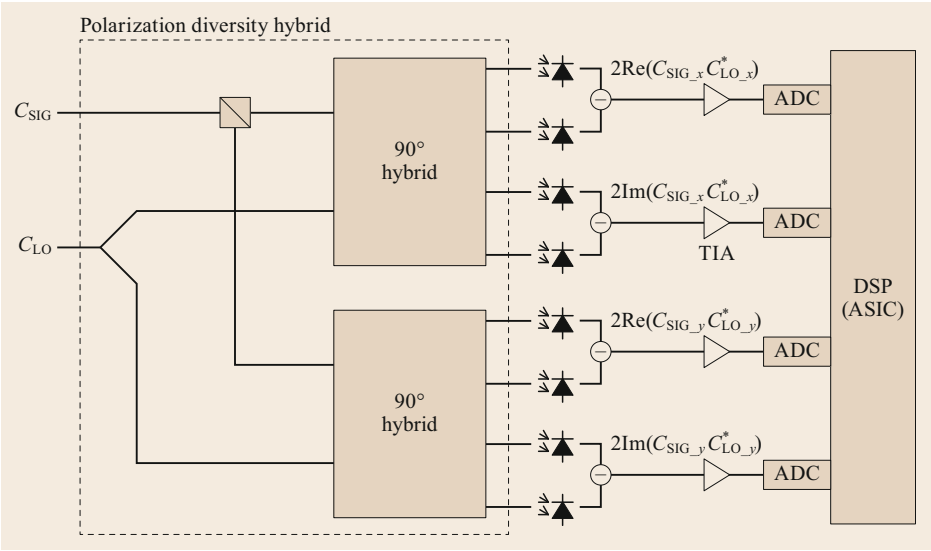

Fig. 5.27 Schematic architecture of a 90° hybrid based coherent receiver with polarization diversity

256 GSa/s with nominal bits of 8 and an ENOB of ≈ 6 bit [5.30]. CMOS ADCs with a digital band interleaving technique and also in the form of real-time sampling scope can have 240 GSa/s [5.33]. More reviews of the ADCs and their role in the signal reception can be found in [5.40].

5.6 Integrated Transmitters and Receivers

When the optical transmitter and receiver are implemented with discrete components, there are many optical and electrical interfaces. For instance, in an optical transmitter, there are 3 optical interfaces (laser output, modulator input, and modulator output) and at least 16 RF interfaces (4 DAC outputs, 4 driver inputs, 4 driver outputs, and 4 modulator inputs). In a polarization diversity coherent receiver, there are a total of 18 optical interfaces (2 optical hybrid inputs, 8 hybrid outputs, and 8 PD inputs). This large number of optical and RF interfaces makes the task of minimizing impairments (reflections, delay mismatch, and bandwidth loss) very challenging when the system is operating at high speed. These impairments degrade the transponder's ability to transmit/recover complex modulation formats with good performance. A few of these impairments, such as delay mismatch could be precompensated in the DSP engine. Reflections and bandwidth loss are difficult to address without sacrificing complexity and energy. However, when all the components are integrated in a small form factor, and the number of interfaces are minimized, these impairments can be mitigated to a great extent. Integrated coherent transmitters (ICT) and integrated coherent receivers (ICR) are typically realized via one of three available technologies. These are all-InP technology, micro-optics with InP technology, and silicon photonics (SiPh) technology with external laser sources. More information about these technologies can be found in papers and textbooks [5.41–43].

The integrated transceivers are packaged into a small-form factor module. Modern line-side optical transponders use C form-factor pluggable (CFP) modules. The CFP is a multisource agreement to produce a common form-factor for the transmission of high-speed digital signals. There are a number of variations of CFP, including CFP, CFP2, and CFP4. Among them, the CFP2 module is being used for 100 Gb/s and 200 Gb/s transceivers. It measures 41.5 mm (width) × 12.4 mm (height) × 107.5 mm (depth) and allows for a maximum of 12 W power usage. The CFP2 module can be a complete coherent transceiver that has the analog front-end and DSP module. This kind of CFP2 transceiver is called CFP2-DCO, where the DCO stands for *digital coherent optics*. The CFP2-DCO can be plugged into a slot that is designed for a CFP and communicates through the socket with digital signals. A CFP2 module can include only the analog parts and not have a DSP module. This type of module is called the CFP2-ACO, where ACO stands for *analog coherent optics*. The CFP2-ACO communicates with the circuit board by sending analog signals across a special connector, and the DSP engine resides outside the CFP2 module.

xi.v.chen@nokia-bell-labs.com

Xi Chen received her PhD degree in 2012 from The University of Melbourne, Australia. From 2013 to 2015, Dr Chen was a Research Fellow at The University of Melbourne, where she received the Discovery Early Carrier Research Award (DECRA) grant. Dr Chen is currently a Member of Technical Staff in Nokia Bell Labs, New Jersey. Her research interests include fiber transmission and advanced digital signal processing for high-speed optical systems.

Sethumadhavan Chandrasekhar

Optical Transmission Research
Nokia Bell Labs
Holmdel, NJ, USA
s.chandrasekhar@ieee.org

Dr S. Chandrasekhar joined Nokia Bell Labs in 1986. He initially worked on semiconductor devices and optoelectronic integrated circuits (OEICs). Since 1999, he has been involved in WDM optical networking research at 100Gb/s and beyond. His current interests include coherent optical transmission systems for high spectral efficiency transport, multicarrier superchannels, and software-defined transponders for efficient end-to-end optical networking.

6. DSP for Optical Transponders

Seb J. Savory, David S. Millar

This chapter outlines the principles of the digital signal processing (DSP) used in modern optical transceivers. The historic developments that have led to the emergence of DSP being applied in optical transceivers is reviewed, including the high-speed complementary metal oxide semiconductor (CMOS) analog to digital converters (ADC) that have facilitated the creation of the application-specific integrated circuit (ASIC) which underpins digital coherent transceivers. Following on from this, the mathematics associated with finite impulse response (FIR) filters is reviewed, including the Wiener and least-squares design of FIR filters. The mathematics associated with the adaptive multiple-input-multiple-output (MIMO) filter employed in the receiver is also discussed, including derivation of the stochastic descent algorithm based on differentiation with respect to a complex vector. Subsequently, we provide an overview of DSP algorithms, before detailing both those required for equalization and synchronization. Following a summary of error correction used in a digital transceiver, we reflect on the current research trends and future opportunities for DSP in optical transceivers.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_6

6.1 Historical Background

The key to realizing digital signal processing (DSP) in optical transceivers has been the development of high-speed analog to digital converters (ADC) that can be realized in CMOS technology. Historically, optical fiber communication systems operated at the technological limits of the electronics available with data encoded as binary intensity modulation at a rate commensurate with the bandwidth of the electronics available. As such, optical line rates were far in excess of those that could be generated or sampled digitally. Consequentially, it seemed unlikely that DSP would be applied to optical fiber communication systems.

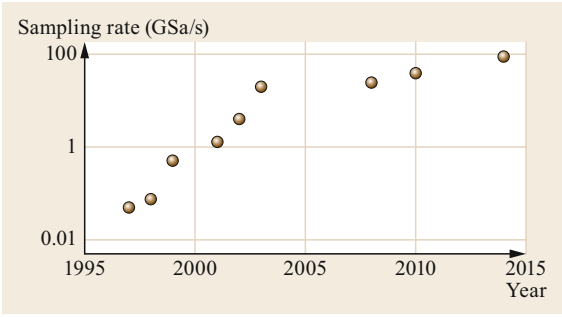

Fig. 6.1 Progress in the maximum CMOS ADC sampling rate reported at the International Solid-State Circuits Conference (ISSCC)

This situation changed significantly at the turn of the century when 40 Gb/s optical systems were being developed. While 40 Gb/s could have been deployed in the early 2000s, the dot com crash delayed commercial deployment by several years, such that the optical line rate stagnated at 10 Gb/s for a decade (from 1997–2007). At the same time, as can be seen in Fig. 6.1, research into CMOS-based ADCs made staggering improvements, with sampling speeds increasing by two orders of magnitude in just 5 years (1997–2002). Critically, in 2003 when 20 GSa/s CMOS ADCs first became available [6.1], it allowed the current 10 Gb/s optical line rate to be digitized. The emergence of high-speed CMOS data converters that could be integrated with the digital signal processing (DSP) into a single application-specific integrated circuit (ASIC) enabled a digital revolution in optical transceiver design.

While DSP was initially applied to the direct detection systems of the time, attention quickly moved toward digital coherent transceivers. Rather than merely directly detecting the power, as in a traditional system, a phase and polarization diverse coherent receiver was employed to linearly detect the electrical field, as illustrated in Fig. 6.2.

As we will discuss in subsequent sections, typically the DSP first equalizes the incoming signal prior to synchronizing the receiver with the transmitter, with

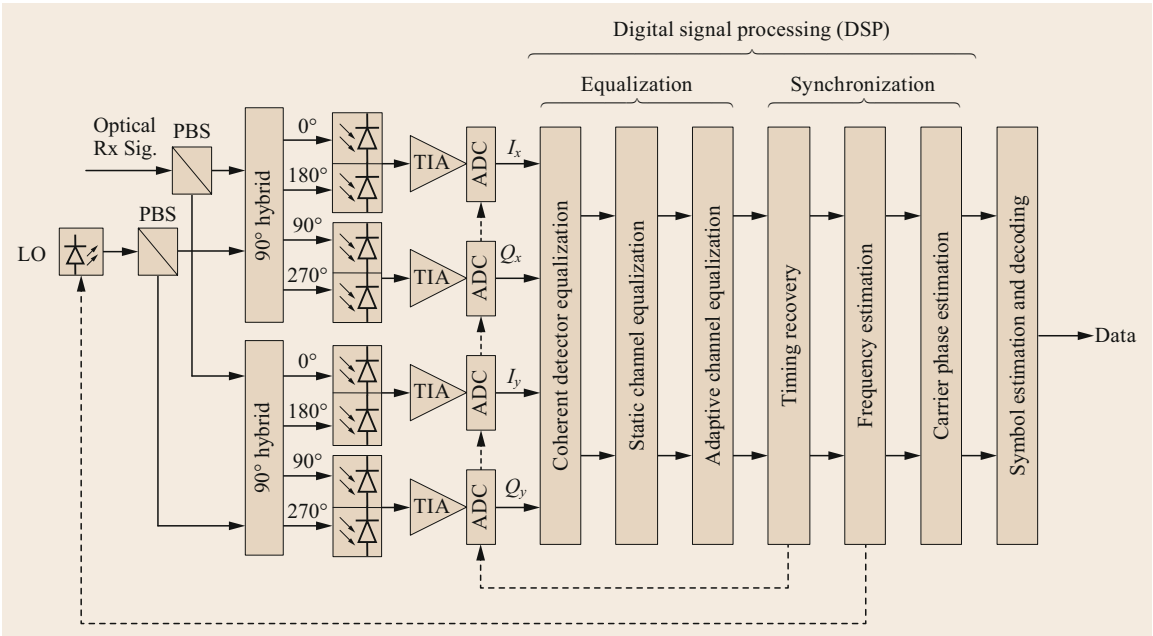

Fig. 6.2 Phase and polarization diverse coherent receiver and associated DSP (TIA: transimpedance amplifier, PBS: polarization beam splitter)

feedback provided to the frequency of the local oscillator laser and the ADC.

The first commercially available digital coherent transceiver emerged in 2008 [6.2], with the Nortel transceiver, which used dual polarization quadriphase shift keying (DP-QPSK) at a line rate of 11.5 GBd to achieve a net data rate of 40 Gb/s. The resulting DSP was realized in a single ASIC using 90 nm CMOS incorporating four 23 GSa/s ADCs with 6 bits of resolution to digitize the 46 Gb/s signal (with the power per bit of resolution reducing from 1.1 W in 0.18 μm CMOS [6.1] to less than 0.5 W in 90 nm CMOS [6.3]). Within a year of the 40 Gb/s product being released a 100 Gb/s product was released in 2009 [6.4], as a dual carrier transceiver with the 46 Gb/s product overclocked at 56 Gb/s, such that from the two carriers a total of 112 Gb/s could be transmitted. This allowed 100 Gb/s coherent transceivers to be realized a year earlier than the single-carrier 100 Gb/s solutions that emerged in 2010 [6.5]. Since then progress has been rapid, with 400 Gb/s systems now commercially deployed and research continuing to 1 Tb/s and beyond.

In this chapter, we will review the DSP currently being applied to optical transceivers. Given the investment required, at present this is limited to coherent transceivers, which will be the focus of this chapter. Nonetheless, as we outline later in this chapter, it seems likely that DSP may progress beyond coherent transceiver to direct detection transceivers. Before going into detail regarding algorithms, we begin by reviewing the underpinning mathematics associated with finite impulse response (FIR) filters that arise in many of the algorithms employed.

6.2 Preliminaries

6.2.1 FIR Filters

A key building block of DSP in optical transceivers is the finite impulse response (FIR) filter. Herein we discuss the underlying mathematics of FIR filters and their optimization (including differentiation with respect to a complex vector). As illustrated in Fig. 6.3, a finite impulse response (FIR) filter is a nonrecursive filter with tap weights $h[n]$, where $n \in \{0, 1, \ldots, N-1\}$, and the time step between taps given by T_s.

In the time domain the taps may be written as

$$h(t) = \sum_{n=0}^{N-1} h[n]\delta(t - nT_s) \,. \tag{6.1}$$

Alternatively, we can write

$$h(t) = \boldsymbol{h}^{\mathrm{T}}\boldsymbol{\delta}_s \tag{6.2}$$

where superscript T denotes the transpose operation and $\boldsymbol{h}$ and $\boldsymbol{\delta}_s$ are defined as

$$\boldsymbol{h}^{\mathrm{T}} = [h[0], h[1].. \, h[N-1]] \tag{6.3}$$

and

$$\boldsymbol{\delta}_s^{\mathrm{T}} = [\delta(t), \delta\,(t - T_s)\,, .. \,\delta\,(t - (N-1)T_s)] \,. \tag{6.4}$$

Hence, the Fourier transform is given by

$$\begin{aligned} H(\omega) &= \int_{-\infty}^{\infty} h(t)\mathrm{e}^{-\mathrm{j}\omega t}\mathrm{d}t = \sum_{n=0}^{N-1} h[n]\mathrm{e}^{-\mathrm{j}n\omega T_s} \\ &= \boldsymbol{h}^{\mathrm{T}}\boldsymbol{e}(\omega)\,, \end{aligned} \tag{6.5}$$

where we have defined

$$\boldsymbol{e}(\omega) = \left[1,\ \mathrm{e}^{-\mathrm{j}\omega T_s}, \mathrm{e}^{-2\mathrm{j}\omega T_s}, \ldots \mathrm{e}^{-\mathrm{j}\omega(N-1)T_s}\right]^{\mathrm{T}} \tag{6.6}$$

and we have assumed throughout this chapter the Fourier transform pair

$$X(\omega) = \int_{-\infty}^{\infty} x(t)\mathrm{e}^{-\mathrm{j}\omega t}\mathrm{d}t \,, \tag{6.7}$$

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)\mathrm{e}^{\mathrm{j}\omega t}\mathrm{d}\omega \,. \tag{6.8}$$

Given the above definitions, if we define $\omega_s = 2\pi/T_s$, it readily follows that since $\mathrm{e}^{-\mathrm{j}nm2\pi} = 1$ for $m \in \mathbb{Z}$, that $H(\omega + m\omega_s) = H(\omega)$ indicating the sampled spectrum is aliased to multiples of the sampling frequency, as expected from sampling theory.

In order to consider the effect of filtering we define an input signal vector $\boldsymbol{x}$ of N samples as

$$\boldsymbol{x}^{\mathrm{T}} = (x[n], x[n-1], .. \, x[n-(N-1)]) \,. \tag{6.9}$$

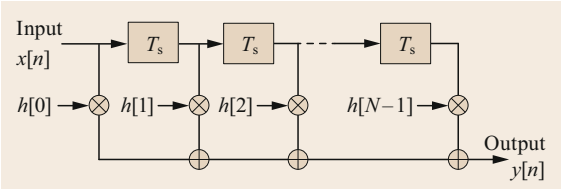

Fig. 6.3 Finite impulse response filter with output $y[n] = \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x} = \sum_{i=0}^{N-1} h[i]x[n-i]$

Then the process of generating an output signal $y[n]$ by filtering an input vector may be written as

$$y[n] = \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x} = \sum_{i=0}^{N-1} h[i]x[n-i]\,, \tag{6.10}$$

indicating that the output is obtained via the discrete time convolution of the input vector with the tap weights. This convolution may be realized in the frequency domain as multiplication, underpinning computationally efficient techniques such as the overlap and save method that we will discuss at the end of this section.

6.2.2 Differentiation with Respect to a Complex Vector

If z is a complex number such that $z = x + \mathrm{j}y$, then we can define differentiation with respect to a complex number as via the Wirtinger derivative given by

$$\frac{\partial}{\partial z} = \frac{1}{2}\frac{\partial}{\partial x} - \frac{\mathrm{j}}{2}\frac{\partial}{\partial y}\,, \tag{6.11}$$

with

$$\frac{\partial}{\partial z^*} = \left(\frac{\partial}{\partial z}\right)^* = \frac{1}{2}\frac{\partial}{\partial x} + \frac{\mathrm{j}}{2}\frac{\partial}{\partial y}\,, \tag{6.12}$$

which in turn gives

$$\frac{\partial z}{\partial z} = 1 \quad \frac{\partial z^*}{\partial z^*} = 1 \quad \frac{\partial z^n}{\partial z} = nz^{n-1}\,, \tag{6.13}$$

which is in keeping with expectations from usual calculus. However, it also follows that

$$\frac{\partial z^*}{\partial z} = \frac{\partial z}{\partial z^*} = 0\,, \tag{6.14}$$

indicating that a complex variable and its conjugate may be considered as independent variables, insofar as differentiation is concerned. If we extend the concept to a vector, such that

$$\frac{\partial}{\partial \boldsymbol{z}} = \frac{1}{2}\frac{\partial}{\partial \boldsymbol{x}} - \frac{\mathrm{j}}{2}\frac{\partial}{\partial \boldsymbol{y}}\,, \tag{6.15}$$

where $\partial/\partial\boldsymbol{x} = (\partial/\partial x_0, \partial/\partial x_1, \ldots \partial/\partial x_{N-1})^{\mathrm{T}}$ etc., then it follows that

$$\frac{\partial \boldsymbol{z}^{\mathrm{T}}}{\partial \boldsymbol{z}} = \frac{\partial}{\partial \boldsymbol{z}}\boldsymbol{z}^{\mathrm{T}} = \mathbf{I} = \frac{\partial \boldsymbol{z}^{*\mathrm{T}}}{\partial \boldsymbol{z}^*} \tag{6.16}$$

and

$$\frac{\partial \boldsymbol{z}^{*\mathrm{T}}}{\partial \boldsymbol{z}} = \mathbf{0} = \frac{\partial \boldsymbol{z}^{\mathrm{T}}}{\partial \boldsymbol{z}^*}\,, \tag{6.17}$$

where $\mathbf{I}$ and $\mathbf{0}$ are the $N \times N$ identity and null matrices, respectively.

6.2.3 Least-Squares Tap Weights

The least-squares formulation gives the tap weights that minimize the squared error ϵ^2 between the desired response $H_{\mathrm{d}}(\omega)$ and the obtained $H(\omega)$ over a frequency range $\omega \in (-\omega_{\mathrm{s}}/2, \omega_{\mathrm{s}}/2)$, such that [6.6]

$$\epsilon^2 = \int_{-\frac{\omega_{\mathrm{s}}}{2}}^{\frac{\omega_{\mathrm{s}}}{2}} |H(\omega) - H_{\mathrm{d}}(\omega)|^2\,\mathrm{d}\omega\,. \tag{6.18}$$

Substituting our definition for $H(\omega) = \boldsymbol{h}^{\mathrm{T}}\boldsymbol{e}(\omega)$ we obtain

$$\frac{\mathrm{d}\epsilon^2}{\mathrm{d}\boldsymbol{h}} = \int_{-\frac{\omega_{\mathrm{s}}}{2}}^{\frac{\omega_{\mathrm{s}}}{2}} \left[\boldsymbol{h}^{\mathrm{T}}\boldsymbol{e}(\omega) - H_{\mathrm{d}}(\omega)\right]^* \boldsymbol{e}(\omega)\mathrm{d}\omega = \mathbf{0}\,, \tag{6.19}$$

which, noting that $\boldsymbol{e}^{\mathrm{T}}(\omega)\,\boldsymbol{h} = \boldsymbol{h}^{\mathrm{T}}\boldsymbol{e}(\omega)$, can be rewritten as

$$\left[\int_{-\frac{\omega_{\mathrm{s}}}{2}}^{\frac{\omega_{\mathrm{s}}}{2}} \boldsymbol{e}^*(\omega)\boldsymbol{e}^{\mathrm{T}}(\omega)\mathrm{d}\omega\right]\boldsymbol{h} = \int_{-\frac{\omega_{\mathrm{s}}}{2}}^{\frac{\omega_{\mathrm{s}}}{2}} \boldsymbol{e}^*(\omega)H_{\mathrm{d}}(\omega)\mathrm{d}\omega\,. \tag{6.20}$$

Noting that $\int_{-\omega_{\mathrm{s}}/2}^{\omega_{\mathrm{s}}/2} \boldsymbol{e}^*(\omega)\boldsymbol{e}^{\mathrm{T}}(\omega)\mathrm{d}\omega = \omega_{\mathrm{s}}\mathbf{I}$, it follows that

$$\boldsymbol{h}_{\mathrm{opt}} = \frac{1}{\omega_{\mathrm{s}}}\int_{-\frac{\omega_{\mathrm{s}}}{2}}^{\frac{\omega_{\mathrm{s}}}{2}} \boldsymbol{e}^*(\omega)H_{\mathrm{d}}(\omega)\mathrm{d}\omega\,, \tag{6.21}$$

where the tap weights $\boldsymbol{h}_{\mathrm{opt}}$ are optimal in a least-squares sense.

6.2.4 Application to Stochastic Gradient Algorithms

In an adaptive equalizer, we frequently have a cost function whose gradient is stochastically estimated and used to update the tap weights. For a complex valued set of taps $\boldsymbol{h}$, the stochastic gradient algorithm is applied to the real ($\mathrm{Re}(\boldsymbol{h})$) and imaginary ($\mathrm{Im}(\boldsymbol{h})$) components of the taps independently, and hence may be written as

$$\mathrm{Re}(\boldsymbol{h}) \leftarrow \mathrm{Re}(\boldsymbol{h}) - \frac{\mu}{2}\left(\frac{\partial\epsilon^2}{\partial\mathrm{Re}(\boldsymbol{h})}\right) \tag{6.22}$$

and

$$\mathrm{Im}(\boldsymbol{h}) \leftarrow \mathrm{Im}(\boldsymbol{h}) - \frac{\mu}{2}\left(\frac{\partial\epsilon^2}{\partial\mathrm{Im}(\boldsymbol{h})}\right), \tag{6.23}$$

where $\leftarrow$ denotes the assignment operation, such that $x \leftarrow y$ indicates that x is assigned to be the value y. These two equations may, however, be written more compactly in terms of the conjugate derivative as

$$\boldsymbol{h} \leftarrow \boldsymbol{h} - \mu \frac{\partial \epsilon^2}{\partial \boldsymbol{h}^*} \,. \tag{6.24}$$

To illustrate the approach, we consider the least mean-squares equalizer whose error term is given by $\epsilon = d - \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}$, where d is the desired output, which gives the squared error term as $|\epsilon|^2 = \left|d - \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}\right|^2 = \left(d - \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}\right)^* \left(d - \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}\right)$, and hence using the product rule for differentiation and the relationships related to differentiation with respect to a complex vector and its conjugate, we obtain

$$\frac{\partial |\epsilon|^2}{\partial \boldsymbol{h}^*} = -\epsilon \boldsymbol{x}^* \,. \tag{6.25}$$

Hence, the tap weight adaption algorithm is given by

$$\boldsymbol{h} \leftarrow \boldsymbol{h} + \mu \epsilon \, \boldsymbol{x}^* \tag{6.26}$$

Equally, for the constant modulus algorithm (CMA) [6.7], the cost function is

$$\epsilon = 1 - \left|\boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}\right|^2 \,. \tag{6.27}$$

Similarly, we find

$$\frac{\partial \epsilon^2}{\partial \boldsymbol{h}^*} = -2\epsilon \, \boldsymbol{x}^* \left(\boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}\right), \tag{6.28}$$

giving the update algorithm for the CMA as

$$\boldsymbol{h} \leftarrow \boldsymbol{h} + 2\mu\epsilon \, \boldsymbol{x}^* \left(\boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}\right). \tag{6.29}$$

6.2.5 The Wiener Filter

We have already shown that the error term is given by $\epsilon = d - \boldsymbol{h}^{\mathrm{T}}\boldsymbol{x}$, such that

$$\frac{\partial |\epsilon|^2}{\partial \boldsymbol{h}^*} = -\epsilon \boldsymbol{x}^* = -\boldsymbol{x}^* \epsilon^{\mathrm{T}} = -\boldsymbol{x}^* \left(d - \boldsymbol{x}^{\mathrm{T}}\boldsymbol{h}\right). \tag{6.30}$$

While we have shown how it is possible to iteratively solve this using a stochastic gradient technique, an alternative is to solve this analytically by setting the expected value of derivative to zero so as to give

$$\langle \boldsymbol{x}^* d \rangle = \langle \boldsymbol{x}^* \boldsymbol{x}^{\mathrm{T}} \boldsymbol{h} \rangle \,, \tag{6.31}$$

where $\langle \cdot \rangle$ is the expectation operator. Hence, if we define $\boldsymbol{P} = \langle \boldsymbol{x}^* d \rangle$ as the cross-correlation vector between the desired signal and the distorted signal, and $\mathbf{R}_{xx} = \langle \boldsymbol{x}^* \boldsymbol{x}^{\mathrm{T}} \rangle$ to be the autocorrelation matrix of the distorted signal, then we can write the Wiener filter solution of the tap weights as

$$\boldsymbol{h} = \mathbf{R}_{xx}^{-1} \boldsymbol{P} \,. \tag{6.32}$$

Often in a coherent optical communication system the situation is further complicated by the presence of phase noise or the frequency difference between the signal and the local oscillator. Nevertheless, it may be readily be applied in a simulation environment where frequency offset correction and carrier recovery is not required.

6.2.6 Frequency Domain Implementation of FIR Filters

For a long-haul communication system, a large number of FIR filter taps N_{f} are typically required to compensate for the accumulated chromatic dispersion. In such a case, the filtering can be done more efficiently in the frequency domain with $\mathcal{O}(\log N_{\mathrm{f}})$ complex multiplications. The algorithm we will outline is traditionally referred to as overlap and save, although overlap and discard would be a more appropriate name. The first key concept is that the convolution is done on a block-by-block basis, with the output of each block combined to give the overall output. A second key concept is that $\mathrm{FFT}^{-1}\{\mathrm{FFT}(x)\mathrm{FFT}(h)\}$ results in the circular convolution between the arrays x and h (rather than the desired linear convolution). If we define the size of the FFT to be N, then the overlap and save algorithm is as follows [6.8]:

1. Append $N - N_{\mathrm{f}}$ zeros to the tap weights to get an array of length N. This we transform into the frequency domain (using an N point FFT). Since this transformation is done just once, it can be neglected insofar as the computational cost (being fundamentally just an alternative way of representing the tap weights) is concerned.
2. Take the block of data of length N and FFT. An N point FFT requires $(N/2)\log_2 N$ complex multiplications.
3. The taps in the frequency domain from stage (1) are multiplied by the data in the frequency domain from part (2). This requires a further N complex multiplications
4. The resulting vector is then transformed back into the time domain using an N point inverse fast Fourier transform IFFT requiring a further $(N/2)\log_2 N$ complex multiplication.
5. Discard the first $N_{\mathrm{f}} - 1$ samples and output the last $N - N_{\mathrm{f}} + 1$ samples.

6. Take the next block of data samples, which starts $N - N_f + 1$ after the preceding block.

The net result is that the number of complex multiplications per output sample is

$$N_{CM} = \frac{N \log_2 N + N}{N - N_f + 1} . \quad (6.33)$$

In general, the size of the FFT can be optimized to minimize the number of complex multiplications to give N_{opt}, with the optimal values plotted in Fig. 6.4.

Given that direct linear convolution would require N_f complex multiplications per sample, it can be shown that the overlap and save is more efficient for $N_f \geq 8$ (using a 32-point FFT), yielding $N_{CM} = 7.7$. Using alternative FFT implementations, such as the radix 4 rather than radix 2, can reduce the computation complexity still further.

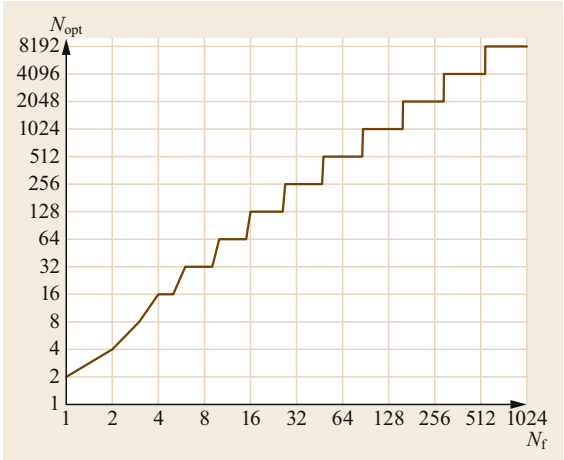

Fig. 6.4 Optimum FFT size to minimize the number of complex multiplications

6.3 Overview of DSP Algorithms

Herein, we will focus on receiver-based digital signal processing; however, many methods are equally applicable to the transmitter. As illustrated in Fig. 6.2, these can be broadly partitioned into equalization and synchronization algorithms with the typical arrangement being to equalize the signal before attempting to perform synchronization.

6.3.1 Equalization Algorithms

Equalization algorithms correct for the channel response and include the following:

- Orthonormalization and de-skew algorithms – these correct for imperfections in the coherent detection, such as the 90° hybrids not being ideal, as well as timing and amplitude differences between the different paths.
- Static channel equalization algorithms – these correct for the accumulated chromatic dispersion (which varies slowly). At the receiver this can also include pulse shaping and matched filtering, assuming that similar processing has been applied at the transmitter.
- Adaptive channel equalization algorithms – these correct for dynamic variations. For example, the polarization axes at the transmitter will be rotated relative to the receiver. These algorithms also compensate for PMD.

6.3.2 Synchronization Algorithms

Once the channel has been equalized, the synchronization algorithms correct for the difference between the oscillators at the transmitter and the receiver, both optical and electrical. In principle, synchronization could be achieved prior to equalization, however, many algorithms perform suboptimally in the presence of distortion and, as such, it is usual to equalize the channel prior to synchronizing the receiver and transmitter. Typical algorithms include:

- Timing recovery algorithms – these ensure that the sample clock at the receiver matches that at the transmitter, by both adjusting the ADC sampling phase and rate, as well as digitally interpolating to give samples at the correct time interval.
- Frequency estimation algorithms – these detect the difference in frequency between the incoming carrier frequency on to which the data is modulated and the local oscillator. The local oscillator wavelength can be adjusted and the residual frequency error corrected digitally.
- Carrier phase estimation algorithms – both the transmitter and local oscillator laser will have phase noise, which follows a random walk (Brownian motion, also known as a Wiener process). These algorithms track the mean phase evolution to reduce the impact of phase noise.

6.4 Orthonormalization and De-skew Algorithms

The aim of these algorithms is to compensate for the imperfections in the optical front end, where optical path lengths may not be perfectly matched or the hybrid may not be exactly 90°. The orthonormalization process compensates for imbalances in amplitude and nonideal 90° hybrids after which de-skew compensates for the path length mismatches between the signals, synchronizing the digital signals with respect to one another in time.

6.4.1 Orthogonalization Algorithms

In order to recover the original signal using a receiver with a suboptimal hybrid it is often necessary to use orthogonalization algorithms. The most common approach is to use the Gram–Schmidt algorithm [6.9], which creates a set of mutually orthogonal vectors, taking the first vector as a reference against which all subsequent vectors are orthogonalized. In a coherent receiver, the primary cause of nonorthogonality is due to a nonideal 90° hybrid. If r_I and r_Q are the received in-phase and quadrature components, then the orthogonalized components are given by

$$I = r_\mathrm{I} \,, \tag{6.34}$$

$$Q = r_\mathrm{Q} - \frac{\langle r_\mathrm{I} r_\mathrm{Q} \rangle}{\langle r_\mathrm{I}^2 \rangle} r_\mathrm{I} \,, \tag{6.35}$$

After the signals have been orthogonalized, they are subsequently normalized to unit power.

6.4.2 De-skew

In order to temporally align the channels any timing skew should be corrected for. This can be implemented using a short FIR filter to interpolate between samples in order to create a temporal delay. Alternatively, it can be readily implemented via the frequency domain, where the temporal delay corresponds to a linear phase response. Since skew is fundamentally a timing offset, the methods employed are similar to those discussed in Sect. 6.7.1 for timing recovery. As such, we will not go into more detail here other than to note that care should be taken to ensure that if the skew is tracked the interaction with the channel is considered [6.10]. While robust estimators exist, such as [6.10], an alternative approach is to perform an initial calibration for the skew, using, for example, a 4×4 equalizer (discussed in Sect. 6.6.7), since such an equalizer can correct for timing skew [6.11].

6.5 Static Equalization

In modern digital coherent transceivers, the static equalizer is used to implement pulse shaping and matched filtering, as well as equalizing for the significant intersymbol interference due to the accumulated chromatic dispersion. Since the application of pulse shaping is well covered by digital communications textbooks such as *Proakis* and *Salehi* [6.12], in this section, we focus on the compensation of chromatic dispersion, since this is specific to optical fiber communication systems.

6.5.1 Nature of Chromatic Dispersion

Chromatic dispersion is a consequence of the frequency-dependent group delay in the optical fiber. If two wavelengths are separated by $\Delta\lambda$ nm, then the temporal spread Δt (in ps) is given by [6.13]

$$\Delta t = D z \Delta\lambda \,, \tag{6.36}$$

where D is the dispersion coefficient of the fiber given in ps/(nm km), and z is the length of the link in km. Given $c = f\lambda$, it follows that $\Delta\lambda = -\Delta f \times \lambda / f$, hence for $f \approx 193$ THz ($\lambda \approx 1553$ nm), then $\Delta\lambda/\Delta f = 8$ pm/GHz. Hence, a signal occupying 35 GHz has a spectral width of 0.28 nm. If the dispersion coefficient is 16.7 ps/(nm km), then for every 1000 km of fiber, the signal disperses by at least 165 symbol periods, with the minimum value obtained by assuming a rectangular spectrum. The number of taps depends on the ADC sampling rate, for example at 40 GSa/s 189 taps per 1000 km of SMF are required, increasing to 330 taps per 1000 km of SMF if two samples per symbol are used with an ADC sampling rate of 70 GSa/s.

6.5.2 Modeling of Chromatic Dispersion in an Optical Fiber

In the absence of fiber nonlinearity, the effect of chromatic dispersion on the envelope $A(z,t)$ of a pulse may be modeled by the following partial differential equation (which is based on the electronic engineer's definition of phase compared with the physicist's con-

vention [6.13])

$$\frac{\partial A(z,t)}{\partial z} = \frac{\mathrm{j}\beta_2}{2}\frac{\partial^2 A(z,t)}{\partial t^2}\,, \tag{6.37}$$

where z is the distance of propagation, t is time variable in a frame moving with the pulse $A(z,t)$, and β_2 the group delay dispersion of the fiber. Taking the Fourier transform of (6.37) and solving gives the frequency domain transfer function $G(z,\omega)$, given by

$$G(z,\omega) = \exp\left(-\frac{\mathrm{j}\beta_2}{2}\omega^2 z\right). \tag{6.38}$$

The dispersion compensating filter is, therefore, given by the all-pass filter $G(-z,\omega)$, which can be approximated using an FIR filter.

6.5.3 Truncated Impulse Response

Herein, we discuss a simple but intuitive means of designing the chromatic dispersion compensating FIR filter [6.14], providing a basis for the discussion of more complex techniques. In contrast to a frequency domain approach, not only does this give a simple closed-form solution for the tap weights, but also it provides bounds on the number of taps required for a given value of dispersion. We begin by obtaining the impulse response $g(z,t)$ of the dispersive fiber by applying the inverse Fourier transform to the frequency domain transfer function $G(z,\omega)$ to give

$$g(z,t) = \frac{1}{\sqrt{2\pi\mathrm{j}\beta_2 z}}\exp\left(\frac{\mathrm{j}}{2\beta_2 z}t^2\right). \tag{6.39}$$

For an arbitrary input, the output can be obtained by convolving this impulse response with the input, and as expected, the impulse response itself satisfies (6.37). By inverting the sign of the chromatic dispersion, we obtain the impulse function of the chromatic dispersion compensating filter $g_c(z,t)$, given by

$$g_c(z,t) = \frac{1}{\sqrt{-2\pi\mathrm{j}\beta_2 z}}\exp[-\mathrm{j}\phi(t)]\,, \tag{6.40}$$

where

$$\phi(t) = \frac{t^2}{2\beta_2 z}\,. \tag{6.41}$$

The impulse response given by (6.40) presents a number of issues for digital implementation. Not only is it infinite in duration, but since it passes all frequencies for a finite sampling frequency, aliasing will occur. The solution to all of these problems is to truncate the impulse response to a finite duration. To determine the length of the truncation window, we note that if we sample every T_s s, then aliasing will occur for frequencies which exceed the Nyquist frequency, given by $\omega_N = \pi/T$, and that the impulse response may be considered as a rotating vector, whose angular frequency is given by

$$\omega = \frac{\partial\phi(t)}{\partial t} = \frac{t}{\beta_2 z}\,. \tag{6.42}$$

When the magnitude of this frequency exceeds the Nyquist frequency, aliasing will occur, giving the criterion that $|\omega| < \omega_N$ and hence,

$$-|\beta_2|\,z\frac{\pi}{T_s} \le t \le |\beta_2|\,z\frac{\pi}{T_s}\,. \tag{6.43}$$

Since the impulse response is of finite duration, this can be implemented digitally using a finite impulse response (FIR) filter. If we assume that the number of taps is large, then the sampled impulse response will approximate the continuous time impulse response. Hence, if we consider a filter with N_{TI} taps, then the tap weights will be given by

$$h_{TI}[n] = \frac{1}{\sqrt{\rho}}\exp\left[-\frac{\mathrm{j}\pi}{\rho}\left(n - \frac{N_{TI}-1}{2}\right)^2\right], \tag{6.44}$$

where

$$\begin{aligned} &\rho = 2\frac{\pi\beta_2 z}{T_s^2}\,,\\ &N_{TI} = \lfloor|\rho|\rfloor\,,\\ \text{and}\quad &n \in [0,1,2,\ldots,N_{TI}-1]\,, \end{aligned} \tag{6.45}$$

where $\lfloor x\rfloor$ is the integer part of x rounded towards minus infinity. These tap weights form the basis for the compensation of chromatic dispersion using an FIR filter.

As an example, we consider the application of this truncated impulse FIR filter design to the compensation of chromatic dispersion for a 35 GBd signal (with a root raised cosine shape with $\beta = 0.01$). As can be seen in Fig. 6.5, for a QPSK signal, the penalty is less than 0.1 dB when the distance exceeds 250 km. Given that the first digital coherent transceivers employed QPSK and operated over thousands of kilometers, this design approach was adequate for the first generation of systems. Nonetheless, as future systems increased the cardinality of the modulation format, moving towards 16 QAM and 64 QAM, this approach proved suboptimal, with for example a 2 dB penalty observed using 64 QAM at 250 km. This resulted in moving to an alternative formulation, namely least-squares (LS) filter design.

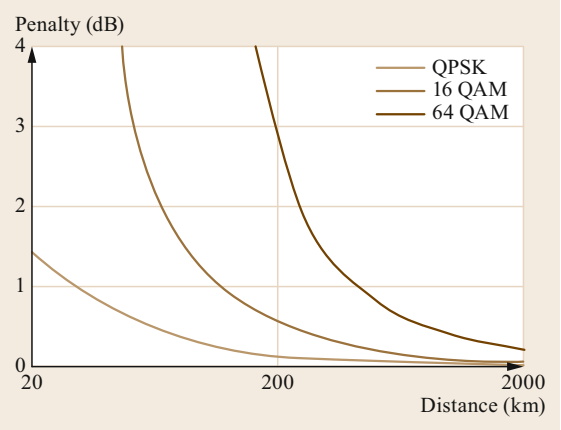

Fig. 6.5 Penalty at BER = 2% for a 35 GBd signal ($\beta = 0.01$) with a truncated impulse response design. The single-mode fiber has a chromatic dispersion of $D = 17\,\mathrm{ps/(nm\,km)}$

6.5.4 LS FIR Filter Design

In order to improve the design of the chromatic dispersion compensation, first, a least-squares approach can be utilized. As previously discussed, the least-squares criterion may be applied to the design of a complex FIR filter, giving optimal tap weights in a least-squares sense

$$\boldsymbol{h}_{\mathrm{LS}} = \frac{1}{\omega_{\mathrm{s}}} \int_{-\frac{\omega_{\mathrm{S}}}{2}}^{\frac{\omega_{\mathrm{S}}}{2}} \boldsymbol{e}^{*}(\omega) H_{\mathrm{d}}(z,\omega)\mathrm{d}\omega \,. \tag{6.46}$$

If, as in the previous section, we define our taps symmetrically such that

$$\boldsymbol{e}(\omega) = \mathrm{e}^{\mathrm{j}\omega(N-1)T_{\mathrm{s}}/2} \times \left[1, \mathrm{e}^{-\mathrm{j}\omega T_{\mathrm{s}}}, \mathrm{e}^{-2\mathrm{j}\omega T_{\mathrm{s}}}, \ldots \mathrm{e}^{-\mathrm{j}\omega(N-1)T_{\mathrm{s}}}\right]^{\mathrm{T}} ,$$

and so as to neglect the combination of any subsequent filtering, we choose $H_{\mathrm{d}}(z,\omega) = 1/G(z,\omega) = G(-z,\omega)$, then we obtain [6.15]

$$h_{\mathrm{LS}}[n] = w[n] \times h_{\mathrm{TI}}[n] \,, \tag{6.47}$$

where

$$w[n] = \frac{1}{2\mathrm{j}} \operatorname{erfi}\left[\sqrt{\frac{\mathrm{j}\pi}{\rho}}\left(n - \frac{N-1}{2} + \frac{\rho}{2}\right)\right] - \frac{1}{2\mathrm{j}} \operatorname{erfi}\left[\sqrt{\frac{\mathrm{j}\pi}{\rho}}\left(n - \frac{N-1}{2} - \frac{\rho}{2}\right)\right], \tag{6.48}$$

where $\operatorname{erfi}(x)$ is the imaginary error function given by $\operatorname{erfi}(x) = -\mathrm{j}\operatorname{erf}(\mathrm{j}x)$ where

$$\operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_{0}^{z} \mathrm{e}^{-t^2}\mathrm{d}t \,. \tag{6.49}$$

It can be shown that $h_{\mathrm{LS}}[n]$ corresponds to the sampled version of the bandlimited impulse response $g_{\mathrm{c_{bl}}}(z,t)$, given by

$$g_{\mathrm{c_{bl}}}(z,t) = \frac{1}{2\pi} \int_{-\frac{\omega_{\mathrm{S}}}{2}}^{\frac{\omega_{\mathrm{S}}}{2}} \exp\left(\frac{\mathrm{j}\beta_2}{2}\omega^2 z\right) \exp(\mathrm{j}\omega t)\mathrm{d}\omega \,. \tag{6.50}$$

We revisit the previous example, designing an FIR filter for compensation of chromatic dispersion for a 35 GBd signal (with root raised cosine shape with $\beta = 0.01$), while using the same number of taps $N = \lfloor 2\pi\beta_2 z/T_{\mathrm{s}}^2 \rfloor$ as for the truncated impulse response. As can be seen in Fig. 6.6, for the distance of 250 km, the penalty for 64 QAM reduces significantly from 2 dB using the truncated impulse response to less than 0.4 dB using the least-squares formulation.

Nevertheless, for highly spectrally efficient formats such as 64 QAM, the penalty can be as high as 3 dB for short distances (≈ 30 km). The penalty may, however, be mitigated by allowing the number of taps in the least-squares design to increase beyond $N = \lfloor 2\pi\beta_2 z/T_{\mathrm{s}}^2 \rfloor$. To illustrate this, we again consider a 35 GBd signal with a near rectangular Nyquist-shaped spectrum (root

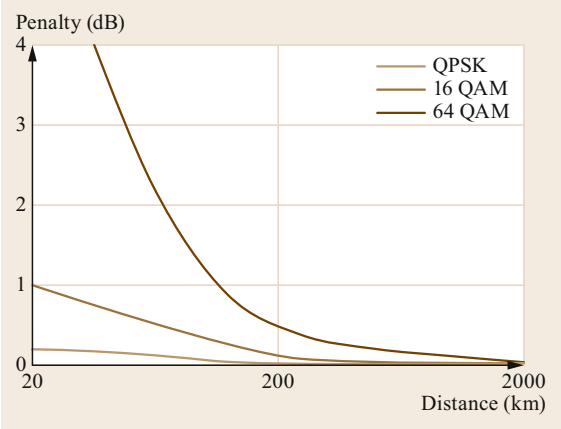

Fig. 6.6 Penalty at BER = 2% for a 35 GBd signal ($\beta = 0.01$) with a least-squares impulse response design. The single-mode fiber has a chromatic dispersion of $D = 17\,\mathrm{ps/(nm\,km)}$

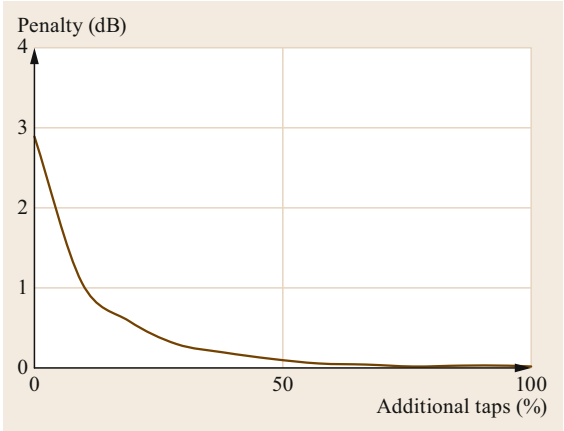

Fig. 6.7 Effect of increasing number of taps on the penalty at BER = 2% for a 35 GBd DP-64 QAM signal transmitted over 31.25 km of standard single-mode fiber ($D = 17\,\mathrm{ps/(nm\,km)}$) ►

raised cosine shape with $\beta = 0.01$), transmitting DP-64 QAM over a distance of 31.25 km of single-mode fiber with $D = 17\,\mathrm{ps/(nm\,km)}$. While this gives a minimum number of taps required of 20, as can be seen in Fig. 6.7, if the number of taps are increased by 50%, the penalty can be made negligible (< 0.1 dB) from the initial value of 2.9 dB with the minimum number of taps. We note that if FIR filtering is implemented via the frequency domain, the increase in the number of complex multiplications to achieve this is less than 10%.

6.6 Adaptive Equalization

Within coherent receivers, adaptive equalization is employed in order to track time-varying phenomena. In general, the cause of temporal variations is due to polarization effects, such as random polarization rotations or polarization mode dispersion (PMD).

6.6.1 Equalization of PMD

Polarization mode dispersion (PMD) arises due to variations in the circular symmetry of the optical fiber, resulting in localized birefringence [6.13]. While the PMD is a unitary operation, generally, compensation of PMD is included within a subsystem that includes mitigation of PDL, relaxing the unitary requirement. By removing the unitary condition polarization, independent effects such as nonideal matched filtering can also be mitigated. Polarization mode dispersion results in information being coupled from one polarization to another, such that the information in the x and y polarization at the output $\boldsymbol{E}_{\mathrm{out}}$ is related to the input states $\boldsymbol{E}_{\mathrm{in}}(\omega)$ via [6.16]

$$\boldsymbol{E}_{\mathrm{out}} = \mathbf{U}(\omega)\boldsymbol{E}_{\mathrm{in}}\,, \tag{6.51}$$

where $\mathbf{U}(\omega)$ is a 2×2 unitary matrix. The simplest manifestation of PMD is as a differential group delay (DGD) of $\Delta\tau$, such that

$$\mathbf{U}(\omega) = \mathbf{R}(-\theta)\begin{pmatrix} \mathrm{e}^{\frac{\mathrm{j}\omega\tau}{2}} & 0 \\ 0 & \mathrm{e}^{-\frac{\mathrm{j}\omega\tau}{2}} \end{pmatrix}\mathbf{R}(\theta)\,, \tag{6.52}$$

where

$$\mathbf{R}(\theta) = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta\,. \end{pmatrix} \tag{6.53}$$

From this, we note that the inverse Jones matrix in the time domain is given by

$$\mathbf{u}(t) = \mathbf{R}(-\theta)\begin{pmatrix} \delta\left(t-\frac{\tau}{2}\right) & 0 \\ 0 & \delta\left(t+\frac{\tau}{2}\right) \end{pmatrix}\mathbf{R}(\theta)\,. \tag{6.54}$$

This reveals that if the equalizer is to correct for a DGD of τ, then the temporal span $(N-1)T_{\mathrm{s}}$ of an N tap FIR filter must exceed τ, requiring $N \geq \lceil \tau/T_{\mathrm{s}} \rceil + 1$. As we will discuss in the subsequent sections, this is very much a lower bound on the number of taps, and in practice, when the convergence time of the equalizer is of concern, more taps may be required. Since PMD is due to random coupling between the polarization modes, DGD has a statistical variation with a Maxwellian distribution [6.17] with a probability density function given by

$$f(\tau) = \frac{32}{\langle\tau\rangle\,\pi^2}\left(\frac{\tau}{\langle\tau\rangle}\right)^2 \exp\left[-\frac{4}{\pi}\left(\frac{\tau}{\langle\tau\rangle}\right)^2\right], \tag{6.55}$$

where $\langle\tau\rangle$ is the mean DGD, and the resulting outage probability given by the corresponding tail distribution $F_{\mathrm{c}}(\tau)$ is given by

$$\begin{aligned} F_{\mathrm{c}}(\tau) &= \int_{\tau}^{\infty} f(x)\mathrm{d}x \\ &= \frac{4}{\pi}\left(\frac{\tau}{\langle\tau\rangle}\right)\exp\left[-\frac{4}{\pi}\left(\frac{\tau}{\langle\tau\rangle}\right)^2\right] \\ &\quad + \mathrm{erfc}\left[\frac{2}{\sqrt{\pi}}\left(\frac{\tau}{\langle\tau\rangle}\right)\right]. \end{aligned} \tag{6.56}$$

For the range that is typically of interest, namely $\tau \in (\langle\tau\rangle, 6\langle\tau\rangle)$, we can approximate the outage probability

by

$$\log_{10} F_c(\tau) \approx 0.25 \left(\frac{\tau}{\langle\tau\rangle}\right) - 0.57 \left(\frac{\tau}{\langle\tau\rangle}\right)^2 . \quad (6.57)$$

Consider data from a field trial of 100 Gb/s with 31.25 GBd DP-QPSK with $\langle\tau\rangle = 36.6$ ps with an adaptive equalizer with 13 taps [6.18]. This gives $\tau/\langle\tau\rangle = 5.2$, and hence an negligible outage probability of 4×10^{-15}. While it was also noted that no penalty was observed with $\langle\tau\rangle$ up to 55 ps, the corresponding outage probability is 8×10^{-7}, and as such a penalty is not expected to be observed.

6.6.2 Obtaining the Inverse Jones Matrix of the Channel

The impact of polarization-dependent effects on the propagation may be modeled by a Jones matrix. In general, this matrix is not unitary due to polarization-dependent loss (PDL), and furthermore, it will be frequency dependent due to polarization mode dispersion (PMD). The task is, therefore, to estimate the Jones matrix and obtain the inverse to compensate for the impairments incurred. In contrast to the chromatic dispersion that may be considered relatively constant, the Jones matrix may evolve in time due to effects such as rapid variations in the polarization state, and, therefore, the compensation scheme must be adaptive. The problem of compensating polarization rotations digitally was first considered by *Betti* et al. [6.19] and later demonstrated utilizing the formalism of multiple-input-multiple-output (MIMO) systems [6.20]. For inputs

$$\boldsymbol{x} = (x[k], x[k-1], \ldots x[k-(N-1)])^{\mathrm{T}}$$

and

$$\boldsymbol{y} = (y[k], y[k-1], \ldots y[k-(N-1)])^{\mathrm{T}} ,$$

the outputs $x_o[k]$ and $y_o[k]$ are given by

$$x_o[k] = \boldsymbol{h}_{xx}^{\mathrm{T}}\boldsymbol{x} + \boldsymbol{h}_{xy}^{\mathrm{T}}\boldsymbol{y} \quad (6.58)$$

and

$$y_o[k] = \boldsymbol{h}_{yx}^{\mathrm{T}}\boldsymbol{x} + \boldsymbol{h}_{yy}^{\mathrm{T}}\boldsymbol{y} , \quad (6.59)$$

where $\boldsymbol{h}_{xx}$, $\boldsymbol{h}_{xy}$, $\boldsymbol{h}_{yx}$ and $\boldsymbol{h}_{yy}$ are adaptive filters each of which have length N taps. While there are a number of methods for adapting the equalizer in MIMO systems, we shall restrict ourselves to a specific example that exploits properties of the data, namely that for dual polarization QPSK (DP-QPSK) the signal for each polarization should have a constant modulus. This constant modulus algorithm (CMA) has also been shown to be effective even when the modulus is not constant, such as higher-order quadrature amplitude modulation.

6.6.3 Constant Modulus Algorithm

For signals of unit amplitude, the equalizer will attempt to minimize, in a mean squares sense, the magnitude of $\epsilon_x = 1 - |x_o|^2$ and $\epsilon_y = 1 - |y_o|^2$. Hence, to obtain the optimal tap weights, a set of stochastic gradient algorithms with convergence parameter μ are used, such that

$$\boldsymbol{h}_{xx} \leftarrow \boldsymbol{h}_{xx} - \mu \frac{\partial \epsilon_x^2}{\partial \boldsymbol{h}_{xx}^*} = \boldsymbol{h}_{xx} + 2\mu\epsilon_x x_o \boldsymbol{x}^* . \quad (6.60)$$

Similarly

$$\boldsymbol{h}_{xy} \leftarrow \boldsymbol{h}_{xy} + 2\mu\epsilon_x x_o \boldsymbol{y}^* , \quad (6.61)$$

$$\boldsymbol{h}_{yx} \leftarrow \boldsymbol{h}_{yx} + 2\mu\epsilon_y y_o \boldsymbol{x}^* , \quad (6.62)$$

$$\boldsymbol{h}_{yy} \leftarrow \boldsymbol{h}_{yy} + 2\mu\epsilon_y y_o \boldsymbol{y}^* , \quad (6.63)$$

where $\boldsymbol{x}^*$ and $\boldsymbol{y}^*$ denote the complex conjugate of $\boldsymbol{x}$ and $\boldsymbol{y}$, respectively. In order to initialize the algorithm, all tap weights are set to zero with the exception of the central tap of $\boldsymbol{h}_{xx}$ and $\boldsymbol{h}_{yy}$, which are set to unity. Given that the equalizer is unconstrained with respect to its outputs, it is possible for both outputs of the equalizer to converge on the same output, corresponding to the Jones matrix becoming singular, albeit, there are numerous means of overcoming this limitation [6.21–23].

6.6.4 Decision-Directed Equalizer

Once the equalizer has converged, the equalizer may move into a decision-directed mode, such that if $D(x)$ is the symbol closest to x, then the decision-directed least mean squared (DD-LMS) algorithm minimizes $\epsilon_x = D(x_0) - x_o$ and $\epsilon_y = D(y_0) - y_o$, giving the update algorithm as [6.24]

$$\boldsymbol{h}_{xx} \leftarrow \boldsymbol{h}_{xx} - \mu \frac{\partial |\epsilon_x|^2}{\partial \boldsymbol{h}_{xx}^*} = \boldsymbol{h}_{xx} + \mu\epsilon_x \boldsymbol{x}^* \quad (6.64)$$

and likewise

$$\boldsymbol{h}_{xy} \leftarrow \boldsymbol{h}_{xy} + \mu\epsilon_x \boldsymbol{y}^* , \quad (6.65)$$

$$\boldsymbol{h}_{yx} \leftarrow \boldsymbol{h}_{yx} + \mu\epsilon_y \boldsymbol{x}^* , \quad (6.66)$$

$$\boldsymbol{h}_{yy} \leftarrow \boldsymbol{h}_{yy} + \mu\epsilon_y \boldsymbol{y}^* . \quad (6.67)$$

One of the challenges of the decision-directed equalizer is needing to combine the carrier recovery with the equalization, since the decisions are made on the phase corrected signal. The resulting feedback path can, therefore, be more challenging for CMOS ASIC implementation than the blind equalizer, which partitions the equalization from the carrier recovery.

6.6.5 Radially-Directed Equalizer Update Algorithm

While the CMA is well suited to constant modulus formats such at QPSK, many of the formats considered for future optical networks are not constant modulus, such as DP-16 QAM, such that the CMA will never converge to zero error [6.24]. Nevertheless, the CMA can be adapted to a radially directed equalizer. In this case,

$$\epsilon_x = Q_\mathrm{r}\left(|x_\mathrm{o}|^2\right) - |x_\mathrm{o}|^2 \tag{6.68}$$

and

$$\epsilon_y = Q_\mathrm{r}\left(|y_\mathrm{o}|^2\right) - |y_\mathrm{o}|^2 \,, \tag{6.69}$$

where $Q_\mathrm{r}(r^2)$ is a function that quantizes the radius according to the number of possible points. Once the notional radius has been determined, the CMA algorithm is used to update the tap weights accordingly. One of the key benefits of using a radially-directed equalizer is that it is invariant to the phase of the incoming signal, and hence allows the equalization and the carrier recovery to be partitioned. However, for more dense modulation formats, often it is preferable to use the CMA initially and then switch to a decision-directed equalizer.

6.6.6 Parallel Realization of the FIR Filter

One of the key benefits of the FIR filter is that it can readily be implemented in CMOS. Thus far, all of the implementations discussed have operated on a symbol-by-symbol basis, rather than based on a lower speed CMOS bus. In this case, the DSP is similar to before, but now we write [6.25]

$$\boldsymbol{x}_\mathrm{o} = \boldsymbol{h}_{xx}^\mathrm{T}\mathbf{X} + \boldsymbol{h}_{xy}^\mathrm{T}\mathbf{Y} \tag{6.70}$$

and

$$\boldsymbol{y}_\mathrm{o} = \boldsymbol{h}_{yx}^\mathrm{T}\mathbf{X} + \boldsymbol{h}_{yy}^\mathrm{T}\mathbf{Y} \,, \tag{6.71}$$

where $\boldsymbol{h}_{xx}$ etc. are vectors of length N containing the tap weights, $\boldsymbol{x}_\mathrm{o}$ and $\boldsymbol{y}_\mathrm{o}$ are vectors of length M containing the outputs, and $\mathbf{X}$ and $\mathbf{Y}$ are $N \times M$ matrices whose columns represent the parallel inputs. In this case, the error term for the CMA becomes $\boldsymbol{\epsilon_x} = \mathbf{1} - \boldsymbol{x}_\mathrm{o} \circ \boldsymbol{x}_\mathrm{o}^*$, and similarly $\boldsymbol{\epsilon_y} = \mathbf{1} - \boldsymbol{y}_\mathrm{o} \circ \boldsymbol{y}_\mathrm{o}^*$, where $\circ$ denotes the Hadamard product (being element-by-element multiplication), with the resulting update algorithm for the CMA becoming

$$\boldsymbol{h}_{xx} \leftarrow \boldsymbol{h}_{xx} + 2\mu\left(\boldsymbol{\epsilon}_x \circ \boldsymbol{x}_\mathrm{o}\right)^\mathrm{T}\mathbf{X}^* \,, \tag{6.72}$$

$$\boldsymbol{h}_{xy} \leftarrow \boldsymbol{h}_{xy} + 2\mu\left(\boldsymbol{\epsilon}_x \circ \boldsymbol{x}_\mathrm{o}\right)^\mathrm{T}\mathbf{Y}^* \,, \tag{6.73}$$

$$\boldsymbol{h}_{yx} \leftarrow \boldsymbol{h}_{yx} + 2\mu\left(\boldsymbol{\epsilon}_y \circ \boldsymbol{y}_\mathrm{o}\right)^\mathrm{T}\mathbf{X}^* \,, \tag{6.74}$$

$$\boldsymbol{h}_{yy} \leftarrow \boldsymbol{h}_{yy} + 2\mu\left(\boldsymbol{\epsilon}_y \circ \boldsymbol{y}_\mathrm{o}\right)^\mathrm{T}\mathbf{Y}^* \,. \tag{6.75}$$

Once the CMA has converged, a decision directed equalizer is employed with

$$\boldsymbol{h}_{xx} \leftarrow \boldsymbol{h}_{xx} + \mu\boldsymbol{\epsilon}_x^\mathrm{T}\mathbf{X}^* \,, \tag{6.76}$$

$$\boldsymbol{h}_{xy} \leftarrow \boldsymbol{h}_{xy} + \mu\boldsymbol{\epsilon}_x^\mathrm{T}\mathbf{Y}^* \,, \tag{6.77}$$

$$\boldsymbol{h}_{yx} \leftarrow \boldsymbol{h}_{yx} + \mu\boldsymbol{\epsilon}_y^\mathrm{T}\mathbf{X}^* \,, \tag{6.78}$$

$$\boldsymbol{h}_{yy} \leftarrow \boldsymbol{h}_{yy} + \mu\boldsymbol{\epsilon}_y^\mathrm{T}\mathbf{Y}^* \,. \tag{6.79}$$

6.6.7 Generalized 4 × 4 Equalizer

Provided that the equalizer is not constrained to be unitary, all of the equalizers discussed in this section can also be used to mitigate the impact of frequency-dependent loss or polarization-dependent loss. The equalizer can, however, be generalized further to the 4×4 equalizer by relaxing the assumptions in the 2×2 complex equalizer that the real and imaginary signals are sampled synchronously and are orthonormal. In this case, the equalizer structure becomes [6.11, 26]

$$x_{\mathrm{o_r}} = \boldsymbol{h}_{x_\mathrm{r}x_\mathrm{r}}^\mathrm{T}\boldsymbol{x}_\mathrm{r} + \boldsymbol{h}_{x_\mathrm{r}x_\mathrm{i}}^\mathrm{T}\boldsymbol{x}_\mathrm{i} + \boldsymbol{h}_{x_\mathrm{r}y_\mathrm{r}}^\mathrm{T}\boldsymbol{y}_\mathrm{r} + \boldsymbol{h}_{x_\mathrm{r}y_\mathrm{i}}^\mathrm{T}\boldsymbol{y}_\mathrm{i} \,, \tag{6.80}$$

$$x_{\mathrm{o_i}} = \boldsymbol{h}_{x_\mathrm{i}x_\mathrm{r}}^\mathrm{T}\boldsymbol{x}_\mathrm{r} + \boldsymbol{h}_{x_\mathrm{i}x_\mathrm{i}}^\mathrm{T}\boldsymbol{x}_\mathrm{i} + \boldsymbol{h}_{x_\mathrm{i}y_\mathrm{r}}^\mathrm{T}\boldsymbol{y}_\mathrm{r} + \boldsymbol{h}_{x_\mathrm{i}y_\mathrm{i}}^\mathrm{T}\boldsymbol{y}_\mathrm{i} \,, \tag{6.81}$$

$$y_{\mathrm{o_r}} = \boldsymbol{h}_{y_\mathrm{r}x_\mathrm{r}}^\mathrm{T}\boldsymbol{x}_\mathrm{r} + \boldsymbol{h}_{y_\mathrm{r}x_\mathrm{i}}^\mathrm{T}\boldsymbol{x}_\mathrm{i} + \boldsymbol{h}_{y_\mathrm{r}y_\mathrm{r}}^\mathrm{T}\boldsymbol{y}_\mathrm{r} + \boldsymbol{h}_{y_\mathrm{r}y_\mathrm{i}}^\mathrm{T}\boldsymbol{y}_\mathrm{i} \,, \tag{6.82}$$

$$y_{\mathrm{o_i}} = \boldsymbol{h}_{y_\mathrm{i}x_\mathrm{r}}^\mathrm{T}\boldsymbol{x}_\mathrm{r} + \boldsymbol{h}_{y_\mathrm{i}x_\mathrm{i}}^\mathrm{T}\boldsymbol{x}_\mathrm{i} + \boldsymbol{h}_{y_\mathrm{i}y_\mathrm{r}}^\mathrm{T}\boldsymbol{y}_\mathrm{r} + \boldsymbol{h}_{y_\mathrm{i}y_\mathrm{i}}^\mathrm{T}\boldsymbol{y}_\mathrm{i} \,, \tag{6.83}$$

where $x_{\mathrm{o_r}} = \mathrm{Re}\,(x_\mathrm{o})$, $x_{\mathrm{o_i}} = \mathrm{Im}\,(x_\mathrm{o})$, $\boldsymbol{x}_\mathrm{r} = \mathrm{Re}(\boldsymbol{x})$, $\boldsymbol{x}_\mathrm{i} = \mathrm{Im}(\boldsymbol{x})$ etc. For the CMA, the update algorithms are of the form

$$\boldsymbol{h}_{x_\mathrm{r}k} \leftarrow \boldsymbol{h}_{x_\mathrm{r}k} + 4\mu\epsilon_x x_{\mathrm{o_r}}\boldsymbol{k} \,, \tag{6.84}$$

$$\boldsymbol{h}_{x_\mathrm{i}k} \leftarrow \boldsymbol{h}_{x_\mathrm{i}k} + 4\mu\epsilon_x x_{\mathrm{o_i}}\boldsymbol{k} \,, \tag{6.85}$$

$$\boldsymbol{h}_{y_\mathrm{r}k} \leftarrow \boldsymbol{h}_{y_\mathrm{r}k} + 4\mu\epsilon_y y_{\mathrm{o_r}}\boldsymbol{k} \,, \tag{6.86}$$

$$\boldsymbol{h}_{y_\mathrm{i}k} \leftarrow \boldsymbol{h}_{y_\mathrm{i}k} + 4\mu\epsilon_y y_{\mathrm{o_i}}\boldsymbol{k} \,, \tag{6.87}$$

where $k \in \{x_\mathrm{r}, x_\mathrm{i}, y_\mathrm{r}, y_\mathrm{i}\}$. The resulting equalizer can not only compensate for frequency and polarization-dependent effects but also receiver skew.

6.7 Carrier and Timing Synchronization Algorithms

The coherent optical transceivers developed for use in optical transport networks (OTN) are asynchronous and use free-running transmitter and receiver lasers. Therefore, the symbol timing frequency and phase must be recovered by the receiver, and the frequency and phase difference between the lasers at the transmitter and receiver must also be estimated at the receiver for complex modulation formats such as QAM.

6.7.1 Symbol Timing Recovery

Since the clocks that determine the symbol rate in the transmitter and receiver of a transmission system are independent and free-running, some control algorithm is required for phase-locking at the receiver [6.27]. One scheme that is often used for phase-locking involves the coarse adjustment of a voltage controlled oscillator in the analog domain, combined with a fine adjustment of a digital retiming circuit (normally an interpolating polyphase filter such as a Farrow filter [6.28]). Both the analog and digital components of such a system can be driven by the same timing-error detector (TED). Due to the lack of an observable *eye* in coherent optical transmission systems before sampling and processing, both the analog and digital parts of the hybrid timing recovery circuit may be driven by a digital-timing error estimator. The hybrid scheme is shown in Fig. 6.8.

Gardner Algorithm

The most commonly used algorithm for the symbol timing error detector (TED) in the coherent optical transmission literature is the Gardner algorithm [6.29]. This algorithm determines an error to be minimized with two samples per symbol input and assumes a constant symbol energy. The TED output ϵ is defined as

$$\epsilon = \mathrm{Re}\left[\sum_{n=0}^{N/2-1}(x_{2n}-x_{2n+2})x_{2n+1}^{*}\right], \tag{6.88}$$

where N is the length of the averaging window in samples, x_n is the input sample x at instant n, * is the complex conjugate, and Re denotes the real part of a complex number.

This error function allows for good performance in terms of locking, tracking, and residual jitter. However, distortions such as polarization mode dispersion (PMD), or residual chromatic dispersion (CD) which was not compensated by the proceeding static equalizer may cause failure. Equally utilizing the Gardner algorithm in systems with multilevel modulation or Nyquist signaling can lead to a reduction in performance or increased frequency of failure. For these reasons, a great many extensions have been proposed to improve the performance of the Gardner and related algorithms in the context of high-capacity optical transmission.

One such extension is to implement the classic Gardner algorithm in the frequency domain [6.30]. By calculating the error function in the frequency domain, it is possible to estimate the distortion due to residual CD and first-order PMD with a simple model that reflects the physical nature of the distortions.

Two extensions were proposed simultaneously in [6.31] and [6.32], which enable performance of a Gardner-derived algorithm for signals with near Nyquist-limited bandwidth. While the architecture of the algorithm is not changed, a correction in the timing error detector calculation as proposed in either of these algorithms eliminates the sensitivity of the timing recovery system on the transmitted pulse shape, thereby permitting the use of signals with minimum support in the frequency domain.

6.7.2 Carrier Phase and Frequency Estimation

The carrier phase and frequency estimation problems may be formulated as follows for a signal after proper equalization

$$y(t) = x(t)\mathrm{e}^{\mathrm{j}[\omega_{\mathrm{IF}}t+\theta(t)]} + N\,, \tag{6.89}$$

where t is time, x is the transmitted symbol sequence, y is the received symbol sequence including all distortions and noise, ω_{IF} is the angular intradyne frequency –

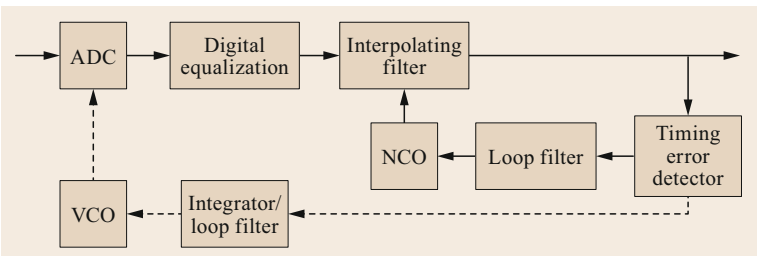

Fig. 6.8 A block diagram showing a hybrid timing-recovery circuit with coarse frequency correction of the clock driving the ADCs using a voltage-controlled oscillator (VCO) and fine phase-locking entirely in the digital domain using a circuit driven by a number-controlled oscillator (NCO)

that is, the difference in angular frequency between transmitter and receiver lasers, θ is the time varying phase noise, and N is the additive noise term.

Carrier phase and frequency estimation algorithms may be considered to fall under two broad categories: pilot-aided and blind [6.12]. Pilot-aided algorithms make use of components of the signal,of which the receiver algorithm has a-priori knowledge. These components may be predetermined symbols, interspersed with unknown data symbols, or sinusoids which have a fixed relation to the optical carrier frequency and phase. Blind algorithms use a nonlinear function operating on the symbols received to remove the influence of modulation on the phase received.

While there is a well-developed literature dedicated to intradyne frequency estimation algorithms [6.33, 34], research in this area has slowed significantly in recent years. Due to the slow variation of frequency in lasers, extremely accurate estimates may be performed with very large observation windows to minimize the effects of noise and distortion. Since these estimates must be obtained infrequently, computational cost is low, and performance good for all practical systems. We, therefore, focus on the problem of carrier phase estimation, which is a much faster varying estimation problem and has continued to prove challenging as modulation and coding techniques have evolved.

Algorithms for CPE

Viterbi and Viterbi. The Viterbi and Viterbi algorithm uses an M-th power instantaneous nonlinearity to eliminate the impact of modulation on phase received. The simple nature of the algorithm, combined with its use of circular symmetry in the constellation mean that it is an algorithm particularly well suited to phase-shift keying (PSK)-based modulation. The most general form, given in [6.35], is

$$\hat{\phi}_k = \frac{\arg\left(\sum_{i=k-L}^{k+L} F(|y_i|) y_i^M\right)}{M}\,, \tag{6.90}$$

where $\hat{\phi}_k$ is the phase estimate at symbol index k, F is an arbitrary nonlinear function, L is the half-length of an averaging filter, M is the nonlinear power, and arg(.) is the complex argument function.

This results in a phase estimate that is bounded on $\pm\pi/M$, which must then be unwrapped. This is done by calculating a per-symbol unwrapping phase as

$$a_k = a_{k-1} + \left\lfloor \frac{1}{2} + \frac{M}{2\pi}(\hat{\phi}_k - \hat{\phi}_{k-1}) \right\rfloor\,. \tag{6.91}$$

The unwrapped phase can then be calculated as

$$\hat{\theta}_k = \hat{\phi}_k + a_k\,. \tag{6.92}$$

Blind Phase Search. Due to the sensitivity to phase noise of high spectral efficiency modulation formats such as QAM, accurate carrier phase estimation is essential. The recent interest in advanced modulation formats and modulation format flexible transceivers also provides motivation for algorithms that are independent of the modulation format being used.

The blind phase search (BPS) algorithm [6.36] uses a search over a set of test phases $\boldsymbol{\Phi}$ with B elements over a range of $\pi/2$, given by

$$\boldsymbol{\Phi} = \frac{b\pi}{2B}\,; \quad b \in \{0, 1, \ldots, B-1\}\,, \tag{6.93}$$

the test vector is used to determine the most likely test phase according to the minimum mean squared error. A wrapped phase estimate $\hat{\phi}_k$ is, therefore, calculated with

$$\hat{\phi}_k = \underset{\Phi}{\operatorname{argmin}} \left[\sum_{i=k-L}^{k+L} \left| \mathrm{e}^{-\mathrm{j}\Phi} y_i - D\left(\mathrm{e}^{-\mathrm{j}\Phi} y_i\right) \right|^2 \right], \tag{6.94}$$

where D is the minimum Euclidean distance symbol decision function, for the modulation format under consideration. As with the Viterbi and Viterbi algorithm, the phase estimate must be unwrapped before being applied to the signal.

As the calculations may be done in parallel for the B elements in the vector $\boldsymbol{\Phi}$, and in parallel for different samples in time, this algorithm may be suitable for implementation in hardware. However, the complexity of the BPS algorithm is linearly dependent on the number of test phases. There has, therefore, been a great deal of interest in developing reduced-complexity alternatives to the BPS algorithm.

Advanced Algorithms for Future Implementation

While advanced modulation formats have enabled the implementation of 200 and 400 Gb/s single carrier systems, the desire of equipment manufacturers to improve performance and reduce complexity also drives research into new carrier recovery algorithms. As system implementations approach the Shannon bound [6.37], the accuracy of purely blind carrier systems is diminished, as signal and noise become harder to distinguish. As a result, research into carrier phase estimation algorithms for capacity approaching systems have focused on two areas: dual-stage algorithms and statistical signal processing approaches.

Dual-stage algorithms have been investigated [6.38–40] in detail for their ability to determine a somewhat accurate initial baseline phase without ambiguity for minimal computation, possibly with the aid of pilot symbols at the cost of a small overhead

in transmission rate. A second stage can then provide more accurate estimation of the carrier phase given the initial estimate is closest to the true phase.

Statistical signal processing algorithms such as Bayesian filtering [6.41] and Kalman filtering [6.40, 42] have been used to accurately recover carrier phase for both non-Lorentzian phase noise, and for Lorentzian systems with very low SNR. Kalman smoothing has also been used to enhance the initial estimate of phase given by a pilot-aided algorithms. While these algorithms are currently prohibitive in their complexity, they indicate the manner of improvement that may be possible in the future as complexity is reduced and computational resources increase.

6.8 Forward Error Correction Coding

The origins of forward error correction coding lie in the renowned paper by *Shannon* [6.37], which provided the genesis for the fields of communication theory, information theory, and coding theory. Shannon's *noisy channel coding theorem* is given by

$$C = B \log_2 \left(1 + \frac{P_{\text{sig}}}{P_{\text{noise}}} \right) . \tag{6.95}$$

This theorem gives us the maximal rate C in bits per second that can be transmitted with good reliability over an AWGN channel with bandwidth B, signal power P_{sig}, and noise power P_{noise}. A corollary to this is that reliable communication may be achieved over any channel with an appropriate channel code or forward error correction (FEC) code.

The basic principle of FEC coding is that when a random sequence is injectively mapped onto a larger space, the set of all possible sequences in this larger space can become sufficiently sparse that different sequences in this larger space may be estimated in the presence of noise with an arbitrarily low probability of error. The increase in dimension between the initial sequence and the sequence after injective mapping may be considered as the overhead required for forward error correction, which must increase as the signal-to-noise ratio decreases in order to maintain reliable communication.

In order to characterize the amount of overhead required for FEC that allows reliable communication at a fixed signal-to-noise ratio, we must account for several factors: the modulation format under consideration, and the nature of the information considered by the decoder (i.e., hard decision or soft decision), the cardinality of the coding scheme under consideration (i.e., binary or over some higher order field). This calculation can, therefore, provide us with an achievable information rate for a given channel, modulation format, and coding strategy.

We note that the FEC strategies used in optical communications systems are generally designed to be optimal for the additive white Gaussian noise (AWGN) channel. While the optical fiber channel is not, in fact, an AWGN channel, it has been shown to be well approximated by AWGN [6.43], and such algorithms are often well suited to implementation in hardware.

The FEC schemes used in optical communications are currently exclusively block coding-based schemes (including the somewhat misleadingly named LDPC convolutional code). We may describe such a linear block coding scheme in the following way

$$\boldsymbol{w} = \boldsymbol{u}\mathbf{G} , \tag{6.96}$$

where $\boldsymbol{u}$ is the uncoded input word, $\mathbf{G}$ is the generator matrix, and $\boldsymbol{w}$ is the resulting codeword. For an input word $\boldsymbol{u}$ of length k and generator matrix $\mathbf{G}$ of dimension $n \times k$, $n-k$ redundant dimensions are introduced to the codeword $\boldsymbol{w}$, resulting in a code rate of

$$R = \frac{k}{n} . \tag{6.97}$$

The parity constraints imposed by the code are described by the parity check matrix $\mathbf{G}$, which is defined by

$$\mathbf{I} = \mathbf{G}\mathbf{H} , \tag{6.98}$$

where $\mathbf{I}$ is the identity matrix. For an estimated codeword $\tilde{\boldsymbol{w}}$, we can calculate the syndrome $\boldsymbol{s}$ as

$$\boldsymbol{s} = \tilde{\boldsymbol{w}}\mathbf{H} . \tag{6.99}$$

Each of the $n-k$ elements in the vector $\boldsymbol{s}$ determines the sum of inputs to each parity equation described by the generator matrix. In the case when the syndrome vector $\boldsymbol{s}$ consists only of zeros, therefore, $\tilde{\boldsymbol{w}}$ represents an estimated codeword that satisfies all parity constraints determined by $\mathbf{H}$, and is, therefore, valid (although not necessarily equal to the transmitted codeword).

6.8.1 Coding Schemes

While early coherent transmission systems employed hard-decision FEC in order to minimize complex-

ity [6.44], subsequent systems have focused on the use of soft-decision coding schemes for increased gain [6.45]. By decoding using not only the bit received, but their relative likelihoods, an increase in coding gain of 2 dB or more can be achieved. As modulation density has increased for advanced transceiver designs, using 8, 16, 32, and 64 QAM, bit-interleaved coded modulation (BICM) [6.46] has been utilized to minimize the complexity of the coding system in hardware. It uses a binary code with an interleaver that assigns equal proportions of each bit-position in the constellation (i.e., from most significant to least significant) to the codeword. This enables the decoder to have an equal proportion of the most reliable bits (that is, the most significant) and least reliable (that is, the least significant). While this is known not to be the optimal strategy, it offers only a small penalty from the optimum in many cases, and has very low complexity.

Low-Density Parity Check Coding

The most widely adopted soft-decision coding scheme for coherent optical transmission systems has been the combination of low-density parity check (LDPC) codes with BICM. LDPC codes were first discovered in the early 1960s by *Gallager* [6.47] as a PhD student and were widely considered impractical until their rediscovery in the 1990s [6.48]. One of the primary drivers for the adoption of LDPC codes recently has been the development of belief propagation (BP)-based approximate decoding algorithms such as the sum-product algorithm (SPA) [6.49]. BP decoding algorithms pass many messages in parallel between two sets of parallel decoders, which perform simple operations. As the decoding algorithm is inherently parallel, the long codewords required by LDPC (on the order of 10 000 bits) are not prohibitive in either latency or complexity.

Advanced Coding Techniques

While coding schemes that approach the Shannon bound for a binary input AWGN channel have been described for more than 50 years, much research is ongoing in the fields of coding and modulation.

A significant development in recent years has been the development of polar codes, which were discovered by *Stolte* [6.50] in 2002 and, later – independently – by *Arikan* [6.51]. Polar codes can achieve capacity approaching performance at far shorter codeword lengths than those of traditional methods such as LDPC [6.52]. While the structure of polar codes does not favor belief-propagation type decoding, much progress has been made recently in decoder algorithms. Particularly influential has been the work of *Tal* and *Vardy*, whose successive cancelation list decoder [6.53] may be realizable in hardware.

Other topics of research have been focused on reducing the loss in capacity due to the use of binary codes with interleaving. Nonbinary coding schemes such as nonbinary LDPC (NB-LDPC) [6.54–56] can achieve better performance than binary codes and are optimal when the cardinality of modulation is equal to the order of the field over which the code is constructed. While nonbinary coding can achieve nontrivial gains in some cases, implementation has proven difficult due to the required increase in complexity. For BP type decoders, a modulation of code constructed in GF(M) requires $M-1$ messages to be passed over each edge in the Tanner graph per decoder iteration.

BICM with iterative demodulation utilizes feedback from the FEC decoder to update the demodulator [6.46]. This technique may also approach the optimal performance bounded by NB-LDPC, albeit with significant complexity. Iterative demodulation may be done with reduced frequency – that is, not at every iteration of the decoder – although this is associated with a reduction in performance [6.57].

6.9 Current Research Trends

6.9.1 Constellation Shaping

Constellation shaping provides a methodology for digital communications systems to approach the Shannon bound for the AWGN channel. While the Shannon bound assumes a source with a continuous Gaussian distribution, a digital communication system with finite code rate must have a discrete source distribution. There are two types of source distribution that are of particular interest in constellation shaping: distributions with equiprobable symbols, which are unevenly distributed in the signal space, known as geometric shaping; and distributions with unequally probable symbols, which are evenly distributed in the signal space, known as probabilistic shaping.

Geometric Shaping

Geometric shaping systems are in their most general form designed to be a throughput maximizing arrangement of equally probable constellation points for a given channel [6.58] (for simplicity, normally assumed to be the AWGN channel). For modulation of

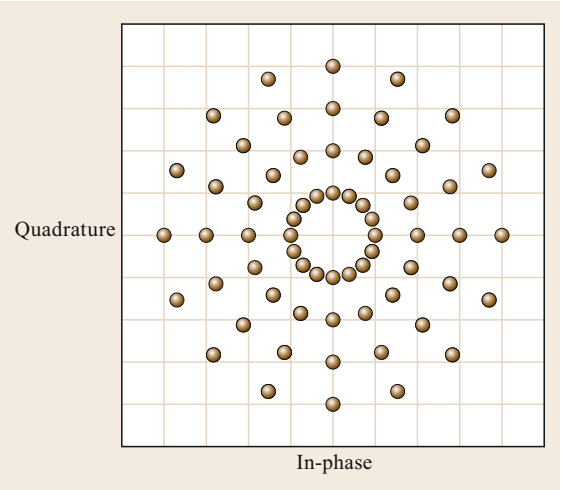

Fig. 6.9 A geometrically shaped constellation with 64 points, able to represent 6 bits of information. There are 16 equally-spaced phase levels, representing 4 bits of information, and 8 amplitude levels, representing 3 bits of information

cardinality M, this is an optimization with $M-2$ dimensions, if we assume that the constellation has zero mean and unit power. As optimization in this number of dimensions quickly becomes impossible for the scale of M which is of interest (for example, 16–1024), some symmetry is often assumed in the constellation such that the number of dimensions can be reduced to the level whereby numerical optimization can be employed.

A common simplification to the constellation is to assume that phase is modulated with equally spaced levels on a number of rings [6.59, 60], and that the amplitude levels of the rings are optimized in order to maximize throughput at a given SNR. This configuration is often denoted amplitude and phase-shift keying (APSK). An example of 64-APSK with 16 amplitude levels and 4 phase levels is shown in Fig. 6.9.

While the performance of APSK is demonstrably superior to that of uniformly distributed square QAM, it is known that APSK approaches the Shannon bound only when symbol metric decoding is used [6.59], that is, in cases where nonbinary coding or BICM with iterative demodulation are used. As has been previously noted, these coding schemes are considered to be prohibitive in terms of complexity, and, therefore, alternative shaping methods are of considerable interest.

Probabilistic Shaping

Probabilistic shaping systems are also in their most general form designed to be a throughput maximizing probability distribution of arbitrarily arranged constellation points for a given channel (for simplicity, normally assumed to be the AWGN channel). In the contemporary literature for optical communications, several other characteristics are near universal. The constellation points are normally considered to be square QAM; constellations are assumed to be shaped in the amplitude domain only (on a per quadrature basis), and, therefore, have reflective symmetry about the real and imaginary axes. This allows for the FEC code to be applied to the stream of shaped bits, and the uniformly distributed parity bits assigned to the sign bits of the constellation – this configuration is also known as *reverse concatenation* of FEC and distribution matching. A further common feature is that each shaped symbol sequence that corresponds to a block of uniformly distributed bits has the desired amplitude probability mass function (PMF) – this is known as constant composition distribution matching (CCDM) [6.61].

The reverse concatenation approach to probabilistic amplitude shaping (PAS) is critical to realizable implementations and is described in the Fig. 6.10. Uniformly distributed bits from a source are mapped by a distribution matcher to symbol sequences, which have the desired distribution of amplitudes. The bits representing the shaped amplitudes are then encoded with an FEC encoder, and the parity bits (which have a uniform distribution) are assigned to the sign bits of the constellation. At the receiver side, the FEC decoder operates on the noisy received symbols in the conventional manner, and the noise-free amplitude sequences are passed to a distribution dematcher, which outputs uniformly distributed data bits. This architecture provides several important benefits: firstly, the Shannon bound may be approached with a BICM coding scheme, which is an important condition for practicality; and secondly, the distribution dematcher can operate on noise-free symbol sequence inputs. This reduces the complexity of the dematching algorithm requirements. By varying the entropy of the target distribution and the rate of the distribution matcher, this also enables the transmission rate to be varied while maintaining a constant code rate and symbol rate [6.62].

While these advances have pointed to possible implementations of probabilistic shaping in the near future, significant hurdles remain. While CCDM remains the most widely studied technique at the time of writing, the high degree of serialism required in the distribution matcher and dematcher, combined with long block lengths required for good performance mean that it is highly challenging to implement CCDM in hardware. There is, therefore, significant impetus in the development of alternative architectures for PAS [6.63–65] that do not suffer the problems of CCDM.

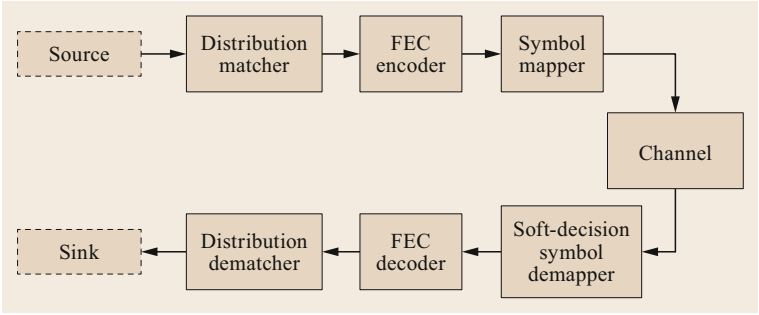

Fig. 6.10 A schematic of a communication system employing probabilistic amplitude shaping. The information bits are first shaped by a distribution matcher, then encoded by an FEC encoder, before being mapped to symbols and transmitted over the channel. The parity bits have uniform distribution and are mapped to the sign bits in the desired constellation. At the receiver, the symbols are demapped before the FEC code is decoded. The noise-free shaped bits are then passed to a distribution dematcher to recover the original information bits

6.9.2 Power Efficient Transceiver Design

As coherent technology has moved into shorter reach transmission systems, the impact of transceiver power consumption on the overall system power consumption has become increasingly important. While steady improvements in CMOS technology have provided a reduction in power consumption per computational operation, reducing the power consumption of the transceiver ASIC is also an active topic for research.

By reducing the sampling rates at the signal converters and throughout the DSP chain, it is possible to reduce the number of samples processed, and, therefore, the power consumed. While these techniques can be employed without fundamental penalty, they require new algorithms for equalization and symbol timing recovery.

Algorithmic improvements in important DSP blocks such as the adaptive equalizer [6.66, 67] and CPE [6.68] can demonstrate significant reductions in the number and complexity of computational operations required to achieve the desired functionality. Furthermore, eliminating the DSP entirely (or almost entirely) has been proposed [6.69].

Computational complexity has also been examined as a primary constraint in the design of FEC codes [6.70]. The ability to trade gain for complexity during the design process is a direct result of the desire to limit complexity for a desired level of performance.

We must also note that recent research has illuminated the importance of hardware emulation as a tool for estimating power consumption improvements. While the broadest effects may be considered by the counting of multipliers and adders, the frequency with which gates are flipped, wiring losses, and the characteristics of different CMOS processes are ignored without a fuller examination of the ASIC design process [6.71].

6.9.3 Nonlinearity Mitigation

Digital nonlinearity mitigation has been popularized over the last several years with two algorithmic designs: split-step type algorithms and perturbation type algorithms [6.72]. While both of these methods have the same performance under ideal conditions, perturbation type algorithms are generally considered to be capable of better performance at the low complexity required for hardware implementation. Despite this popularity, the gain available from digital nonlinearity compensation seems to be limited to the region of 1 dB or less for realistic system configurations [6.73].

An alternative approach is nonlinear frequency division multiplexing. The nonlinear Fourier transform (NLFT) has been known as an application of the inverse scattering transform to the nonlinear Schrödinger equation (NLSE) since the 1970s [6.74]. More recently, the elements of the discrete NLFT were proposed as a basis for transmitting information in parallel nonlinear channels [6.75]. This basis – which may be considered as a set of orthogonal solitons [6.76] – can be used to transmit information over the nonlinear optical channel without accumulating distortion due to nonlinearity during transmission. This technique has been referred to as nonlinear frequency-division multiplexing or NFDM [6.77].

More recently, an algorithm with reduced complexity – the fast nonlinear Fourier transform [6.78] – was developed to enable efficient modulation of an optical carrier in the domain of this nonlinear basis, with $\mathcal{O}(n \log n)$ complexity.

A great deal of research effort has been expended in developing transmission systems based on these ideas [6.79–81]. However, limitations on the amount of bandwidth that is possible to jointly process, along with nonlinear distortions induced by copropagating noise have limited the gains achieved thus far to approximately those already available with other methods of digital nonlinearity mitigation [6.82].

6.10 Future Opportunities

6.10.1 High-Capacity Core Transport

Commercial systems operating at 1 Tb/s on a single wavelength may be a reality in only a few years with systems transmitting 600 Gb/s per wavelength already under development. Increasingly, transceivers are using all of the available options, being bit-rate adaptive, using constellation shaping to enable a single transceiver to flex from QPSK up to 128 QAM for each polarization. Such transceivers are bit-rate adaptive, enabling 400 Gb/s to be transmitted over 1200 km [6.72]. Most demonstrations of 1 Tb/s have used in the region of 100 GHz optical bandwidth, which will require RF and mixed signal circuits to operate in the region of 60 GHz or more RF bandwidth. While test equipment is available at these levels, new optical devices will be required to take advantage of such high bandwidths. In terms of aggregate capacity, space division multiplexed systems can offer significant increases in capacity. This again offers significant opportunities for DSP, in particular for systems with mode mixing.

6.10.2 Metro-Access

While DSP has become a key technology for long-haul systems, as power consumption reduces it can be expected to be applied to shorter-reach systems. Efforts are underway at the time of writing to provide standards for 400 Gb/s transmission systems, suitable for distances of 10–100 km. These systems are particularly important in the growing market for data center interconnect products. In metro-access systems, the increase in the demands of wireless networks indicate a growing potential space for coherent systems in wireless backhaul, and potential in midhaul and even fronthaul.

6.10.3 Short-Reach Systems

At present, a very promising avenue for research relates to DSP for direct-detection systems. While for the shortest of links, the power consumption and footprint of full digital coherent systems appears prohibitive, DSP-enabled direct-detection systems may be capable of bridging this gap and providing gains in performance and functionality for short-reach and low-cost applications. One such proposal is the introduction of equalization to the receiver DSP chain for Ethernet systems operating at 100–400 Gb/s using 4-ary pulse amplitude modulation (4-PAM). A short feed-forward equalizer (FFE) and decision-feedback equalizer (DFE) pair can mitigate the bandwidth constraints of the optical and electronic components, while having only small penalties in complexity and latency [6.83]. Single-sideband modulation, combined with the Kramers–Kronig receiver, which utilizes a minimum phase criterion to link the amplitude and phase via a Hilbert transform [6.84], offers the possibility of compensating the effects of chromatic dispersion, while requiring only an increase in DSP complexity at the receiver, and the use of an I/Q modulator. Alternately, by utilizing a dual-polarization I/Q modulator and a more complex receiver, Stokes-vector direct detection may be implemented in order to increase spectral efficiency and compensate for transmission impairments [6.85].

6.11 Closing Remarks

DSP has emerged as a key technology for modern optical fiber communication systems. Enabling, for example, 1 Tb/s to be transmitted over fiber which could not previously have been used for 10 Gb/s due to PMD. It has had a significant impact also on the design of systems, optical chromatic dispersion compensation is now all but obsolete, but also moving to a digital transceiver has resulted in a better quality of transceiver, requiring less system margin to account for variability. Improvements in power consumption have been predicated on Moore's law, with modern coherent transceivers utilizing over 1 billion transistors, compared to just 20 million in the first coherent ASIC deployed just a decade ago [6.2]. Going forward we, can expect DSP to impact all optical fiber communication systems from short-reach systems within a data center to transoceanic submarine links.

Seb J. Savory

Dept. of Engineering
University of Cambridge
Cambridge, UK
sjs1001@cam.ac.uk

Seb J. Savory received his PhD in Engineering from the University of Cambridge and then worked for Nortel in Harlow. He moved from Nortel to UCL in 2005, departing in 2015 to take up a position at the University of Cambridge where he is currently a Professor. He is a Chartered Engineer and Fellow of the IEEE, IET, OSA, and HEA.

David S. Millar

Mitsubishi Electric Research Laboratories
Cambridge, MA, USA
millar@merl.com

David S. Millar received his PhD from University College London (UCL) in 2011. Since 2012, he has been a researcher at Mitsubishi Electric Research Laboratories (MERL) in Cambridge, MA, USA. His research is primarily focused on signal processing algorithms and coded modulation for coherent optical communications.

7. Forward Error Correction for Optical Transponders

Alexandre Graell i Amat, Laurent Schmalen

Forward error correction (FEC) is an essential technique required in almost all communication systems to guarantee reliable data transmission close to the theoretical limits. In this chapter, we discuss the state-of-the-art FEC schemes for fiber-optic communications. Following a historical overview of the evolution of FEC schemes, we first introduce the fundamental theoretical limits of common communication channel models and show how to compute them. These limits provide the reader with guidelines for comparing different FEC codes under various assumptions. We then provide a brief introduction to the general basic concepts of FEC, followed by an in-depth introduction to the main classes of codes for soft-decision decoding and hard-decision decoding. We include a wide range of performance curves, compare the different schemes, and give the reader guidelines on which FEC scheme to use. We also introduce the main techniques to combine coding and higher-order modulation (coded modulation), including constellation shaping. Finally, we include a guide on how to evaluate the performance of FEC schemes in transmission experiments. We conclude the chapter with an overview of the properties of some state-of-the-art FEC schemes used in optical communications, and an outlook.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_7

The fundamental problem of communication is that of sending information from one point to another (either in space or time) efficiently and reliably. Examples of communication are the data transmission between a ground station and a space probe through the atmosphere and free space, the write and read of information on flash memory, and communication between servers in a data center through optical interconnects. The transmission over the physical medium, e.g., the optical fiber, is prone to noise due to amplification, distortion, and other impairments. As a consequence, the transmitted (digital) message may be received with errors.

To reduce the probability of error, one could (if possible) increase the signal-to-noise ratio (SNR), i.e., transmit at a higher power, or transmit using a larger bandwidth. In his landmark 1948 paper [7.1], *Claude E. Shannon* showed that there is a third parameter one can play with: the system complexity. Shannon proved that, for any given channel (e.g., a given SNR and bandwidth), there is a fundamental limit, the so-called *channel capacity*, at which information can be transmitted reliably, i.e., with diminishing error probability. Aside from determining the channel capacity, he also showed how this limit can be achieved: by the use of coding.

Shannon's contribution marks the birth of the fields of information theory and coding theory. While information theory aims at determining the fundamental limits of communication, coding theory aims at finding *practical* codes that achieve (or approach) these limits. The principle of coding is very simple: to introduce redundancy in the transmitted sequence in a controlled manner, such that it can be exploited by the receiver to correct the errors introduced by the channel. However, while Shannon proved the *existence* of capacity-achieving codes, he did not provide any insight on how to construct *practical codes*. His proof was based on a random-coding argument. Informally, the argument says that a random code will achieve capacity with high probability. Unfortunately, random codes are not practical, as both encoding and decoding require computational complexity and storage that grow exponentially with the block length (and Shannon showed that to achieve capacity, large block lengths—in truth infinitely large—are required!). Therefore, since the late 1940s, finding practical codes that are able to perform close to capacity with reasonable decoding complexity has been the holy grail of coding theory. For decades, researchers worked to develop powerful codes with a rich algebraic structure, among them the celebrated Bose–Chaudhuri–Hocquenghem (BCH) codes and Reed–Solomon codes, which unfortunately still performed far from the channel capacity with feasible decoding algorithms. Two breakthroughs came in the 1990s, the first when two researchers, *Claude Berrou* and *Alain Glavieux*, introduced turbo codes, the first class of codes that was shown to approach capacity with reasonable decoding complexity, and the second with the rediscovery of low-density parity-check (LDPC) codes (originally introduced in 1960 by *Robert Gallager*) by *David MacKay*. The advent of turbo codes and the rediscovery of LDPC codes constituted a cornerstone in coding theory and gave birth to what nowadays is referred to as the field of *modern coding theory*, which is also intimately related to the iterative decoding of these codes. LDPC codes and turbo codes have now been adopted in a plethora of communication standards.

The application of coding goes far beyond the classical communication and storage problem. Coding is a very powerful, fundamental tool that plays a key role in many other applications and research fields, including distributed storage and caching [7.2, 3], uncoordinated multiple access [7.4], to speed up distributed computing tasks [7.5, 6], for quantum key distribution [7.7], and post-quantum cryptography [7.8].

Coding theory is a vast field that is impossible to cover in a single book chapter. This is certainly not our aspiration. The aim of this chapter is simply to provide a brief and accessible introduction to the main concepts underlying the art of coding and a simple but rather complete overview of the main coding schemes that will arguably be used in future optical communications systems. It is intended to be an entrance door to the exciting and important realm of coding for researchers in the field of optical communications that, while perhaps not ambitioning to become experts on coding, would like to become familiar with the field or are simply interested in widening their knowledge. It is also a handy source intended for engineers and practitioners of optical communication systems who are faced with the choice of a coding scheme.

One of the purposes of this chapter is to review the principal coding schemes for optical communications.

Because of the limited space, while we briefly describe classical codes such as BCH and Reed–Solomon codes, the main focus of the chapter is on *modern codes*, in particular LDPC codes and product-like codes such as staircase codes. Modern codes are also commonly referred to as *graph-based* codes or *codes on graphs*, since they can be conveniently described by means of a graph. LDPC and product-like codes are the two main code classes currently being used in fiber-optic communications with soft-decision and hard-decision decoding, and will likely continue being adopted in future systems. We will briefly describe the main building blocks of these codes, which are *rooted* in classical coding theory.

The remainder of the chapter is organized as follows. The chapter starts with a brief overview of the history of coding, with a special focus on the field of optical communications. In Sect. 7.2, an introduction to the fundamental performance limits, to which the performance of practical coding schemes can be compared, is provided. We then introduce the basic definitions and concepts of coding in Sect. 7.3. Sections 7.4 and 7.5 are devoted to soft-decision forward error correction (FEC) and hard-decision FEC, respectively. In Sect. 7.6, the combination of coding and higher-order modulation, dubbed *coded modulation*, is discussed, and some basics of constellation shaping are given. In Sect. 7.7, we discuss how to evaluate the performance of FEC schemes in transmission experiments. Finally, in Sect. 7.8 we draw some conclusions and provide an outlook on open research problems.

Notation: The following notation is used throughout the chapter. We use boldface letters to denote vectors and matrices, e.g., $\boldsymbol{x}$ and $\mathbf{X}$, respectively, and calligraphic letters to denote sets, e.g., $\mathcal{X}$. The cardinality of a set $\mathcal{X}$ is given by $|\mathcal{X}|$. The real and imaginary parts of a complex number are denoted by $\mathrm{Re}\{\cdot\}$ and $\mathrm{Im}\{\cdot\}$, respectively. The probability mass function (PMF) and the probability density function (PDF) of a random variable (RV) X are denoted by $P_X(x)$ and $p_X(x)$, respectively, as shorthand for $P_X(X=x)$ and $p_X(X=x)$. Sometimes we will simply write P_X and p_X. Also, we write $p_{XY}(x,y)$ to denote the joint PDF of two RVs X and Y, and $p_{Y|X}(y|x)$ to denote the conditional PDF of Y conditioned on $X=x$. We use similar notation for the joint and conditional PMFs. Probability is denoted by $\Pr(\cdot)$ and expectation by $\mathbb{E}$. More precisely, the expectation of a function $g(X)$ with respect to p_X is denoted as $\mathbb{E}_{p_X}[g(x)]$, or, in short, $\mathbb{E}_X[g(x)]$, i.e., $\mathbb{E}_X[g(x)] = \int g(x)p_X(x)\mathrm{d}x$. Likewise, the expectation of a function $g(x)$ with respect to a (discrete) PMF X is given by $\mathbb{E}_{P_X}[g(x)] = \sum_x g(x)P_X(x)$. Vector and matrix transpose are denoted by $(\cdot)^\top$, and $\|x\|$ denotes the ℓ_2-norm of x; $\mathbb{1}_{\{s\}}$ denotes the indicator function returning 1 if the statement s is true and 0 otherwise.

7.1 History of Forward Error Correction in Optical Communications

Forward error correction (FEC) in optical communications was first demonstrated in 1988 [7.9]. Since then, it has evolved significantly. This pertains not only to the techniques themselves but also to the encoder and decoder architectures. The history of FEC is, however, much older and has found more widespread application than only optical communications. In this section, we give a historical overview of FEC and link the historical developments to the developments in fiber-optic communications.

The first error-correcting codes, introduced by *Richard Hamming* in 1950 [7.10], were binary linear block codes that were designed to improve the reliability of electromechanical computing machines [7.11, 12]. Hamming codes are based on simple algebraic descriptions and have a straightforward hard-decision decoding (HDD) algorithm to correct single errors. Hamming codes were one of the first codes applied in optical communications. In 1988, *Wayne Grover* [7.9] reported a performance improvement not only with respect to the required received power and the observed residual error floor, but also with respect to chromatic dispersion tolerance and resilience to laser mode hopping.

Following the introduction of Hamming codes and the emergence of the field of coding theory, many new classes of codes were introduced, some with important properties and applications. One very powerful early code was the binary triple-error-correcting Golay code of length 23 bit and its ternary double-error-correcting counterpart (length 11 ternary digits) that were constructed by the Swiss engineer *Marcel Golay* in 1949 [7.13]. We should note that, while Hamming only published his work in 1950 after Golay's code, his work was already known to Shannon in 1948 and highlighted in [7.1], and hence several authors consider Hamming codes to be the first error-correcting codes. It is surprising that the ternary Golay code was in fact first discovered by the Finnish football fan *Juhani Virtakallio*, who published it in the 1947 issue of the Finnish football magazine *Veikkaaja* as a betting system [7.14]. The paper [7.14] gives an excellent overview of the early days of coding theory and its connections with neighboring scientific fields. The Golay

code is an exceptional code, as it is the *only* binary *perfect code* that can correct more than a single error ([7.15, Chap. 6, Sect. 10]). This means that there is no other binary code of smaller size that can correct up to three errors with HDD. The Golay code has found widespread application, and it was famously used in the two 1977 Voyager space missions [7.11]. The introduction of Hamming codes and the Golay code is a landmark in coding theory. For this reason, together with Shannon, Hamming and Golay are considered the fathers of the mathematical discipline of coding theory [7.15].

The 1950s saw the development of many new coding schemes that could correct multiple errors, for example the important Reed–Muller codes, with a construction first presented by *David Muller* in 1954 [7.16], and the decoding algorithm given by *Irving Reed* in the same year [7.17]. Also in 1954, *Peter Elias* introduced product codes (PCs) [7.18], a very relevant class of codes and the first example of codes built from smaller component codes. PCs are adopted nowadays for data storage on magnetic media and flash memory [7.19, 20], in the WiMAX (Worldwide Interoperability for Microwave Access) wireless communication standard [7.21], and for transmission over fiber-optic links [7.22]. Their excellent performance is due to a decoding algorithm that iterates between the decoding of the component codes. This iterative decoding algorithm was not originally envisaged by Elias, but only a few decades later, which explains why PCs were not initially adopted after their invention. A year later, *Elias* himself introduced the concept of convolutional codes [7.23] as an alternative to the then dominant block codes. In contrast to block codes, convolutional codes contain memory, and the output of the decoder depends not only on the input at the current time instant, but also on previous inputs. Because of their excellent performance with relatively low decoding latency, they have found their way into numerous communication standards. They are used in satellite and spacecraft links [7.11], for cellular radio (e.g., Global System for Mobile Communications (GSM)) [7.24], wireless local area networks [7.25], and Ethernet cables [7.26]. A particularly popular class of convolutional codes is based on simple binary linear shift registers. In this case, the encoder is a simple shift register with only a few memory elements. The key enabler for the success of convolutional codes was the Viterbi algorithm, introduced in 1967 [7.27, 28], which provides an efficient means of implementing optimal maximum likelihood (ML) decoding. The Viterbi algorithm enabled—for the first time—low-complexity soft-decision decoding (SDD) exploiting the full output of the channel. This represented a big step forward, as we will later see in Sect. 7.4. Despite their widespread use in many communication standards, convolutional codes have not yet found widespread use in fiber-optic communications. This is mostly due to the fact that parallelization of the decoder is not trivial, and to the availability of stronger codes at the time coding was adopted in fiber-optic communications. However, some notable exceptions are an early study of on-off-keying (OOK) modulation with different types of error-correcting codes, including convolutional codes [7.29], a paper analyzing the combination of convolutional codes and bandwidth-efficient modulation formats for fiber-optic communications [7.30], and a paper describing the use of low-rate convolutional codes to protect some levels in multilevel coding schemes [7.31].

The 1950s ended with the invention of one of the most important coding schemes still in use today, BCH codes, which were independently introduced by two groups [7.32, 33]. BCH codes are a class of cyclic error-correcting codes defined over a finite field that are able to correct multiple bit errors using simple syndrome decoding based on efficient closed-form solutions for computing the error locations [7.15, 34, 35]. After Hamming codes, single-error-correcting BCH codes of length 65 kbit, and two-error- and three-error-correcting BCH codes [7.36] were the next codes adopted in fiber-optic communication systems. These codes have overhead of less than 1%, while allowing the post-FEC bit error rate (BER) to be met with a channel pre-FEC BER of approximately 10^{-6}.

Shortly after the introduction of BCH codes, *Reed* and *Gustave Solomon* [7.37] introduced nonbinary cyclic error-correcting codes that are able to correct and/or detect a predetermined number of erroneous nonbinary symbols, consisting of groups of bits. The corresponding algebraic decoding algorithm was proposed by *Elwin Berlekamp* [7.38] and *James Massey* [7.39]. A widely used code is the Reed–Solomon code RS(255, 239) code (the notation will be introduced in Sect. 7.3) consisting of 255 nonbinary symbols, with each symbol composed of 8 bits. This code can correct up to eight symbol errors (or a single burst error of up to 57 bits) with 6.7% overhead and achieves a net coding gain (NCG) of 6.2 dB in SNR at a post-FEC BER of 10^{-15}. This means that we can tolerate an effective net SNR, taking into account the extra bandwidth required for the coding overhead, that is four times lower than without coding. This Reed–Solomon code was the first to find widespread use in fiber-optic communication systems, starting from submarine transmission [7.40], to metro and optical access systems [7.41]. Because of its low encoder and decoder implementation complexity, this code is still in use for applications with low coding gain requirements

and strict constraints on transceiver power consumption. It is included in several standards and described in detail in the ITU-T G.975 standard [7.42]. This code is commonly referred to as *first-generation* coding for light-wave systems [7.43].

In the decades that followed, coding research focused mostly on the construction of new, more powerful codes from the now existing schemes (i.e., following the same principle proposed originally by Elias with his PCs!). One such construction was the concatenation of simple component codes (e.g., convolutional codes, BCH codes, and Reed–Solomon codes), leading to long and powerful codes capable of achieving significant coding gains with low decoding complexity. Concatenated codes were first introduced by *Dave Forney* in 1965 in the form of serially concatenated codes (SCCs), with a cascaded *inner* and *outer* code [7.12, 44]. At the receiver, both component codes are decoded separately, resulting in much lower complexity compared with optimal ML decoding of the entire concatenated code, at the cost of some performance degradation. Typically, the inner code is a convolutional code decoded using SDD, while the outer code is a block code, usually a Reed–Solomon code, decoded using HDD. Concatenated codes soon became a popular code construction for satellite communications. A simple concatenated coding scheme was used already in the 1971 Mariner Mars orbiter mission, but regular use of concatenated codes for deep space communications began with the Voyager program. A concatenated code with an inner convolutional code decoded using Viterbi decoding and an outer Reed–Solomon code was first used in the 1977 NASA space mission Voyager 2, which was launched with the goal of studying the outer planets of our solar system. Concatenated codes are also used in the digital television broadcast standard DVB-S [7.45].

The so-called *second-generation* FEC schemes for fiber-optic communications are based mainly on PCs and concatenated codes, where the component codes are simple algebraic codes such as Hamming, BCH, or Reed–Solomon codes, or convolutional codes. The decoding of concatenated block codes is usually performed iteratively by alternately decoding each of the component codes, improving the overall result after each iteration. Almost all 6.7% overhead codes specified in the ITU-T G.975.1 standard [7.46] are concatenated codes. For instance, the code defined in [7.46, Appendix I.2] is composed of a convolutional inner code and a Reed–Solomon outer code. Similarly, the code defined in [7.46, Appendix I.5] is composed of an inner Hamming code and an outer Reed–Solomon code. All concatenated codes specified in [7.46] are very long codes, with block lengths of around 500 kbit. These codes achieve very good performance, with low error floors, and have moderate implementation complexity. For example, the concatenated code specified in [7.46, Appendix I.9], with inner and outer BCH codes, has an NCG of 9.24 dB and provides an output BER of less than 10^{-16} at an input BER of about 4×10^{-3}.

Second-generation coding schemes continue to evolve today for low-complexity applications such as metro networks [7.47] or data center interconnects. Three very recent developments in second-generation HDD FEC codes are continuously interleaved codes [7.48], staircase codes [7.49], and braided BCH codes [7.50], which can be considered generalizations of Elias' PCs with an additional convolutional-like structure. The NCG of the staircase code in [7.49] amounts to 9.41 dB at a BER of 10^{-15}, which is only 0.56 dB from the capacity of the hard-decision channel [7.49].

With the advent of coherent transmission schemes and high-resolution analog-to-digital converters (ADCs), SDD became an attractive means of increasing the NCGs and hence the transmission reach. Although SDD is the natural way to decode a code exploiting the full knowledge of the transmission statistics, HDD was prevalent in early fiber-optic communication systems due to the lack of ADCs and the requirements for simple high-speed receivers that carry out a binary 0/1 decision using analog radio-frequency (RF) circuits.

A breakthrough in the history of coding occurred in 1993, when Berrou and Glavieux introduced turbo codes, together with a simple iterative SDD algorithm, the *turbo principle* (due to its similarities to a turbo engine). Turbo codes are built from the parallel concatenation of two convolutional codes and were the first codes to approach capacity with acceptable decoding complexity. After the invention of turbo codes, a sudden interest in iteratively decodable codes arose in the research community. This led to the rediscovery of LDPC codes by *MacKay* [7.51, 52]. LDPC codes were originally introduced in 1960 by *Gallager* in his landmark PhD thesis [7.53, 54]. In his thesis, Gallager also proposed algorithms for both HDD and SDD. However, LDPC codes were not further investigated for many years because of the perceived higher decoding complexity for long codes. In the years that followed the invention of turbo codes and the rediscovery of LDPC codes, numerous publications from various researchers paved the way for a thorough understanding of these classes of codes, leading to numerous applications in various communication standards, such as WLAN (IEEE 802.11) [7.55], DVB-S2 [7.56], and 10G Ethernet (IEEE 802.3) [7.57].

In the realm of optical communications, FEC schemes with (iterative) SDD are typically classified as

third-generation FEC schemes. Today, there are largely two competing classes of codes that allow for SDD and that are attractive for implementation in optical receivers at decoding throughputs of 100 Gbit/s and above. The first class corresponds to the natural extension of the second-generation decoding schemes, i.e., PCs with SDD. Iterative low-complexity SDD of PCs was pioneered by *Ramesh Pyndiah* in 1998 [7.58], following the invention of turbo codes. Because of their similarities with turbo codes, PCs decoded using SDD are also often denoted as turbo product codes (TPCs) or block turbo codes (BTCs). The error floor of these codes tends to be low, with a steep BER slope. However, they require large block lengths to realize a small overhead, leading to a larger decoding latency. A further disadvantage is that flexibility with respect to varying frame sizes and overheads is more difficult to realize. Additionally, the decoder implementation requires the tweaking of many parameters to achieve the best possible performance. Furthermore, with overheads of more than 15% to 20%, these codes no longer perform well. The application of BTCs with iterative SDD in the context of fiber-optic communications was demonstrated in [7.59]. The second popular class of soft-decision decodable codes in optical communication systems is LDPC codes. One instance of an LDPC code has already been standardized in ITU-T G.975.1 ([7.46, Appendix I.6]). However, it was designed mostly for HDD. LDPC codes for SDD in optical communications were originally studied in [7.60], with work proposing complete coding schemes and frame structures shortly thereafter [7.61]. The popularity of LDPC codes is chiefly due to the existence of a suboptimal, conceptually very simple, low-complexity decoder for SDD: the belief propagation (BP) decoder. In addition to binary LDPC codes, nonbinary LDPC codes were promoted for optical communication systems in [7.62]. In short, nonbinary codes operate on symbols (e.g., modulation symbols), rather than bits. They come, however, at a cost of higher decoding complexity.

LDPC codes often suffer from an *error floor* at BERs of 10^{-8}–10^{-10} if no extra preventive measures are taken. Above a certain SNR, the BER no longer drops rapidly, but follows a curve with a smaller slope [7.63]. This effect is due to some structures in the code that lead to error patterns that cannot be recovered with BP decoding. Some modern high-performance FEC systems are therefore often constructed using an LDPC inner code decoded using SDD, which reduces the BER to a level of 10^{-3}–10^{-5}, and an outer block code (typically a BCH code or a Reed–Solomon code) decoded using HDD, which pushes the system BER to levels below 10^{-15} [7.61]. The implementation of a coding system with an outer cleanup code requires a thorough understanding of the LDPC code, the decoding algorithm, and its error mechanisms, and a properly designed interleaver between the LDPC code and the outer code so that errors at the output of the LDPC decoder—which typically occur in bursts—do not cause uncorrectable blocks after outer decoding. With increased computing resources, it is now also feasible to evaluate very low target BERs of LDPC codes and design LDPC codes that have very low error floors below the maximum acceptable BER [7.64].

Over the past decade, the field of coding theory has seen two important milestones: polar coding and spatial coupling. In 2008, *Erdal Arıkan* introduced the concept of channel polarization [7.65, 66], which led to the new concept of *polar codes*. The design of polar codes is based entirely on information-theoretic principles and differs radically from previously known code constructions. Despite the beauty of their construction and the fact that they are capacity-achieving with a simple *successive cancellation decoder*, which successively decodes the single bits of the codeword, polar codes are not immediately suited for practical application in optical communications. While polar codes show competitive performance for short block lengths with an improved *list decoder* [7.67] (which is one of the reasons they were chosen for transmitting control messages in the 5G radio standard [7.68]), for long block lengths, frequently used in optical communications to achieve high coding gains, their performance is not yet comparable to that of state-of-the-art LDPC codes. Furthermore, the decoder is inherently sequential, complicating their application in high-speed communication systems requiring high levels of parallelization. These drawbacks are currently topics of active research [7.69, 70].

The second breakthrough in the past decade was the introduction of the concept of *spatial coupling*. Spatial coupling itself has its own history. In 1999, *Alberto Jiménez Feltström* and *Kamil Zigangirov* investigated LDPC convolutional codes [7.71], a generalization of LDPC codes with a superimposed convolutional structure. It was only later fully realized that these codes, now known as *spatially coupled* LDPC (SC-LDPC) codes, possess outstanding performance. In fact, *Michael Lentmaier* and others realized that the asymptotic decoding performance of a certain class of SC-LDPC codes approaches the performance of optimal decoding [7.72–74] with simple suboptimal BP decoding. This effect, dubbed *threshold saturation*, was later rigorously proven in [7.75, 76]. The main advantage of spatially coupled codes is that it is possible to construct very powerful codes that can be decoded with a simple windowed decoder [7.77]. Spatial coupling is a very general concept that applies to other

classes of codes, such as turbo-like codes [7.78], as well as to other scenarios, including lossy compression [7.79], code-division multiple access [7.80], and compressed sensing [7.81]. Some product-like codes such as staircase codes and braided codes can also be seen as instances of spatially coupled codes.

Spatially coupled codes are now emerging in various forms. Two examples are the staircase code and the braided BCH code presented in [7.49] and [7.50], respectively, which are both codes with 6.7% overhead targeted for low-complexity applications with HDD (Sect. 7.5.3). Both codes can be classified as spatially coupled BCH PCs, and hence enable a natural windowed decoder implementation. Spatially coupled codes and polar codes are also being considered for SDD in optical communications [7.82–84]. However, as of today, the commercial application of polar codes in high-speed fiber-optic communications still seems further away than that of spatially coupled codes. The latter are a very general and broad concept that allows one to update many existing schemes and to reuse existing decoder hardware, at least to some extent. Therefore, we believe that the commercial application of spatially coupled codes is viable as of today.

The evaluation of the different generations of coding schemes for fiber-optic communications is shown in [7.85, Fig. 1.7]. In summary, we can say that within the span of only two decades, FEC in fiber-optic communication systems has evolved from the use of very simple schemes toward the implementation of state-of-the-art coding schemes in conjunction with high-speed decoding engines that operate at low complexity. Today, modern high-speed optical communication systems require high-performing FEC systems featuring throughput of 100 Gbit/s or multiples thereof, low power consumption, coding gains close to the theoretical limits, and adaptation to the peculiarities of the optical channel [7.86]. The stringent complexity requirements have even driven the investigation of new coding schemes, such as staircase codes [7.49], which are probably the first class of codes proposed specifically for optical transmission.

7.2 A Glimpse at Fundamental Limits and Achievable Rates

Before moving into the basics of coding, in this section we review the fundamental limits against which the performance of the coding schemes discussed in this chapter can be compared.

A simplified block diagram of a communication system is depicted in Fig. 7.1. The block of k source data bits $\boldsymbol{u} = (u_1, \ldots, u_k)$ is first encoded by an error-correcting code into a codeword $\boldsymbol{c} = (c_1, \ldots, c_n)$ consisting of n code bits, which is then modulated into a sequence of $\bar{n}$ constellation symbols $\boldsymbol{x} = (x_1, \ldots, x_{\bar{n}})$ that is transmitted over the channel. The received sequence $\boldsymbol{y}$ is demodulated and fed to the decoder, which aims at recovering the source data.

If the channel is memoryless, $p_{\boldsymbol{Y}|\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{x}) = \prod_i p_{Y|X}(y_i|x_i)$. In other words, the channel is completely specified by the conditional probability $p_{Y|X}(y|x)$ of receiving a single symbol y when a single symbol x is transmitted. The probability $p_{Y|X}(y|x)$ is often referred to as the *channel law*. Because of its prevalence and widespread use in modeling, throughout the chapter we will focus mainly on the case of memoryless channels with additive white Gaussian noise (AWGN), for which the channel law per real dimension (i.e., in each I/Q dimension in the case of complex constellation symbols) is expressed as

$$p_{Y|X}(y|x) = \frac{1}{\sqrt{2\pi}\sigma} \mathrm{e}^{-\frac{(y-x)^2}{2\sigma^2}} , \tag{7.1}$$

where σ^2 is the noise variance. We note that when using complex constellations, we often assume that the noise of the real and imaginary parts are independent. In this case, the circularly symmetric complex channel law is expressed as

$$\begin{aligned} p_{Y|X}(y|x) &= p_{Y_I|X_I}(\mathrm{Re}\{y\}|\,\mathrm{Re}\{x\}) p_{Y_Q|X_Q}(\mathrm{Im}\{y\}|\,\mathrm{Im}\{x\}) \\ &= \frac{1}{\pi N_0} \mathrm{e}^{-\frac{\|y-x\|^2}{N_0}} \end{aligned}$$

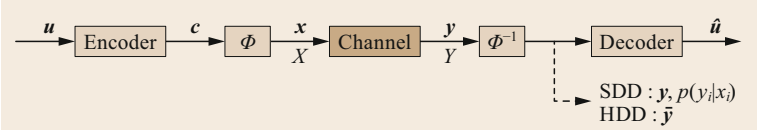

Fig. 7.1 Simplified block diagram of a communication system. For SDD, the decoder estimates the transmitted codeword based on $\boldsymbol{y}$ (equivalently the transition probabilities $p(y_i|x_i)$), while for HDD the decoder estimates the transmitted codeword based on the hard-detected sequence $\bar{\boldsymbol{y}}$

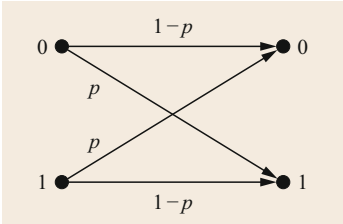

Fig. 7.2 The BSC. A bit is received correctly with probability $1-p$ and flipped with probability p

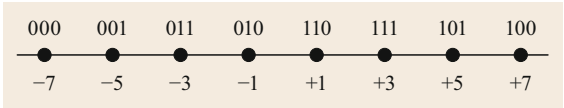

Fig. 7.3 8-PAM constellation with binary reflected Gray code labeling. The channel input X takes values on a set of 8 different symbols

The SNR is defined as $\mathrm{SNR} = E_\mathrm{s}/N_0$, where E_s is the average energy per symbol and $N_0/2 = \sigma^2$ the double-sided noise power spectral density.

We will also consider the binary symmetric channel (BSC), which is an important channel model for HDD. In fact, for an AWGN channel and binary phase-shift keying (BPSK) modulation, if hard detection is performed at the output of the channel, the resulting discrete memoryless channel between the encoder and the decoder can be modeled as a BSC with bits at the input and at the output, where a bit is flipped with probability

$$p = Q\left(\sqrt{\frac{2E_\mathrm{s}}{N_0}}\right) \tag{7.2}$$

and is received correctly with probability $1-p$. In (7.2), $Q(x) = (1/\sqrt{2\pi})\int_x^\infty \exp\left(-\tau^2/2\right)\mathrm{d}\tau$ is the tail probability of the standard normal distribution. The BSC is depicted in Fig. 7.2.

Let X be the channel input that takes values on the alphabet $\mathcal{X} = \{\mathsf{X}_1, \mathsf{X}_2, \ldots, \mathsf{X}_M\} \subset \mathbb{C}$, i.e., $\mathcal{X}$ is the constellation of cardinality M imposed by the modulation (e.g., $M = 16$ for a 16-QAM format) and Y the channel output. Note that X and Y are random variables (x and y are their realizations). We assume that the channel output Y is a continuous random variable. As an example, consider transmission using the eight-pulse-amplitude modulation (PAM) constellation depicted in Fig. 7.3. In this case, X is a random variable that takes values on the set $\mathcal{X} = \{-7, -5, -3, -1, +1, +3, +5, +7\}$ according to a given distribution P_X. For conventional constellations, all symbols are equiprobable, i.e., $P_X(\mathsf{X}_i) = 1/M$ for all X_i.

For a given distribution P_X of the channel input, the mutual information (MI) between the channel input X and channel output Y,

$$\begin{aligned} I(X;Y) &\triangleq \sum_{x\in\mathcal{X}} P_X(x) \int p_{Y|X}(y|x) \\ &\quad \times \log_2 \frac{p_{Y|X}(y|x)}{\sum_{x'\in\mathcal{X}} p_{Y|X}(Y|x')P_X(x')}\mathrm{d}y \\ &= \mathbb{E}_{XY}\left[\log_2\left(\frac{p_{Y|X}(Y|X)}{\sum_{x'\in\mathcal{X}} p_{Y|X}(Y|x')P_X(x')}\right)\right], \end{aligned} \tag{7.3}$$

determines the upper limit on the achievable rate. Here, by rate we mean the transmission rate, denoted by R, in bits per symbol (or bits per channel use). Note that in (7.3), the expectation is with respect to the PDF $P_X p_{Y|X}$. The rate R is sometimes referred to as spectral efficiency in the literature. This implicitly assumes ideal pulse shaping with infinitely extended $\sin(x)/x$ pulses and transmission at the Nyquist rate. In practice, the spectral efficiency (given in (bit/s)/Hz) and the transmission rate (given in bit/symbol or bit/channel use) often differ by a *spectral utilization factor* that depends on the pulse shaping, pre-emphasis, and other system parameters.

A rate R is called achievable if there exists a sequence of coding schemes such that the probability of a decoding error can be made arbitrarily small in the limit of infinitely large block lengths n. In other words, it is possible to transmit with vanishing error probability if $R < I(X;Y)$. Conversely, a sequence of coding schemes with vanishing error probability must have $R \le I(X;Y)$, and transmitting at a rate $R > I(X;Y)$ will always result in a probability of error bounded above zero. The highest possible achievable rate is given by the channel capacity, obtained by maximizing $I(X;Y)$ over all possible input distributions,

$$C \triangleq \max_{P_X} I(X;Y)\,. \tag{7.4}$$

Achieving the rate of (7.3) is possible with an optimal decoder or a typical sequence decoder for the channel $p_{Y|X}(Y|X)$ (in the limit of infinitely large block lengths). Furthermore, for some channels, suboptimal decoders may also achieve (7.3). In general, a communication system imposes some constraints on the transmitter and on the receiver (e.g., detection method, decoding strategy such as SDD or HDD), and thus for a specific communication system, the MI in (7.3) is not necessarily achievable. A lower bound on the true MI can be obtained using the mismatched decoding framework [7.87, 88]. The key idea behind mismatched decoding is to design a receiver that is optimal for an auxiliary channel (a good approximation of the true channel) and then computing (7.3) by averaging with respect to the true channel but using in the argument of the logarithm the conditional distribution of the auxil-

iary channel, i.e.,

$$\tilde{I}(X;Y) \triangleq \mathbb{E}_{XY}\left[\log_2\left(\frac{q_{Y|X}(Y|X)}{\sum_{x'\in\mathcal{X}} q_{Y|X}(Y|x')P_X(x')}\right)\right], \tag{7.5}$$

where $q_{Y|X}(Y|X)$ is the conditional distribution of the auxiliary channel and the expectation is taken with respect to $P_X p_{Y|X}$. The rate $\tilde{I}(X;Y)$ is achievable by using the optimal decoder for the auxiliary channel $q_{Y|X}(Y|X)$ over the real channel and is a lower bound of the MI, i.e., $I(X;Y) \geq \tilde{I}(X;Y)$.

Note that, in practice, the channel may not be memoryless. In this case, X and Y should be interpreted as vectors, $\boldsymbol{X}$ and $\boldsymbol{Y}$, and the conditional distribution $p_{\boldsymbol{Y}|\boldsymbol{X}}(\boldsymbol{Y}|\boldsymbol{X})$ should be considered. The fiber-optic channel, indeed, has memory. In this section, to compute achievable rates, we make the common assumption that the memory of the fiber-optic channel can be neglected. In practice, most common receivers neglect the memory of the channel or remove it by sufficient interleaving; hence the memoryless assumption yields meaningful achievable rates for actual receivers.

To achieve high spectral efficiencies and performance close to the theoretical limits, fiber-optic communications employ coding in combination with higher-order constellations, a scheme known as coded modulation (CM). At the receiver side, both SDD and HDD may be used. For SDD, the decoder estimates $\boldsymbol{c}$ based on the full observation $\boldsymbol{y}$, i.e., $\boldsymbol{y}$ (or, equivalently, the transition probabilities $p(y_i|x_i)$) is fed to the decoder. For HDD, the demodulator takes hard decisions at the channel output, and the sequence of hard-detected symbols, denoted by $\bar{\boldsymbol{y}}$, is fed to the decoder (Fig. 7.1). Furthermore, binary codes and nonbinary codes may be employed, which lead to two decoding strategies, namely bit-wise decoding and symbol-wise decoding, respectively. In the following, we briefly discuss achievable rates for SDD and HDD with both bit-wise and symbol-wise decoding. We restrict ourselves to the conventional uniform input distribution, i.e., $p_X(x) = 1/M$ for all $x \in \mathcal{X}$. A brief discussion of CM with probabilistic shaping is provided in Sect. 7.6.

For further reading, achievable rates for fiber-optic communications assuming a memoryless channel have been addressed in [7.89, 90]. Achievable rates for probabilistic shaping are discussed in [7.91]. The capacity of the nonlinear optical channel with finite memory is addressed in [7.92, 93], where the joint effect of nonlinearity and dispersion was modeled as a finite-state machine and the capacity was estimated. Capacity lower bounds for a variety of scenarios were obtained in [7.94]. Achievable rates for a nonlinear wavelength-division-multiplexed (WDM) fiber-optic system using the mismatched decoding framework were obtained in [7.95].

7.2.1 Achievable Rates for Soft-Decision Decoding

In the following, we review some achievable rates for SDD. We consider both symbol-wise and bit-wise decoding, suitable for nonbinary codes and binary codes, respectively, which lead to different achievable rates.

Symbol-Wise Soft-Decision Decoding

Consider first a CM scheme that employs a nonbinary code to encode the data and symbol-wise SDD (SW-SDD). Using mismatched decoding, an achievable rate is given by

$$R_{\text{SW-SDD}} = \sup_{s\geq 0} \mathbb{E}_{XY}\left[\log_2\left(\frac{q_{Y|X}(Y|X)^s}{\frac{1}{M}\sum_{x\in\mathcal{X}} q_{Y|X}(Y|x)^s}\right)\right], \tag{7.6}$$

where sup stands for supremum (which can be interpreted as a maximization), s is an optimization parameter, and the expectation is taken with respect to $P_X(x)p_{Y|X}(y|x)$, where $P_X(x) = 1/M$ assuming equiprobable symbols. To obtain the results in Sect. 7.2.3 below, we will assume that the auxiliary channel $q_{Y|X}(Y|X)$ is an AWGN channel, which is a good approximation of the fiber-optic channel under certain conditions. Note that for transmission over the AWGN channel, (7.6) boils down to (7.3), i.e., for transmission over the AWGN channel, the MI is indeed an achievable rate using nonbinary coding and SW-SDD.

Bit-Wise Soft-Decision Decoding

In fiber-optic communications, CM is typically implemented according to the bit-interleaved coded modulation (BICM) paradigm [7.96], where a binary code is used in combination with a higher-order constellation, and the code bits are interleaved prior to the mapping to constellation symbols (BICM and other CM schemes are discussed in Sect. 7.6.3). Accordingly, bit-wise decoding is performed at the receiver. While the rate (7.6) is achievable by a symbol-wise soft-decision decoder, it is not necessarily achievable by a bit-wise decoder. In the following, we give an achievable rate for bit-wise decoding.

The BICM decoder treats the different bits of a given symbol as independent. Note that the bits are independent only in the case of perfect interleaving. However, the BICM decoder treats bits as though they were truly independent, which simplifies the decoding. We denote by $m = \log_2 M$ the number of bits

used to label each constellation symbol, and by $\mathsf{L}(x) = (b^{(1)}(x), \ldots, b^{(m)}(x))$ the m-bit labeling associated with symbol $x \in \mathcal{X}$. An example of 8-PAM with the binary reflected Gray code labeling is shown in Fig. 7.3. In the figure, $\mathcal{X} = \{-7, -5, -3, -1, +1, +3, +5, +7\}$ and $\mathsf{L}(+1) = (1, 1, 0)$. To simplify notation, we will sometimes write $\mathsf{L}(x) = (b_1, \ldots, b_m)$, hence omitting the argument x on the $b^{(i)}$'s. Also, we denote by $\mathcal{X}_b^{(i)}$, $i = 1, \ldots, m$, the subset of constellation points such that $b^{(i)} = b$, i.e., $\mathcal{X}_b^{(i)} \triangleq \{x \in \mathcal{X} : b^{(i)}(x) = b\}$. For the example in Fig. 7.3, $\mathcal{X}_0^{(2)} = \{-7, -5, +5, +7\}$ and $\mathcal{X}_1^{(2)} = \{-3, -1, +1, +3\}$.

Similar to symbol-wise decoding, we can compute an achievable rate using the mismatched decoding framework. In particular, an achievable rate for BW-SDD is given by the generalized mutual information (GMI),

$$R_{\text{BW-SDD}} = \text{GMI}_{\text{BW-SDD}} \triangleq \sup_{s>0} \mathbb{E}\left[\log_2\left(\frac{q(X,Y)^s}{\frac{1}{M}\sum_{x\in\mathcal{X}} q(x,Y)^s}\right)\right]. \tag{7.7}$$

Assuming that bit levels are independent (i.e., assuming that the random variables $B^{(i)}$, $i = 1, \ldots, m$, are independent), the GMI of the BICM mismatched decoder is equal to the sum of the GMI of the independent binary-input parallel channels [7.97, Th. 2],

$$R_{\text{BW-SDD}} = \sup_{s>0} \sum_{i=1}^{m} \mathbb{E}_{B^{(i)}Y}\left[\log_2\left(\frac{q_i(b^{(i)},Y)^s}{\frac{1}{2}\sum_{b'\in\{0,1\}} q_i(b',Y)^s}\right)\right], \tag{7.8}$$

where the expectation is over $P_{B^{(i)}}(b^{(i)})p_{Y|B^{(i)}}(y|b^{(i)})$, with $P_{B^{(i)}}(b^{(i)}) = 1/2$, and where the i-th bit decoding metric $q_i(b, y)$, $i = 1, \ldots, m$, is given by

$$q_i(b,y) \triangleq q_i(b^{(i)}(x) = b, y) = \sum_{x'\in\mathcal{X}_b^{(i)}} q_{Y|X}(y|x'), \tag{7.9}$$

with the auxiliary channel $q_{Y|X}(Y|X)$ being the AWGN channel.

7.2.2 Achievable Rates for Hard-Decision Decoding

HDD consists of two steps. First, hard decisions on the received symbols are performed, and then the decoder employs the Hamming distance metric to decode. By doing so, the discrete-input, continuous-output channel with discrete input $x \in \mathcal{X}$ and continuous output y is turned into an M-ary input, M-ary output discrete memoryless channel with input $x \in \mathcal{X}$ and output $\bar{y} \in \mathcal{X}$ (the hard-detected symbols) with transition probabilities $P_{\bar{Y}|X}(\bar{Y} = \bar{y}|X = x)$. We denote by $\boldsymbol{x} = (x_1, \ldots, x_n)$, $x_i \in \mathcal{X}$ the codeword of modulated symbols and by $\bar{\boldsymbol{y}} = (\bar{y}_1, \ldots \bar{y}_n)$, $\bar{y}_i \in \mathcal{X}$, the sequence at the output of the hard detector.

Symbol-Wise Hard-Decision Decoding

A possible strategy for computing an achievable rate is to resort to the mismatched decoding framework [7.87, 88]. With optimal Hamming-metric decoding, the decoding rule is

$$\hat{\boldsymbol{x}}_{\text{SW-HDD}} = \arg\min_{\boldsymbol{x}\in C} d_{\text{H}}(\boldsymbol{x}, \bar{\boldsymbol{y}}), \tag{7.10}$$

where $d_{\text{H}}(\boldsymbol{x}, \bar{\boldsymbol{y}})$ is the Hamming distance between vectors $\boldsymbol{x}$ and $\bar{\boldsymbol{y}}$, i.e., the number of positions in which the two vectors differ (see Definition 7.4 in Sect. 7.3 for a formal definition).

For symbol-wise decoding, assuming that the channel is memoryless, employing HDD based on the Hamming decoding metric is equivalent to maximizing the codeword mismatched decoding metric [7.90]

$$q(\boldsymbol{x}, \bar{\boldsymbol{y}}) = \prod_{i=1}^{n} q(x_i, \bar{y}_i) \tag{7.11}$$

with

$$q(x, \bar{y}) = \begin{cases} 1-\xi & \text{if } \bar{y} = x \\ \dfrac{\xi}{M-1} & \text{otherwise} \end{cases}, \tag{7.12}$$

where ξ is an arbitrary value in $(0, (M-1)/M)$. In fact (see [7.90] for details),

$$\begin{aligned} \hat{\boldsymbol{x}}_{\text{SW-HDD}} &= \arg\max_{\boldsymbol{x}\in C} \prod_{i=1}^{n} q(x_i, \bar{y}_i) \\ &= \arg\max_{\boldsymbol{x}\in C} \left(\frac{\xi}{(1-\xi)(M-1)}\right)^{d_{\text{H}}(\boldsymbol{x},\bar{\boldsymbol{y}})} \\ &\overset{\text{(a)}}{=} \arg\min_{\boldsymbol{x}\in C} d_{\text{H}}(\boldsymbol{x}, \bar{\boldsymbol{y}}), \end{aligned} \tag{7.13}$$

where (a) holds if and only if $0 < \xi < (M-1)/M$.

The metric in (7.12) corresponds to the optimal (i.e., ML) metric for an M-ary symmetric channel with symbols $x \in \mathcal{X}$ at its input and symbols $\bar{y} \in \mathcal{X}$ at its output and error probability ξ (i.e., the probability that symbol $x \in \mathcal{X}$ is received erroneously is $\Pr(\bar{y} \neq x|x) = \xi$). Implicitly, a Hamming distance metric decoder treats the channel $P_{\bar{Y}|X}$ as a symmetric channel, ignoring the

information provided by the actual channel transition probabilities.

An achievable rate for symbol-wise HDD is given by the GMI [7.87, 98]

$$R_{\text{SW-HDD}} = \text{GMI}_{\text{SW-HDD}} \triangleq \sup_{s>0} \mathbb{E}_{X\bar{Y}} \left[\log_2 \left(\frac{q(X,\bar{Y})^s}{\frac{1}{M}\sum_{x\in\mathcal{X}} q(x,\bar{Y})^s} \right) \right], \tag{7.14}$$

where the expectation is over $P_{X\bar{Y}}$, with $P_X(x) = 1/M$, and $q(x,\bar{y})$ is the (symbol) mismatched decoding metric. Using (7.12) as the mismatched metric in (7.14), after some simple derivations, the achievable rate for SW-HDD is obtained as [7.90]

$$R_{\text{SW-HDD}} = \log_2 M - h_{\text{b}}(\delta) - \delta \log_2(M-1), \tag{7.15}$$

where

$$h_{\text{b}}(\delta) = -\delta \log_2 \delta - (1-\delta)\log_2(1-\delta) \tag{7.16}$$

is the binary entropy function evaluated in δ, with δ being the pre-FEC channel symbol error probability, i.e., $\delta = \Pr(\bar{Y} \neq X)$.

Bit-Wise Hard-Decision Decoding

As before, let $\mathsf{L}(x) = (b^{(1)}, \ldots, b^{(m)})$ be the m-bit labeling associated with symbol $x \in \mathcal{X}$. Also, denote by $\mathsf{L}(\bar{y})$ the binary labeling associated with the hard-detected symbol $\bar{y}$. Assuming BICM, we can model the m-bit level channels as m parallel independent BSCs. Let ϵ_i be the bit error probability of the i-th channel, i.e., $\epsilon_i = \Pr(\hat{B}^{(i)} \neq B^{(i)})$. Analogous to SW-HDD, an achievable rate for BW-HDD is given by the GMI (7.14). For bit-wise decoding employing the Hamming distance metric decoding, the mismatched metric is

$$q(x,\bar{y}) = \xi^{d_{\text{H}}(\mathsf{L}(x),\mathsf{L}(\bar{y}))}, \tag{7.17}$$

where ξ is an arbitrary value in $(0,1)$, and $d_{\text{H}}(\mathsf{L}(x),\mathsf{L}(\bar{y}))$ is the Hamming distance between the binary vectors $\mathsf{L}(x)$ and $\mathsf{L}(\bar{y})$.

Using (7.17) in (7.14), after some simple derivations the achievable rate for BW-HDD is obtained as [7.90]

$$R_{\text{BW-HDD}} = m[1 - h_{\text{b}}(\bar{\epsilon})], \tag{7.18}$$

where $h_{\text{b}}(\bar{\epsilon})$ is the binary entropy function (7.16) evaluated in $\bar{\epsilon}$ and

$$\bar{\epsilon} = \frac{1}{m}\sum_{i=1}^{m} \epsilon_i . \tag{7.19}$$

We note that, rather than taking hard decisions over the received symbols, one may first compute bit-wise log-likelihood ratios (LLRs) and then take hard decisions at the bit level. This leads to an achievable rate different from the one in (7.18). However, the two achievable rates are very similar.

7.2.3 Comparison of Achievable Rates for Bit-Wise and Symbol-Wise Decoding

In Fig. 7.4, we plot the achievable rates (7.6), (7.8), (7.15), and (7.18) for transmission over the AWGN channel using 16-QAM and 64-QAM modulation as a function of the SNR. The achievable rate curves have to be interpreted as follows: for each SNR, they determine the maximum spectral efficiency that *can be achieved* (with vanishing probability of error for infinite code length and ideal pulse shaping) by a given decoding strategy (SW-SDD, BW-SDD, SW-HDD, or BW-HDD). Alternatively, for a given spectral efficiency, a given decoding strategy can yield vanishing error probability if operating at an SNR of at least the value provided by the curve. It is observed that for SDD, the achievable rates for bit-wise and symbol-wise decoding are similar. More precisely, the achievable rate for bit-wise decoding is slightly smaller, especially for low spectral efficiencies. However, bit-wise decoding entails virtually no loss in the region of interest (i.e., for spectral efficiencies where the curve starts bending toward its maximum

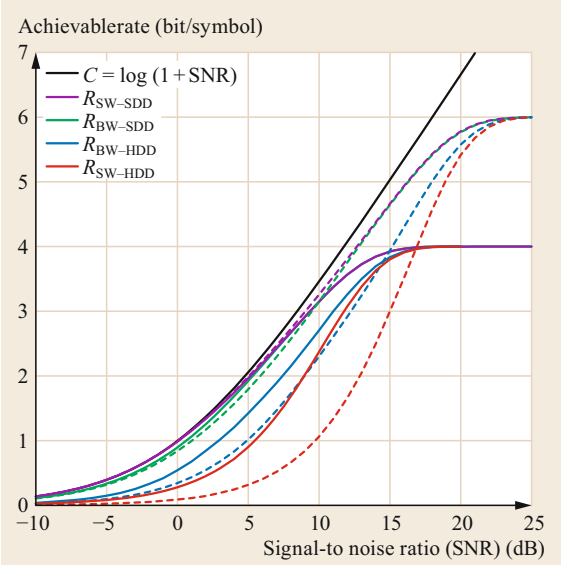

Fig. 7.4 Achievable rates for transmission over the AWGN channel with 16-QAM modulation (*solid curves*) and 64-QAM modulation (*dashed curves*) for SDD and HDD with both bit-wise and symbol-wise decoding

Table 7.1 Fiber and simulation parameters for the SSFM

Attenuation (α)	0.2 dB/km
Dispersion (D)	17 ps/nm/km
Nonlinear coefficient (γ)	1.3 $(\text{Wkm})^{-1}$
Wavelength λ	1550 nm
Symbol rate	32 Gbaud
Span length	80 km
EDFA noise figure	4.5 dB
SSFM step size	0.1 km

value m) with respect to symbol-wise decoding. On the other hand, as shown in [7.90], for HDD the achievable rates for bit-wise decoding (using BICM) are higher than those for symbol-wise decoding. As can be seen in the figure, the penalty incurred by using symbol-wise decoding yields a significantly lower achievable rate for low-to-medium SNRs. Equivalently, to achieve a given rate, the symbol-wise decoder requires a significantly higher SNR. According to these results, for HDD, binary FEC codes and bit-wise decoding are preferable to nonbinary FEC codes and symbol-wise decoding [7.90]. Furthermore, the decoding complexity of binary codes is lower than that of nonbinary codes. In the figure, we also plot the channel capacity. It is very important to realize that for high spectral efficiencies, there is a gap between the achievable rate $R_{\text{SW-SDD}}$, which coincides with the MI for the AWGN channel as explained in Sect. 7.2.1, *Symbol-Wise Soft-Decision Decoding*, and the capacity. This gap, referred to as the *shaping loss*, occurs because QAM constellations with equiprobable symbols are not capacity-achieving. The shaping loss induced by standard constellations is discussed in Sect. 7.6.5, together with methods to reduce it.

In Fig. 7.5, we plot the achievable rates as a function of the transmission distance for a polarization-multiplexed (PM) single-channel transmission system with electronic dispersion compensation (EDC) to compensate for the chromatic dispersion for 64-QAM and 256-QAM. Here, we neglect the polarization mode dispersion and the state of polarization (SOP) drift. Therefore, the two polarizations are independent of each other. The parameters of the optical fiber are summarized in Table 7.1. The results are for optimal launch power. The span loss is compensated for using erbium-doped fiber amplifiers (EDFAs), and a root-raised cosine pulse with a roll-off factor of 0.25 is used. The split-step Fourier method is used to simulate the fiber-optic channel and estimate $p_{Y|X}(y|x)$ for SDD and the transition probabilities $P_{\bar{Y}|X}(\bar{y}|x)$, the error probability $\bar{\epsilon}$ in (7.19), and the pre-FEC channel symbol error probability δ for HDD, and correspondingly calculate the achievable rates.

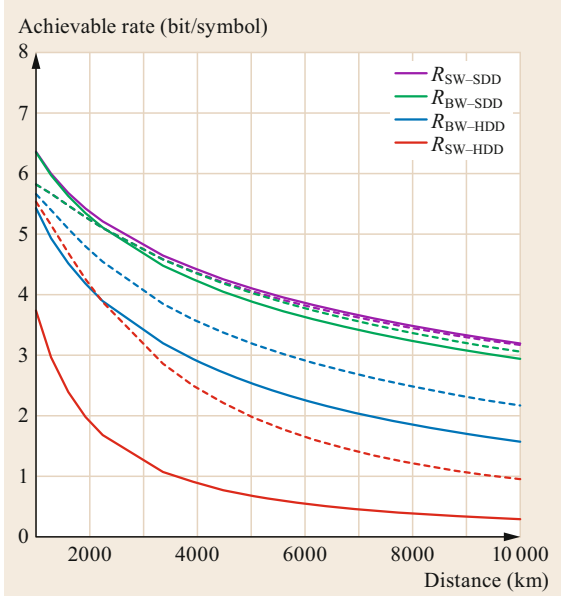

Fig. 7.5 Achievable rates for a PM single-channel transmission system with EDC as a function of the transmission distance for SDD and HDD with both bit-wise and symbol-wise decoding and optimal launch power. *Dashed curves* correspond to 64-QAM modulation and *solid curves* to 256-QAM modulation

In Fig. 7.6, we plot the achievable rates for a WDM transmission system with 81 channels and the parameters of Table 7.1. The optical channel for such a system is well approximated by the AWGN channel, a model known as the GN model in the literature [7.99, 100]. The achievable rates for the middle channel with 64-QAM and 256-QAM are shown in Fig. 7.6.

The results in Figs. 7.5 and 7.6 for the PM single-channel and WDM systems lead to similar conclusions as those of the results for the AWGN channel. We observe in Fig. 7.6 that for SDD, the bit-wise and symbol-wise decoding achievable rate curves for 16-QAM are indistinguishable, while for 64-QAM, bit-wise decoding incurs only a small penalty compared with symbol-wise decoding for 64-QAM for low spectral efficiencies. For 256-QAM, the achievable transmission reach for symbol-wise decoding is higher than that for bit-wise decoding. However, for the spectral efficiencies of interest, bit-wise SDD and symbol-wise SDD yield almost identical transmission reach. Similar results are observed in Fig. 7.5. In contrast, for HDD, bit-wise decoding yields larger achievable rates than symbol-wise decoding, which leads to a significant optical reach enhancement.

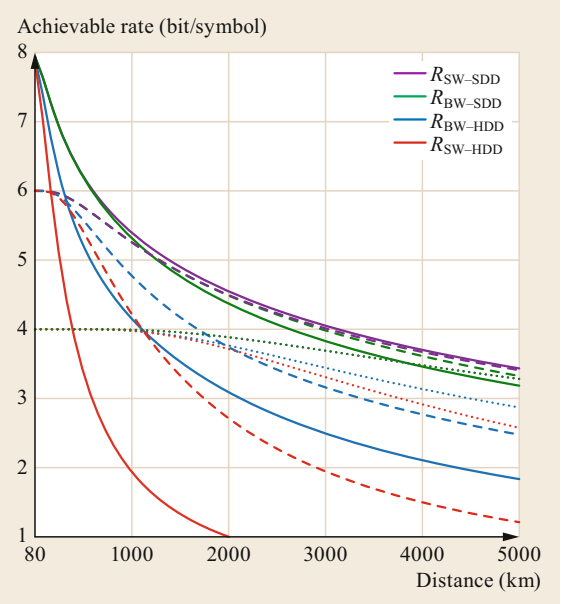

Fig. 7.6 Achievable rates for a WDM transmission system using the GN model as a function of the transmission distance for SDD and HDD with both bit-wise and symbol-wise decoding and optimal launch power. *Dotted curves* correspond to 16-QAM modulation, *dashed curves* to 64-QAM modulation, and *solid curves* to 256-QAM modulation

7.2.4 Achievable Rates and Actual Code Performance

It is important to stress that the achievable rates provided by information theory, as those discussed above, determine a rate that can be achieved, i.e., *there exists* a code that, with infinite block length, achieves that particular transmission rate. However, achievable rates tell little about the actual performance of particular FEC codes in general. A given code, decoded using a certain (suboptimal) decoding algorithm, does not necessarily achieve them. For example, regular LDPC codes (with growing degree) are capacity-achieving for binary transmission over the AWGN channel under maximum a posteriori (MAP) decoding, but not under practical iterative decoding. Similarly, staircase codes decoded with (suboptimal) iterative bounded distance decoding (Sect. 7.5.6) are not capacity-achieving. Therefore, in general, practical codes (in the sense of codes decoded using suboptimal decoding algorithms) do not achieve the achievable rates discussed above, and a performance gap will be observed. Furthermore, the gap with respect to the achievable rate may depend on the code rate (see (7.22) in Sect. 7.3 for the formal definition of code rate). For example, for staircase codes, the gap relative to the achievable rate increases for low rates. Nonetheless, achievable rates provide a very useful benchmark for comparing the performance of practical codes and are still informative.

Note that above, by capacity-achieving we mean a code that achieves the Shannon limit. For instance, for binary transmission using BPSK and SDD, the ultimate limit, also called the Shannon limit, is the corresponding MI. A code that achieves the MI for binary transmission over the AWGN channel does not achieve the capacity of the AWGN channel (since this requires Gaussian input). However, with some abuse of language, in coding theory jargon, such a code is called capacity-achieving.

As we will discuss in Sects. 7.4 and 7.5, for LDPC codes, generalized product codes, and modern codes in general, the performance limits (in the limit of infinite block length) for a certain code ensemble are given by density evolution. The so-called decoding threshold obtained from density evolution can be seen as the *effective capacity* (i.e., the effective performance limit) for a given code ensemble. One should then compare the threshold of a given code ensemble with the corresponding achievable rate to see how much is lost because of the choice of a particular code and decoding algorithm. Designing codes that approach the fundamental limits given by information theory is the ultimate goal of coding theory.

7.3 Basics of Forward Error Correction

Forward error correction (FEC), also known as *error-correcting coding*, *channel coding*, or simply *coding*, is an indispensable technique for achieving reliable communication and storage that has become ubiquitous in any communication and storage system. The role of FEC is to protect the data to be transmitted (or stored) from the channel impairments. It does so by following a basic principle: adding redundancy.

In this section, we introduce the basic concepts of FEC. Our focus is on binary codes, since their lower decoding complexity with respect to nonbinary codes makes them by far the most popular and widely used (except, perhaps, Reed–Solomon codes). However, the concepts introduced in this section can be extended to nonbinary codes in a straightforward manner.

We first give a layman's definition of an error-correcting code.

Definition 7.1 Error-correcting code
An error-correcting code is a device that adds redundancy to a block of data bits and uses this redundancy to correct potential transmission errors.

In this chapter, we focus on the most important and ubiquitous class of codes, *block codes*, and give the most basic definition of a block code.

Definition 7.2
A binary block code C of code length n and dimension k, denoted by $C(n,k)$, is a collection of 2^k binary vectors of length n bits, called n-vectors, i.e.,

$$C(n,k) \triangleq \left\{\boldsymbol{c}^{[1]}, \boldsymbol{c}^{[2]}, \ldots, \boldsymbol{c}^{[2^k]}\right\}, \quad \boldsymbol{c}^{[m]} \in \{0,1\}^n \,. \tag{7.20}$$

The n-vectors $\boldsymbol{c}^{[m]}$ are called *codewords*, and k is also referred to as the *information block length* of the code. The set of binary numbers is also often denoted as the *Galois field* of two elements and notated as $\mathrm{GF}(2) \triangleq \{0,1\}$. Note that the notion of Galois field also defines the operations of addition and multiplication of its elements. Loosely speaking, $\mathrm{GF}(q)$ is a finite set of q objects over which addition and multiplication are defined with similar properties as addition and multiplication of real numbers. For details and rigorous definitions, see [7.101, Chap. 2].

Example 7.1
Consider the 3-repetition code with parameters $n = 3$ and $k = 1$, consisting of $2^k = 2$ codewords of length 3 bits,

$$C_{\mathrm{rep}}(n=3, k=1) = \{(0,0,0), (1,1,1)\} \,. \tag{7.21}$$

One may consider an *encoder* that assigns to the information bit $u = 0$ the codeword $(0,0,0)$ and to the information bit $u = 1$ the codeword $(1,1,1)$. The assignment of codewords to information words (in this case to a single bit) is usually referred to as *encoding*.

An important parameter is the *code rate* R, or simply rate, defined as

$$R \triangleq \frac{k}{n} < 1 \,. \tag{7.22}$$

The rate is a measure of the redundancy of the code. Since $R < 1$, then $n > k$, i.e., the information words are encoded into longer sequences, thereby introducing redundancy. In contrast to the field of coding theory, in the optical communications literature the code rate is rarely used. Therein, the *code overhead*, or simply overhead, defined as

$$\mathrm{OH} \triangleq \frac{1}{R} - 1 = \frac{n-k}{k} \,, \tag{7.23}$$

is frequently used instead. The overhead denotes the relative portion of redundant bits that are added to the information bits. Note that the rate of the code is expressed in information bits per transmitted bit and is thus a measure of the *bandwidth efficiency* of the code. For example, the rate of the 3-repetition code of Example 7.1 is $R = 1/3$, which corresponds to overhead of $\mathrm{OH} = 200\%$. For fiber-optic communications, practical codes with much lower overhead are desired.

We now define one of the most important parameters of error-correcting codes, the minimum Hamming distance. We will first need the definition of Hamming weight and Hamming distance.

Definition 7.3 Hamming weight
For a binary vector $\boldsymbol{c} = (c_1, \ldots, c_n)$ of length n, the Hamming weight, denoted by $w_{\mathrm{H}}(\boldsymbol{c})$, is the number of entries in which $c_i = 1$, i.e.,

$$w_{\mathrm{H}}(\boldsymbol{c}) \triangleq |\{i \,:\, c_i = 1\}| \,. \tag{7.24}$$

Definition 7.4 Hamming distance
For any two binary vectors $\boldsymbol{c}$ and $\tilde{\boldsymbol{c}}$ of length n, the Hamming distance, $d_{\mathrm{H}}(\boldsymbol{c}, \tilde{\boldsymbol{c}})$, is the number of entries in which $\boldsymbol{c}$ and $\tilde{\boldsymbol{c}}$ differ, i.e.,

$$d_{\mathrm{H}}(\boldsymbol{c}, \tilde{\boldsymbol{c}}) \triangleq |\{i \,:\, c_i \neq \tilde{c}_i\}| \,. \tag{7.25}$$

Definition 7.5 Minimum Hamming distance
The minimum Hamming distance of a code C, denoted by $d_{\min}(C)$, is the smallest Hamming distance between any two distinct codewords of the code and is defined as

$$d_{\min}(C) \triangleq \min_{\substack{\boldsymbol{c}, \tilde{\boldsymbol{c}} \in C \\ \boldsymbol{c} \neq \tilde{\boldsymbol{c}}}} d_{\mathrm{H}}(\boldsymbol{c}, \tilde{\boldsymbol{c}}) \,. \tag{7.26}$$

As we will later see, the minimum Hamming distance of a code is related to its *error-correcting capability*. Since the notion of minimum Hamming distance is so important in coding, an (n,k) block code with minimum Hamming distance $d_{\min}$ is sometimes denoted as an $(n,k,d_{\min})$ block code.

The following simple but powerful upper bound on the minimum Hamming distance holds.

Theorem 7.1 Singleton bound
The minimum Hamming distance of an $(n, k, d_{\min})$ code C over GF(q) is upper bounded by $d_{\min} \leq n - k + 1$.

Codes whose minimum Hamming distance attains the Singleton bound achieve the best possible error-correcting capability for a given overhead and are referred to as maximum distance separable (MDS) codes. A very important class of MDS codes are Reed–Solomon codes, which are briefly discussed in Sect. 7.5.1. In contrast, there are no binary MDS codes, except trivial codes—the repetition code and the parity-check code.

7.3.1 Linear Block Codes

Linear block codes are a very important class of codes. Indeed, almost all practical codes in use today are linear codes. The reason is that linear codes are sufficient to achieve capacity [7.23, 102], and linearity allows for efficient encoding and decoding circuits. All codes considered in this chapter are linear codes.

Definition 7.6 Linear block code
A binary block code $C(n, k)$ is a linear block code if and only if its codewords $\boldsymbol{c}^{[1]}, \ldots, \boldsymbol{c}^{[2^k]}$ form a k-dimensional subspace of the n-dimensional vector space $\{0, 1\}^n$.

For a linear block code, the *all-zero* codeword $(0, 0, \ldots, 0)$ is always a codeword, i.e., $(0, 0, \ldots, 0) \in C$, and the (binary) addition of two codewords is also a codeword, i.e., for $\boldsymbol{c} \in C$ and $\tilde{\boldsymbol{c}} \in C$, then $\boldsymbol{c} + \tilde{\boldsymbol{c}} \in C$, with $+$ denoting the binary (modulo-2) addition. In other words, the set of codewords is closed under component-wise binary addition, where binary addition corresponds to the logical exclusive OR (XOR) operation, and binary multiplication corresponds to the logical AND operation. For any two binary vectors $\boldsymbol{c}$ and $\tilde{\boldsymbol{c}}$,

$$d_{\mathrm{H}}(\boldsymbol{c}, \tilde{\boldsymbol{c}}) = w_{\mathrm{H}}(\boldsymbol{c} + \tilde{\boldsymbol{c}}) \,, \tag{7.27}$$

and the minimum Hamming distance of a linear block code is equal to the minimum codeword weight, i.e.,

$$d_{\min}(C) = \min_{\substack{\boldsymbol{c} \in C \\ \boldsymbol{c} \neq \boldsymbol{0}}} w_{\mathrm{H}}(\boldsymbol{c}) \,. \tag{7.28}$$

Linear codes have appealing properties for analysis and implementation. It is easy to see that the 3-repetition code of Example 7.1 is a linear code. For this code, the three-dimensional subspace representation is shown in Fig. 7.7.

Since a linear block code is a k-dimensional subspace, we can find k linearly independent basis vectors $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_k$ in $\{0, 1\}^n$ that span C, i.e., every codeword in C is a linear combination of these k basis vectors. Then, the codeword $\boldsymbol{c} = (c_1, \ldots, c_n)$ for the message $\boldsymbol{u} = (u_1, \ldots, u_k)$ is obtained as the product of $\boldsymbol{u}$ and $\mathbf{G}$ as

$$\boldsymbol{c} = \boldsymbol{u}\mathbf{G} \,, \tag{7.29}$$

where $\mathbf{G}$ is a $k \times n$ binary matrix with rows $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_k$. Since $\mathbf{G}$ spans (i.e., generates) the code C, it is usually referred to as the *generator matrix* of the code. Note that the basis vectors $\boldsymbol{g}_1, \ldots, \boldsymbol{g}_k$ are also codewords.

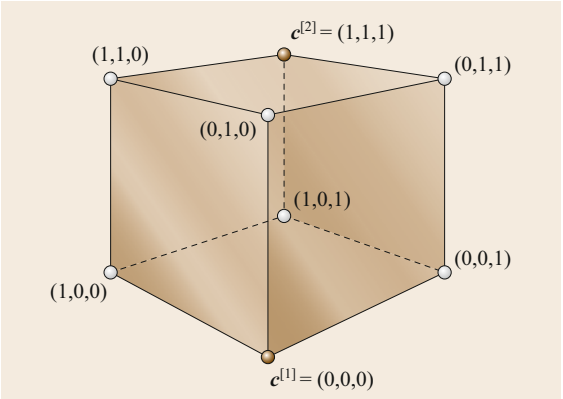

Fig. 7.7 Subspace representation of the $(3, 1)$-repetition code

The code, as well as the encoder (i.e., the mapping of information words to codewords), is completely specified by the generator matrix $\mathbf{G}$. Alternatively, a linear block code can be defined through its $(n-k) \times n$ parity-check matrix $\mathbf{H}$. Since a binary (n, k) linear block code C is a k-dimensional subspace of $\{0, 1\}^n$, its *null* (or *dual*) space, i.e., the set of all binary words of length n that are orthogonal to every element in C, is an $(n-k)$-dimensional subspace of $\{0, 1\}^n$. Two vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ are orthogonal if their inner product is zero, i.e., $\langle \boldsymbol{a}, \boldsymbol{b} \rangle = \boldsymbol{a}\boldsymbol{b}^{\top} = 0$. We denote the null space of C by $C_{\perp}$ and write

$$C_{\perp} = \{\tilde{\boldsymbol{c}} : \langle \tilde{\boldsymbol{c}}, \boldsymbol{c} \rangle = 0 \quad \text{for all } \boldsymbol{c} \in C\} \,. \tag{7.30}$$

Note that $C_{\perp}$ is a binary $(n, n-k)$ linear block code, usually referred to as the *dual code* of C. Let $\mathbf{H}$ be a generator matrix of the code $C_{\perp}$, of dimensions $(n-k) \times n$. The rows of $\mathbf{H}$, $\boldsymbol{h}_1, \ldots, \boldsymbol{h}_{n-k}$, are linearly independent codewords of $C_{\perp}$, i.e., $\boldsymbol{h}_1, \ldots, \boldsymbol{h}_{n-k} \in C_{\perp}$, and every codeword in $C_{\perp}$ is a linear combination of these $n-k$ codewords. Since every codeword $\boldsymbol{c} \in C$ is orthogonal to every codeword $\tilde{\boldsymbol{c}} \in C_{\perp}$, it follows that

$$\boldsymbol{c}\mathbf{H}^{\top} = \mathbf{0} \,. \tag{7.31}$$

Note that (7.31) is satisfied *if and only if* $\boldsymbol{c} \in C$. Therefore, we can define a code C through the generator matrix of its dual code $C_{\perp}$, $\mathbf{H}$.

Definition 7.7

A binary vector $\boldsymbol{c}$ is a codeword of C if and only if $\boldsymbol{c}\mathbf{H}^\top = \mathbf{0}$, i.e., the code C is defined as the null space of $\mathbf{H}$,

$$C = \left\{\boldsymbol{c} : \boldsymbol{c}\mathbf{H}^\top = \mathbf{0}\right\}. \tag{7.32}$$

Therefore, a linear block code is uniquely specified by $\mathbf{G}$ or $\mathbf{H}$. Usually, the generator matrix is used for encoding, while the decoding is based on $\mathbf{H}$.

A way to interpret (7.31) is by noting that $\boldsymbol{c}\mathbf{H}^\top = \mathbf{0}$ is a set of $n-k$ linearly independent equations

$$\begin{array}{ccccccc} h_{1,1}c_1 & + & h_{1,2}c_2 & + \ldots + & h_{1,n}c_n & = 0 \\ h_{2,1}c_1 & + & h_{2,2}c_2 & + \ldots + & h_{2,n}c_n & = 0 \\ \vdots & & \vdots & \ddots & \vdots & \vdots \\ h_{(n-k),1}c_1 & + & h_{(n-k),2}c_2 & + \ldots + & h_{(n-k),n}c_n & = 0 \end{array} \tag{7.33}$$

where $h_{i,j}$ is the entry of the matrix $\mathbf{H}$ at row i and column j. These equations are known as *parity-check equations*, and are the equations that each codeword must satisfy. As a result, the matrix $\mathbf{H}$ is commonly referred to as the *parity-check matrix* of the code C.

A practically important class of (linear) codes is the class of *systematic* codes.

Definition 7.8 Systematic code

A *systematic code* is a code with an encoder that generates codewords $\boldsymbol{c}$ containing the information word $\boldsymbol{u}$ as verbatim copy in $\boldsymbol{c}$.

The generator matrix of a *systematic linear code* (assuming that the k information bits appear in the first k positions of the codeword) can always be written as $\mathbf{G} = (\mathbf{I}_k \ \mathbf{P})$, where $\mathbf{I}_k$ is a $k \times k$ identity matrix. The codewords of a systematic code can then be written as

$$\begin{aligned} \boldsymbol{c} &= (c_1 \ldots, c_n) = (u_1, , \ldots, u_k, p_1, \ldots p_{n-k}) \\ &= (\boldsymbol{u} \ \boldsymbol{p}), \end{aligned} \tag{7.34}$$

i.e., the first k bits of the codeword are a replica of the information bits. The code bits $p_1, p_2, \ldots, p_{n-k}$ are referred to as the *parity bits* of the code.

Example 7.2

Consider the $(7, 4)$ binary block code defined by the 4×7 generator matrix

$$\mathbf{G} = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \end{pmatrix}. \tag{7.35}$$

Table 7.2 Codewords of the $(7, 4)$ Hamming code

u_1	u_2	u_3	u_4	p_1	p_2	p_3
0	0	0	0	0	0	0
0	0	0	1	1	0	1
0	0	1	0	1	1	1
0	0	1	1	0	1	0
0	1	0	0	0	1	1
0	1	0	1	1	1	0
0	1	1	0	1	0	0
0	1	1	1	0	0	1
1	0	0	0	1	1	0
1	0	0	1	0	1	1
1	0	1	0	0	0	1
1	0	1	1	1	0	0
1	1	0	0	1	0	1
1	1	0	1	0	0	0
1	1	1	0	0	1	0
1	1	1	1	1	1	1

Table 7.2 lists all codewords of this code, which is the famous $(7, 4)$ Hamming code. We observe that the first four bits of each codeword correspond to the information bits, i.e., the code is systematic.

7.3.2 Error Detection and Error Correction Capability of a Block Code over the Binary Symmetric Channel

Consider an $(n, k, d_{\min})$ block code that is used for transmission over the AWGN channel using BPSK modulation. As discussed in Sect. 7.2, if hard decisions on the received vector are taken, the discrete channel between the encoder and the decoder can be modeled as a binary symmetric channel (BSC).

For transmission over the BSC, a block code with minimum Hamming distance $d_{\min}$ can *correct* all error patterns with

$$t = \left\lfloor \frac{d_{\min} - 1}{2} \right\rfloor \tag{7.36}$$

or fewer errors, where $\lfloor \tau \rfloor$ denotes the largest integer smaller than or equal to τ. The parameter t is usually referred to as the *error correction capability* of the code, and a code that can correct up to t errors is called a t-error-correcting code. Furthermore, a block code with minimum Hamming distance $d_{\min}$ can *detect* all error patterns with

$$d = d_{\min} - 1 \tag{7.37}$$

or fewer errors.

Example 7.3

The minimum Hamming distance of the 3-repetition code (Example 7.1) and the $(7,4)$ Hamming code in Example 7.2 is $d_{\min} = 3$; hence both codes can correct up to $t = 1$ error and detect up to $d = 2$ errors. The repetition code has rate $R = 1/3$, while the rate of the Hamming code is $4/7$; hence the latter is spectrally more efficient.

The minimum Hamming distance of a code is a very relevant parameter that determines how many errors the code can correct (or detect) for transmission over the BSC. For other channels, the minimum Hamming distance does not completely determine the code performance, but it dominates the code performance (under ML decoding) for high SNRs. Thus, to achieve low error rates, one should construct codes with good minimum Hamming distance.

7.3.3 Optimal Decoding of Block Codes

We have seen that we can characterize a block code in terms of its minimum Hamming distance. We now derive the optimal decoder for block codes for both SDD and HDD. We consider binary transmission using BPSK modulation (i.e., $\mathcal{X} = \{\pm 1\}$) by modulating every code bit c_i, $i = 1, \ldots, n$, of the codeword as $x_i = (-1)^{c_i}$, i.e., without loss of generality we assume the mapping $0 \mapsto +1$ and $1 \mapsto -1$. For example, for $\boldsymbol{c} = (0,0,1,1,0)$, we get $\boldsymbol{x} = (+1,+1,-1,-1,+1)$. Instead of BPSK, we can also consider quadrature phase-shift keying (QPSK) by independently modulating the I and Q components of the constellation. We assume transmission over a memoryless AWGN channel with zero mean and noise variance σ^2. At the output of the channel, we observe a (noisy) vector $\boldsymbol{y} = \boldsymbol{x} + \boldsymbol{n}$, where $\boldsymbol{x} = (x_1, \ldots, x_n)$ is the transmitted (modulated) codeword and $\boldsymbol{n}$ is the noise vector.

Based on the noisy observation $\boldsymbol{y}$, the role of the decoder is to optimally *estimate* the transmitted codeword $\boldsymbol{c}$. Decoding is a probabilistic *inference* problem: the decoder estimates the *most likely* transmitted codeword $\boldsymbol{c}$ (from which it can reverse-lookup the information bit sequence) given the noisy channel output $\boldsymbol{y}$. The most natural decoding criterion is that of minimizing the probability of error. If the decoding criterion is to minimize the probability that the decoder fails to decode to the correct codeword, i.e., minimize the *codeword error probability*, it can be shown that this is equivalent to maximizing the a posteriori probability $P_{C|Y}(\boldsymbol{c}|\boldsymbol{y})$. The *maximum a posteriori* (MAP) decoding rule is therefore

$$\hat{\boldsymbol{c}} = \arg\max_{\boldsymbol{c}\in C} P_{C|Y}(\boldsymbol{c}|\boldsymbol{y}) = \arg\max_{\boldsymbol{c}\in C} \frac{p_{Y|C}(\boldsymbol{y}|\boldsymbol{c}) P_C(\boldsymbol{c})}{p_Y(\boldsymbol{y})} , \tag{7.38}$$

where in the last equality we used Bayes' law. Typically, we can assume that all codewords are equiprobable, i.e., $P_C(\boldsymbol{c}_i) = 1/|C|$, for all i. In this case, and since $p_Y(\boldsymbol{y})$ is independent of $\boldsymbol{c}$, (7.38) can be rewritten as

$$\hat{\boldsymbol{c}} = \arg\max_{\boldsymbol{c}\in C} p_{Y|C}(\boldsymbol{y}|\boldsymbol{c}) , \tag{7.39}$$

which is referred to as the ML decoding rule. Note that the situation changes if probabilistic amplitude shaping (PAS), as described in Sect. 7.6.5, is used. In this case, not all codewords are equiprobable. For a detailed exposure, see [7.91].

In the next two sections, we expand the ML decoding rule (7.39) for SDD and HDD.

Soft-Decision Decoding

Starting from the ML decoding rule (7.39) and assuming a memoryless channel, i.e., $p_{Y|C}(\boldsymbol{y}|\boldsymbol{c}) = \prod_{i=1}^{n} p_{Y|C}(y_i|c_i)$, we can proceed as

$$\begin{aligned}
\hat{\boldsymbol{c}} &= \arg\max_{\boldsymbol{c}\in C} \prod_{i=1}^{n} p_{Y|C}(y_i|c_i) \\
&\overset{(a)}{=} \arg\max_{\boldsymbol{c}\in C} \ln \prod_{i=1}^{n} p_{Y|C}(y_i|c_i) \\
&= \arg\max_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \ln p_{Y|C}(y_i|c_i) ,
\end{aligned} \tag{7.40}$$

where (a) follows because $\ln(\cdot)$ is a monotonically increasing function. To perform ML decoding, we need to have access to the channel law $p_{Y|C}(y_i|c_i)$, which is the conditional probability (density) that we have received y_i given that c_i was transmitted. If known, the true channel law can be used in (7.40). However, we usually resort to models. In the case of coherent optical communications, the channel is reasonably well modeled by an AWGN channel, as predicted by the GN models and their extensions [7.99, 103]. Another example is the case of amplitude-modulated solitons, where the channel law can be modeled as a noncentral chi-squared distribution with four degrees of freedom [7.104]. Furthermore, when higher-order modulation formats with bit-wise decoding (often called BICM) are used (see also Sect. 7.6.3), the equivalent noise that the FEC decoder observes does not necessarily follow a Gaussian distribution [7.105] but can be closely approximated by one.

We will now focus on the case of AWGN, where the channel law is given in (7.1). Continuing the derivation, we have with $x_i = (-1)^{c_i}$,

$$\begin{aligned}
\hat{\boldsymbol{c}} &= \arg\max_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \ln\left(\frac{1}{\sqrt{2\pi}\sigma} \mathrm{e}^{-\frac{(y_i-(-1)^{c_i})^2}{2\sigma^2}} \right) \\
&= \arg\max_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \left[\ln\left(\frac{1}{\sqrt{2\pi}\sigma} \right) - \frac{[y_i-(-1)^{c_i}]^2}{2\sigma^2} \right]
\end{aligned}$$

$$\stackrel{(b)}{=} \arg\max_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \frac{-[y_i-(-1)^{c_i}]^2}{2\sigma^2}$$
$$\stackrel{(c)}{=} \arg\min_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \frac{[y_i-(-1)^{c_i}]^2}{2\sigma^2}$$
$$\stackrel{(d)}{=} \arg\min_{\boldsymbol{c}\in C} \sum_{i=1}^{n} [y_i-(-1)^{c_i}]^2 \,, \tag{7.41}$$

where in (b) we exploit the fact that addition of a constant does not change the maximization, in (c) we use the fact that maximizing is equivalent to minimizing the negation, and finally in (d) dividing by the constant $2\sigma^2$ does not change the minimization. Equation (7.41) is the famous Euclidean distance metric, as we take the squared Euclidean distance between (modulated) codewords and the received values. Therefore, for SDD and transmission over the AWGN channel, the ML decoder chooses among all possible transmitted codewords the codeword $\boldsymbol{c}$ that minimizes the Euclidean distance $d_{\mathrm{E}}(\boldsymbol{x},\boldsymbol{y}) \triangleq \|\boldsymbol{x}-\boldsymbol{y}\|$ between $\boldsymbol{y}$ and the BPSK-modulated codeword $\boldsymbol{x} = (x_1,\ldots,x_n) = ((-1)^{c_1},\ldots,(-1)^{c_n})$, i.e.,

$$\hat{\boldsymbol{c}} = \arg\min_{\boldsymbol{c}\in C} d_{\mathrm{E}}(\boldsymbol{x},\boldsymbol{y}) \,. \tag{7.42}$$

Note that the Euclidean distance follows solely from the assumption of Gaussian noise.

We can further simplify the expression (7.41) yielding

$$\hat{\boldsymbol{c}} = \arg\min_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \left[y_i^2 + (-1)^{2c_i} - 2y_i(-1)^{c_i}\right]$$
$$= \arg\min_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \left[y_i^2 + 1 - 2y_i(-1)^{c_i}\right]$$
$$\stackrel{(e)}{=} \arg\min_{\boldsymbol{c}\in C} \sum_{i=1}^{n} \left[-2y_i(-1)^{c_i}\right]$$
$$\stackrel{(f)}{=} \arg\max_{\boldsymbol{c}\in C} \sum_{i=1}^{n} y_i(-1)^{c_i} \,, \tag{7.43}$$

where in (e) we used the fact that addition of y_i^2+1 does not change the maximization and in (f) we replaced minimization by maximization of the negation.

Hard-Decision Decoding

We now derive the optimal decoder for HDD. We start again from the ML decoding rule, assuming a memoryless channel,

$$\hat{\boldsymbol{c}} = \arg\max_{\boldsymbol{c}\in C} p_{Y|C}(\boldsymbol{y}|\boldsymbol{c})$$
$$= \arg\max_{\boldsymbol{c}\in C} \prod_{i=1}^{n} p_{Y|C}(y_i|c_i) \,. \tag{7.44}$$

Note that for HDD, the output sequence $\boldsymbol{y} = (y_1,\ldots,y_n)$ is also a binary sequence, and the channel can be modeled as a BSC with crossover probability p (see (7.2)), i.e.,

$$p_{Y|X}(y_i|x_i) = p_{Y|C}(y_i|c_i) = \begin{cases} p & y_i \neq c_i \\ 1-p & y_i = c_i \,. \end{cases} \tag{7.45}$$

Using this in (7.44),

$$\hat{\boldsymbol{c}} = \arg\max_{\boldsymbol{c}\in C} p^{d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y})}(1-p)^{n-d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y})}$$
$$= \arg\max_{\boldsymbol{c}\in C} \ln\left[p^{d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y})}(1-p)^{n-d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y})}\right]$$
$$= \arg\max_{\boldsymbol{c}\in C} d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y}) \ln p + [n-d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y})] \ln(1-p)$$
$$= \arg\max_{\boldsymbol{c}\in C} d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y}) \ln\left(\frac{p}{1-p}\right)$$
$$= \arg\min_{\boldsymbol{c}\in C} d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{y}) \,, \tag{7.46}$$

where in the last equality we assume that $p < (1/2)$.

We see that for HDD, the ML decoder must choose among all possible transmitted codewords the codeword $\boldsymbol{c}$ that minimizes the Hamming distance between $\boldsymbol{x}$ and $\boldsymbol{y}$.

We illustrate the ML decoder using a simple example.

Example 7.4

Assume that we want to transmit the data bit $u = 0$ using the 3-repetition code of Example 7.1. Information bit $u = 0$ is encoded onto codeword $\boldsymbol{c} = (0,0,0)$, which is modulated to $\boldsymbol{x} = (+1,+1,+1)$. After transmission over the AWGN channel, we receive $\boldsymbol{y} = (-0.2,+1.1,-0.7)$. We can see that two sign changes occurred during transmission, so a HDD looking purely at the sign (and hence minimizing the Hamming distance) will erroneously assume that the codeword $(1,1,1)$ was transmitted. However, when we carry out the SDD ML decoding rule, we observe that for codewords $(0,0,0)$ and $(1,1,1)$ we get

$$(0,0,0): \quad \sum_{t=1}^{3} y_t(-1)^0 = +0.2 \,, \tag{7.47}$$
$$(1,1,1): \quad \sum_{t=1}^{3} y_t(-1)^1 = -0.2 \,. \tag{7.48}$$

We can see that the sum is maximized for $(0,0,0)$; thus the decoder (correctly) decides for $\hat{\boldsymbol{c}} = (0,0,0)$ and hence $\hat{u} = 0$.

The example above highlights that HDD incurs a performance penalty with respect to SDD. On the other hand, HDD is usually significantly less complex than SDD.

Decoding Complexity

The complexity of the ML decoder scales exponentially with the number of data bits k. Therefore, ML decoding is only feasible for simple (short) codes and quickly becomes prohibitive as k increases. For practical codes, k is easily above 10 000, which means that the code can contain more than 2×10^{3010} codewords. If we assume that we have access to the 500 largest supercomputers worldwide, which have an aggregated computational capacity of 748 PFlop/s [7.106], and that we only require a single floating point operation to compute the sum required in (7.43) or the Hamming distance in (7.44), we would still require 2.7×10^{2992} seconds to evaluate all codewords. As the universe has existed for roughly 4.3×10^{17} seconds, we see that all efforts to carry out ML decoding for such codes are futile. Therefore, suboptimal decoding strategies which yield an acceptable decoding complexity are required.

The quest for long, powerful codes with low decoding complexity has given rise to so-called *modern codes*, such as LDPC codes and product-like codes, which build upon simpler component codes and are decoded using suboptimal (iterative) decoding algorithms, with reasonable decoding complexity and yet astonishing performance. Suboptimal decoding strategies are discussed in Sects. 7.4 and 7.5.

7.3.4 Coding Gain and Net Coding Gain

An important measure for comparing different coding schemes is the NCG. To determine the NCG, bipolar signaling and an AWGN channel are frequently used. However, the definition can be easily extended to other types of channels. Consider an AWGN channel with SNR E_s/N_0. Since the modulated symbol x is obtained as $x = (-1)^{c_i}$, all modulation symbols have the same energy, and hence E_s also denotes the *energy per coded bit* in this setting. We therefore have $E_s = \mathbb{E}[X^2] = 1$. In a transmission system, E_s is usually fixed (for example, to the value corresponding to the laser transmit power). Here, we assume a normalized transmit energy $E_s = 1$. Instead of the SNR E_s/N_0, for a fair comparison of coding schemes it is helpful to use the ratio E_b/N_0, where E_b denotes the average *energy per information bit*. For example, if a code of rate $R = 4/5$ is used, corresponding to overhead OH = 25%, the ratio of code bits n versus information bits k amounts to $n/k = 5/4 = 1.25$, i.e., 1.25 code bits are transmitted for each information bit. This means that if the code bits are transmitted each with energy E_s, the equivalent amount of energy conveyed by each information bit amounts to $E_b \triangleq E_s/R \geq E_s$. As E_b is normalized to the information bits of the transmission system, it allows us to evaluate the NCG, i.e., the gain that is actually achievable by taking into account the coding. The NCG is defined as the gain (in dB) of the coded transmission in terms of E_b/N_0 relative to uncoded transmission for a given output BER.

Figure 7.8 illustrates the NCG and the influence of E_b/N_0 versus E_s/N_0. First, we consider uncoded transmission ($R = 1$), where $E_b = E_s = 1$. In this case, the BER is obtained as $Q(\sqrt{2E_b/N_0}) = Q(\sqrt{2E_s/N_0})$. If we now apply coding with a rate $R = 4/5$, we get

$$\frac{E_b}{N_0} = \frac{E_s}{R N_0} = \frac{1}{R}\frac{E_s}{N_0}, \tag{7.49}$$

i.e., E_b/N_0 is scaled by a factor $1/R$, corresponding to $-10\log_{10}(R) = 0.969$ dB. Hence, by applying coding, the energy per information bit is scaled by this factor, i.e., each information bit carries 0.969 dB additional energy compared with an uncoded transmission. We may also take on a different perspective and fix the energy per information bit E_b (e.g., to $E_b = 1$). From this perspective, as coding increases the effective number of transmitted bits per information bit, the effective energy per transmitted symbol is decreased. In this case, when the receiver cannot apply decoding but needs to recover only the (systematic) information bits from the sequence of transmitted bits, it requires an SNR that is increased by 0.969 dB to achieve the same BER. By carrying out decoding, we can now significantly improve the post-decoding BER starting from this shifted curve, as can be seen in Fig. 7.8. This increase corresponds to the coding gain (sometimes also called *gross* coding gain), indicated by the bottom arrow in Fig. 7.8. The NCG is reduced by the 0.969 dB required for transmitting the extra parity bits. In this example, we see that the coding scheme employed here yields an NCG of 11.9 dB at a BER of 10^{-15}.

In optical communications, the optical signal-to-noise ratio (OSNR) is also frequently employed. The OSNR is the SNR measured in a reference optical bandwidth, where frequently a bandwidth B_{ref} of 12.5 GHz is used, corresponding to 0.1 nm-resolution wavelength at a carrier wavelength of 1550 nm. The OSNR relates to the E_s/N_0 as follows

$$\begin{aligned} 10\log_{10}\mathrm{OSNR} &= 10\log_{10}\frac{E_s}{N_0} + 10\log_{10}\frac{R_s}{B_{ref}} \\ &= 10\log_{10}\frac{E_b}{N_0} + 10\log_{10}\frac{mRR_s}{B_{ref}}, \end{aligned} \tag{7.50}$$

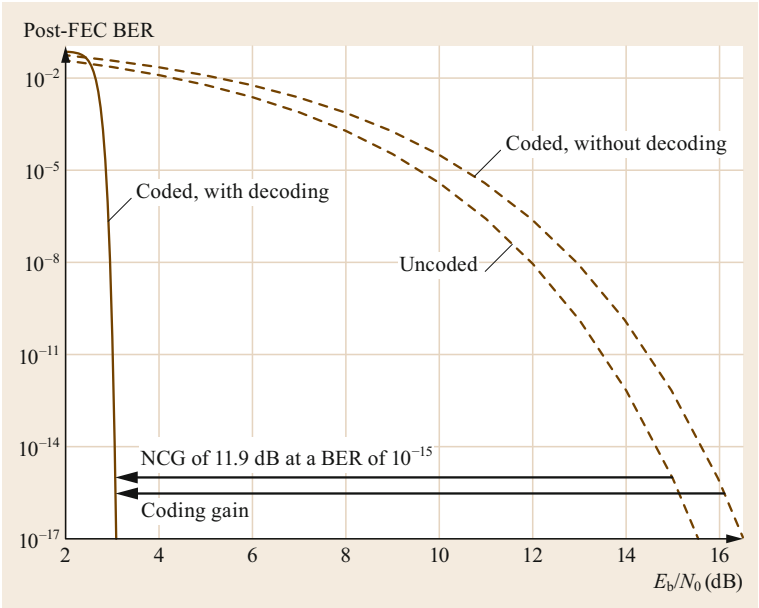

Fig. 7.8 Net coding gain definition

where B_{ref} is the reference bandwidth, R_s corresponds to the symbol rate of the transmission, R is the code rate, and m is the number of bits mapped to each modulation symbol.

7.3.5 Bounds on the Performance of Block Codes

From information theory (Sect. 7.2), we know that the required SNR for successful transmission, based on Shannon's capacity results, assumes infinite block lengths. This is usually not a valid assumption in practical communication systems. Unfortunately, selecting a finite (moderate) code length does not necessarily lead to good performance. Much work has been dedicated to obtaining precise bounds on the performance of transmission systems employing codes of finite block length n. A good overview of results can be found in [7.107] and [7.108], where the latter provides refined finite-length performance bounds. Shannon already provided a lower bound on the codeword error probability P_w, i.e., the probability that the decoder decodes an incorrect codeword $\hat{\boldsymbol{c}} \neq \boldsymbol{c}$, based on geometric arguments [7.107, 109].

In the following we use the normal approximation of the finite-block-length bound for the binary-input AWGN channel given in [7.110]. This bound allows us to compute an approximation of the gap relative to capacity for the binary-input AWGN channel (which describes BPSK and QPSK modulation with AWGN noise, see also at the beginning of Sect. 7.3.3). We assume that the decoder targets a codeword error probability of $P_w = 10^{-13}$, which means that one in 10^{13} codewords can be decoded erroneously. With this, the bit error probability P_b can be bounded as

$$\frac{1}{Rn} P_w \leq P_b \leq P_w \,, \tag{7.51}$$

where the upper bound assumes that all bits inside an erroneously decoded codeword are in error, and the lower bound assumes a single bit error only. Figure 7.9 shows

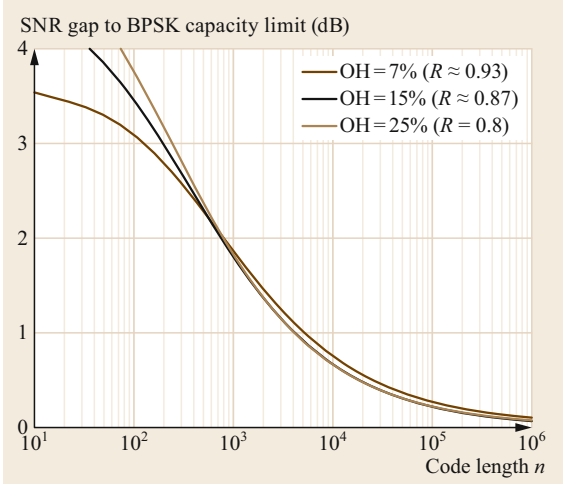

Fig. 7.9 Gap to the BPSK capacity as a function of the block size n for codes of different rates R and a codeword error probability $P_w = 10^{-13}$

the normal approximation for OH $\in \{7\%, 15\%, 25\%\}$ and a target codeword error rate of $P_w = 10^{-13}$, which is a value commonly used in fiber-optical communications (when the target P_b is around 10^{-15}). We often use Monte Carlo simulations to estimate the probabilities P_w and P_b. In this case, the estimated quantities are referred to as frame error rate (FER) and BER, respectively. In the remainder of this chapter, with some abuse of language, we will often use FER to refer to P_w and BER to refer to P_b.

We see in Fig. 7.9 that we need block sizes $n >$ 5 kbit to be able to operate within 1 dB from the channel capacity. Unfortunately, most classical coding schemes are only defined for small to medium n (usually less than 1 kbit) or do not perform well for large n. Code concatenation was a first step toward the realization of longer codes that proved to be very successful with HDD. In the next section, we will introduce different coding schemes that naturally allow the construction of long codes.

7.4 Soft-Decision Forward Error Correction

Contrary to the historical development of FEC in fiber-optic communications, we start by introducing SDD, and later discuss HDD in Sect. 7.5. The reason for doing so is that SDD immediately follows when optimally decoding many channels that are encountered in optical communications, such as the AWGN channel (Sect. 7.3.3). Furthermore, recently proposed hard-decision FEC schemes have strong ties with soft-decision FEC schemes (such as LDPC codes) and their analysis tools; hence it is somewhat natural to discuss these first. In this section, we introduce some popular coding schemes for SDD in fiber-optic communications, including LDPC codes, SC-LDPC codes, and polar codes. We discuss these codes and their variants in detail, and give detailed descriptions of the most popular decoding algorithms and construction methods. We further show the strengths and weaknesses of the different schemes by means of various simulation examples.

7.4.1 Low-Density Parity-Check Codes

We have seen in Sect. 7.3.5 that codes with large block sizes n are required to operate close to the achievable rate or capacity of the channel. For example, from Fig. 7.9, n should be $\geq 2\times10^4$ if we want to operate within 0.5 dB of the capacity of the binary-input AWGN channel with a code of overhead OH = 25%. As seen in Sect. 7.3.1, a code is completely specified by its parity-check matrix $\mathbf{H}$, of dimensions $m \times n$, with $m < n$. Most of classical coding theory focused on finding algebraic constructions for $\mathbf{H}$ (e.g., BCH codes), avoiding the need to store $\mathbf{H}$. However, in the general case, when $\mathbf{H}$ does not contain any *structure* and is random-like, storing it is difficult. The storage requirements for $\mathbf{H}$ scale as $O(n^2)$, and hence it may already not be feasible to store $\mathbf{H}$ for relatively small values of n.

We thus need practical codes that have enough structure to enable storage of $\mathbf{H}$ using data structures with low memory requirements and that allow operation close to the achievable rate. Inspired by the fact that random parity-check codes, i.e., codes where the entries $h_{i,j}$ of $\mathbf{H}$ are chosen to be *0* or *1* with probability 1/2, are capacity-achieving, to construct codes with high coding gains and efficient storage of $\mathbf{H}$, *Gallager* introduced LDPC codes in the 1960s [7.54].

An LDPC code is generally defined by a *sparse* binary parity-check matrix $\mathbf{H}$. Recall from Sect. 7.3 that each column of the parity-check matrix $\mathbf{H}$ corresponds to a code bit. Likewise, each row of $\mathbf{H}$ corresponds to a parity-check equation and ideally defines a single parity bit (if $\mathbf{H}$ has full rank). Sparse means that the number of *1*s in $\mathbf{H}$ is small compared with the number of zero entries. Practical codes usually have a fraction of *1*s that is below 1% by several orders of magnitude. Usually, provided that the parity-check matrix has full row rank, i.e., rank($\mathbf{H}$) $= m$, the number of information bits equals $k = n - m$. If the parity-check matrix $\mathbf{H}$ is rank-deficient, the number of information bits k can be larger, i.e., $k \geq n - m$. In the remainder of this chapter, we fix $k = n - m$, i.e., we do not actively use any possible additional information bits. In this case, the rate is given by $R = (n-m)/n$ and the overhead equals OH $= m/(n-m)$.

LDPC codes are often subdivided into two major classes, *regular* and *irregular* LDPC codes. We describe both classes in what follows.

Regular Low-Density Parity-Check Codes

Definition 7.9 Regular (d_v, d_c) LDPC Code
A regular (d_v, d_c) LDPC code is an LDPC code where each column of $\mathbf{H}$ is of weight d_v (i.e., it contains exactly d_v *1*s), and each row of $\mathbf{H}$ is of weight d_c. We assume $d_v \geq 2$ and $d_c \geq 2$.

The storage complexity of (d_v, d_c) LDPC codes is only $O(n)$, as the column weight is constant (and indepen-

dent of n), which enables efficient implementation of LDPC codes with low memory requirements.

As an example, consider the $(3, 6)$ LDPC code of rate $R = 1/2$, with $n = 18$, $m = 9$ defined by the parity-check matrix

$$\mathbf{H} = \begin{pmatrix} 0&1&0&0&1&0&0&0&1&0&1&0&0&0&1&0&1&0 \\ 1&0&0&0&0&1&1&0&0&0&0&1&0&1&0&1&0&0 \\ 0&0&1&1&0&0&0&1&0&1&0&0&1&0&0&0&0&1 \\ 0&1&0&0&0&1&0&0&1&0&1&0&0&0&1&1&0&0 \\ 0&0&1&0&1&0&0&1&0&0&0&1&0&1&0&0&1&0 \\ 1&0&0&1&0&0&1&0&0&1&0&0&1&0&0&0&0&1 \\ 0&1&0&0&0&1&0&0&1&1&0&0&1&0&0&1&0&0 \\ 1&0&0&0&1&0&1&0&0&0&0&1&0&1&0&0&1&0 \\ 0&0&1&1&0&0&0&1&0&0&1&0&0&0&1&0&0&1 \end{pmatrix} . \tag{7.52}$$

We summarize in the following some of the properties of regular $(d_\mathrm{v}, d_\mathrm{c})$ LDPC codes:

- $n\,d_\mathrm{v} = m\,d_\mathrm{c}$ has to hold, as the total number of *1*s of $\mathbf{H}$ is identical regardless of the way we count them. Therefore, the rate R is given by

$$R = 1 - \frac{m}{n} = 1 - \frac{n\,d_\mathrm{v}}{n\,d_\mathrm{c}} = 1 - \frac{d_\mathrm{v}}{d_\mathrm{c}} \,. \tag{7.53}$$

- If d_v is even, then the summation of all rows of $\mathbf{H}$ is the all-zero row, i.e., there is at least one linearly dependent row, i.e., $\mathrm{rank}(\mathbf{H}) \leq m - 1$.
- With high probability, the parity-check matrix of a regular LDPC code has asymptotically full rank [7.111], i.e.,

$$\lim_{n\to\infty} P(\mathrm{rank}(\mathbf{H}) = m - \mathbb{1}_{\{d_\mathrm{v}\ \mathrm{even}\}}) = 1 \,. \tag{7.54}$$

Already for small values of n, the limit in (7.54) is approached.

Irregular Low-Density Parity-Check Codes

In some cases it can be advantageous to relax the regularity and allow codes where the *distribution* of *1*s in the parity-check matrix is *irregular* [7.112]. This gives rise to *irregular* LDPC codes, which are formally defined as follows.

Definition 7.10 Irregular $(\boldsymbol{\delta}_\mathrm{v}, \boldsymbol{\delta}_\mathrm{c})$ LDPC Code

An irregular $(\boldsymbol{\delta}_\mathrm{v}, \boldsymbol{\delta}_\mathrm{c})$ LDPC code, with $\boldsymbol{\delta}_\mathrm{v} = (\delta_{\mathrm{v},1}, \delta_{\mathrm{v},2}, \ldots, \delta_{\mathrm{v},d_{\mathrm{v,max}}})$ and $\boldsymbol{\delta}_\mathrm{c} = (\delta_{\mathrm{c},1}, \delta_{\mathrm{c},2}, \ldots, \delta_{\mathrm{c},d_{\mathrm{c,max}}})$ is an LDPC code with $\delta_{\mathrm{v},i}\,n$ columns of $\mathbf{H}$ of weight i and $\delta_{\mathrm{c},j}\,m$ rows of $\mathbf{H}$ of weight j. We assume that $\delta_{\mathrm{v},1} = \delta_{\mathrm{c},1} = 0$ and that $\delta_{\mathrm{v},i}\,n$ and $\delta_{\mathrm{c},j}\,m$ are integers for all $i \in \{2, \ldots, d_{\mathrm{v,max}}\}$ and $j \in \{2, \ldots, d_{\mathrm{c,max}}\}$, respectively. Note that $\sum_{i=1}^{d_{\mathrm{v,max}}} \delta_{\mathrm{v},i} = \sum_{j=1}^{d_{\mathrm{c,max}}} \delta_{\mathrm{c},j} = 1$. The vectors $\boldsymbol{\delta}_\mathrm{v}$ and $\boldsymbol{\delta}_\mathrm{c}$ are called the *degree distribution* (from a node perspective) of the code.

Note that irregular codes comprise the class of regular LDPC codes. Indeed, a regular $(d_\mathrm{v}, d_\mathrm{c})$ LDPC code is described by the degree distribution vectors $\boldsymbol{\delta}_\mathrm{v}$ and $\boldsymbol{\delta}_\mathrm{c}$ with $\delta_{\mathrm{v},d_\mathrm{v}} = 1$ and $\delta_{\mathrm{v},i} = 0$, $\forall i \neq d_\mathrm{v}$, and $\delta_{\mathrm{c},d_\mathrm{c}} = 1$ and $\delta_{\mathrm{c},i} = 0$, $\forall i \neq d_\mathrm{c}$. The rate of an irregular LDPC code can be expressed as a function of the vectors $\boldsymbol{\delta}_\mathrm{v}$ and $\boldsymbol{\delta}_\mathrm{c}$, namely

$$R = 1 - \frac{\sum_{i=1}^{d_{\mathrm{v,max}}} i\,\delta_{\mathrm{v},i}}{\sum_{j=1}^{d_{\mathrm{c,max}}} j\,\delta_{\mathrm{c},j}} \,. \tag{7.55}$$

An important generalization of regular and irregular LDPC codes are multi-edge type (MET) LDPC codes [7.111, Sect. 7.1]. In this class of codes, the parity-check matrix is divided into different regions, called types. Each such region shares some common properties. Some high-performing codes with low error floors have been constructed using this approach. One example is the so-called AR4JA codes [7.113] which have been standardized for deep-space communications [7.114]. These codes, which often require punctured state variables, have not yet found widespread application in fiber-optic communications, as their convergence is relatively slow and a larger number of decoding iterations is required to reach the desired performance.

Graphical Representation of Low-Density Parity-Check Codes

A widespread representation of LDPC codes is based on the so-called *Tanner graphs*, introduced in 1981 by *Michael Tanner* [7.115] as a tool for building large codes from small component codes. Tanner graphs are useful for the design and analysis of LDPC codes and can also serve as a tool for deriving and understanding the most basic decoding algorithm. In what follows, we introduce Tanner graphs by means of an example.

Let C be a binary (LDPC) code with parity-check matrix $\mathbf{H}$ of size $m \times n$. The Tanner graph of the code C is a *bipartite graph*, i.e., it has two types of nodes, and every edge connects a node of the first type with a node of the second type (i.e., there are no connections between nodes of the same type):

- The first type of nodes are called variable nodes (VNs) (they are also sometimes called *bit nodes*), and there are n of them, each one corresponding to a code bit c_i and thus to *column* i of $\mathbf{H}$. We draw the VNs by open circles ○.

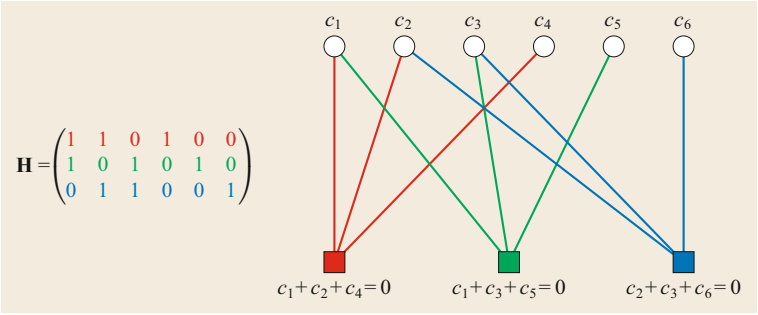

Fig. 7.10 Tanner graph representation of the $(6, 3)$ code given by the parity-check matrix $\mathbf{H}$ in (7.56)

- The second type of nodes are called check nodes (CNs), and there are m of them. Each CN corresponds to a parity-check constraint of the code and thus to a *row* of $\mathbf{H}$. We draw the CNs by filled squares ■.

CN j is connected by an edge to VN c_i if and only if $h_{j,i} = 1$, i.e., if $\mathbf{H}$ contains a 1 in row j and column i. We then say that code bit c_i participates in the j-th parity-check constraint.

Let us illustrate the construction of a Tanner graph using the following $(6, 3)$ code with parity-check matrix

$$\mathbf{H} = \begin{pmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 1 \end{pmatrix} . \tag{7.56}$$

The Tanner graph of this code is shown in Fig. 7.10. We use different colors to illustrate the relation between CNs and rows of $\mathbf{H}$ (which use the same coloring).

Consider as a second example the parity-check matrix in (7.52). The Tanner graph corresponding to this matrix is shown in Fig. 7.11. Each of the nine CNs corresponds to a row of the parity-check matrix $\mathbf{H}$. Every code bit has $d_v = 3$ adjacent edges, and every CN has $d_c = 6$ adjacent edges.

The Tanner graph can be described by the connection sets $\mathcal{M}(j)$ and $\mathcal{N}(i)$. The set $\mathcal{M}(j) = \{i : h_{j,i} \neq 0\}$ contains the positions (columns) of nonzero entries at row j of the parity-check matrix $\mathbf{H}$. For the exemplary matrix in (7.52) we have $\mathcal{M}(1) = \{2, 5, 9, 11, 15, 17\}$ and $\mathcal{M}(4) = \{2, 6, 9, 11, 15, 16\}$. Additionally, the set $\mathcal{N}(i) = \{j : h_{j,i} \neq 0\}$ contains the positions (rows) of nonzero entries at column i of the parity-check matrix $\mathbf{H}$. For the matrix in (7.52) we have $\mathcal{N}(1) = \{2, 6, 8\}$ and $\mathcal{N}(2) = \{1, 4, 7\}$.

Decoding Behavior of Low-Density Parity-Check Codes

Before discussing the decoder implementation in detail, we give a high-level overview of the post-FEC BER behavior of LDPC codes as a function of the channel quality (e.g., E_b/N_0). The decoding behavior of LDPC codes is visualized in Fig. 7.12 for an example code. We can distinguish three regions of the BER curve. Up to a specific E_b/N_0 value, the post-FEC BER does not change significantly. For E_b/N_0 values above this value, in the so-called *waterfall region* (highlighted in gray color in the figure), the post-FEC BER decreases rapidly. The slope of this rapidly decreasing BER curve depends mainly on the length of the code n, with longer codes leading to narrower waterfall regions. Finally, at a certain E_b/N_0, the waterfall region ends, the slope of the BER curve abruptly changes, and we observe an *error floor*. In the error floor region, the post-FEC BER only slowly decreases with increasing E_b/N_0. This effect is due mainly to the presence of some structures in

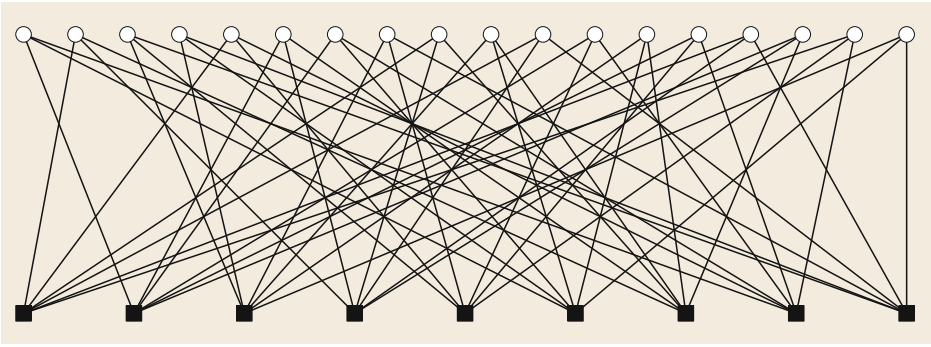

Fig. 7.11 Tanner graph representation of the code with parity-check matrix given by (7.52)

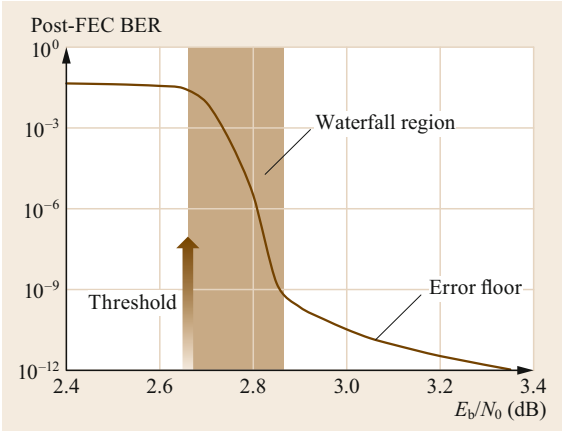

Fig. 7.12 Description of the post-FEC BER behavior for LDPC codes with waterfall region and error floor

the parity-check matrix and Tanner graph of the code that cause the decoder to stall for some specific error patterns [7.63, 116].

The value of E_b/N_0 where the LDPC code performance curve bends into the characteristic waterfall behavior, to which with some abuse of language we refer here as *threshold* (Fig. 7.12), depends on the parameters of the code (i.e., $\boldsymbol{\delta}_v$ and $\boldsymbol{\delta}_c$) and the channel. It can be determined using a technique called *density evolution* [7.117] or approximations thereof [7.118]. Formally speaking, the threshold denotes the E_b/N_0 value at which decoding will be successful (the BER tends to zero), with probability approaching 1 in the asymptotic limit of large block length ($n \to \infty$), provided that the decoder complexity is not constrained. For a detailed discussion, we refer the interested reader to [7.117]. Thresholds of some codes for the binary-input AWGN channel are given in Table 7.3, together with the channel capacity.

From Table 7.3, we see that the thresholds of some irregular LDPC codes are very close to the capacity limits of the binary-input AWGN channel. Indeed, irregular LDPC codes are a very important class of capacity-approaching codes [7.119]. Unfortunately, capacity-approaching irregular LDPC codes typically require parity-check matrices with many weight-2 columns (i.e., $\delta_{v,2} > 0$). Such codes usually have error floors in the range of 10^{-4} to 10^{-8}, depending also on n, that are unacceptable in fiber-optic communications. Hence, there is a trade-off between regular LDPC codes, which usually have low error floors but thresholds bounded away from capacity, and irregular codes, which have thresholds closer to capacity, but often entail unacceptably high error floors. Irregular codes have found important application in fiber-optic communications, especially when designed jointly with iterative decoding and demodulation schemes [7.120, 121]. Later, in Sect. 7.4.5, we will show a simulation example illustrating irregular LDPC codes.

Due to the rapid decrease in BER in the waterfall region, and because of other outstanding properties, LDPC codes for SDD in fiber-optic communications have been studied in multiple publications [7.60, 61, 86, 121, 122]. Due to the error floor, some modern high-performance FEC systems are constructed using a soft-decision LDPC inner code, which reduces the BER to a level of 10^{-3} to 10^{-5}, and a hard-decision outer code which pushes the system BER to levels below 10^{-12} [7.61]. The implementation of a coding system with an outer cleanup code requires a thorough understanding of the LDPC code and a properly designed interleaver between the LDPC and outer code so that the errors at the output of the LDPC decoder—which typically occur in bursts—do not cause uncorrectable blocks after outer decoding. With increasing computing resources, and in particular field-programmable gate array (FPGA)-based decoders, it has now also become feasible to evaluate very low target BERs of LDPC codes and optimize the codes to have very low error floors, below the target BER of the system [7.64, 86].

Construction of Low-Density Parity-Check Matrices

Unlike classical codes such as BCH codes or Reed–Solomon codes, there is no commonly accepted design rule for LDPC codes. Instead, a plethora of LDPC code design methodologies and heuristics exist, each with its own advantages and disadvantages. The goal of an

Table 7.3 Decoding thresholds of some regular and irregular LDPC codes on the AWGN channel

Code	Rate R	E_b/N_0 threshold (dB)	Capacity (E_b/N_0)
Regular (3, 6)	1/2	1.113 dB	0.187 dB
Regular (4, 8)	1/2	1.618 dB	0.187 dB
Irregular code from [7.119]	1/2	0.192 dB	0.187 dB
Regular (3, 15)	4/5	2.586 dB	2.039 dB
Regular (4, 20)	4/5	2.669 dB	2.039 dB
Irregular $\boldsymbol{\delta}_v = (0, 0, (9/10), 0, 0, 0, 0, 0, (1/10))$, $d_c = 18$	4/5	2.441 dB	2.039 dB
Irregular $\boldsymbol{\delta}_v = (0, 0.4, 0.36, 0, 0, 0, 0, 0.24)$, $d_c = 19$	4/5	2.232 dB	2.039 dB

LDPC code designer is to find a code that yields high coding gains and possesses some structure facilitating the implementation of the encoder and decoder. We point the interested reader to numerous articles published on this topic [7.111, 123, 124] and references therein. We provide in the following two ways of constructing parity-check matrices that can serve as a starting point for developing own coding schemes based on LDPC codes.

Regular $(d_\mathrm{v}, d_\mathrm{c})$ LDPC codes can be constructed using Gallager's method [7.54]. This simple method leads to codes that are sufficient for many purposes. In this method, we define the $m \times n$ matrix $\mathbf{H}$ by a *banded* structure. The rows in $\mathbf{H}$ are divided into d_v sets with m/d_v rows in each set (i.e., m must be an integer multiple of d_v). The first set of rows contains d_c consecutive *1*s ordered from left to right across columns, such that each row in the set contains exactly d_c *1*s. Note that this implies that n must be an integer multiple of d_c. Every other set is given by a *randomly chosen column permutation* of the first set. For example, a parity-check matrix of a $(3, 4)$ LDPC code of size 9×12 is constructed as

$$\mathbf{H} = \left(\begin{array}{cccccccccccc}
1&1&1&1&0&0&0&0&0&0&0&0\\
0&0&0&0&1&1&1&1&0&0&0&0\\
0&0&0&0&0&0&0&0&1&1&1&1\\
\hline
1&0&1&0&0&1&0&0&0&1&0&0\\
0&1&0&0&0&0&1&1&0&0&0&1\\
0&0&0&1&1&0&0&0&1&0&1&0\\
\hline
1&0&0&1&0&0&1&0&0&1&0&0\\
0&1&0&0&0&1&0&1&0&0&1&0\\
0&0&1&0&1&0&0&0&1&0&0&1
\end{array}\right) . \quad (7.57)$$

In practice, the permutations should be chosen such that any sub-matrix of the form $\left(\begin{smallmatrix}1&1\\1&1\end{smallmatrix}\right)$, i.e., two columns sharing *1*s in two common rows, is avoided. This is the so-called *row-column (RC) constraint*, which can improve the decoding performance significantly. Note that the RC constraint cannot be fulfilled for the matrix in (7.57), as, by the pigeonhole principle, a necessary condition to fulfill the RC constraint with Gallager's construction is that $m \geq d_\mathrm{v} d_\mathrm{c}$. Further note that due to the constraints of the banded Gallager design method, the rank of $\mathbf{H}$ is upper bounded as $\mathrm{rank}(\mathbf{H}) \leq m - d_\mathrm{v} + 1$.

Parity-check matrices can also be obtained via the Tanner graph. This method is particularly useful for irregular LDPC codes. We start with an empty graph and first place the n VNs and the m CNs. Note that each VN of degree i is equipped with i (empty) sockets that connect to an edge in the final graph. Similarly, each CN of degree j is equipped with j empty sockets. In the next step, we place the $n \sum_{i=1}^{d_{\mathrm{v,max}}} i\delta_{\mathrm{v},i}$ edges of the graph as follows: we connect each empty VN socket with a randomly chosen, empty CN socket by an edge such that no VN is connected to the same CN more than once (i.e., parallel edges in the Tanner graph are avoided). As there is a one-to-one correspondence between the Tanner graph and the parity-check matrix, we can construct $\mathbf{H}$ from the graph. Such a matrix will most likely not fulfill the RC constraint. In that case, we may either add a post-processing step that reshuffles some of the edges (i.e., entries of $\mathbf{H}$) such that the RC constraint is fulfilled without changing the degree distribution, or try to fulfill the RC constraint directly while picking the sockets.

These constructions can serve only as a starting point for good designs of parity-check matrices. A popular improvement to the graph-based construction described above is the progressive edge growth (PEG) algorithm [7.125], which adds edges sequentially such that the length of the shortest cycle in the graph is kept small. The ACE algorithm [7.126] also attempts to design LDPC codes with large minimum distance. It can be combined with the PEG algorithm [7.127] as well. In this chapter, we are able to just scratch the surface of all the possibilities and point to the vast body of literature describing different construction methods. For a deep treatment of LDPC codes together with an overview of construction methods, we refer the interested reader to [7.101, Chaps. 6, 10–12].

Quasi-Cyclic Low-Density Parity-Check Codes

The parity-check matrices $\mathbf{H}$ constructed using the methods highlighted in the previous section will be random-like due to the random permutations used in the construction. Unfortunately, when trying to construct a decoder application-specific integrated circuit (ASIC) or implement a decoder on an FPGA, the wiring and routing complexity will usually be prohibitively high even for moderate values of n. Hence, we need constructions with structures that can be leveraged to simplify the wiring and routing in the decoder. For this reason, most LDPC codes that are implemented in practice today are so-called quasi-cyclic (QC) LDPC codes. They have a parity-check matrix with a structure that allows for inherent parallelization of the decoder, reduced wiring complexity, and an efficient encoder realization. QC LDPC codes are constructed using a so-called lifting matrix $\mathbf{A}$. The lifting matrix has integer entries $a_{i,j} \in \{-1, 0, 1, \ldots, S-1\}$, where S denotes the *lifting factor*. The parity-check matrix $\mathbf{H}$ is constructed from $\mathbf{A}$ by replacing each element $a_{i,j}$ with either an all-zero matrix of size $S \times S$ or a cyclically permuted identity matrix of size $S \times S$. If $a_{i,j} = -1$, then the all-zero matrix of size $S \times S$ is used, and if $a_{i,j} \geq 0$, then $a_{i,j}$ denotes the number of cyclic right shifts of the identity matrix that are carried out. If $\dim(\mathbf{A}) = m' \times n'$, then $\dim(\mathbf{H}) = m \times n$, with $m = m'S$ and $n = n'S$.

Formally, we construct the parity-check matrix $\mathbf{H}$ as

$$\mathbf{H} = \begin{pmatrix} \mathbf{P}^{a_{1,1}} & \mathbf{P}^{a_{1,2}} & \dots & \mathbf{P}^{a_{1,n'}} \\ \mathbf{P}^{a_{2,1}} & \mathbf{P}^{a_{2,2}} & \dots & \mathbf{P}^{a_{2,n'}} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{P}^{a_{m',1}} & \mathbf{P}^{a_{m',2}} & \dots & \mathbf{P}^{a_{m',n'}} \end{pmatrix}, \tag{7.58}$$

where $\mathbf{P}$ is the matrix of size $S \times S$ with $p_{i,i+1} = 1$, $\forall i \in \{1, \dots, S-1\}$, $p_{S,1} = 1$, and zeros everywhere else. We note that $\mathbf{P}^0 = \mathbf{I}$, the identity matrix, and

$$\mathbf{P}^j = \underbrace{\mathbf{P}\mathbf{P}\cdots\mathbf{P}}_{j \text{ times}} \tag{7.59}$$

equals the identity matrix cyclically shifted to the right by j. We further define $\mathbf{P}^{-1} \triangleq \mathbf{0}$, the all-zero matrix.

Typically, in modern FEC schemes, a small code with parity-check matrix $\tilde{\mathbf{H}}$ is first constructed, for example, based on Gallager's method or more advanced schemes such as the PEG and ACE algorithms [7.125, 126, 128], MET analysis and design [7.129], protographs [7.130], or finite geometries [7.101, Chap. 10]. See also [7.131] for an extensive overview and attempts at unifying construction methods. In a second step, we replace the nonzero elements of $\tilde{\mathbf{H}}$ by appropriately selected shift values. As an example, we can take the matrix of (7.57) and convert it to a lifting matrix to obtain, with $S = 16$,

$$\mathbf{A} = \begin{pmatrix} 0 & 0 & 0 & 0 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 & 0 & 0 & 0 & 0 & -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & 0 & 0 & 0 & 0 \\ 3 & -1 & 7 & -1 & -1 & 1 & -1 & -1 & -1 & 3 & -1 & -1 \\ -1 & 5 & -1 & -1 & -1 & -1 & 3 & 6 & -1 & -1 & -1 & 5 \\ -1 & -1 & -1 & 5 & 9 & -1 & -1 & -1 & 9 & -1 & 2 & -1 \\ 7 & -1 & -1 & 3 & -1 & -1 & 12 & -1 & -1 & 10 & -1 & -1 \\ -1 & 4 & -1 & -1 & -1 & 0 & -1 & 4 & -1 & -1 & 7 & -1 \\ -1 & -1 & 14 & -1 & 14 & -1 & -1 & -1 & 8 & -1 & -1 & 9 \end{pmatrix}. \tag{7.60}$$

After replacing the entries of the lifting matrix by $\mathbf{P}^{a_{i,j}}$, we obtain the *lifted*, structured parity-check matrix $\mathbf{H}$ of size 144×192 shown in Fig. 7.13, where we added dashed lines to serve as visual guides. The *1*s are represented by black dots in Fig. 7.13, and the *0*s are omitted. The main task of the code designer is to find good values $a_{i,j}$. Many design rules for finding these values have been proposed in the literature. Commonly, the values $a_{i,j}$ are selected to maximize the so-called girth of the code, which is indirectly related to the decoding performance [7.132]. In the example above, we have selected the entries $a_{i,j}$ to yield a girth-10 code. Other constructions are aimed at maximizing a bound of the minimum distance [7.133], and use finite geometries [7.101, Chap. 10], matrix dispersions

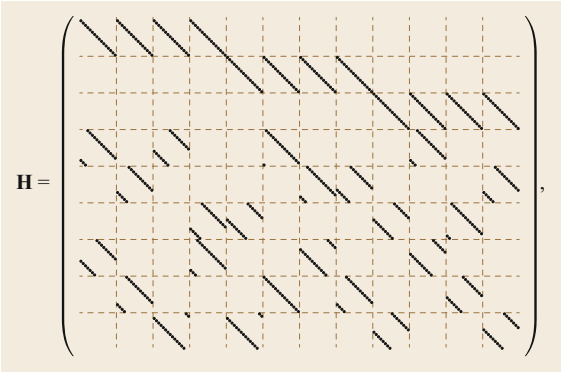

Fig. 7.13 Lifted structured parity-check matrix of size 144×192 obtained by lifting the entries of (7.60) with cyclic permutation matrices of size 16×16

of finite fields [7.101, Chap. 11], [7.131], combinatorial designs [7.101, Chap. 12], the Chinese remainder theorem [7.134], and other methods.

Encoding Low-Density Parity-Check Codes

In general, LDPC codes can be treated as any other block code when it comes to encoding. The generator matrix $\mathbf{G}$ of the LDPC code must be orthogonal to $\mathbf{H}$, i.e., $\mathbf{G} \cdot \mathbf{H}^\top = \mathbf{0}$. If $\mathbf{H}$ can be rearranged such that $\mathbf{H} = \left(\mathbf{P}^\top \ \mathbf{I}_{n-k}\right)$, then $\mathbf{G} = \left(\mathbf{I}_k \ \mathbf{P}\right)$.

Using Gauss–Jordan elimination, any $\mathbf{H}$ can in principle be converted to $\mathbf{H}' = \left(\bar{\mathbf{H}}^\top \ \mathbf{I}_m\right)$ with $\bar{\mathbf{H}}^\top$ an $m \times k$ binary matrix and $\mathbf{I}_m$ the identity matrix of size $m \times m$. The generator matrix is then obtained as $\mathbf{G} = \left(\mathbf{I}_k \ \bar{\mathbf{H}}\right)$. However, there is a fundamental problem with this simple approach: $\mathbf{G}$ will most likely *not be sparse*; thus the encoding complexity and the storage requirements will be $O(n^2)$, which we initially wanted to avoid when introducing LDPC codes.

Fortunately, there is a method to directly encode LDPC codes from $\mathbf{H}$ [7.111, App. A] that allows for an encoding complexity that scales (almost) linearly with the code length n. Instead of finding a generator matrix $\mathbf{G}$ for a given parity-check matrix $\mathbf{H}$, the encoding is carried out directly from $\mathbf{H}$. In a first step, $\mathbf{H}$ is transformed into an approximate triangular form: Using *only row and column permutations*, we construct $\mathbf{H}'$ from $\mathbf{H}$ with

$$\mathbf{H}' = \begin{pmatrix} \mathbf{A} & \mathbf{B} & \mathbf{T} \\ \mathbf{C} & \mathbf{D} & \mathbf{E} \end{pmatrix}, \tag{7.61}$$

where $\mathbf{T}$ is a *lower triangular matrix* of size $(m-g) \times (m-g)$, $\mathbf{B}$ is of size $(m-g) \times g$, and $\mathbf{A}$ is of size $(m-g) \times k$ (if $\mathbf{H}'$ is full rank). The parameter g denotes the number of rows left in $\mathbf{C}$, $\mathbf{D}$, and $\mathbf{E}$ and is called the *gap* of the approximate representation. The smaller g is,

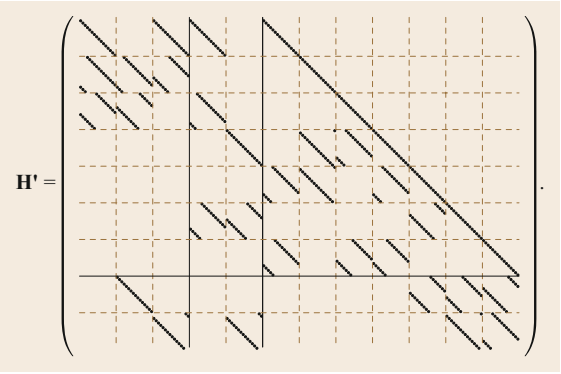

Fig. 7.14 Parity-check matrix of Fig. 7.13 after transformation into the form of (7.61)

the lower the encoding complexity will be. If the permutation operations are chosen well, we have $g \ll m$. A simple, greedy column- and row-swapping algorithm is presented in [7.111, App. A]. Applying this algorithm yields, for the running example, the matrix $\mathbf{H}'$ shown in Fig. 7.14.

Starting from $\mathbf{H}'$, we can clear $\mathbf{E}$ by Gaussian elimination, or equivalently

$$\begin{pmatrix} \mathbf{I}_{m-g} & \mathbf{0} \\ \mathbf{E}\mathbf{T}^{-1} & \mathbf{I}_g \end{pmatrix} \mathbf{H}' = \begin{pmatrix} \mathbf{A} & \mathbf{B} & \mathbf{T} \\ \widetilde{\mathbf{C}} & \widetilde{\mathbf{D}} & \mathbf{0} \end{pmatrix} \triangleq \widetilde{\mathbf{H}} \,, \tag{7.62}$$

with $\widetilde{\mathbf{C}} = \mathbf{E}\mathbf{T}^{-1}\mathbf{A} + \mathbf{C}$ and $\widetilde{\mathbf{D}} = \mathbf{E}\mathbf{T}^{-1}\mathbf{B} + \mathbf{D}$. Note that addition $+$ and subtraction $-$ are equivalent when operating over GF(2); hence, we can replace all subtractions by additions. Further note that inverting $\mathbf{T}$ is easy, as it is a lower triangular matrix [7.86, App. A]. Also, $\mathbf{T}^{-1}$ will retain its QC structure. Finally, the codeword $\boldsymbol{c}$ is divided into three parts

$$\boldsymbol{c} = (\boldsymbol{u} \;\; \boldsymbol{p}_1 \;\; \boldsymbol{p}_2) \,,$$

where $\boldsymbol{u}$ is the k-bit message, $\boldsymbol{p}_1$ holds the first g parity bits, and $\boldsymbol{p}_2$ the remaining $n-k-g$ parity bits. Vector $\boldsymbol{p}_1$ is then obtained from

$$\boldsymbol{p}_1^\top = \widetilde{\mathbf{D}}^{-1}\widetilde{\mathbf{C}}\boldsymbol{u}^\top \,. \tag{7.63}$$

Using back-substitution, $\boldsymbol{p}_2$ can be calculated as

$$\boldsymbol{p}_2^\top = \mathbf{T}^{-1}\left(\mathbf{A}\boldsymbol{u}^\top + \mathbf{B}\boldsymbol{p}_1^\top\right) = \mathbf{T}^{-1}\left(\mathbf{A} + \mathbf{B}\widetilde{\mathbf{D}}^{-1}\widetilde{\mathbf{C}}\right)\boldsymbol{u}^\top \,. \tag{7.64}$$

Although not obvious at first glance, this procedure has some complexity advantages. Many of the intermediate terms needed in the computation are *sparse* and can be precomputed and stored with low complexity. It can be shown that the total encoding complexity is $O(n+g^2)$, which means that if g is very small, the complexity approaches $O(n)$. Note that if the rank of the original matrix $\mathbf{H}$ is not m, some parity bits are linearly dependent, and the procedure must be modified slightly to accommodate this fact by either fixing the linearly dependent parity bits to some predetermined value or assigning additional information bits to them. For further details, see also [7.135].

Decoding Low-Density Parity-Check Codes

As the complexity of optimal MAP decoding grows exponentially with the number of information bits k, MAP decoding is usually not feasible for practical codes, and we need to resort to suboptimal decoding algorithms. The success of LDPC codes is largely due to the existence of very powerful suboptimal decoding algorithms that can be implemented with relatively low complexity. These decoding algorithms belong to the class of *message-passing* algorithms, which work by exchanging messages along the edges of the Tanner graph, with very simple operations to compute the messages inside the nodes. The BP algorithm is the most popular message-passing algorithm for decoding LDPC codes. It works by exchanging *beliefs* about the code bits along the edges of the Tanner graph. The BP algorithm is used in many neighboring fields, for instance in machine learning [7.101, 136, 137], but it was described already in the 1960s to decode LDPC codes [7.54].

We describe the decoder starting from the received, noisy codeword $\boldsymbol{y} = (y_1, \ldots, y_n)$. The goal of the decoder is to compute the bit-wise *a posteriori* probability based on the received codeword $\boldsymbol{y}$,

$$P_{C|\boldsymbol{Y}}(c_i = 1|\boldsymbol{y}) = 1 - P_{C|\boldsymbol{Y}}(c_i = 0|\boldsymbol{y}) \,, \tag{7.65}$$

which can be used to estimate the value of the bit c_i as $\hat{c}_i = \arg\max_{c_i \in \{0;1\}} P_{C|\boldsymbol{Y}}(c_i|\boldsymbol{y})$. Note that this rule is in slight contrast to the MAP rule in (7.38), which estimates the most probable codeword instead of the most probable bit. This rule is therefore also called the bit-wise MAP rule, and minimizes the bit error probability.

Most decoders for LDPC codes (which can include simplified versions such as binary message-passing decoders [7.138]) rely on the knowledge of the channel. The communication channel, or an equivalent communication channel comprising the physical channel as well as various inner receiver and signal processing stages, can be characterized by its *conditional probability mass function* $P_{Y|X}$, or equivalently $P_{Y|C}$, as described in Sect. 7.2. Continuous channels are characterized by their *conditional probability density function* $p_{Y|X}$. Here, we assume a binary-input AWGN channel with $x_i = (-1)^{c_i}$. However, the decoder can easily be

extended to other modulation formats using the respective bit-wise decoder (Sects. 7.2.1 and 7.6.3).

The beliefs that are passed by the BP decoder are conditional probabilities, but for numerical reasons, it is much more convenient to work in the logarithmic domain and use LLRs [7.139]. The use of LLRs also facilitates hardware implementation. The channel-related LLR l_i is defined as

$$l_i = \log \frac{p_{Y_i|C_i}(y_i|0)}{p_{Y_i|C_i}(y_i|1)} \,. \tag{7.66}$$

A simple computation reveals that for the AWGN channel with binary, antipodal ± 1 channel input ($x_i = (-1)^{c_i}$) and channel law given by (7.1), we have

$$l_i = \frac{2}{\sigma_n^2} y_i \triangleq L_c^{[\mathrm{AWGN}]}\, y_i \,. \tag{7.67}$$

Equation (7.67) means that the LLR l_i is obtained simply by multiplication of y_i with a constant $L_c^{[\mathrm{AWGN}]} \triangleq 2/\sigma_n^2$, which depends only on the noise variance. Estimating the noise variance at the receiver is an old problem, and many different solutions exist [7.140, 141]. In many cases, the true noise variance is not even necessary. For example, with the min-sum decoder introduced below, we can assume the noise variance to be constant, and hence the constant $L_c^{[\mathrm{AWGN}]}$ is predetermined and set to a value suitable for implementation. If higher-order modulation formats are used with BICM or PAS, we use the bit-wise decoder (see Sects. 7.6.3 and 7.6.5 for details) to compute the LLRs passed to the decoder.

A vast collection of different varieties of the BP message-passing decoding algorithm for LDPC codes exists. We refer the interested reader to [7.101, 142] for an in-depth treatment of these variations. In the following, we describe the two most popular variants: the flooding and the layered decoder.

The Flooding Sum–Product Decoder. The flooding sum-product decoder is perhaps the most widely used decoder for LDPC codes. It can be best explained using the Tanner graph representation of the code. The decoding algorithm itself is iterative, and each iteration can be split into two half-iterations. In the first half-iteration, each VN of degree d_v computes d_v outgoing messages, one for each of its outgoing edges. In the second half-iteration, each CN of degree d_c computes d_c messages, one for each of its outgoing edges. We repeat this procedure until a maximum number of iterations has been achieved or the bits have been successfully recovered.

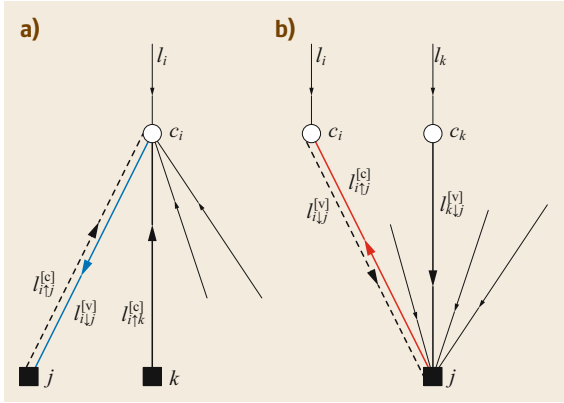

Fig. 7.15a,b Illustration of messages of the sum-product flooding decoding inside the Tanner graph. **(a)** VN perspective; **(b)** CN perspective

We denote by $l_{i\downarrow j}^{[v]}$ the message that is computed by VN i (corresponding to code bit c_i) and passed to CN j via the edge in the Tanner graph. Similarly, we denote by $l_{i\uparrow j}^{[c]}$ the message computed by CN j and passed (via the edge in the Tanner graph) to VN c_i. The superscript [v] or [c] describes the origin of the message (VN or CN), and the direction of the arrow ($\downarrow$ or $\uparrow$) denotes the *direction of the message flow* in the Tanner graph.

Figure 7.15 illustrates the flow of messages along the edges of the Tanner graph, from both a VN perspective (Fig. 7.15a) and a CN perspective (Fig. 7.15b).

We are now ready to state the sum-product algorithm:

1. *(Initialize)* For all $i \in \{1, \ldots, n\}$, set $l_{i\downarrow j}^{[v]} = l_i$, $\forall j \in \mathcal{N}(i)$, where l_i is calculated either using (7.67) (AWGN channel with binary inputs) or using the bit-wise decoder given by (7.93) in Sect. 7.6.3 (if higher-order modulation with BICM or PAS is used).
2. *(CN update)* For every CN j, with $j \in \{1, \ldots, m\}$, compute $|\mathcal{M}(j)| = d_c$ outgoing messages

$$l_{i\uparrow j}^{[c]} = 2 \tanh^{-1}\left[\prod_{i' \in \mathcal{M}(j)\setminus\{i\}} \tanh\left(\frac{l_{i'\downarrow j}^{[v]}}{2}\right)\right], \quad \forall i \in \mathcal{M}(j) \,. \tag{7.68}$$

This update equation follows from the probability that a single parity-check equation is fulfilled when the input bits are 0 or 1 with a certain probability and the conversion of probabilities to LLRs. A detailed derivation can be found for instance in [7.101, Sect. 5.4.3].

3. *(VN update)* For every VN c_i, with $i \in \{1, \ldots, n\}$, compute $|\mathcal{N}(i)|$ outgoing messages

$$l_{i\downarrow j}^{[\mathrm{v}]} = l_i + \sum_{j' \in \mathcal{N}(i)\backslash\{j\}} l_{i\uparrow j'}^{[\mathrm{c}]}, \qquad \forall j \in \mathcal{N}(i)\,. \quad (7.69)$$

4. *(A posteriori estimate)* For $i \in \{1, \ldots, n\}$, compute

$$\hat{c}_i = \begin{cases} 1 & \text{if } l_i + \sum_{j \in \mathcal{N}(i)} l_{i\uparrow j}^{[\mathrm{c}]} < 0, \\ 0 & \text{otherwise.} \end{cases} \quad (7.70)$$

If $\mathbf{H}\hat{\boldsymbol{c}}^{\top} = \mathbf{0}$, with $\hat{\boldsymbol{c}} = (\hat{c}_1, \ldots, \hat{c}_n)$ or if the maximum number of iterations is reached, then stop; otherwise go to step 2.

The notation $\mathcal{N}(i)\backslash\{j\}$ denotes all the elements of $\mathcal{N}(i)$ except j. For the example code of (7.52), we have $\mathcal{N}(2)\backslash\{4\} = \{1, 7\}$.

A straightforward hardware implementation of this algorithm is challenging due to the nature of (7.68). Hence, we will resort to simplified approximations to this update rule that only slightly affects the performance of the decoder. One particularly widely used approximation is the scaled min-sum rule [7.143], which is expressed as

$$l_{i\uparrow j}^{[\mathrm{c}]} = \alpha \left[\prod_{i' \in \mathcal{M}(j)\backslash\{i\}} \operatorname{sign}\left(l_{i'\downarrow j}^{[\mathrm{v}]}\right) \right] \min_{i' \in \mathcal{M}(j)\backslash\{i\}} \left| l_{i'\downarrow j}^{[\mathrm{v}]} \right|, \quad (7.71)$$

where α is an appropriately chosen scaling factor, which is usually determined offline and which depends on the code. The factor may also be iteration dependent and change during decoding [7.144]. An overview of other approximations and variants is presented in [7.145], [7.101, Sect. 5.5]. The theoretical foundations of this decoding algorithm are beyond the scope of this book. We refer the interested reader to [7.111] for an in-depth treatment of the underlying theory.

The Layered Decoder. In what follows, we describe the row-layered variant of the flooding sum-product decoder [7.146]. This variant is optimized for fast convergence and low complexity, and therefore is often used in optical communications. The row-layered decoder can be described directly from the parity-check matrix.

In a first step, the row-layered decoder copies the received LLRs l_j to a memory $\boldsymbol{\mu} = (\mu_1, \mu_2, \ldots, \mu_n)$ of size n with $\mu_j = l_j$, which is continuously updated by the decoder. This memory will be referred to as *a posteriori memory*, as it comprises estimates of the bit-wise a posteriori probabilities. Additionally, the decoder requires an *extrinsic* memory consisting of $m \times d_{\mathrm{c}}$ entries (for a regular code, $m \sum_i i\delta_{\mathrm{c},i}$ for an irregular code), corresponding to the nonzero elements of $\mathbf{H}$. The memory cell $e_{j,i}$ corresponds to row j and column i of $\mathbf{H}$ and is only defined when $h_{j,i} = 1$. We initialize $e_{j,i} = 0, \forall j \in \{1, \ldots, m\}, i \in \mathcal{M}(j)$.

The row-layered decoding operation sequentially carries out three steps for each of the m rows of the parity-check matrix $\mathbf{H}$. After all m rows have been processed, a single decoding iteration has been carried out, and the decoder may restart with the first row to perform an additional iteration. Next we describe the steps for row j of $\mathbf{H}$:

1. *(Computation of input values)* Compute $|\mathcal{M}(j)|$ temporary values $t_{j,i} = \mu_i - e_{j,i}$, $\forall i \in \mathcal{M}(j)$, for all nonzero entries (indexed by i) of the j-th row of $\mathbf{H}$.
2. *(CN update)* The parity-check update rule is carried out to compute new extrinsic information using the full update rule

$$e_{j,i} = 2 \tanh^{-1}\left[\prod_{i' \in \mathcal{M}(j)\backslash\{i\}} \tanh\left(\frac{t_{j,i'}}{2}\right) \right], \ \forall i \in \mathcal{M}(j)\,, \quad (7.72)$$

where the product is again taken over all entries in $\mathcal{M}(j)$ except the one under consideration, i. Alternatively, e.g., for a hardware implementation, the scaled min-sum update rule

$$e_{j,i} = \alpha \left[\prod_{i' \in \mathcal{M}(j)\backslash\{i\}} \operatorname{sign}(t_{j,i'}) \right] \min_{i' \in \mathcal{M}(j)\backslash\{i\}} |t_{j,i'}|\,. \quad (7.73)$$

can also be used.
3. *(A posteriori update)* The $|\mathcal{M}(j)|$ a posteriori memory positions that take part in the parity-check equation are updated according to $\mu_i = t_{j,i} + e_{j,i}$, $\forall i \in \mathcal{M}(j)$.

After having carried out the three steps for row j, the LDPC decoder continues with decoding row $j+1$ or, if $j = m$ has been reached, it restarts either at $j = 1$ or terminates if the number of iterations has reached a predefined limit. After termination, we can get an estimate of the codeword by evaluating for every code bit

$$\hat{c}_i = \frac{1}{2}\left[1 - \operatorname{sign}(\mu_i)\right]. \quad (7.74)$$

If the code is systematic, the information portion can be recovered by taking the decision at the respective systematic positions.

Because of its sequential updates, this layered decoding algorithm is not immediately suited for massively parallel decoding of arbitrary LDPC codes. However, when used together with QC LDPC codes, we can see that groups of S consecutive rows of $\mathbf{H}$ are always non-interacting. In a decoder, the respective memory accesses are all to different locations, and hence the operations are non-interacting and can be parallelized. The cyclic shifts can be easily realized using barrel shifter circuits. See for instance [7.147] for further details.

7.4.2 Spatially Coupled Low-Density Parity-Check Codes

While so far we have focused mostly on block codes (e.g., LDPC codes), a significant number of practical codes were and still are based on simple convolutional codes using simple binary shift registers. About two decades ago, LDPC convolutional codes were introduced [7.71], which superimpose LDPC codes with a convolutional structure. The initial goal was to combine the advantages of convolutional and LDPC codes, and the resulting codes were called *LDPC convolutional codes*. A similar idea had already been pursued in the late 1950s and early 1960s with the concept of recurrent codes ([7.148] and references therein). The full potential of LDPC convolutional codes was not realized until a few years later, when *Lentmaier* et al. noticed that the performance of some LDPC convolutional code constructions asymptotically approached the performance of optimal ML decoding [7.72, 74]. Soon thereafter, this was formally proven for a wide range of channels by *Shrinivas Kudekar* et al. [7.75, 76]. As a proof technique, Kudekar et al. modified the original LDPC convolutional codes slightly and introduced a variation of the construction, denoted as spatially coupled codes. Because of the similarity between the two schemes, we use the term SC-LDPC codes to refer to both constructions for the remainder of this chapter. An alternative proof technique to the one in [7.75, 76] was proposed in [7.149, 150]. The analysis of nonbinary SC-LDPC codes was addressed in [7.151, 152].

Definition and Basic Construction

We now extend our description of LDPC codes to SC-LDPC codes. We first take on an encoder perspective. An LDPC encoder is a block encoder, i.e., it encodes a block of information bits $\boldsymbol{u}_t$ into a codeword $\boldsymbol{c}_t$. This is shown in Fig. 7.16a. The encoder of an SC-LDPC code can be interpreted as an encoder of a recurrent code [7.148] and is shown in Fig. 7.16b. The recurrent

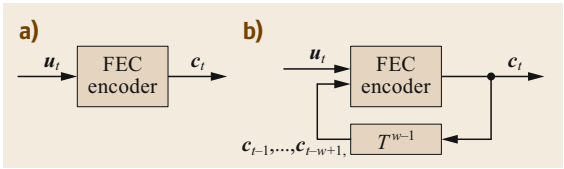

Fig. 7.16a,b Comparison of (a) conventional block LDPC encoder and (b) spatially coupled (SC) LDPC encoder

encoder generates *batches* $\boldsymbol{c}_t$ of a codeword which consists of a sequence of such batches. The batch $\boldsymbol{c}_t$ at time t depends not only on $\boldsymbol{u}_t$ but also on $w-1$ previous batches $\boldsymbol{c}_{t-1}, \ldots, \boldsymbol{c}_{t-w+1}$. The parameter w is called the *coupling width* of the code. The term *spatial coupling* highlights the dependence of $\boldsymbol{c}_t$ on previous batches along the *spatial* dimension t (this new, additional dimension was referred to as *spatial* dimension in [7.75]; however, note that it does *not* refer to a physical spatial dimension). Each batch is hence also called a *spatial position*.

At the beginning of the transmission (for $t = 1$), we assume that the contents of the feedback memory are zero, i.e., the previous batches at undefined times $t < 1$ are $\boldsymbol{c}_0 = \boldsymbol{c}_{-1} = \boldsymbol{c}_{-2} = \ldots = \mathbf{0}$. After starting the transmission, we could in principle run the encoding procedure without interrupting it. This is sometimes called *left-termination* or *unterminated* operation. Frequently, however, the encoding is terminated after the transmission of L batches, where L denotes the *replication factor* or *spatial length* of the code. Termination means that $\boldsymbol{c}_t = \mathbf{0}$ for $t > L$, provided that the input $\boldsymbol{u}_t = \mathbf{0}$ for $t > L$. Termination yields a block code again, where the length n of the block code amounts to Ln_b bits, with n_b being the size of one batch $\boldsymbol{c}_t$. Termination is realized by slightly reducing the number of information bits to $k'_\mathrm{b} < k_\mathrm{b}$ in the final $w-1$ batches, i.e., $\boldsymbol{u}_{L-w+2}, \ldots, \boldsymbol{u}_L$. The encoder then generates $k_\mathrm{b} - k'_\mathrm{b}$ extra parity bits that are required to enforce the termination condition. These extra parity bits lead to a *rate loss* (i.e., reduce the effective number of information bits). However, note that the effect of the rate loss becomes negligible if L is increased. Termination is often used to fit multiple FEC frames into a larger super-frame (e.g., an optical transport network (OTN) frame [7.153]) or a networking container [7.154], or to prevent error propagation.

Instead of interpreting the terminated encoding procedure as a recurrent procedure of L batches, it is often customary to group the L batches $\boldsymbol{c}_1, \ldots, \boldsymbol{c}_L$ into the codeword $\boldsymbol{c}^{[\mathrm{SC}]} \triangleq (\boldsymbol{c}_1 \quad \boldsymbol{c}_2 \quad \ldots \quad \boldsymbol{c}_L)$. We denote the parity-check matrix of the corresponding *terminated* (and non-time-varying) SC-LDPC code with coupling

width w by $\mathbf{H}^{[\mathrm{SC},w]}$. It is given by

$$\mathbf{H}^{[\mathrm{SC},w]} = \begin{pmatrix} \mathbf{H}_1 & & & \\ \vdots & \mathbf{H}_1 & & \\ \mathbf{H}_w & \vdots & \ddots & \\ & \mathbf{H}_w & \ddots & \mathbf{H}_1 \\ & & \ddots & \vdots \\ & & & \mathbf{H}_w \end{pmatrix}, \tag{7.75}$$

with sub-matrices $\mathbf{H}_i$ of dimensions $m_\mathrm{b} \times n_\mathrm{b}$, with n_b denoting the length of one batch. The simplest case is obtained for $w = 2$ (which we sometimes call *unit-memory* coupling), for which we have

$$\mathbf{H}^{[\mathrm{SC},2]} = \begin{pmatrix} \mathbf{H}_1 & & & \\ \mathbf{H}_2 & \mathbf{H}_1 & & \\ & \mathbf{H}_2 & \ddots & \\ & & \ddots & \mathbf{H}_1 \\ & & & \mathbf{H}_2 \end{pmatrix}. \tag{7.76}$$

The parity-check matrix $\mathbf{H}^{[\mathrm{SC},w]}$ is of dimensions $(L + w - 1)m_\mathrm{b} \times Ln_\mathrm{b}$, and consequently, assuming full rank, the rate of the terminated SC-LDPC code is given by

$$R = 1 - \left(1 + \frac{w-1}{L}\right)\frac{m_\mathrm{b}}{n_\mathrm{b}} \leq 1 - \frac{m_\mathrm{b}}{n_\mathrm{b}}, \tag{7.77}$$

i.e., the rate is decreased by spatial coupling due to the extra rows in $\mathbf{H}^{[\mathrm{SC},w]}$ required for the termination. Note that this *rate loss* vanishes when $L \to \infty$, which is why we usually want to select L that is quite large. Multiple techniques for reducing the rate loss have been investigated [7.155–158].

Tanner Graph and Construction of Spatially Coupled Low-Density Parity-Check Codes

Due to the structured parity-check matrix $\mathbf{H}^{[\mathrm{SC},w]}$, the Tanner graph of an SC-LDPC code has a particularly simple structure. An SC-LDPC code and the corresponding Tanner graph can be constructed starting from an LDPC code. We show the construction of both the parity-check matrix $\mathbf{H}^{[\mathrm{SC},w]}$ and the Tanner graph by means of an example. We use the *edge-spreading* technique introduced in [7.72], which can be carried out directly in the Tanner graph of an LDPC code.

We start with a Tanner graph of an LDPC code. The first step consists in *coloring* the edges of the graph in w distinct colors or *edge types*. One possibility for coloring the edges is to carry out a random experiment for each edge and assign to it color w with probability $1/w$. This is called *uniform coupling*. The coloring probabilities can also be optimized, for example, to improve the performance of the code [7.158]. The coloring procedure is illustrated in Fig. 7.17. We start with the Tanner graph of a $(3, 6)$ LDPC code which is shown in Fig. 7.17a. We then apply the edge coloring where the two colors are represented by solid and dashed lines, respectively. This is shown in Fig. 7.17b. For each of the two edge colors, we can construct a new Tanner graph by removing all edges of different colors, and from this graph obtain the corresponding parity-check matrices $\mathbf{H}_1$ and $\mathbf{H}_2$. For the example in Fig. 7.17b with $w = 2$, we obtain

$$\mathbf{H}_1 = \begin{pmatrix} 1 & 0 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \end{pmatrix} \quad \text{and}$$

$$\mathbf{H}_2 = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}. \tag{7.78}$$

Hence, by this technique, we have decomposed the matrix $\mathbf{H}$ into w *binary* matrices $\mathbf{H}_i$ of same dimension such that

$$\sum_{i=1}^{w} \mathbf{H}_i = \mathbf{H},$$

where the sum is taken over the natural numbers. We can also describe the edge-spreading technique in the following way: for every column i of $\mathbf{H}$, partition (either randomly or according to some deterministic procedure) the set $\mathcal{N}(i)$ into w pairwise disjoint subsets $\mathcal{N}_j(i)$ such that $\bigcup_{j=1}^{w} \mathcal{N}_j(i) = \mathcal{N}(i)$. Then use $\mathcal{N}_j(i)$ to set the *1* values of $\mathbf{H}_j$.

In the next step, we can construct the Tanner graph of the SC-LDPC code. For this, we start from our basic LDPC graph, and we first generate $w - 1$ additional copies of the VNs. This gives us w groups of VNs, each corresponding to one of the w colors. In the next step, we assign the edges of a single color to the corresponding group of VNs. For the colored graph in Fig. 7.17b, this leads to the graph shown in Fig. 7.18. Note that this graph corresponds to the parity-check matrix $(\mathbf{H}_2 \ \mathbf{H}_1)$. The Tanner graph of the final spatially coupled code with $w = 2$ is obtained by superimposing $L + 1$ of these Tanner graphs with an overlap of one spatial position (and combining the superimposed VNs into one new

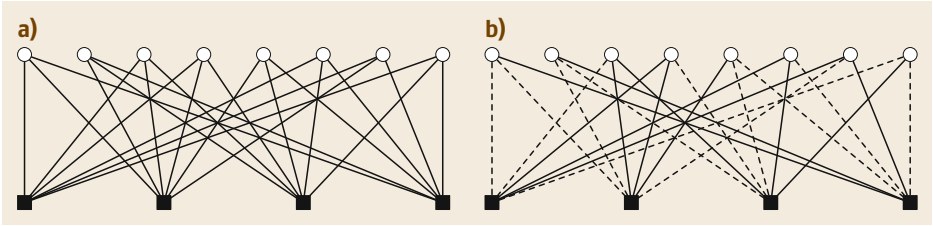

Fig. 7.17a,b Illustration of the edge-coloring principle for designing an SC-LDPC code from an LDPC code. **(a)** Tanner graph of a $(3, 6)$ LDPC code; **(b)** Tanner graph with edge coloring

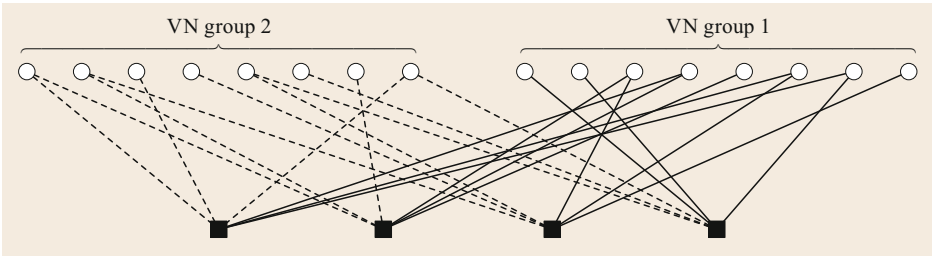

Fig. 7.18 Tanner graph representation of the example code with parity-check matrix $(\mathbf{H}_2 \ \mathbf{H}_1)$ of (7.78)

VN) and then removing the first and last n VNs together with their associated edges. For $L = 4$, this is illustrated in Fig. 7.19. We can clearly see the repetitive structure of the code. In the general case (i.e., for any $w \geq 2$), we superimpose $L + w - 1$ of the Tanner graphs corresponding to $(\mathbf{H}_w \ \cdots \ \mathbf{H}_2 \ \mathbf{H}_1)$ with an overlap of $w - 1$ spatial positions and then remove the first and last $(w - 1)n$ VNs with their associated edges.

Because of the edge-spreading technique, we have conserved $\boldsymbol{\delta}_\mathrm{v}$, i.e., the VN degree distribution (as well as $\boldsymbol{\delta}_\mathrm{c}$). The number of *1*s in each row of $\mathbf{H}^{[\mathrm{SC},w]}$ is the same everywhere as in the starting matrix $\mathbf{H}$, except in rows 1 to $(w - 1)m$ and $(L + 1)m$ to $(L + w - 1)m$, where we have lower degrees. These correspond to the lower-degree CNs at the boundaries of the Tanner graph (Fig. 7.19). This lack of *1*s, which is due to termination, is crucial for the outstanding performance of SC-LDPC codes [7.75, 159]. This leads to low-degree parity-check equations at the boundaries, which better protect the code bits at the boundaries. These, in turn, after decoding, protect their neighbors in a ripple- or wave-like fashion.

Encoding Spatially Coupled Low-Density Parity-Check Codes

As an SC-LDPC code is in principle an LDPC code with a structured parity-check matrix, the technique introduced in Sect. 7.4.1, can be directly applied to $\mathbf{H}^{[\mathrm{SC},w]}$. However, as the length of $\mathbf{H}^{[\mathrm{SC},w]}$ is usually relatively long, it can be advantageous to take on the recurrent coding perspective of Fig. 7.16b. In this case, we merely apply the triangularization to $\mathbf{H}_1$ and then encode the different $\boldsymbol{c}_t$s on a batch-by-batch basis. The encoding procedure can be simplified significantly by slightly modifying the construction procedure and enforcing that $\mathbf{H}_1$ has the structure $\mathbf{H}_1 \triangleq (\tilde{\mathbf{H}}_1 \ \mathbf{I}_m)$, where $\mathbf{I}_m$ denotes the $m \times m$ identity matrix. In this case, systematic encoding (see Definition 7.8) of $\boldsymbol{u}_t$ into $\boldsymbol{c}_t = (\boldsymbol{u}_t \ \boldsymbol{p}_t)$ is accomplished by computing

$$\boldsymbol{p}_t^\top = \tilde{\mathbf{H}}_1 \boldsymbol{u}_t^\top + \sum_{i=2}^{w} \mathbf{H}_i \boldsymbol{c}_{t-i+1}^\top \tag{7.79}$$

during the first $L - w + 1$ batches with the initialization $\boldsymbol{c}_0 = \boldsymbol{c}_{-1} = \cdots = \mathbf{0}$. The last batch(es) require special

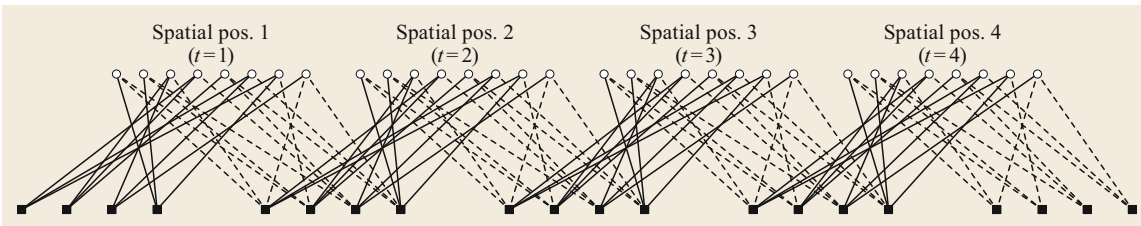

Fig. 7.19 Tanner graph representation of the example code with parity-check matrix $(\mathbf{H}_2 \ \mathbf{H}_1)$ of (7.78), with $L = 4$

treatment to fulfill the termination constraints, such that $\mathbf{H}^{[\mathrm{SC},w]}(\boldsymbol{c}^{[\mathrm{SC}]})^\top = 0$. We require up to $m(w-1)$ extra parity bits to fulfill these constraints. These are usually accommodated in the last batch or spread over the final $w-1$ batches, at a cost of a smaller number of information bits in these batches. A detailed, in-depth treatment of the encoder and related hardware architecture can be found in [7.71, 160, 161].

Decoding Spatially Coupled Low-Density Parity-Check Codes

In principle, an SC-LDPC code is merely an LDPC code with a parity-check matrix $\mathbf{H}$ structured in a particular way. Hence, decoding SC-LDPC codes is possible in a straightforward manner using the decoders given in Sect. 7.4.1. However, the decoding can be greatly simplified by exploiting the structure of the parity-check matrix and the decoding mechanics of such codes using a so-called windowed decoder, which operates on only a part of the codeword [7.77]. In the following, we first describe the conventional layered windowed decoder and then an extension that can improve the decoding performance without increasing the decoding latency.

Conventional Windowed Decoder. The conventional windowed decoder extends the flooding or layered decoders presented in Sect. 7.4.1 by some extra data flow and message handling to account for the memory of the code. We can define a decoding window size W_D and extract a portion $\mathbf{H}_\mathrm{W}$ of $m_\mathrm{b}W_\mathrm{D}$ rows of $\mathbf{H}^{[\mathrm{SC},w]}$ (with the corresponding nonzero columns) of size $\dim(\mathbf{H}_\mathrm{W}) = m_\mathrm{b}W_\mathrm{D} \times n_\mathrm{b}(W_\mathrm{D}+w-1)$ that has the form

$$\mathbf{H}_\mathrm{W} \triangleq \begin{pmatrix} \mathbf{H}_w & \mathbf{H}_{w-1} & \cdots & \mathbf{H}_1 & & \\ & \mathbf{H}_w & \mathbf{H}_{w-1} & \cdots & \mathbf{H}_1 & \\ & & \ddots & \ddots & \cdots & \ddots \\ & & & \mathbf{H}_w & \mathbf{H}_{w-1} & \cdots & \mathbf{H}_1 \end{pmatrix}. \tag{7.80}$$

We focus here only on the layered decoder, as it has most practical relevance due to its fast convergence. We initialize an a posteriori memory of size $n_\mathrm{b}(W_\mathrm{D}+w-1)$ as follows: $\mu_1 = \mu_2 = \cdots = \mu_{n_\mathrm{b}(W_\mathrm{D}+w-1)} = +\infty$. In practice, a sufficiently large constant (e.g., the largest value representable with the fixed-point representation) is used instead of $+\infty$. As in the layered decoder, we initialize an extrinsic memory as $e_{j,i} = 0$, $\forall j \in \{1,\ldots,m_\mathrm{b}W_\mathrm{D}\}$, $i \in \mathcal{M}_\mathrm{W}(j)$, where $\mathcal{M}_\mathrm{W}(j) = \{k : h_{\mathrm{W},j,k} \neq 0\}$ is the set of all nonzero entries of row j of $\mathbf{H}_\mathrm{W}$.

The windowed decoder then processes in each step a batch of n_b received values $\boldsymbol{y}_t$ that correspond to the transmitted batch $\boldsymbol{c}_t$, where t also denotes the spatial position. At the start of a codeword $\boldsymbol{c}^{[\mathrm{SC}]}$, we set $t = 1$. The windowed decoder is described as follows:

1. (*Receive and shift*) Upon reception of a new batch of n received values $\boldsymbol{y}_t = (y_{t,1},\ldots,y_{t,n})$ that correspond to the batch $\boldsymbol{c}_t$ of $\boldsymbol{c}^{[\mathrm{SC}]}$, shift the a posteriori memory by n positions and append the newly received LLRs $l_{t,i}$, i.e.,

$$\begin{aligned} &\mu_i \leftarrow \mu_{i+n_\mathrm{b}}, \quad \text{for } i \text{ from 1 to } (W_\mathrm{D}+w-2)n_\mathrm{b} \\ &\mu_{(W_\mathrm{D}+w-2)n_\mathrm{b}+i} \leftarrow l_{t,i}, \quad \text{for } i \text{ from 1 to } n_\mathrm{b}\,. \end{aligned}$$

   Note that the decoder must run even when $t > L$ until all batches of the codeword have been decoded. If $t > L$, there are no newly received values, and we define $l_{t,i} = +\infty$ for $t > L$ and $i \in \{1,\ldots,n_\mathrm{b}\}$. Similarly, we shift the extrinsic memory and initialize the unused part with zeros,

$$\begin{aligned} &e_{j,i} \leftarrow e_{j+m_\mathrm{b},i}, \quad \text{for } j \text{ from 1 to } (W_\mathrm{D}-1)m_\mathrm{b}, \forall i \\ &e_{(W_\mathrm{D}-1)m_\mathrm{b}+j,i} \leftarrow 0, \quad \text{for } j \text{ from 1 to } m_\mathrm{b}, \forall i\,. \end{aligned}$$

2. (*Decoding*) Run the layered decoder as described in Sect. 7.4.1, *Decoding Low-Density Parity-Check Codes* using $\mathbf{H}_\mathrm{W}$ as parity-check matrix for a predetermined number of iterations I with extrinsic memory $e_{j,i}$ and a posteriori memory μ_i.
3. (*Decision*) Recover the estimated code bits

$$\hat{c}_{t-W_\mathrm{D}-w+2,i} = \frac{1}{2}[1-\mathrm{sign}(\mu_i)], \quad \forall i \in \{1,\ldots,n_\mathrm{b}\} \tag{7.81}$$

   of the batch corresponding to $\boldsymbol{c}_{t-W_\mathrm{D}-w+2}$ of $\boldsymbol{c}^{[\mathrm{SC}]}$. Note the additional delay of $W_\mathrm{D}+w-2$ introduced by the windowed decoder, which adds extra latency to the decoding process.

Note that the number of effective iterations per spatial position is $I(W_\mathrm{D}+w-1)$, i.e., in order to compare SC-LDPC codes with conventional (block) LDPC codes, we need to choose the effective number of iterations accordingly. Also note that the windowed decoder introduces a decoding *delay* of $W_\mathrm{D}+w-2$ batches and hence potentially increases the decoding latency with respect to that of a conventional LDPC code, unless n_b is chosen to be significantly smaller than the length n of the LDPC code to compensate for this delay. Also note that the decoder will not output meaningful information in the first $W_\mathrm{D}+w-2$ batches and hence must run following the reception of all L transmitted batches for an additional $W_\mathrm{D}+w-2$ batches until all bits have been decoded. These extra executions must be addressed by

the decoder and require attention inside an FPGA or ASIC. However, as the windowed decoder essentially wraps around a conventional LDPC decoder, the effort of a very-large-scale integration VLSI implementation is potentially simple.

Multi-Engine Windowed Decoder. Usually $W_D > w$, and hence, as a decoding engine operates on some rows of $\mathbf{H}_W$, only some of the corresponding memory locations are updated, while a significantly large part of $\mathbf{H}_W$ is not considered due to the particular banded structure of $\mathbf{H}_W$. For example, all rows of $\mathbf{H}_W$ that are at least wm_b rows apart do not share common code bits and could hence be treated independently in parallel inside the decoder. For this reason we introduce a multi-engine layered decoder that consists of E engines that operate independently in parallel [7.83]. The only modification is step 2 of the windowed decoder. While the first engine processes the rows from 1 to $m_b W_D$ in that order, the second engine starts with an offset $O_2 \geq wm_b$ and operates on the sequence of rows $(O_2, \ldots m_b W_D, 1, \ldots, O_2 - 1)$, i.e., it wraps around the matrix. In general, engine i operates on the sequence of rows $(O_i, \ldots, m_b W_D, 1, \ldots, O_i - 1)$, and we define $O_1 = 1$. The offsets need to fulfill the following condition: $|O_i - O_j| \geq wm_b$, $\forall (i,j) \in \{1, \ldots, E\}^2$, $i \neq j$. By the pigeonhole principle, the number of engines is hence upper bounded as $E \leq \lfloor W_D / w \rfloor$, where $\lfloor x \rfloor$ denotes the largest integer smaller than or equal to x.

Optimization of Spatially Coupled Low-Density Parity-Check Codes

In contrast to LDPC codes, which are well understood and have now commonly accepted design rules, the design of high-performing SC-LDPC codes is still part of active research efforts. In this section, we highlight some of these activities and recent results that seem promising for the design and evaluation of future close-to-capacity SC-LDPC codes.

Despite their similarity to LDPC codes, SC-LDPC codes have significantly different error correction behavior. This behavior was rigorously analyzed in [7.75, 76, 159], where it was shown that decoding behaves like a *wave* that propagates through the codeword, which is also in line with the windowed decoding mechanism. To optimize codes during construction, knowing the speed of this wave is crucial. An analysis of the speed of this wave together with upper and lower bounds was provided in [7.162–164]. This analysis was used in [7.165] to show that we can design SC-LDPC codes with irregular VN degrees that lead to performance improvements when decoded with a complexity-constrained decoder.

While the asymptotic performance of SC-LDPC codes is now well understood, the influence of the various parameters on the practical, non-asymptotic decoding performance is much less clear. Some attempts to better understand the influence on the different parameters are given in [7.166, 167] which could help to design codes in the future. It turns out that for highly optimized codes, L should be small. In order not to reduce the rate given by (7.77) too much, w should be kept small as well, ideally $w \in \{2, 3\}$, to keep the rate loss and complexity and latency of windowed decoding small. Such codes have been called *weakly coupled* in [7.165]. To construct good codes in this case, *non-uniformly* coupled SC-LDPC codes were constructed in [7.158], which have both superior decoding performance and reduced rate loss.

While selecting a small coupling width w can have its advantages, the choice of a larger w together with very sparse matrices $\mathbf{H}_i$ can also be useful in some applications. In [7.165], the latter case was called *strongly coupled*. Although the windowed decoder needs to cover a potentially longer decoding window, this is compensated for by the fact that we can have a shorter n_b and that the sub-matrices $\mathbf{H}_i$ are very sparse, limiting the effective amount of operations to be done. Constructions for such strongly coupled codes, which closely resemble traditional convolutional codes with large syndrome-former memory, are given for instance in [7.168–170].

As already discussed, one of the main challenges for implementing SC-LDPC codes in practice is the rate loss due to termination. The rate loss, which scales with w, can be made arbitrarily small by increasing L; however, in some cases we want to avoid a large L, as it can worsen the finite-length performance of SC-LDPC codes [7.166]. Nevertheless, in some cases we can let L go to infinity and still achieve gains compared with LDPC codes, as we have demonstrated in [7.171]. For a fixed L, there exist multiple proposals for mitigating the rate loss [7.172, 173], which however often introduce extra structure at the boundaries. Such extra structure is usually undesired, as it complicates the decoder data flow. Other approaches use tail-biting codes (without termination) and mimic the termination (summoning the positive effects of termination) by shortening [7.155, 157, 174], energy shaping [7.175], using intelligent interleaving together with the properties of higher-order modulation formats [7.156, 176–178], or iterative demapping and equalization [7.179], just to name a few.

Another line of research is the optimization of the windowed decoder of SC-LDPC codes, which is itself not free of issues. Some of these issues are highlighted for instance in [7.166, 180]. In systems with heavy complexity constraints, the scheduling of the operations inside the decoder can lead to some performance im-

provements [7.181]. The windowed decoder itself can lead to unrecoverable burst errors, significantly degrading the system performance. These burst errors can be addressed as well by intelligent scheduling of the decoder operations [7.182]. A general introduction to SC codes and an overview of some further research problems is given in [7.183].

7.4.3 Polar Codes

In addition to spatially coupled codes, another coding scheme has emerged in the past few years that is asymptotically capacity-achieving and has appealing encoding and decoding complexity. This scheme, called *polar coding*, was invented by *Arıkan* in 2008 [7.65, 66] and was the first low-complexity coding scheme that could (provably) achieve the capacity over binary discrete memoryless symmetric channels (DMSCs), nonbinary DMSCs [7.184], and asymmetric channels [7.185]. In fact, polar codes had been proposed already in 2002 by *Norbert Stolte* [7.186] but did not receive much attention until Arıkan proved that they were capacity-achieving. A polar code encodes a vector $\tilde{\boldsymbol{u}}$ of length $n = 2^\eta$, containing the k information bits in specific, predetermined positions and (known) frozen values otherwise, by $\boldsymbol{c} = \tilde{\boldsymbol{u}}\mathbf{F} = \tilde{\boldsymbol{u}} \left(\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right)^{\otimes\eta}$, where $\otimes\eta$ denotes η successive applications of the Kronecker product. If the positions of the k information bits are carefully chosen, then after decoding with a *successive cancellation* decoder or variants thereof, these positions are unaffected by channel noise. More precisely, each component of $\tilde{\boldsymbol{u}}$ *sees* its own equivalent sub-channel, so that in total there are 2^η sub-channels. As η tends to infinity, the error probability of each sub-channel converges to zero (a *good* sub-channel) or one-half (a *bad* sub-channel). This phenomenon is referred to as *channel polarization*. The k information bits can be reliably transmitted over the k good sub-channels. Arıkan showed that the fraction of good sub-channels converges to the channel capacity under successive cancellation decoding. Figure 7.20 shows an example of a rate $R = 3/4$ polar encoder for a short toy code with $n = 8$ ($\eta = 3$ and hence $k = 6$). An offline procedure, as described for instance in [7.187], determines the $k = 6$ *good* sub-channels over which we transmit information, and the frozen bits, which we set to a predetermined value, e.g., *0*. Note that the codeword $\boldsymbol{c}$ is *not* systematic by default. Polar codes can, however, also be rendered systematic following the procedure given in [7.188].

The successive cancellation decoder of polar codes consists of relatively simple binary operations and is of complexity $O(n \log n)$. The elegance of the construction has made polar codes an attractive choice in research with many applications and scenarios, such as 5G. An early application to fiber-optic communications has been given in [7.82, 189]. However, there are multiple areas where polar codes can be further improved. Extremely long block lengths n are required to achieve low error probabilities with polar codes [7.66] and simple successive cancellation decoding. Recently, list decoding [7.67] in conjunction with a concatenated cyclic redundancy check CRC code was proposed to improve the error performance for finite code lengths, albeit at a cost of increased receiver complexity. Furthermore, the original successive cancellation decoder proposed by *Arıkan* [7.66] is not directly suited for parallelization, which is however mandatory if this class of codes is to be used in fiber-optic communications. Recent research efforts are aimed at studying new concepts for building hardware-efficient, parallelizable decoders [7.69, 70, 190, 191], which is still an active area of research. A promising line of research is the use of the sum-product algorithm developed for LDPC for polar codes, enabling efficient parallelization [7.192].

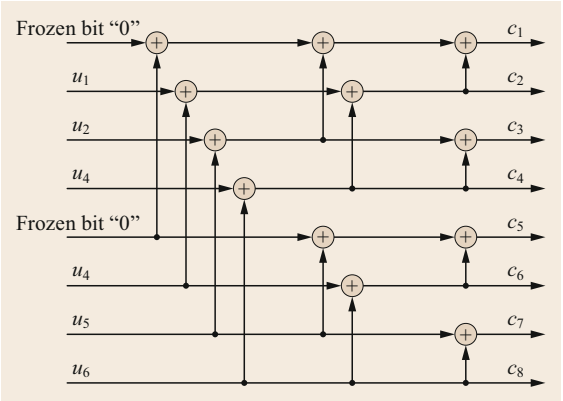

Fig. 7.20 Threefold application ($\eta = 3$) of the basic channel transform

7.4.4 Other Coding Schemes

In addition to LDPC, SC-LDPC, and polar codes, many other coding schemes exist for SDD. However, most of these have not found widespread application in optical communications. Perhaps the most prominent one is SDD of TPCs or concatenated BCH codes, which we will briefly discuss in the next section. In the 3G and 4G mobile wireless communication standards, turbo codes [7.193] (which are parallely concatenated codes based on convolutional component codes) are still the dominant error-correcting codes. However, they have found no application so far in optical communications. They suffer from the disadvantage of a non-negligible error floor and little to no available decoder implementations that can operate at the speeds required in optical

communications. In the upcoming 5G wireless communication standard, turbo codes will be at least partly superseded by LDPC codes (for some data channels) and polar codes (for some control channels) [7.68].

7.4.5 Performance Curves

Performance of Low-Density Parity-Check Codes

To show the potential of LDPC codes with the simple SDD algorithm described above, we generate two regular QC LDPC codes with parameters $d_v = 3$ and $d_v = 4$, and we fix d_c to obtain codes of rate $4/5$ (OH $= 25\%$). We generate small base matrices of size $n = 300$ using an algorithm similar to Gallager's algorithm and then use lifting with cyclically shifted identity matrices of size 128×128. We have selected the shifts to maximize the girth parameter of the code by avoiding *Fossorier*'s conditions for low-girth codes [7.132]. In Fig. 7.21, we show simulation results with the non-simplified CN update rule and the normalized min-sum decoding rule (with $\alpha = 3/4$) after transmission over a binary-input AWGN channel. We can see that the code with $d_v = 3$ outperforms the code with $d_v = 4$, and the performance loss due to scaled min-sum decoding is almost negligible. For $d_v = 4$, the performance loss due to scaled min-sum decoding is more pronounced, which is due to a mismatched choice of the scaling factor α. The increasing color scales in Fig. 7.21 indicate the number of iterations (1, 2, 3, 5, 10 and 30). We can see that after only 10 decoding iterations, we have achieved a very good performance, and increasing the number of iterations to 30 yields additional gains of only 0.1 dB, which may not be worth the effort.

Figure 7.22 illustrates the advantage of the layered decoder compared with the flooding decoder. We use the $(d_v = 3, d_c = 15)$ regular LDPC code at a channel quality of $E_b/N_0 = 2.9$ dB. We plot the post-FEC BER as a function of the iterations that are carried out inside the decoder. We can see that the BER decreases significantly faster in the case of the layered decoder, and when targeting a specific post-FEC BER, the layered decoder roughly halves the number of required iterations. Especially in high-speed fiber-optic communications, this can lead to dramatic reductions in VLSI complexity, as only a relatively small number of iterations need to be carried out. The convergence speed can be further improved by combining two layered decoders with different schedules, as highlighted in [7.194], at a cost of increased hardware complexity.

We consider as a second simulation example LDPC codes for transmission over the BSC. This case occurs for instance in systems without ADC at the receiver, using a simple thresholding device. Other examples are high-speed communications with different dedicated digital signal-processing (DSP) and FEC chips. In this case, the chip-to-chip interface may not be able to transfer the quasi-continuous decoder input LLRs to the FEC chip, and heavy quantization is necessary. Although the channel output undergoes a decision, we can still carry out SDD by passing *soft* messages inside the decoder and exploiting the channel statistics. Note that for the

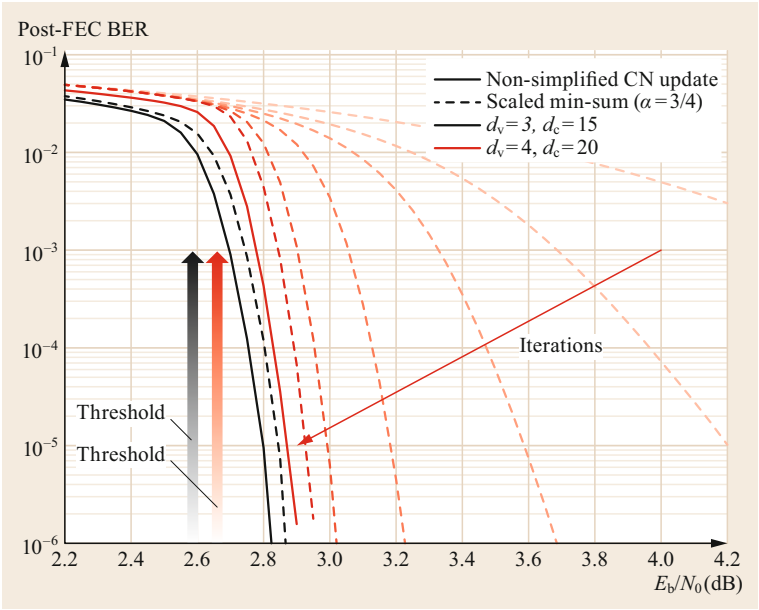

Fig. 7.21 Simulation of two regular LDPC codes of rate $R = 4/5$ (OH $= 25\%$) with parameters $(d_v = 3, d_c = 15)$ (*black lines*) and $(d_v = 4, d_c = 20)$ (*red lines*) with the full update rule (*solid lines*) and scaled min-sum (*dashed lines*) with layered decoding and 30 decoding iterations

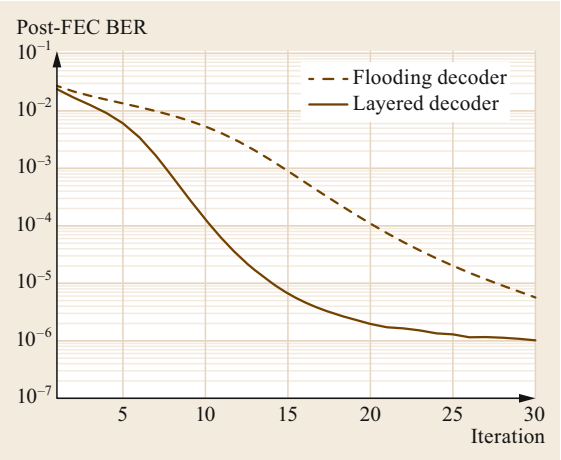

Fig. 7.22 Comparison of flooding decoder and layered decoder with min-sum update rule ($\alpha = 0.875$) for a regular LDPC code with parameters $d_v = 3$ and $d_c = 15$ ($R = 4/5$, 25% OH) at a channel quality of $E_b/N_0 = 2.9$ dB

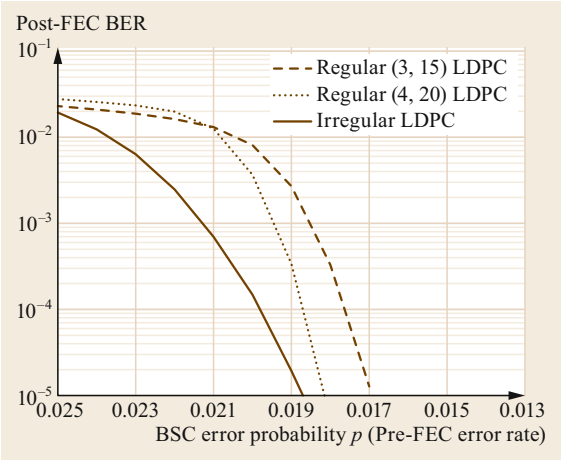

Fig. 7.23 Simulation of three LDPC codes of rate $R = 4/5$ (25% OH) with scaled min-sum update rule ($\alpha = 3/4$), layered decoding, and 30 decoding iterations

BSC, the achievable rates $R_{\text{SDD-BW}}$ and $R_{\text{HDD-BW}}$ coincide. We compute the channel-related LLRs as

$$l_i = \log \frac{p_{Y_i|X_i}(y_i|+1)}{p_{Y_i|X_i}(y_i|-1)} = y_i \log \frac{1-p}{p} \triangleq y_i L_c^{[\text{BSC}]}, \tag{7.82}$$

where we assume BPSK modulation $x_i = (-1)^{c_i}$ and received values $y_i \in \{\pm 1\}$. The error probability of the BSC is given by p and is known at the receiver. We consider a normalized min-sum decoder with $\alpha = 3/4$. Figure 7.23 shows simulation results for three different codes of rate $R = 4/5$: two regular LDPC codes with parameters $d_v \in \{3, 4\}$ and one irregular LDPC code with $\delta_{v,3} = 4/5$, $\delta_{v,10} = 1/5$, and $d_c = 22$ ($\delta_{c,22} = 1$). We keep $\delta_{v,2} = 0$ in order not to increase the error floor. We can see that in this case, the code with $d_v = 4$ outperforms the code with $d_v = 3$ (contrary to the case of the AWGN channel shown in Fig. 7.21). The irregular code enables further coding gains, especially at post-FEC BERs above 10^{-5}, but the slope of the BER curve is less steep than that of the BER for the two regular codes.

Comparison of Low-Density Parity-Check and Polar Codes

In [7.165], LDPC codes, SC-LDPC codes, and polar codes with successive cancellation decoding were compared, and it was concluded that as of today, SC-LDPC codes are the most promising for high-speed optical transponders. In Fig. 7.24, we compare the performance of a ($d_v = 3, d_c = 15$) regular LDPC code of length 38 400 and a polar code of length $n = 2^{15} = 32\,768$, both of rate $R = 4/5$. Note that we use the full update equation (7.72) for both cases to have a fair comparison. We use the successive cancellation list decoder described in [7.67] with list sizes of $L_S = 4$ and $L_S = 32$ and additionally concatenate the polar code with a short CRC (adding 32 parity bits), which is used to improve the selection of candidate codewords kept in the list. We can see that with list-based decoding, polar codes now have comparable performance as LDPC codes. However, the slope of the polar code is significantly less steep than that of the LDPC code. Hence, if low BERs of around 10^{-15} are targeted, LDPC codes will still show better performance. Polar codes may have an advantage for low-error-rate applications due to the absence of error floors under successive cancellation decoding [7.195]. In addition, note that the complexity of the list decoder, required for achieving good performance, scales linearly with the list size L_S. Furthermore, the baseline complexity of the decoder is significantly larger than that of an LDPC decoder. Hence, polar codes may become attractive in the future when highly parallel and efficient low-complexity decoders become available.

Performance of Spatially Coupled Low-Density Parity-Check Codes

In this section, we compare a few constructions of SC-LDPC codes. The possibilities for optimizing SC-LDPC codes are vast, and depending on the application, different setups might be useful. We again summarize the parameters of SC-LDPC codes and their influence on performance:

- The degree distribution will affect the performance. Although regular codes already achieve outstand-

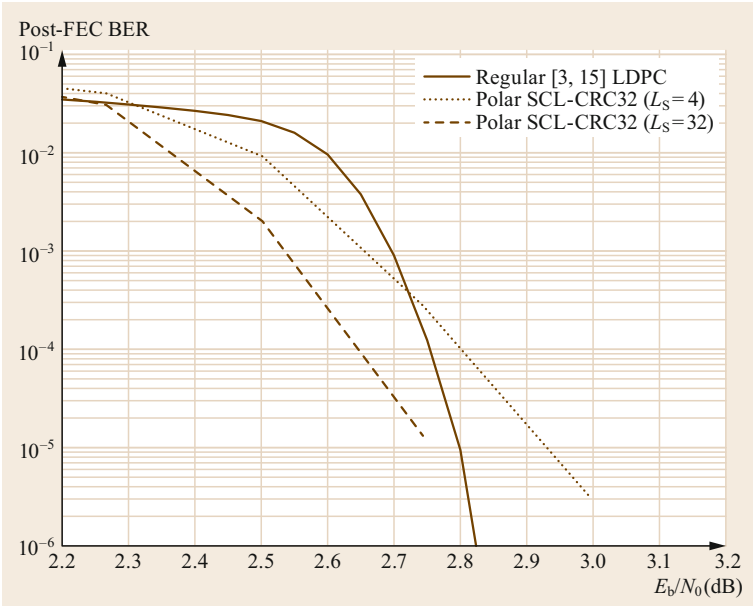

Fig. 7.24 Comparison of LDPC codes with polar codes with successive cancellation list decoding

ing performance, some improvements are expected with irregular codes, especially if the decoder complexity is constrained, as shown in [7.83].

- The coupling width w has a direct influence on the performance as well. In [7.83], a distinction between weakly coupled codes (small w, usually $w < 5$) and strongly coupled codes (large w, often $w > 5$) was noted. Both schemes may have their advantages and disadvantages.
- The replication factor L has an influence on the rate loss of the code and also an influence on the error probability of the windowed decoder as shown in [7.166, 180]. However, its influence is not as obvious as the influence of the other parameters.
- The parameters of the windowed decoder have a significant influence on the performance. The complexity of the windowed decoder equals $I\,(W_D + w - 1)$. However, when W_D is chosen that is too small, even a large number of iterations will not lead to good decoding performance. If W_D is too large, we may carry out too many unnecessary operations.

In the following, we will highlight some of these parameter trade-offs with simulation examples. In all simulations we fix $L = 100$. In a first example, we fix the (approximate) decoding complexity to $W_D\,I = 10$, corresponding to an equivalent of roughly 10 layered decoding iterations of conventional LDPC codes. We construct an SC-LDPC of rate $R = 4/5$ using the spreading technique explained in Sect. 7.4.2. We start from a QC-LDPC base matrix $\mathbf{A}$ of size 60×300 and fix the lifting parameter to $S = 32$. We apply the spreading construction to the base matrix. Hence, the sub-matrices $\mathbf{H}_i$ are of size 1920×9600. We show the simulation results in Fig. 7.25. For the configuration with $W_D = 5$ and $I = 2$ (Fig. 7.25a.), the code with $w = 2$ yields the best performance. When we switch the configuration to $W_D = 10$ and $I = 1$ (Fig. 7.25b), we can see that the code with $d_v = 4$ and $w = 4$ has the best performance and already outperforms the conventional LDPC code by about 0.1 dB. As the code with $d_v = 4$ gives superior performance, we will no longer consider the scheme with $d_v = 3$ in the following.

In Fig. 7.26, we consider the performance of codes with varying windowed decoder complexity. We consider complexities of $W_D\,I \in \{10, 20, 40, 80\}$ and compare the codes for different coupling factors w. We can see that the decoder performance does not saturate early, but keeps improving if we increase the complexity. We picked the window configuration among a few tested such that the coding gains are maximized. Furthermore, we see that, as observed already before, increasing w leads to significant performance improvements. In particular, the code with $w = 6$ improves about 0.5 dB with respect to the LDPC code of Fig. 7.24 at a BER of 10^{-6}, and approaches the achievable rate of the channel by about 0.3 dB. Considering that the slope of the BER curve is much steeper, the additional coding gain at a low BER of 10^{-15} is even larger. Hence, SC-LDPC codes are future-proof in the sense that we can use them today with low complexity, but with only small coding gains. In the future, when high-performing circuits are available, we can spend more complexity to achieve higher NCGs. In the next section, we look at the performance at low BERs.

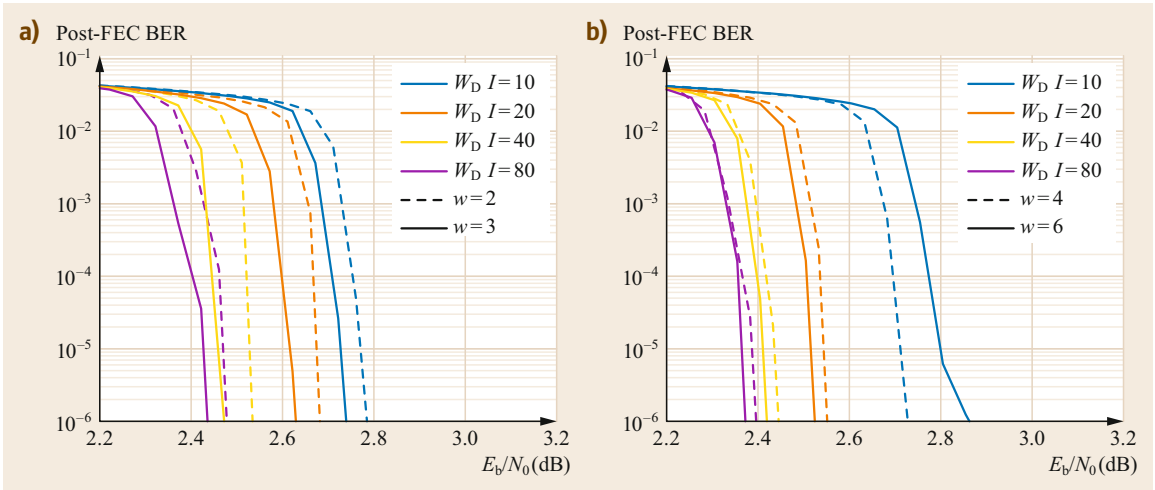

Fig. 7.26a,b Performance simulation of regular SC-LDPC codes of rate $R = 4/5$ with windowed decoding (full update rule) for four windowed decoding configurations of increasing complexity: $W_D = 10$ and $I = 1$, $W_D = 20$ and $I = 1$, $W_D = 20$ and $I = 2$, $W_D = 20$ and $I = 4$. **(a)** $w = 2$ and $w = 3$; **(b)** $w = 4$ and $w = 6$

FPGA-Based Evaluation of Decoding Performance of Spatially Coupled Low-Density Parity-Check Codes

A drawback of LDPC and SC-LDPC codes is that no analytic expression exists for the error performance, and the FEC designer must resort to Monte Carlo simulations. As optical communication systems usually require extremely low post-FEC error rates in the range of 10^{-15}, we require either extremely large compute clusters or FPGAs.

In order to verify the performance of some LDPC and SC-LDPC codes at low BERs, we use an FPGA platform, whose high-level diagram is illustrated in Fig. 7.27 and which is described in detail in [7.165]. This platform is similar to other platforms reported in the literature [7.84, 196, 197] and consists of three parts: a Gaussian noise generator, an FEC decoder, and an error-detecting circuit. The Gaussian noise generator is built upon a Tausworthe pseudo-random number generator with a sequence length of $\approx 10^{88}$, followed by a Box–Muller circuit transforming two uniformly distributed random numbers into two Gaussian-distributed numbers [7.198]. The output of the Gaussian noise generator is multiplied with a weighting factor in order to adjust N_0 and added to the all-zero codeword ($\boldsymbol{x} = (+1, \ldots, +1)$), yielding LLRs, which are then fed to

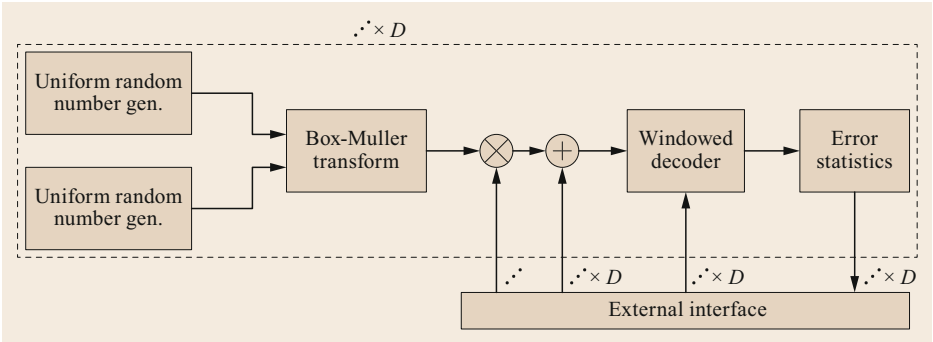

Fig. 7.27 High-level schematic of the FPGA evaluation platform

the LDPC decoder after quantization to 15 levels. The LDPC decoder is based on the layered decoding algorithm and uses a scaled min-sum CN computation rule.

The windowed decoder carries out I layered decoding iterations as described in Sect. 7.4.2. The effective number of iterations, i.e., the number of updates of each batch, thus corresponds to $I(W_\mathrm{D} + w - 1)$. For simplicity, we set $I = 1$ in most examples such that the window length corresponds roughly to the number of iterations in a conventional decoder. The output of the LDPC decoder is connected to the BER evaluation unit, which counts the bit errors and reports the error positions. A single Virtex-7 FPGA is able to emulate a block LDPC code with 12 decoding iterations at a rate of about 5 Gbit/s and an SC-LDPC code with $w = 3$, $W_\mathrm{D} = 13$, and a single iteration ($I = 1$) at approximately 1.5 Gbit/s. This lower rate is mainly due to increased memory requirements of the windowed decoder compared with the block decoder, which only requires a single a posteriori memory of size n, while the windowed decoder requires $(W_\mathrm{D} + w - 1)n_\mathrm{b}$ memory blocks. Note that in an ASIC implementation with an iteration-unrolled decoder, these numbers will be approximately equal.

The decoder we implemented uses a decoding window of size $W_\mathrm{D} = 13$, carries out a configurable number of iterations I, and can use either a single engine ($E = 1$) or two decoding engines ($E = 2$), in which case the offset of the second engine is $O_2 = 6m_\mathrm{b} + 1$. The decoder uses a scaled min-sum update rule with either $\alpha = 0.75$ or $\alpha = 0.875$ (depending on the code, different α will be better). We evaluate the performance of several coding schemes of rate $R = 4/5$ (OH = 25%). We consider a ($d_\mathrm{v} = 3, d_\mathrm{c} = 15$) regular LDPC code as reference. This code is a QC code constructed from cyclic permutation matrices of size 32×32 and has girth 10 and length $n = 31\,200$.

In addition to the block code, we also compare two SC-LDPC codes, where we select $L \to \infty$ to avoid any termination effects and to simplify the decoder data flow. The performance of such a code is an upper bound of the BER performance of a code with finite L, as decreasing L will only improve the BER of the code (note that it may not necessarily improve the NCG as the rate R of the code decreases and hence E_b/N_0 changes). We consider two codes in the simulation:

- □ SC-LDPC code A (marker □) is an irregular code with coupling width w, VN degree distribution $\boldsymbol{\delta}_\mathrm{v} = (0, 0, 4/5, 0, 0, 1/5)$, and regular $d_\mathrm{c} = 18$. This degree distribution has been optimized to maximize the decoding velocity at a target BER of 10^{-6}, as detailed in [7.165]. The batch size is $n_\mathrm{b} = 7500$ ($\dim(\mathbf{H}_i) = 1500 \times 7500$).
- ◊ SC-LDPC code B (marker ◊) is a regular code with $d_\mathrm{v} = 4$, $d_\mathrm{c} = 20$, coupling width $w = 2$, and batch size $n_\mathrm{b} = 7500$, with $m_\mathrm{b} = 1500$.

Both SC-LDPC codes are QC codes constructed from cyclic permutation matrices of size 32×32. Note that the batch size n_b of the spatially coupled codes is significantly smaller than the length n of the LDPC code, which may simplify the decoder implementation, especially the routing network.

The simulation results are shown in Fig. 7.28. As expected, the LDPC code performs quite well, albeit slightly worse than the code shown in Fig. 7.21. This is because here, the channel output and the messages inside the decoder have been quantized, which leads to a small performance penalty of ≈ 0.12 dB. First we look at the case $I = 1$ and $E = 1$. The LDPC code is decoded with $I = 13$ iterations, and hence the number of operations per bit is equivalent for both cases. We can see that both SC-LDPC codes outperform the LDPC code. SC-LDPC code A, which has been optimized for convergence speed, shows a very early start of the waterfall region. However, the slope of the BER curve starts to decrease slowly, such that the performance at low BERs is relatively poor and is expected to cross the BER curve of the block LDPC code. The situation is reversed for SC-LDPC code B, which exhibits a late start of the waterfall curve, which then drops exceptionally

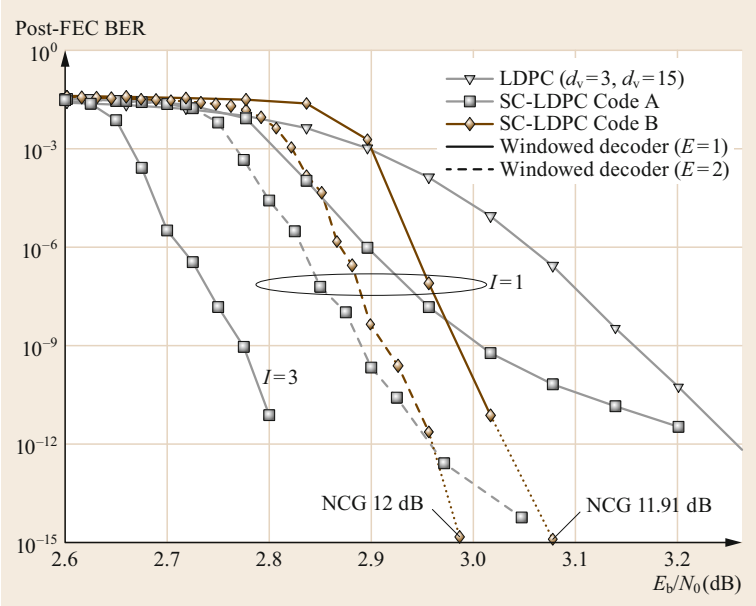

Fig. 7.28 Decoding results of the FPGA platform for two different codes and two setups of the decoder

quickly. We did not observe any error patterns for the next E_b/N_0 point (3.08 dB) of the curve after simulation of 7.9×10^{14} bits, so by extrapolating the BER curve, we may conjecture that SC-LDPC code B has an NCG of 11.91 dB at a post-FEC BER of 10^{-15}. This NCG is achievable with a modest number of $(W_D + w - 1) = 14$ equivalent iterations.

In order to show the potential of the proposed code, we increase the number of iterations I in step 2 of the windowed decoder of SC-LDPC code A from $I = 1$ to $I = 3$. This result is shown by the leftmost curve in Fig. 7.28. By extrapolating the curve, we conjecture an NCG of approximately 12.14 dB. If an error floor occurs at BERs lower than 10^{-13}–10^{-14}, it can usually be well compensated for by adequate post-processing techniques, as detailed in [7.196].

As increasing the number of iterations to $I = 3$ also increases the decoder latency, we keep $I = 1$ and increase the number of decoding engines to $E = 2$. We can see an improvement in the NCG by around 0.1 dB without an increase in latency (although a doubling of the number of iterations is required). We can also see that the slope of the BER curve of SC-LDPC code A becomes significantly steeper such that it becomes almost comparable in performance to SC-LDPC code B.

To reuse these codes in, for example, transmission experiments, we provide the most common thresholds in terms of MI/GMI and pre-FEC BER in Table 7.4. For a detailed discussion about threshold-based performance evaluation, we refer the reader to Sect. 7.7.

To summarize, we can say that SC-LDPC codes generally outperform conventional (block) LDPC codes. The performance can be further improved if the number of iterations is increased; hence such candidates can be used to build a future-proof communication standard. Although they are being used today with low decoding complexity, the systems could be upgraded in the future by a more complex decoder carrying out a higher number of iterations with increased NCG still guaranteeing backward compatibility.

In order to compare SC-LDPC and conventional LDPC codes, we show the potential of both codes by performing a simulation of regular codes with different rates and compute the extrapolated NCG at a target BER of 10^{-15}. For the SC-LDPC codes, we consider regular codes with $d_v = 4$ and we vary d_c to achieve different rates. Motivated by the results in Fig. 7.26, we select $w = 6$ and we carry out windowed decoding with different window configurations. We compare these codes with regular LDPC codes with $d_v = 3$,

Table 7.4 Common thresholds for the two SC-LDPC code B of rate $R = 4/5$ shown in Fig. 7.28

	GMI	Pre-FEC BER				
	$R_{\text{BW-SDD}}$	BPSK/QPSK	8-QAM	16-QAM	32-QAM	64-QAM
SC-LDPC Code B, $W_D = 13$, $I = 1$, $E = 1$	0.866	0.0358	0.0362	0.0363	0.0367	0.0372
SC-LDPC Code B, $W_D = 13$, $I = 1$, $E = 2$	0.862	0.0370	0.0375	0.0377	0.0379	0.0385
SC-LDPC Code A, $W_D = 13$, $I = 3$, $E = 1$	0.853	0.0387	0.0395	0.0399	0.0398	0.0405

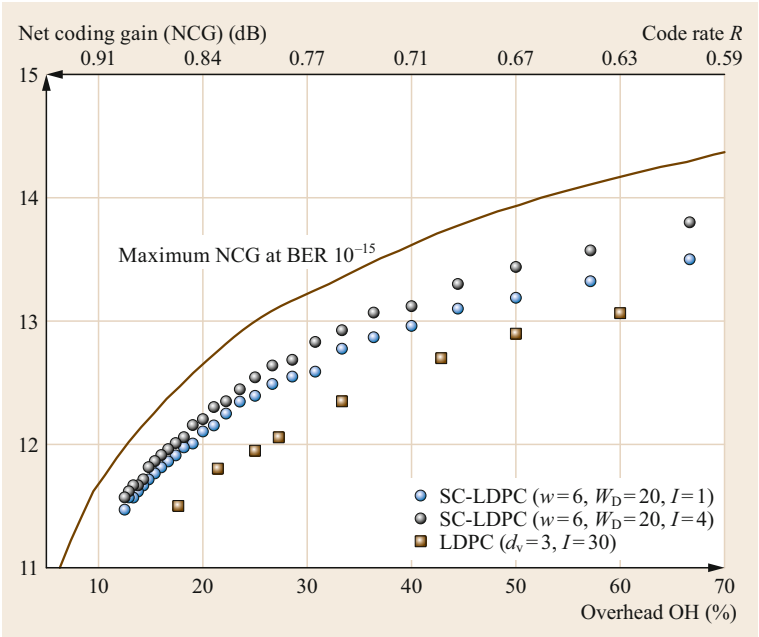

Fig. 7.29 Achievable NCG at a BER of 10^{-15} for several coding schemes

which are frequently used because of their good error floor properties. Figure 7.29 shows the achievable NCGs. We can clearly see that, if we can spend the complexity to run $I = 4$ iterations per windowed decoding step, we can nearly close the gap to the limit, and gains of around 0.8 dB are possible when compared with LDPC codes. However, already with $I = 1$, we can significantly outperform regular LDPC codes.

7.5 Hard-Decision Forward Error Correction

The adoption of SDD in fiber-optic communications represented a breakthrough with respect to the classical schemes based on algebraic codes (BCH and Reed–Solomon codes) and HDD. As we have discussed in the previous sections, LDPC codes and SDD provide very large net coding gains and achieve performance close to the Shannon limit. However, the implementation of BP decoding of LDPC codes still presents several challenges at very high data rates. This motivates the use of HDD for applications where complexity and throughput is a concern, since HDD can yield significantly reduced complexity and decoder data flow compared with SDD. HDD-based FEC is currently used in regional/metro optical transport networks [7.22] and for other applications such as optical data center interconnects [7.199]. Powerful code constructions for HDD date back to the 1950s, when *Elias* introduced PCs [7.18]. In recent years, the introduction of new code constructions such as staircase codes [7.49] and braided codes [7.50, 200], which can be seen as generalizations of PCs, and the link between these constructions and codes on graphs has fostered a revival of HDD for optical communications.

In this section, we focus on FEC codes for HDD that belong to the second and third generation of FEC, i.e., staircase codes and braided codes, as well as similar structures. These codes are built from algebraic block codes as component codes, usually BCH codes and Reed–Solomon codes for binary and nonbinary codes, respectively. They can be seen as concatenated codes and also fall within the category of codes on graphs or modern codes.

We start this section by briefly describing BCH and Reed–Solomon codes. We then review Elias' PCs and the underlying iterative decoding algorithm based on bounded distance decoding (BDD) of the component codes. We also discuss some interesting generalizations of PCs, including staircase codes and braided codes, and their connection to LDPC codes and SC-LDPC codes. Finally, we briefly discuss the link between iterative BDD (iBDD) of product-like codes and BP decoding and how to analyze the performance of product-like codes.

7.5.1 Classical Block Codes: Bose–Chaudhuri–Hocquenghem and Reed–Solomon Codes

BCH codes and Reed–Solomon codes are two of the most important classes of linear block codes. They are characterized by a rich algebraic structure that enables the use of efficient decoding algorithms that can be implemented with acceptable complexity.

Bose–Chaudhuri–Hocquenghem Codes

BCH codes, invented independently by *Alexis Hocquenghem* in 1959 [7.32] and by *Raj Chandra Bose* and *Dijen Ray-Chaudhuri* in 1960 [7.33], form a large class of cyclic codes. For short block lengths (up to a few hundred bits), BCH codes are among the best known codes of the same length and rate. For any pair of positive integers $\nu \geq 3$ and $t < 2^{\nu-1}$, there exists an $(n, k, d_{\min})$ binary BCH code with parameters

$$n = 2^{\nu} - 1, \quad n - k \leq \nu t, \quad d_{\min} \geq 2t + 1 \,, \tag{7.83}$$

where ν is the Galois field extension. This code can correct all error patterns of t or fewer errors, and it is usually referred to as a t-error-correcting BCH code.

BCH codes offer great flexibility in the choice of code length, rate, and error-correcting capability. To achieve further flexibility in terms of code length and rate, BCH codes may be shortened. An $(n', k', d_{\min})$ BCH code of parameters

$$(n', k', d'_{\min}) = (n - s, k - s, d'_{\min} \geq d_{\min}) \tag{7.84}$$

is obtained from an $(n, k, d_{\min})$ BCH code by setting s information bits to zero and not transmitting them. The parameter s is commonly referred to as the shortening parameter. At the receiver, the shortened positions can then be assumed to be transmitted without error. Since the parameters ν, t, and s completely determine (n, k), sometimes it is useful to define a BCH code through the triple (ν, t, s).

The rich structure of BCH codes allows for simple syndrome-based HDD. A very efficient algebraic HDD for BCH codes is the *Berlekamp–Massey* algorithm [7.38, 39], which finds the most probable error pattern introduced by the channel iteratively given the syndrome corresponding to the received binary vector. If the number of redundancy symbols $n-k$ is very large, however, (complete) syndrome decoding may be too complex. To lower the decoding complexity, *incomplete* syndrome decoding can be used. Incomplete syndrome decoding is usually referred to as BDD, which can also be implemented based on the Berlekamp–Massey algorithm. For a block code with error correction capability t, BDD corrects all error patterns with Hamming weight less than or equal to t and no others. Note that BDD is not ML; therefore, it incurs a penalty in performance.

For details on the construction of BCH codes and the Berlekamp–Massey algorithm, the interested reader is referred to [7.15, Chap. 9] and [7.101, Chap. 3]. A nice overview of syndrome decoding can be found in [7.201, Chap. 10].

Reed–Solomon Codes

Reed–Solomon codes are the most important and widely used class of nonbinary block codes. Reed–Solomon codes have made their way into multiple applications and standards, such as Digital Video Broadcasting (DVB) [7.202] and deep-space communications [7.203], as well as for data storage and distributed data storage systems such as RAID 6 [7.204].

Reed–Solomon codes were introduced in 1960 by *Reed* and *Solomon* [7.37] and can be seen as a subclass of BCH codes generalized to the nonbinary case. For Reed–Solomon codes, both the construction field and the symbol field are the same, i.e., the code symbols are over a nonbinary field. An $(n, k, d_{\min})$ Reed–Solomon code over the Galois field GF(2^{ν}) has parameters

$$n = 2^{\nu} - 1, \quad k = 2^{\nu} - 2t - 1, \quad d_{\min} = 2t + 1 \,, \tag{7.85}$$

where the code symbols are over GF(2^{ν}). The Galois field GF(2^{ν}) is an extension field of the binary numbers $\{0, 1\}$ and contains 2^{ν} nonbinary symbols, which can be represented using ν bits, together with well-defined addition and multiplication operations. A Reed–Solomon code with these parameters is capable of correcting all error patterns of t or fewer symbol errors.

The minimum Hamming distance of Reed–Solomon codes achieves the Singleton bound, $d_{\min}(C_{\mathrm{RS}}) = n - k + 1$ (this is readily seen from (7.85)), i.e., their minimum Hamming distance is the maximum possible for a linear code of parameters (n, k) (see Theorem 7.1 in Sect. 7.3).

Note that the code symbols of a Reed–Solomon code can also be interpreted as binary vectors by representing each symbol by a binary tuple of ν bits. In this case, Reed–Solomon codes can be used for binary transmission (e.g., using BPSK) and are well suited for burst-error correction.

Similar to BCH codes, Reed–Solomon codes can also be shortened to yield higher flexibility in terms of block length and code rate. A shortened Reed–Solomon code with shortening parameter s obtained from an

$(n, k, d_{\min})$ Reed–Solomon code over the Galois field GF(2^{ν}) has parameters

$$(n', k', d'_{\min}) = (n - s, k - s, d_{\min}) \,. \tag{7.86}$$

Reed–Solomon codes can also be efficiently decoded using the Berlekamp–Massey algorithm.

7.5.2 Product Codes

PCs, introduced by *Elias* in 1954 [7.18], are one of the first examples of a construction of long, powerful codes from short component codes. Let C_1 be an (n_1, k_1, d_1) linear block code of rate $R_1 = k_1/n_1$ and minimum Hamming distance d_1, and C_2 an (n_2, k_2, d_2) linear block code of rate $R = k_2/n_2$ and minimum Hamming distance d_2. A two-dimensional $(n, k, d_{\min})$ PC $C_{\mathrm{PC}} = C_1 \times C_2$ is defined by a rectangular array $\mathbf{C}$ such that each row of $\mathbf{C}$ is a codeword of C_1 and each column is a codeword of C_2. The codes C_1 and C_2 are commonly referred to as *component codes*. Both binary and nonbinary PCs can be constructed. In the first case, the component codes are typically BCH codes, although other (simpler) linear block codes such as single parity-check codes and Hamming codes can also be used. The component codes of nonbinary PCs, on the other hand, are usually Reed–Solomon codes. The code array $\mathbf{C}$ for a PC with component codes with parameters $(n_1, k_1) = (6, 4)$ and $(n_2, k_2) = (6, 3)$ is depicted in Fig. 7.30.

A PC can be conveniently described by the encoding procedure. The $k = k_1 k_2$ information bits are arranged in a $k_2 \times k_1$ array $\mathbf{U}$ and placed in the upper-left quadrant of the code array (in orange in Fig. 7.30). Each row of the array $\mathbf{U}$ is then encoded by the component code C_1 to generate $n_1 - k_1$ parity bits, marked in blue in the figure. Each column of the resulting array, of dimensions $k_2 \times n_1$, is then encoded by the code C_2 to generate $n_2 - k_2$ parity bits, marked in green. The resulting PC is a systematic code with parameters $k = k_1 k_2$, $n = n_1 n_2$, and rate $R = k_1 k_2/(n_1 n_2) = R_1 R_2$. It is also easy to show that the minimum Hamming distance of a PC is the product of the minimum Hamming distances of the component codes, i.e., $d_{\min} = d_1 d_2$. Thus, PCs are usually characterized by a large minimum Hamming distance. On the other hand, the minimum Hamming distance multiplicity, i.e., the number of codewords of weight $d_{\min}$, of a PC is equal to the product of the minimum Hamming distance multiplicities of the component codes [7.205]. As a result, the minimum Hamming distance multiplicities of PCs are typically high.

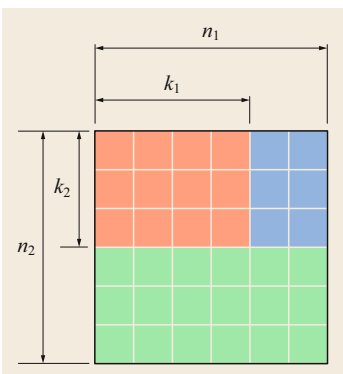

Fig. 7.30 Code array of a PC with component codes C_1 and C_2 of parameters $(n_1, k_1) = (6, 4)$ and $(n_2, k_2) = (5, 3)$, respectively. *Orange squares* correspond to data bits; *blue* and *green squares* correspond to parity bits

With the construction above, it is apparent that each row of $\mathbf{C}$ is a codeword of C_1 and each column of C is a codeword of C_2. Therefore, all code bits of a PC are protected by two component codes, or in other words, each code bit participates in two *code constraints*, a row code constraint and a column code constraint. For example, the second data bit is protected by the second row and second column constraints.

Irregular Product Codes and Multidimensional Product Codes

PCs, as described above, are based on a single row and column code, i.e., the same code is used for all rows and the same code is used for all columns. However, all row and column codes do not need to be the same, and codes of different rates and erasure-correcting capabilities can be used as row and column codes. The resulting PC is referred to as an *irregular* PC [7.206, 207]. Like irregular LDPC codes, irregular PCs based on code mixtures may yield performance improvements. It is also important to note that PCs may be built over arrays with more than two dimensions [7.18]. However, two-dimensional PCs are the most common, and therefore in this chapter we restrict ourselves to two-dimensional PCs.

7.5.3 Generalized Product Codes

The construction of PCs, with their row-column encoding and the underlying rectangular code array, is a natural construction for constructing long codes from simpler codes. However, more general code arrays, where each row and each column of the array are codewords of given linear block codes, can also be constructed. This gives rise to so-called *product-like codes*, which we will refer to here as generalized product codes (GPCs), since they can be seen as generalizations of PCs. Two of the most popular classes of GPCs are staircase codes and braided codes.

Staircase Codes

Staircase codes are an important class of error-correcting codes proposed by *Benjamin Smith* et al. [7.49] for optical transport networks. A staircase code is defined by a two-dimensional code array that has the form of a staircase. Formally, given a component code C of length n_c, a staircase code is defined as the set of all binary matrix sequences $\mathbf{B}_i$, $i = 1, 2, \ldots$, of dimensions $a \times a$, where $a = n_c/2$, such that each row of $[\mathbf{B}_i^\top, \mathbf{B}_{i+1}]$ is a valid codeword of C. The matrix $\mathbf{B}_1$ is assumed to be initialized to all zeros. The code array of a staircase code with component code C of code length $n_c = 12$ and dimension $k_c = 10$ is depicted in Fig. 7.31. Encoding is performed in batches, where each batch corresponds to one of the matrices $\mathbf{B}_i$. Specifically, batch i corresponds to $\mathbf{B}_i^\top$ for i odd and to $\mathbf{B}_i$ for i even. The number of bits per batch, denoted by B, is $B = a^2 = n_c^2/4$.

Like PCs, staircase codes are well defined through the encoding procedure. With reference to Fig. 7.31, the first batch (matrix $\mathbf{B}_1^\top$) is initialized to all zeros. Then, $(k_c - n_c/2)(n_c/2) = 4 \times 6$ data bits are placed in the left part of batch 2 (marked with a thick red frame in the figure), and the the rows of batches 1 and 2 are encoded by the component code C, thus generating $(n_c - k_c)(n_c/2) = 2 \times 6$ parity bits, i.e., $n_c = 2$ parity bits per row. $(k_c - n_c/2)(n_c/2)$ data bits are then placed in the upper part of batch 3, and the columns of the array formed by batches 2 and 3 are encoded using C, generating $n_c - k_c = 2$ parity bits per column. The row/column encoding process continues accordingly for the next batches. The code rate of the staircase code, R_{SC}, is the ratio between the number of information bits per batch and B, i.e.,

$$R_{SC} = \frac{(k_c - n_c/2)(n_c/2)}{n_c^2/4} = 2\frac{k_c}{n_c} - 1 \,. \tag{7.87}$$

Note that, as for PCs, each bit of a staircase code is protected by two code constraints, a row constraint and a column constraint. Also, it is worth mentioning that staircase codes are stream-oriented. Indeed, the code array in Fig. 7.31 can grow infinitely large.

Good (binary) staircase codes with BCH component codes and overhead ranging from 6% to 33% can be found in [7.208], where the parameters of the component BCH codes were optimized based on computer simulations. An optimization of the staircase code parameters based on density evolution (see Sect. 7.5.7 below) is addressed in [7.209]. An extension of the original code construction with larger staircase block sizes by allowing for multiple code constraints per row/column in the staircase array is also proposed in [7.209], leading to codes with steeper waterfall performance. Nonbinary staircase codes with Reed–Solomon component codes are discussed in [7.90, 210].

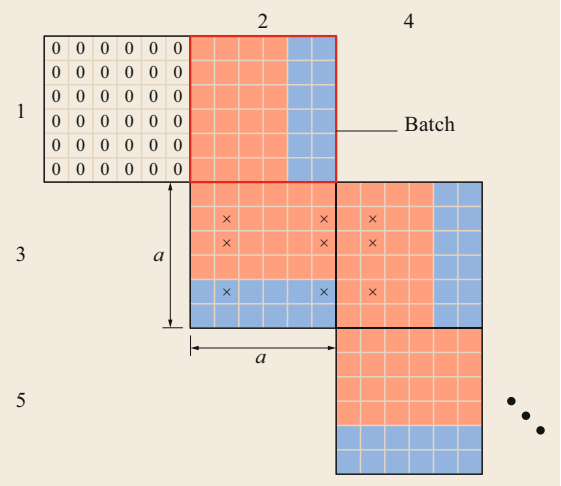

Fig. 7.31 Code array of a staircase code with component code of code length $n_c = 12$ and dimension $k_c = 10$. The *orange squares* correspond to data bits, while the *blue squares* correspond to parity bits

Braided Codes

Braided codes were originally proposed by *Jiménez Feltström* et al. [7.200]. Similar to PCs and staircase codes, the code construction is defined by a two-dimensional array where each bit is protected by a row and a column code. Braided codes can be constructed using both convolutional and block codes as component codes. Correspondingly, the resulting codes are referred to as braided convolutional codes and braided block codes, respectively. Here we are interested mainly in block braided codes, as they are more suitable for HDD, and for ease of exposition we will refer to them simply as braided codes.

Braided codes come in many flavors, depending on the structure of the code array. In Fig. 7.32, we depict the code array of a so-called block-oriented braided code with component code C of code length $n_c = 12$ and dimension $k_c = 10$. The encoding is similar to that of product and staircase codes: Data bits are placed in the code array in the parts marked in orange, and parity bits (in blue) are generated by row and column encoding. Encoding is better understood with reference to Fig. 7.32. The code array consists of blocks of dimensions $b \times b$, where $b = n_c/3$. The blocks are grouped in batches comprising three blocks. The number of bits per batch is $B = 3b^2 = n_c^2/3$. The first batch is shown by the thick red frame in the figure. The leftmost and uppermost blocks of the code array are initialized to all zeros. Then, $b^2 + 2(k_c - 2b)b = n_c^2/9 + 2(k_c - 2n_c/3)(n_c/3) =$

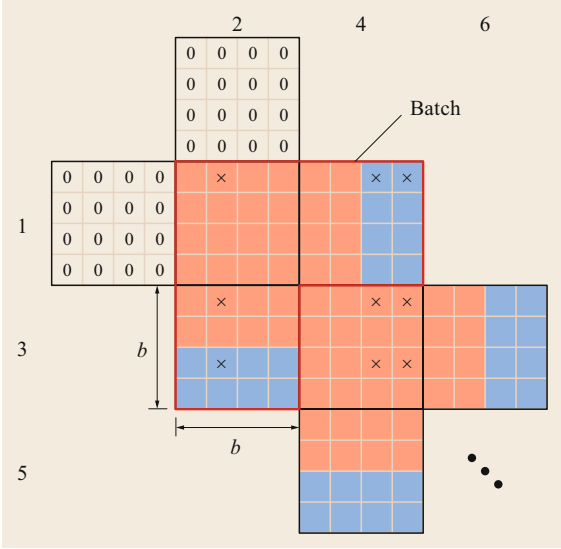

Fig. 7.32 Code array of a braided code with component code of code length $n_c = 12$ and dimension $k_c = 10$. The *orange squares* correspond to data bits, while the *blue squares* correspond to parity bits

32 data bits are placed in the orange squares of the first batch. The rows of the blocks at (horizontal) position 1 are then encoded by the (n_c, k_c) component code C, generating $(n_c - k_c)(n_c/3) = 2 \times 4 = 8$ parity bits, i.e., $n_c = 2$ parity bits per row (marked in blue in the figure). The columns of the array formed by the three blocks in (vertical) position 2 are encoded using C, generating $n_c - k_c = 2$ parity bits per column. The row/column encoding process continues accordingly for the next batches. The code rate of the braided code, R_{BC}, is the ratio between the number of information bits per batch and B, i.e.,

$$R_{BC} = \frac{(n_c^2/9) + 2(k_c - 2n_c/3)(n_c/3)}{n_c^2/3} = 2\frac{k_c}{n_c} - 1 \,. \tag{7.88}$$

Braided codes have been explicitly considered for use in fiber-optic communication systems in [7.50].

Half-Product Codes and Half-Braided Codes

Consider a PC based on component codes of lengths $n_1 = n_2 = n_c$ (Fig. 7.30). Based on this PC, a new code can be obtained by retaining only codeword arrays with zeros in the main diagonal that are symmetric, in the sense that the array is equal to its transpose. The code bits in the main diagonal of the resulting array do not carry any information (they are known), and hence they can be punctured, i.e., they are not transmitted. Also,

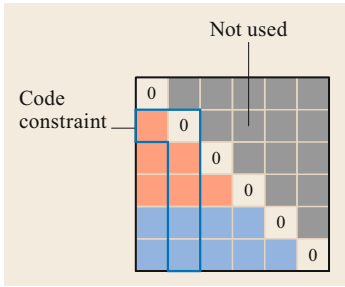

Fig. 7.33 Code array of an HPC with component code of code length $n_c = 6$ and dimension $k_c = 3$. The *orange squares* correspond to data bits, while the *blue squares* correspond to parity bits. The bits corresponding to the *gray squares* are not transmitted

the bits in the upper triangular part are identical to those in the lower triangular part and can also be punctured. The resulting code has length $n = \binom{n_c}{2}$ and is referred to as a half-product code (HPC) [7.211]. The code array of an HPC with component codes of length $n_c = 6$ is depicted in Fig. 7.33, where one particular code constraint is marked with the thick blue frame. In [7.212], it is shown that HPCs can achieve larger normalized minimum distance than PCs and superior performance in both the waterfall region and the error floor compared with PCs of similar length and rate.

The concept above can be extended to other code arrays. For example, the same symmetry constraint can be applied to braided codes, and the resulting codes are referred to as half-braided codes. The code array of a half-braided code with component codes with block length $n_c = 12$ and dimension $k_c = 10$ is depicted in Fig. 7.34. It is easy to see that the code rate of a half-braided code in the form of Fig. 7.34, R_{HBC}, is

$$R_{HBC} = 2\frac{k_c - 1}{n_c - 1} - 1 \,. \tag{7.89}$$

HPCs and half-braided codes belong to a larger class of symmetric GPCs [7.212]. Symmetric GPCs are in turn a subclass of GPCs that use symmetry to reduce the block length of a GPC while using the same component code. In [7.213], it was shown that half-braided codes can outperform both staircase codes and braided codes in waterfall performance, at a lower error floor and decoding delay.

Similar to staircase codes, braided codes, HPCs, and half-braided codes, other generalizations of PCs (leading to other code arrays) can be envisaged. In Sect. 7.5.5, we discuss a general construction of GPCs that encompasses staircase codes and braided codes, as well as other classes of GPCs.

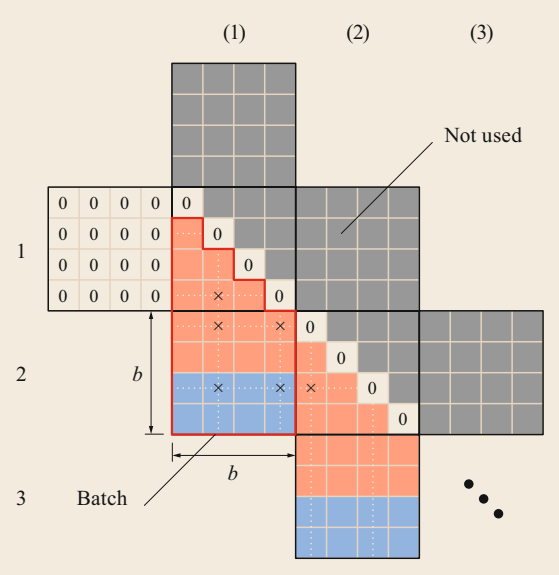

Fig. 7.34 Code array of a half-braided code with component code of code length $n_c = 12$ and dimension $k_c = 10$. The *orange squares* correspond to data bits, while the *blue squares* correspond to parity bits. The bits corresponding to the *gray squares* are not transmitted

7.5.4 Generalized Product Codes as Instances of Generalized Low-Density Parity-Check Codes

It is interesting to observe that GPCs can be interpreted as instances of generalized LDPC (G-LDPC) codes. The link between GPCs and G-LDPCs is relevant because it allows us to borrow tools for the analysis of LDPC codes (and codes on graphs in general) to analyze the behavior of GPCs. G-LDPC codes are a generalization of LDPC codes, where the constraint nodes are not simple single parity-check codes as for LDPC codes, but general linear block codes, e.g., Hamming codes or BCH codes [7.101]. A G-LDPC code is also defined by a bipartite graph where an edge between a VN and a CN indicates that the code bit corresponding to the VN participates in the code constraint enforced by the component code represented by the CN.

To clarify the link between GPCs and G-LDPC codes, let us first consider the Tanner graph representation of a PC. As any block code, PCs can be represented by a Tanner graph where VNs represent code bits and CNs represent row and column codes. For a PC with component codes of code lengths n_1 and n_2, the corresponding Tanner graph has $n_1 + n_2$ CNs (n_1 CNs corresponding to the column codes and n_2 CNs corresponding to the row codes, Fig. 7.30) and $n_1 n_2$ VNs corresponding to the $n_1 n_2$ code bits. The (bipartite) Tanner graph of the PC with component codes with parameters $n_1 = n_2 = 6$ in Fig. 7.30 is depicted in Fig. 7.35. Note that each CN has degree 6, since the component codes have code length $n_1 = n_2 = 6$, and each VN has degree 2, since each code bit participates in two code constraints. A simplified version of the Tanner graph of Fig. 7.35 is illustrated in Fig. 7.36. In the simplified Tanner graph, we distinguish between two types of CNs, corresponding to row and column constraints. The VNs (corresponding to code bits) are represented by edges. Since each code bit is protected by a row and a column code, each edge is connected to one CN of each type. The resulting Tanner graph is a complete graph where each CN of one type is connected to all CNs of the other type through an edge. There are $n_1 n_2$ edges, each corresponding to one code bit. Note that the code array in Fig. 7.30, the *standard* Tanner graph in Fig. 7.35, and the simplified Tanner graph in Fig. 7.36 are equivalent representations of the PC. For compactness reasons, it is more convenient to represent PCs with the simplified Tanner graph than with the conventional Tanner graph of Fig. 7.35.

Similar to PCs, GPCs can be represented by a Tanner graph. The standard Tanner graph and the simplified Tanner graph of a staircase code (Fig. 7.31) with component code of code length $n_c = 6$ are depicted in Fig. 7.37 and Fig. 7.38, respectively. The standard Tanner graph of a staircase code is defined by a number of positions, L, corresponding to the the total number

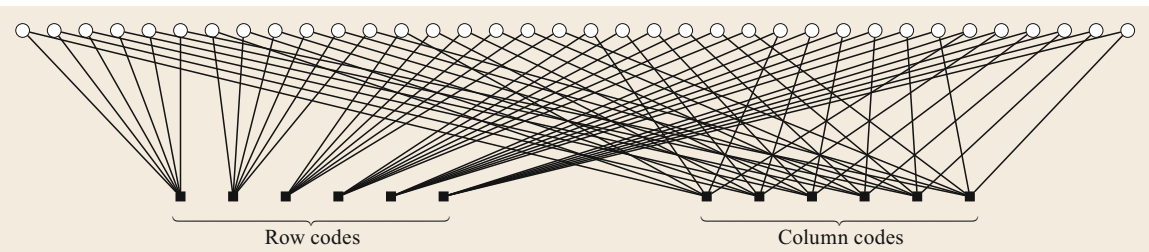

Fig. 7.35 Bipartite (Tanner) graph of a PC with component codes of lengths $n_1 = n_2 = 6$ of Fig. 7.30

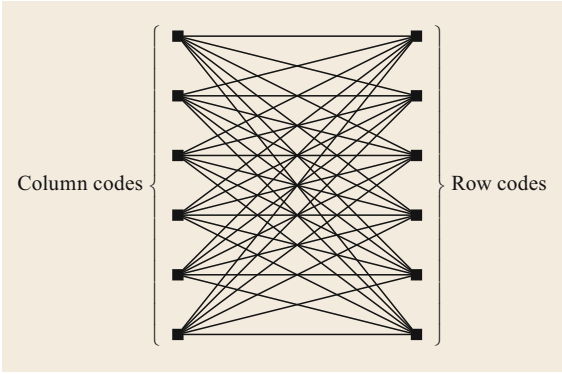

Fig. 7.36 Simplified Tanner graph of a PC with component codes of lengths $n_1 = n_2 = 6$ of Fig. 7.30

of batches minus one. Each position corresponds to one batch of code bits and correspondingly has $a^2 = (n_c/2)^2$ VNs, corresponding to the a^2 code bits in the batch, and $a = n_c/2$ CNs, corresponding to the row (or column) codes defined by the batches $[\mathbf{B}_i^\top, \mathbf{B}_{i+1}]$ for position i, $i = 1, 2, \ldots, L$. Accordingly, the simplified Tanner graph is also defined by L positions, with a CNs per position. Each CN in position i is then connected to all CNs in spatial position $i+1$ by an edge (a VN, corresponding to a code bit), Fig. 7.38. Note that all VNs have degree 2, since a code bit participates in two code constraints, and all CNs have degree 6, since $n_c = 6$.

Figures 7.35–7.38 make apparent the link between GPCs and G-LDPC codes. In particular, the bipartite Tanner graph of a staircase code resembles that of an SC-LDPC code (Fig. 7.37 and Fig. 7.19 in Sect. 7.4.2). Indeed, staircase codes can be seen as spatially coupled versions of PCs, and as such, as a subclass of spatially coupled G-LDPC codes with coupling width $w = 2$. Similar to staircase codes, other GPCs such as braided codes and half-braided codes can be classified as SC-GLDPC codes.

The connection of GPCs to G-LDPC codes enables the use of tools for the analysis of codes on graphs, such as density evolution, to analyze GPCs. This is discussed in Sect. 7.5.7.

7.5.5 A General Code Construction of Generalized Product Codes

In the previous sections, we described some of the most popular classes of GPCs. In this section, we briefly review a deterministic construction of GPCs proposed in [7.214, 215] that is sufficiently general to encompass several classes of GPCs, including irregular PCs, HPCs, staircase codes, block-wise braided codes, and half-braided codes.

The code construction in [7.214, 215] is defined in terms of three parameters, $\boldsymbol{\eta}$, $\boldsymbol{\gamma}$, and $\boldsymbol{\tau}$, and is specified over the simplified Tanner graph. We denote the corresponding GPC by $C_m(\boldsymbol{\eta}, \boldsymbol{\gamma}, \boldsymbol{\tau})$, where m denotes the total number of CNs in the underlying Tanner graph; $\boldsymbol{\eta}$ is a binary, symmetric $L \times L$ matrix, where L is the number of positions of the Tanner graph, and $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_L)^\top$ is a probability vector of length L, i.e., $\sum_{i=1}^{L} \gamma_i = 1$ and $\gamma_i \geq 0$. The parameters $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$ determine the graph connectivity. Considering the representation of a GPC in terms of the two-dimensional code array (Figs. 7.30–7.34), one may alternatively think about $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$ as specifying the array shape. Different choices for $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$ recover well-known code classes. The parameter $\boldsymbol{\tau}$ is used to specify GPCs employing component codes with different erasure-correcting capabilities.

The simplified Tanner graph describing the GPC $C_m(\boldsymbol{\eta}, \boldsymbol{\gamma}, \boldsymbol{\tau})$ is constructed as follows. Assume that the Tanner graph spans L positions. Then, place $m_i \triangleq \gamma_i m$ CNs at each position $i = 1, \ldots L$, where it is assumed that m_i is an integer for all i. Then, connect each CN at position i to each CN at position j through a VN (i.e., an edge) if and only if $\eta_{i,j} = 1$.

Example 7.5

A PC is obtained by choosing $L = 2$ and $\boldsymbol{\eta} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. The two positions correspond to the row and column codes. Choosing $\boldsymbol{\gamma} = (1/2, 1/2)$ leads to a standard PC (with a square code array) with component codes C_1 and C_2 of length $n_1 = n_2 = m/2$. Note that by selecting $m = 12$, we recover the Tanner graph of the PC in Fig. 7.36.

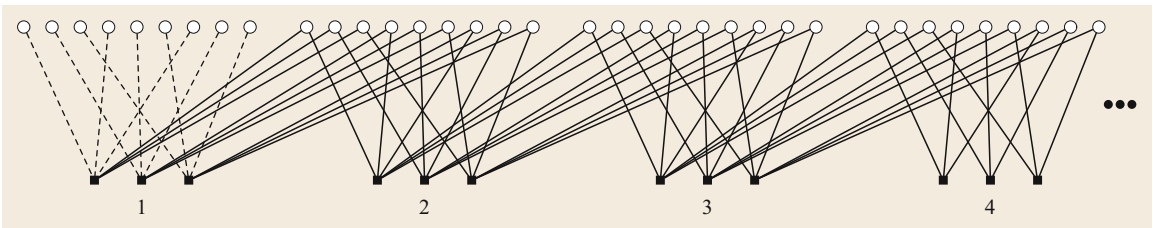

Fig. 7.37 Bipartite (Tanner) graph of a staircase code (Fig. 7.31) with component code of code length $n_c = 6$

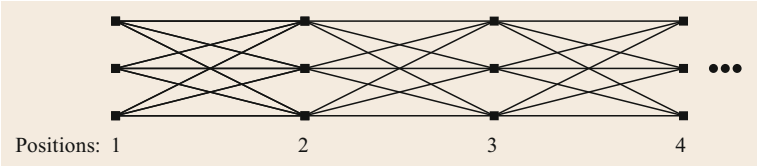

Fig. 7.38 Simplified Tanner graph of a staircase code (Fig. 7.31) with component code of code length $n_c = 6$

Example 7.6

For a fixed $L \geq 2$, the matrix $\boldsymbol{\eta}$ describing a staircase code has entries $\eta_{i,i+1} = \eta_{i+1,i} = 1$ for $i = 1, \ldots, L-1$ and zeros elsewhere. The distribution $\boldsymbol{\gamma}$ is uniform, i.e., $\gamma_i = 1/L$ for all $i \in [L]$. For example, the staircase code corresponding to the code array shown in Fig. 7.31, where $L = 4$ and $m = 24$ (i.e., $m_i = 6$), is defined by

$$\boldsymbol{\eta} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \tag{7.90}$$

and $\gamma_i = 1/6$. The CNs at all positions have the same degree $2n\gamma_i = 12$, except for positions 1 and L, where the degrees are $n\gamma_i = 6$. With this choice of $\boldsymbol{\eta}$ we recover the simplified Tanner graph in Fig. 7.38.

For more details on this general code construction, the interested reader is referred to [7.215].

7.5.6 Decoding of Product-Like Codes: Iterative Bounded Distance Decoding

PCs may be decoded with SDD using an iterative decoding algorithm based on the iterative exchange of soft information between two soft-input soft-output (SISO) decoders matched to the two component codes. The decoding is similar to that of turbo codes, and for this reason, PCs with iterative SDD are often referred to as turbo product codes (TPCs) or block turbo codes (BTCs). Similarly, GPCs can also be decoded by exchanging soft information between the SISO decoders of the component codes in an iterative fashion. The SISO decoders of the component codes may implement the MAP decoding rule, which can be done based on a trellis representation of the block code. However, MAP decoding of algebraic block codes is complex, and therefore iterative SDD of GPCs based on MAP decoding of the component codes is impractical. An efficient, lower-complexity iterative SDD algorithm for PCs with near-optimal performance was proposed by *Pyndiah* [7.58]. In this algorithm, the SISO decoders of the component codes are based on a modification of the Chase decoding algorithm, a low-complexity suboptimal algorithm for near-ML decoding of linear block codes proposed by *David Chase* in 1972 [7.216]. Since the Chase decoder is a vital component of the iterative SDD algorithm proposed in [7.58], the algorithm used to decode the component codes is usually referred to as the Chase–Pyndiah decoding algorithm. The advantage of this decoding algorithm is that it is highly parallelizable.

The iterative decoding of GPCs employing SISO component decoding is usually referred to as turbo product decoding (TPD) and is typically implemented in practice via the Chase–Pyndiah algorithm. However, it is worth mentioning that TPD can also be based on other component decoders, such as the forward-backward algorithm applied to the component code trellis.

The complexity of the Chase–Pyndiah decoder may still be unacceptable for some applications. Alternatively, one can decode PCs and GPCs using HDD. Indeed, PCs and GPCs are very well suited for HDD thanks to the fact that the component codes (typically BCH or Reed–Solomon codes) have a rich algebraic structure, which enables efficient implementation of BDD.

Iterative Bounded Distance Decoding of Product Codes

For large block codes, optimal (ML) HDD is a formidable task. As mentioned in Sect. 7.5.1, to reduce the decoding complexity, incomplete BDD can be used. However, even BDD of powerful codes such as PCs and GPCs is a challenging task. To achieve acceptable complexity, an iterative (suboptimal) decoding algorithm, based on BDD of the component codes, can then be used. Let us first consider HDD of PCs. The decoding of a PC can be accomplished by iteratively applying BDD to the row and column codes, described as follows. The received bits are arranged in an $n_2 \times n_1$ array corresponding to the code array (Fig. 7.30). Decoding is then carried out on the columns of the array, i.e., BDD decoding of the column component codes C_2 is performed, and subsequently on the rows of the array, i.e., BDD decoding of the row component codes C_1 is performed. Errors remaining after the first column decoding may be corrected by the bounded distance decoders of the row codes. The column-row decoding is then iterated until a maximum number of iterations is reached. We refer to this algorithm as iBDD.

iBDD achieves excellent performance-complexity trade-off. The decoding complexity of iBDD is roughly the sum of the decoding complexity of the BDD of the component codes times the number of iterations. Hence, the complexity of iBDD is much lower than that of ML decoding of the PC. On the other hand, since iBDD is suboptimal, the lower decoding complexity comes at a cost of lower performance. The complexity of iBDD of PCs and GPCs in general is also much lower than that of (suboptimal) BP decoding of LDPC codes. Moreover, the decoder data flow requirements are estimated to be more than one order of magnitude smaller than the requirements for a comparable LDPC code with BP decoding [7.49].

Iterative Bounded Distance Decoding of Generalized Product Codes

Like PCs, GPCs can be decoded using iBDD by iterating between the row and column decoders. For simplicity, in this section we describe the decoding of staircase codes. However, the decoding of other GPCs such as braided codes and half-braided codes follows the same principle.

Since staircase codes may be very long (as mentioned earlier, they are stream-oriented in nature), waiting to receive the entire code array prior to the start of decoding would entail a very long delay, which is not acceptable in fiber-optic communications. Fortunately, the batch-oriented structure of staircase codes allows us to perform decoding in a sliding-window fashion, similar to windowed decoding of SC-LDPC codes (Sect. 7.4.2). The windowed decoder operates on part of the array consisting of a window comprising a subset of W received batches. The decoder then iterates between the BDD decoders for all rows and all columns within the window. After a predetermined number of iterations, the window slides to the next position, and iterative decoding is performed within the new window. The decoding delay (in bits) is given by $D = WB$, where $B = a^2$ is the number of code bits per batch (Sect. 7.5.3). The window size provides a trade-off between performance and decoding latency, i.e., one expects a performance improvement by increasing the window size at a cost of higher decoding latency. In general, small values of W (6 to 8) are typically sufficient.

Despite the suboptimality of the iBDD algorithm, staircase codes—and GPCs in general—provide excellent performance for high code rates. For example, the $R = 0.937$ staircase code designed in [7.49] performs only about 0.56 dB from the channel capacity of the BSC.

It is worth mentioning that BDD of the component codes may lead to *miscorrections*, i.e., the component decoders may declare successful decoding, but the decoded codeword is not the correct one. Miscorrections introduce additional bit errors into the iterative decoding process, which result in performance degradation. The impact of miscorrections becomes less severe as the error-correcting capability t increases. In [7.217], a decoding algorithm for staircase codes was proposed, called *anchor decoding*, which reduces the effect of undetected component code miscorrections. The algorithm significantly improves performance, in particular when t is small, while retaining low-complexity implementation.

Iterative Bounded Distance Decoding as a Message-Passing Algorithm

With reference to the Tanner graph representation of GPCs, iBDD of GPCs can be interpreted as an iterative message-passing decoding algorithm similar to that of LDPC codes, where *hard* (binary) messages are exchanged between VNs and CNs in the Tanner graph describing the code. This opens the door to the analysis of the performance of iBDD of GPCs using codes-on-graphs tools.

It is worth pointing out that the classical message-passing rule typically used to decode PCs and GPCs violates the principle that only *extrinsic* information should be exchanged during the iterative decoding process [7.218], since the computation of the messages passed from CNs to VNs use the input messages at the CNs. For this reason, we will use the same terminology introduced in [7.50] and refer to the decoding algorithm described above as iterative HDD with intrinsic message passing (IMP). In [7.219], a modified message-passing algorithm that exchanges only extrinsic information, dubbed extrinsic message passing (EMP), was proposed. EMP yields better performance than IMP at a cost of some increase in complexity (mostly memory complexity, which is doubled). A low-complexity EMP HDD algorithm is given in [7.50].

7.5.7 Analysis and Optimization of Generalized Product Codes

Similar to LDPC codes and codes on graphs in general, the BER curve of GPCs is characterized by two well-defined regions. In the first one, called the waterfall region, the BER decreases sharply with E_b/N_0. The curve then flattens out in the so-called error floor region. The error floor is usually caused by combinations of errors that cannot be corrected by the decoder. For GPCs with iBDD, these patterns are usually referred to as *stall patterns* [7.49]. A stall pattern for the staircase code, the braided code, and the half-braided code in Figs. 7.31, 7.32, and 7.34, respectively, assum-

ing $t = 2$ error-correcting component codes, is shown by the crosses in the figures. Since every component codeword involved has three errors, decoding will not be able to proceed, and stalls.

Let $s_{\min}$ be the size of the minimum stall pattern, defined as the minimum number of array positions that, when all received in error, cause the decoder to stall. A stall pattern is said to be assigned to a batch if at least one of its array positions belongs to the batch and no positions belong to previous batches. The error floor of staircase codes, braided codes, and half-braided codes can be approximated by

$$\mathrm{BER} \approx \frac{s_{\min} M p^{s_{\min}}}{B}, \tag{7.91}$$

where M denotes the number of minimum stall patterns that can be assigned to a batch. For staircase codes, M is derived in [7.49, Sect. V-B]. Using similar arguments, the values of M for braided codes and half-braided codes were obtained in [7.213].

The performance of GPCs in the waterfall region is more difficult to analyze. However, the asymptotic performance of GPCs in the limit of infinite block lengths can be analyzed exploiting the connection with G-LDPC codes. The analysis of codes on graphs such as LDPC codes and G-LDPC codes is commonly based on an ensemble argument, i.e., rather than analyzing a particular code, which is very cumbersome, it is customary to analyze the average behavior of a code ensemble. A code ensemble can be regarded as a family of codes that share some common characteristics, such as the degree distribution. The asymptotic behavior of a code ensemble can be analyzed via a tool called density evolution [7.117], which can be used to find the so-called decoding threshold. The decoding threshold divides the channel parameter range (e.g., SNR) into a region where reliable decoding is possible and another region where it is not, and accurately predicts the region where the code performance curve *bends* into the characteristic waterfall behavior. There exists a concentration phenomenon that ensures with high probability that a particular code taken uniformly at random from the ensemble will have actual performance close to th predicted by density evolution.

The parameters of GPCs, i.e., the parameters of the component codes, can be optimized to achieve good performance in the waterfall region based on extensive software simulations for predicting the code performance, as was done in [7.208] for staircase codes. Alternatively, one can use the fact that a specific GPC, e.g., a staircase code, is contained in a given ensemble of G-LDPC codes, and can optimize the code parameters based on density evolution to optimize the decoding threshold. The optimization approach based on density evolution offers significantly reduced optimization time (or the possibility of exploring a larger parameter space) with respect to a simulation-based approach. The optimization of staircase code parameters based on density evolution was addressed in [7.209].

It is very important to emphasize that, contrary to LDPC codes, which are drawn from an ensemble, GPCs are deterministic codes, i.e., they have a very regular structure in terms of their Tanner graph and are not at all random-like. Thus, while the optimization of GPCs via ensemble-based density evolution yields good codes, formally speaking, the asymptotic performance of GPCs is not necessarily characterized by density evolution of the corresponding spatially coupled G-LDPC code ensemble. For transmission over the binary erasure channel (BEC), the density evolution equations that characterize the asymptotic decoding performance of a broad class of GPCs with a fixed Tanner graph were derived in [7.213–215], without relying on the definition of a code ensemble. The results obtained can also be used to analyze the code performance over the BSC assuming idealized BDD, i.e., completely ignoring miscorrections (idealized BDD over the BSC is conceptually equivalent to transmission over the BEC). However, the rigorous characterization of the asymptotic performance of GPCs over the BSC, including the effect of decoder miscorrections, is still an open problem. An asymptotic analysis taking into account the impact of miscorrections for a code ensemble related to staircase codes is given in [7.220].

7.5.8 Soft-Aided Decoding of Product-Like Codes

In Sect. 7.4 and in this section, we have provided an extensive review of soft-decision FEC and hard-decision FEC, respectively. Roughly speaking, soft-decision FEC yields higher NCGs at a cost of higher decoding complexity and data flow compared with hard-decision FEC. Thus, despite its smaller NCG, for applications where very high throughput and low power consumption are required, hard-decision FEC is still an appealing alternative. An interesting question is whether it is possible to close the gap between the performance of hard-decision and soft-decision FEC while keeping the decoding complexity low. One line of research recently pursued in this direction is to concatenate an inner soft-decision FEC code, e.g., an LDPC code decoded via BP, with an outer staircase code [7.221, 222]. Another alternative, recently investigated in [7.223, 224], is to improve the performance of iBDD of product-like codes by exploiting some level of soft information while keeping the core

algebraic decoding of the component codes, an approach that we refer to here as *soft-aided* decoding of product-like codes. Without going into detail, the algorithm in [7.223], dubbed iBDD-SR, exploits the channel reliabilities while still only exchanging binary (hard-decision) messages between component codes. iBDD improves performance over conventional iBDD, with only a minor increase in complexity. In [7.224], another soft-aided decoding algorithm was proposed, based on generalized minimum distance (GMD) decoding of the component codes. The algorithm, referred to as iterative GMD decoding with scaled reliability (iGMDD-SR) yields more significant coding gains while maintaining significantly lower complexity than SDD. In particular, for a PC, it was shown that iGMDD-SR closes over 50% of the performance gap relative to turbo product decoding, while maintaining significantly lower complexity. We note that while the algorithms in [7.223, 224] were demonstrated for PCs, their extension to staircase codes and other product-like codes is straightforward. The implementation of iBDD for a PC has been considered in [7.225], where it is shown that, using a single bit of soft information, the NCG can be improved by 0.2 dB with respect to iBDD, reaching 10.3−10.4 dB, which is similar to that of more complex hard-decision staircase decoders, but with significantly lower circuit area and energy dissipation.

7.5.9 Performance Curves

In Fig. 7.39, we plot the BER performance of two staircase codes of rate $R = 0.75$ (corresponding to a code overhead of 33.33%) for transmission over the BSC. The net coding gain is also shown. In particular, the figure shows the performance of the staircase code with BCH component codes with parameters $(\nu, t, s) = (9, 5, 151)$, i.e., $(n_c, k_c) = (360, 315)$ [7.208, Table II], referred to as C_1 in the figure. The parameters of the BCH component code were optimized in [7.208] based on extensive simulations. The performance of the code is shown for both IMP decoding, as originally proposed in [7.49], and EMP decoding, as proposed in [7.50]. The decoding is performed in a sliding-window fashion as explained in Sect. 7.5.6. A window size $W = 7$ and $\ell = 8$ iterations within a window are considered. It is observed that EMP yields better performance than IMP in the waterfall region. In the figure, we also plot density evolution results [7.209]. The density evolution curve predicts the pre-FEC BER region where the simulated curve (with EMP) bends into the characteristic waterfall.

In the figure, we also plot the performance of a staircase code of the same code rate whose parameters have been optimized based on density evolution [7.209], and

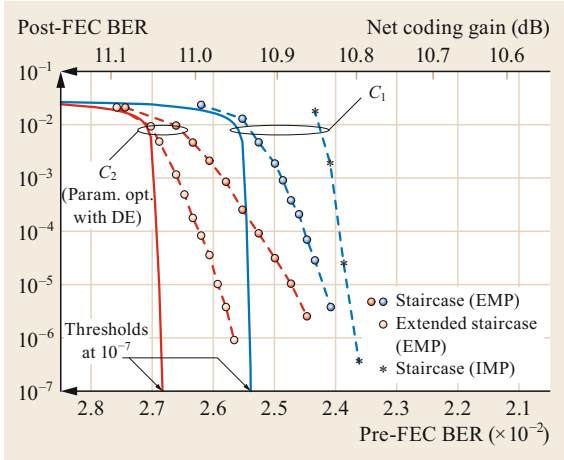

Fig. 7.39 Simulation results (*dashed curves with markers*) and density evolution results (*solid curves*) for staircase codes and extended staircase codes

which is referred to as C_2 in the figure. The component BCH code has parameters $(\nu, t, s) = (8, 3, 63)$, i.e., $(n_c, k_c) = (192, 168)$. As can be seen, the optimization of the code parameters based on density evolution yields better performance in the waterfall region. The poorer slope of the staircase code with component code C_2 than with component code C_1 is due to the fact that for the former, the size of one staircase block, a (Fig. 7.31), is smaller, namely $a = 96$ versus $a = 180$, corresponding to a decoding delay of $D = 64\,512$ bits and $D = 226\,800$ bits, respectively [7.209, Table 1]. Finally, in the figure we also plot the performance of an extended staircase code with block size $a = 192$ [7.209], which has a decoding delay comparable to that of the staircase code based on C_1. The extended staircase code has a steeper curve in the waterfall region.

In Fig. 7.40, we plot simulation results for a staircase code (red curve with markers), a braided code (blue curve with markers), and a half braided code (green curve with markers) with BCH component codes with parameters $(n_c, k_c) = (720, 690)$ and $t = 3$. All three codes have roughly the same code rate, $R \approx 0.917$, corresponding to an FEC overhead of 9.1%. Transmission over a BSC is assumed, and we plot the post-FEC BER as a function of the channel transition probability p. The decoding is performed using a windowed decoder with window size $W = 8$ for the staircase code and $W = 6$ for the braided code, such that the two codes have the same delay, $D = 1\,036\,800$ bits, while the decoding delay of the half-braided code with $W = 6$ is roughly half, $D = 517\,680$ bits. The staircase and braided codes are decoded by iterating $\ell = 8$ times between rows and columns within each window.

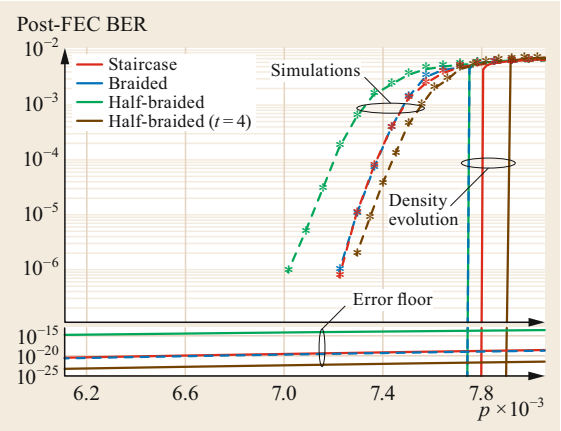

Fig. 7.40 Simulation results (*dashed curves with markers*), density evolution results, and error floor curves for staircase, braided, and half-braided codes

For the half-braided code, all component codes within each window are decoded simultaneously and ℓ is increased to 16 to maintain the same decoding complexity (note that the number of component codes per window is reduced by half for half-braided codes).

In the figure, we also plot density evolution results and the error floor approximation given in (7.91). The density evolution results show a slight performance advantage for the staircase code in the asymptotic regime of large block lengths. However, for the chosen parameters at finite lengths, the simulation curves for the staircase code and the braided code are virtually on top of each other. The density evolution results for the braided code and the half-braided code are roughly the same. However, the simulated half-braided code has worse performance than the staircase and braided codes, caused by different scaling behavior at finite length due to the reduced number of bits within the decoding window. Furthermore, the error floor is increased from $\approx 10^{-20}$ for the staircase and braided codes to $\approx 10^{-14}$ because of the reduction of $s_{\min}$. On the other hand, the half-braided code operates at only half the decoding delay. In the figure, we also plot the performance of a half-braided code with a BCH component code of parameters $(960, 920, 4)$. The code rate is the same, but the decoding delay is now $D = 920\,640$ bits, which is slightly less than that of the staircase and braided codes. The code shows a reduced error floor ($\approx 10^{-23}$) and also improves the waterfall performance, as predicted by density evolution and confirmed by the simulations.

In Fig. 7.41, we plot the BER performance of a PC with double-error-correcting extended BCH (eBCH) codes with parameters $(256, 239, 6)$ as component codes for transmission over the AWGN channel. The code rate of the resulting PC is $R = 239^2/256^2 \approx 0.8716$, which corresponds to overhead OH $\approx 15\%$. In the figure, we plot the performance of both iBDD (red curve with triangle markers) and TPD based on the Chase–Pyndiah algorithm (blue curve with blue markers). Both iBDD and TPD perform about 1 dB from the respective capacity limits at a BER of 10^{-5}. TPD yields a coding gain of about 1.5 dB with respect to iBDD, at a cost of significantly higher decoding complexity. As a reference, we also show the performance of ideal iBDD, where a genie prevents all miscorrections. Additionally, we plot the performance of the

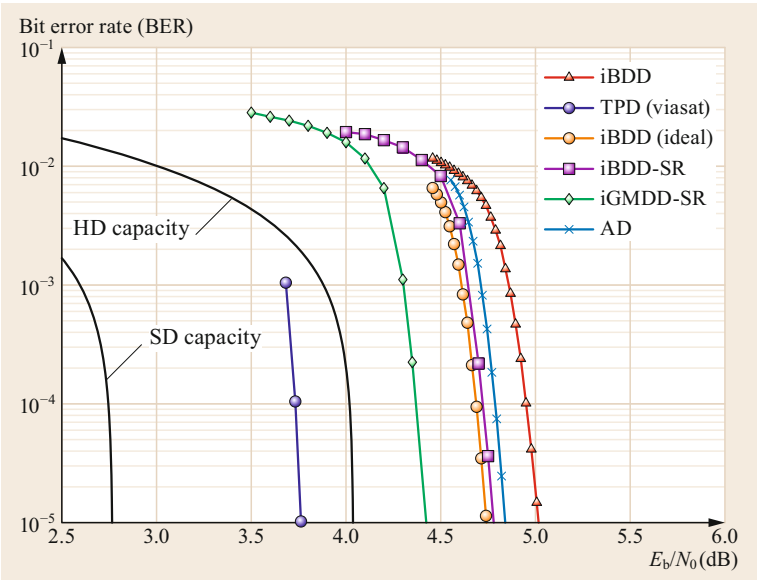

Fig. 7.41 Simulation results for a PC with $(256, 239, 6)$ double-error-correcting eBCH codes as component codes and different decoding algorithms

anchor decoding algorithm proposed in [7.217] and of iBDD-SR [7.223]. We can observe that both anchor decoding and iBDD-SR are effective algorithms for combating miscorrections. The performance degradation of iBDD-SR compared with ideal iBDD is very small (<0.01 dB). iBDD-SR outperforms the conventional iBDD by 0.25 dB at a BER of 10^{-5}, with only a very small increase in complexity [7.223, 225]. Finally, we also plot the performance of iGMDD-SR, which outperforms iBDD, anchor decoding, and iBDD-SR. In particular, the performance gain for iGMDD-SR over iBDD is 0.60 dB. Furthermore, iGMDD-SR performs 0.52 dB from TPD, i.e., it closes over 50% of the performance gap between iBDD and TPD [7.224].

7.6 Coded Modulation—An Introduction

In the previous sections we have focused mostly on binary codes and binary (BPSK) transmission. As we have seen, to operate close to the Shannon limit, (powerful) error-correcting codes are required. Forward error correction (FEC) increases the power efficiency of the system but introduces redundancy to the transmitted sequence. The added redundancy requires the modulator to operate at a higher data rate and hence requires a larger bandwidth, i.e., the spectral efficiency is decreased. Achieving higher spectral efficiency can be realized by using a higher-order signal constellation (i.e., constellations with cardinality larger than 2). Therefore, to transmit reliably at high spectral efficiencies, as required in fiber-optic communications, error-correcting codes must be combined with the use of a higher-order constellation. The combination of error-correcting coding and higher-order constellations is usually referred to as coded modulation (CM).

CM has been studied since the 1970s and comes in different flavors, depending on the code used (binary or nonbinary) and the way the code is coupled with the higher-order constellation. In this section, we briefly review the most important CM schemes, namely trellis-coded modulation (TCM), multilevel coding (MLC), bit-interleaved coded modulation (BICM), and CM with nonbinary codes. We also briefly discuss constellation shaping as a means to close the fundamental gap relative to capacity that the use of conventional signal constellations with equally spaced signal points and uniform signaling entails.

7.6.1 Trellis-Coded Modulation

One of the first CM schemes to appear was TCM, a CM scheme proposed by *Gottfried Ungerboeck* in the late 1970s/early 1980s [7.226, 227] as a way to increase the spectral efficiency of communication systems. It consists of the concatenation of a binary trellis code (a convolutional code) and a higher-order constellation through a careful mapping of the code bits to the constellation symbols based on the set partitioning principle. Due to the correspondence of signal sequences and paths along the trellis of the convolutional code, TCM enables efficient ML decoding using Viterbi decoding.

We have seen in Sect. 7.3.3 that, for transmission over the AWGN channel, the ML rule for SDD is to select from among all possible (modulated) codewords the one at the minimum Euclidean distance to the received vector. However, the mapping of the code bits of a (binary) code optimized in terms of its minimum Hamming distance into constellation points does not guarantee that a good Euclidean distance is obtained. The basic notion of TCM is to optimize the code (now seen as the combination of a binary code and the modulation) in the Euclidean space instead. The signal set (i.e., the constellation) $\mathcal{X}$, of cardinality $M = 2^m$ symbols, is successively partitioned into smaller disjoint subsets of sizes $M/2, M/4, M/8, \ldots$, such that the minimum intra-subset Euclidean distance (the minimum Euclidean distance between signal points within each subset) is maximized. The number of subsets into which the constellation is partitioned depends on the binary code used. The partitioning defines a mapping of binary labels $\mathsf{L}(x) = (b^{(1)}(x), \ldots, b^{(m)}(x))$ to signal points $x \in \mathcal{X}$.

The next step is to assign constellation points to branches of the trellis code. In particular, assume the use of a rate $R = k_1/n_1$, $n_1 \leq m$, convolutional code. In this case, the constellation is successively partitioned into 2^{n_1} subsets, each containing 2^{m-n_1} constellation points. Each block of k data bits is then split into two sub-blocks of lengths k_1 and $k_2 = m - n_1$. The block of k_1 data bits is encoded by the convolutional encoder, generating n_1 code bits, which are used to select one of the 2^{n_1} subsets in which the constellation has been partitioned. The remaining k_2 data bits are used to select one of the points within the selected subset. Note that the presence of uncoded bits introduces parallel transitions in the trellis. Ungerboeck showed that by choosing $n_1 = k_1 + 1$ and $k_2 = 1$ (a single uncoded bit), it is possible to design CM schemes with coding gains of between

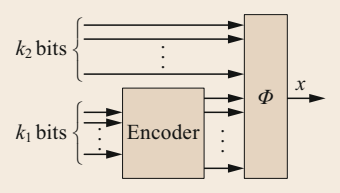

Fig. 7.42 TCM encoder

3 and 6 dB. A block diagram of the TCM encoder is shown in Fig. 7.42.

Finally, the assignment of constellation points to the branches of the code trellis can be done by means of an exhaustive computer search in order to maximize the minimum Euclidean distance of the coded sequences. Ungerboeck introduced a set of rules that are conjectured to give rise to the best TCM schemes:

1. Members of the same partition are assigned to parallel transitions.
2. Members of the next larger partition are assigned to transitions originating from the same state or converging to the same state.
3. All signal points are used equally often.

After its introduction, TCM became very popular and was the object of intensive research. It was also quickly adopted for modem standards in the early 1990s. A thorough description and analysis of TCM can be found in [7.228]. The concept of TCM was later extended to turbo TCM [7.229] by replacing the convolutional code with a turbo code to decrease the gap relative to the Shannon limit for AWGN channels. TCM with multidimensional constellations was proposed in [7.230]. TCM was first proposed for fiber-optic systems in [7.231]. The concatenation of TCM with an outer Reed–Solomon and BCH code was studied in [7.232], yielding NCGs of 8.4 and 9.7 dB, respectively, at a BER of 10^{-13} for the AWGN channel.

7.6.2 Multilevel Coding

In parallel to TCM, an alternative CM modulation scheme, MLC, was proposed by *Hideki Imai* and *Shuji Hirakawa* [7.233] in 1977. The key idea underlying MLC is to protect each bit of the constellation symbol by an individual binary error-correcting code C_i. In other words, MLC transforms the nonbinary channel into a set of m parallel binary sub-channels, and then uses individual binary error-correcting codes for each sub-channel. Specifically, MLC works as follows: A block $\boldsymbol{u} = (u_1 \ldots, u_k)$ of k data bits is partitioned into m blocks $\boldsymbol{u}^{(i)} = (u_1^{(i)}, \ldots, u_{k_i}^{(i)})$ of length k_i bits, $i = 1, \ldots, m$, with $\sum_{i=1}^{m} k_i = k$. Each data block $\boldsymbol{u}^{(i)}$ is then encoded by an individual binary encoder of rate $R_i = k_i/n$, generating codewords $\boldsymbol{c}^{(i)} = (c_1^{(i)}, \ldots, c_n^{(i)})$, of length n bits, where we assume for simplicity and ease of exposition that all codes have equal code length n (however, in principle, the choice of the component codes is arbitrary). The code rate of the overall coding scheme is equal to the normalized sum of the individual code rates, i.e.,

$$R = \frac{1}{m}\sum_{i=1}^{m} R_i = \frac{1}{m}\sum_{i=1}^{m} \frac{k_i}{n} = \frac{k}{nm} \,. \tag{7.92}$$

At each time instant t, the string of m code bits $c_t^{(1)}, \ldots, c_t^{(m)}$ at the output of the m encoders is mapped to a constellation symbol. As for TCM, the mapping is also derived by successively partitioning the signal set into subsets. Note that each component code has a different rate, i.e., each constellation bit is protected differently. A block level of the multilevel encoder is depicted in Fig. 7.43.

ML decoding of MLC requires joint decoding of all component codes, which is unfeasible. Fortunately, decoding of MLC can be efficiently performed using multistage decoding. The multistage decoder operates by decoding the m component codes separately. More precisely, the component codes C_i are decoded sequentially, starting with code C_1. We denote by $\mathcal{D}_i$ the decoder corresponding to component code C_i. At stage i, $i = 1, \ldots, m$, the decoder $\mathcal{D}_i$ is fed the received sequence and also the decisions of the previous decoding stages, i.e., $\hat{\boldsymbol{u}}^{(1)}, \ldots, \hat{\boldsymbol{u}}^{(i-1)}$ (or equivalently $\hat{\boldsymbol{c}}^{(1)}, \ldots, \hat{\boldsymbol{c}}^{(i-1)}$). The block diagram of the multistage decoder is shown in Fig. 7.44. Multistage decoding achieves good performance in practice, with limited complexity, and it has been shown to achieve the channel capacity [7.234].

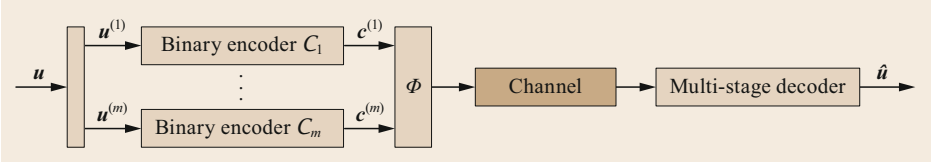

Fig. 7.43 MLC encoder

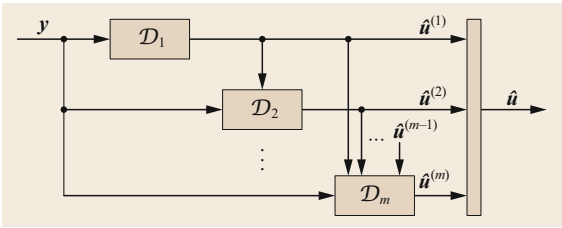

Fig. 7.44 Multistage decoder for MLC

7.6.3 Bit-Interleaved Coded Modulation

BICM was introduced by *Ephraim Zehavi* et al. in 1992 [7.235]. Given its simplicity, flexibility, and capacity-approaching performance, it is nowadays perhaps the most popular CM scheme and has become the de facto standard in many communication standards and modern communication systems.

BICM is a *pragmatic* approach to CM consisting in the concatenation of a (single) binary code with a higher-order constellation through a binary *interleaver* π. The effect of the interleaver is to uniformly distribute the code bits among the different sub-channels corresponding to the different constellation bits. Therefore, in contrast to TCM and MLC, BICM decouples the code from the modulation, which greatly simplifies the CM scheme design (the code is optimized independently of the modulation).

The block diagram of a BICM encoder and decoder is shown in Fig. 7.45. The information sequence $\boldsymbol{u}$ is first encoded by a binary encoder into codeword $\boldsymbol{c}$, which is interleaved by the interleaver π. The interleaver permutes the sequence $\boldsymbol{c}$ into another sequence $\tilde{\boldsymbol{c}}$. The interleaved sequence $\tilde{\boldsymbol{c}}$ is then parsed in blocks of m bits each, thus generating m parallel bit streams, denoted by $\boldsymbol{b}^{(1)}, \ldots, \boldsymbol{b}^{(m)}$. At time instant i, the modulator Φ takes m bits $(b_i^{(1)}, \ldots, b_i^{(m)})$, and maps them onto symbols of a constellation $\mathcal{X}$ of cardinality $M = 2^m$ according to the binary labeling of the constellation (usually Gray labeling). The resulting (modulated) sequence $\boldsymbol{x}$ is transmitted over the channel. The sequence at the output of the channel is denoted by $\boldsymbol{y}$.

At the receiver side, for SDD, the demodulator Φ^{-1} computes soft reliability information about the bits $(b_i^{(1)}, \ldots, b_i^{(m)})$ of the bitstreams $\boldsymbol{b}^{(1)}, \ldots, \boldsymbol{b}^{(m)}$ in the form of LLRs

$$l_i^{(j)} \triangleq \log\left(\frac{p_{Y_i|B_i^{(j)}}(y_i|0)}{p_{Y_i|B_i^{(j)}}(y_i|1)}\right) = \log\left(\frac{\sum_{x\in\mathcal{X}_0^{(j)}} p_{Y_i|X_i}(y_i|x)}{\sum_{x\in\mathcal{X}_1^{(j)}} p_{Y_i|X_i}(y_i|x)}\right), \tag{7.93}$$

where $l_i^{(j)}$ is the LLR for the j-th bit at time instant i; X_i, Y_i, and $B_i^{(j)}$ are the RVs corresponding to the channel input x_i, channel output y_i, and bit $b_i^{(j)}$, respectively; and $\mathcal{X}_0^{(j)} \subset \mathcal{X}$ and $\mathcal{X}_1^{(j)} \subset \mathcal{X}$ are the sub-constellations consisting of all constellation points with binary labeling with a 0 or a 1 in the j-th position, respectively, i.e., $\mathcal{X}_z^{(j)} = \{x \in \mathcal{X} : b^{(j)}(x) = z\}$, $z = \{0, 1\}$. The LLRs are then multiplexed, de-interleaved, and fed to a bit-wise soft-decision decoder.

It is also possible to use iterative decoding/demodulation at the receiver. In this case, the decoder and the demodulator exchange extrinsic information in an iterative fashion, and the scheme is referred to as BICM with iterative decoding (BICM-ID) [7.236–238]. Note that, here, *iterative decoding* refers to the iterations between the decoder and the demodulator, and not to the iterative decoding of the binary code. BICM-ID brings performance gains with respect to plain BICM for mappings other than Gray and non-square constellations, at a cost of higher complexity. With Gray labeling and square constellations, there is only a negligible advantage in iterating between the decoder and the demodulator.

For HDD, the demodulator performs minimum distance symbol-by-symbol detection of the received symbols (assuming uniform distribution at the input of the channel) and outputs the binary labeling associated with the detected symbol. The resulting stream of bits (after multiplexing) is de-interleaved and fed to a bit-wise hard-decision decoder.

7.6.4 Coded Modulation with Nonbinary Codes

As discussed in Sect. 7.2.1, the MI of nonbinary transmission over the AWGN channel is achievable with

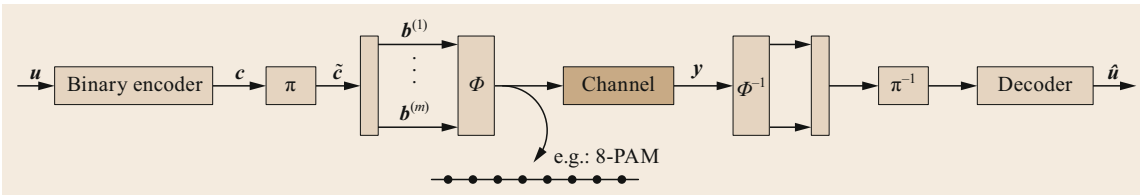

Fig. 7.45 BICM encoder and decoder

a symbol-wise soft-decision decoder. A natural way to couple an error-correcting code with a higher-order constellation is therefore to consider a nonbinary code that is matched to the constellation size. One can then assign each of the 2^m different code symbols to one of the constellation points. Note that in this case, the mapping between code symbols to constellation points becomes trivial. CM with nonbinary LDPC codes is discussed in [7.239].

In practice, the loss with respect to the MI due to the use of a BICM system is very small for most constellations, labeling, and channels in use today. Therefore, since the decoding of nonbinary codes is generally significantly more complex than the decoding of their binary counterparts, it is difficult to justify the use nonbinary codes, and BICM is perhaps the most reasonable CM scheme to consider.

7.6.5 Signal Shaping

So far we have assumed nonbinary transmission using a conventional signal constellation with equidistant signal points and uniform signaling, i.e., each signal point is transmitted with the same probability. This is the case for conventional PAM and quadrature amplitude modulation (QAM) constellations used in current fiber-optic systems. However, such constellations exhibit a gap relative to the Shannon limit. The reason is that conventional constellations are not capacity-achieving. For instance, for the AWGN channel, the capacity-achieving distribution is the Gaussian distribution. The use of a discrete signal constellation with equidistant signal points and uniform signaling instead leads to an asymptotic loss of 1.53 dB (asymptotic in the sense of high spectral efficiencies and number of signal points). In Fig. 7.46, the MI curves (see (7.3)) for 4, 8, 16, 32, 64, 128, and 256-QAM constellations are depicted for transmission over the AWGN channel and compared with the channel capacity curve. A gap with respect to the capacity curve is observed.

Thus, to achieve capacity, the use of powerful error-correcting codes is not enough. To reduce the fundamental 1.53 dB gap, constellation-shaping techniques that produce a Gaussian-like distribution, i.e., *shape* the constellation such that it mimics a Gaussian distribution (or the capacity-achieving distribution for a given channel) are required [7.240]. In other words, to achieve capacity, coding and CM techniques must be complemented with signal shaping.

There are two main classes of signal shaping, geometric shaping and probabilistic shaping [7.241, 242]. In geometric shaping, the constellation points are arranged in a non-equally spaced manner to mimic the capacity-achieving distribution. The best constellation

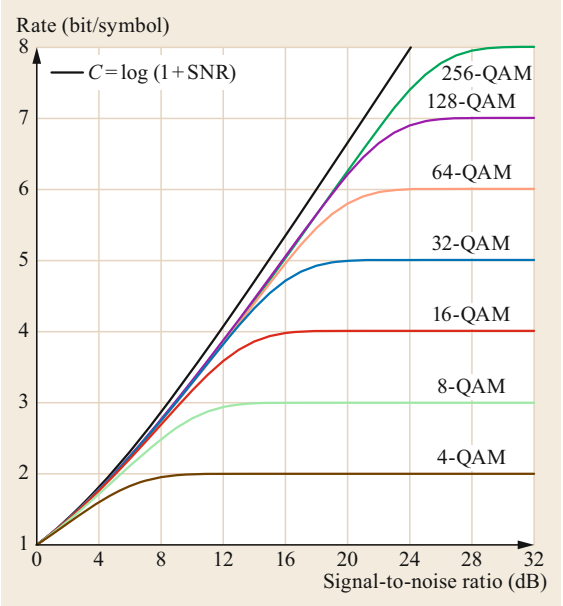

Fig. 7.46 Mutual information curves for several QAM constellations over the AWGN channel. There is a gap between the MI and the capacity of the channel

depends on the SNR and the decoding metric. Probabilistic shaping, on the other hand, starts with a conventional constellation with equidistant signal points, e.g., PAM or QAM, and assigns different probabilities to different constellation points to induce a Gaussian-like probability distribution. In Fig. 7.47, we plot a probabilistically shaped 8-PAM constellation. The inner signal points have higher probability than the outer signal points, mimicking a Gaussian distribution. A significant advantage of probabilistic shaping is that it builds upon off-the-shelf constellations. In general, geometric shaping requires more complex hardware, such as higher-resolution ADCs, than probabilistic shaping. Furthermore, in [7.243] it was shown that for the AWGN channel and bit-wise decoding, geometric

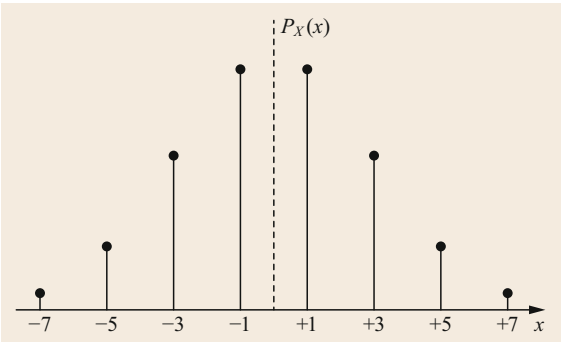

Fig. 7.47 Probabilistically shaped 8-PAM constellation

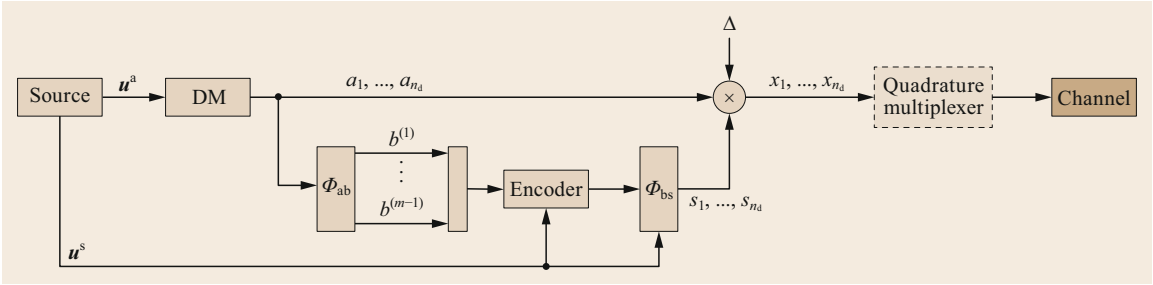

Fig. 7.48 Block diagram of the PAS scheme

shaping suffers from performance loss compared with probabilistic shaping.

Both geometric and probabilistic shaping have been considered for fiber-optic communications as a means of increasing the spectral efficiency, showing significant gains with respect to classical constellations [7.244–250].

Probabilistic Amplitude Shaping

A particularly appealing probabilistic shaping scheme, dubbed probabilistic amplitude shaping (PAS), was recently proposed in [7.251]. It achieves performance within 1.1 dB of the capacity of the AWGN channel for a wide range of spectral efficiencies with off-the-shelf LDPC codes [7.251]. More recently, this scheme was considered for fiber-optic communications in [7.246, 248] and is currently receiving a great deal of attention in the optical communications research community. In [7.249, 250], PAS was applied to HDD and adapted for the use of staircase codes.

PAS exploits the fact that, for the AWGN channel (and symmetric channels in general), the capacity-achieving distribution is symmetric. For one-dimensional and two-dimensional constellations, the capacity-achieving distribution is symmetric around zero. This means that the signs of the constellation points are uniformly distributed. A sketch of the capacity-achieving distribution based on a 8-PAM underlying constellation is depicted in Fig. 7.47. The optimal probability mass function is symmetric around zero, i.e., $\Pr(|x|) = \Pr(-|x|)$, and $\Pr(\mathrm{sign}(X) = 1) = \Pr(\mathrm{sign}(X) = -1) = 1/2$. The key idea in PAS is then to move the shaping of the amplitudes *before* the encoding, as opposed to geometric shaping and conventional probabilistic shaping, and use the (uniformly distributed) parity bits at the output of a systematic encoder and some information bits to generate the signs with the desired uniform distribution.

The PAS scheme proposed in [7.251] is depicted in Fig. 7.48. For simplicity, we consider PAM modulation as the underlying modulation, i.e., the channel input alphabet is given by $\mathcal{X} \triangleq \{-2^m + 1, \ldots, -1, 1, \ldots, 2^m - 1\}$, where m is the number of bits per symbol. The information sequence at the output of the source, $\boldsymbol{u} = (u_1, \ldots, u_k)$, where the information bits are uniformly distributed, i.e., $\Pr(U = 0) = \Pr(U = 1) = 1/2$, is split into two sequences $\boldsymbol{u}^s$ and $\boldsymbol{u}^a$. The sequence $\boldsymbol{u}^a$ is used to generate a sequence of amplitudes $\boldsymbol{a} = (a_1, \ldots, a_{n_d})$ with the desired distribution through a so-called distribution matcher (DM) [7.251]. The distribution matcher transforms blocks of uniformly distributed bits into blocks of amplitudes $a_i \in \{1, \ldots, 2^{m-1}\}$ with the desired probability mass function $P_A(a)$. The binary image of the amplitudes $\boldsymbol{b}$ and the remaining information bits, i.e., $\boldsymbol{u}^s$, are then multiplexed and encoded using a binary code (an LDPC code in [7.251]) with a systematic encoder. The parity bits generated by the systematic encoder and $\boldsymbol{u}^s$ are used to generate n_d sign labels $s_1, \ldots, s_{n_d}$. Since the parity bits at the output of the encoder tend to be approximately uniformly distributed, the distribution of the signs is the desired uniform distribution. Finally, the element-wise multiplication of the sequence of amplitudes $(a_1, \ldots, a_{n_d})$ with the sequence of signs $(s_1, \ldots, s_{n_d})$ and with a scaling factor Δ generates a sequence of symbols $\boldsymbol{x} = (x_1, \ldots, x_{n_d})$ with the desired distribution that is transmitted over the channel. The scaling factor Δ is chosen to meet the power constraint.

Note that since square QAM constellations can be obtained as the Cartesian product of two PAM constellations, the design of the PAS scheme described above readily extends to QAM constellations. In Fig. 7.48, the dashed block multiplexes two PAM modulated sequences, corresponding to the real and imaginary components of the QAM constellation.

7.6.6 Performance Curves

In Fig. 7.49, we give BER results for terminated and tail-biting SC-LDPC codes with SDD and for staircase codes and extended staircase codes with HDD, for an AWGN channel and 64-QAM with BICM. The code rate is $R = 0.75$ for all codes, corresponding to overhead OH = 33%, except for the terminated SC-LDPC

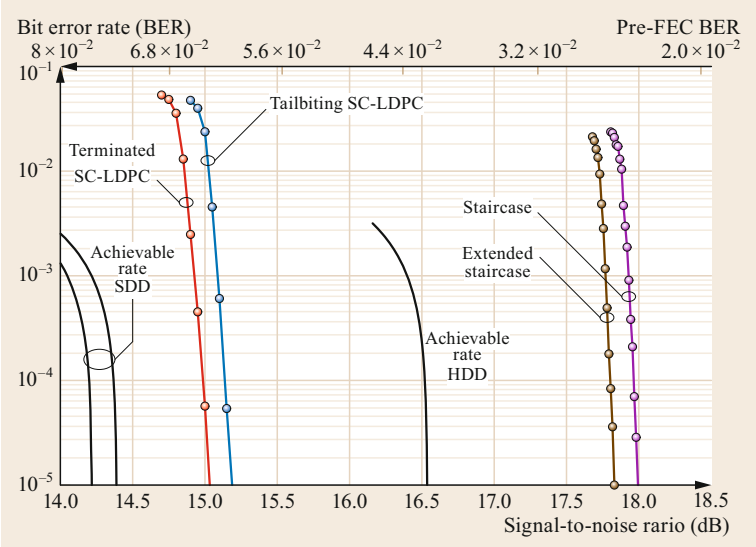

Fig. 7.49 Simulation results (*solid curves with markers*) and achievable rates (*solid curves*) for a BICM system with SC-LDPC codes, a staircase code, and an extended staircase code for transmission over the AWGN channel with 64-QAM

code, for which the code rate is $R = 0.741$. Staircase codes and extended staircase codes perform at 1.5 dB and 1.3 dB from the achievable rate at a BER of 10^{-5}. An extra coding gain of 2.6–2.8 dB can be achieved by using SC-LDPC codes and SDD, at a cost of a higher complexity and power consumption. SC-LDPC codes perform around 0.8 dB from capacity. The fact that the staircase code and the extended staircase code perform further from capacity is due to the moderate code rate. As explained in Sect. 7.5, GPCs perform very close to capacity for higher rates.

In Fig. 7.50, we plot the achievable rates for SDD and HDD with a (conventional) uniform 256-QAM constellation and with PAS assuming an underlying 256-QAM for transmission over the AWGN channel, and compare them with the capacity curve $C = \log(1 + \mathrm{SNR})$. Here, we consider a BICM scheme, and the achievable rates are computed as explained in Sects. 7.2.1 and 7.2.2. It is observed that for SDD, transmitting with uniform 256-QAM (dashed blue curve) entails a shaping loss. The solid blue curve is the achievable rate with PAS, which closes the gap relative to the capacity curve significantly, except for the spectral efficiency range, for which the curve bends to the maximum spectral efficiency with 256 signal points, i.e., 8 bits/symbol. The dashed red curve is the achievable rate with HDD and uniform signaling. HDD entails a loss with respect to SDD, and the loss increases for lower spectral efficiencies, as can be seen from the two different slopes of the dashed curves. As for SDD, PAS yields a performance improvement (cf. red dashed and solid curves). Interestingly, the gap with respect to the corresponding achievable rate for SDD (cf. solid red and solid blue curves) is now reduced, and an almost constant gap of about 1.5 dB is observed. Therefore, shaping seems to help in reducing the gap relative to SDD. In the figure, we also plot the performance of practical staircase codes with parameters in [7.249, 250], which are in agreement with the behavior predicted by the achievable rates.

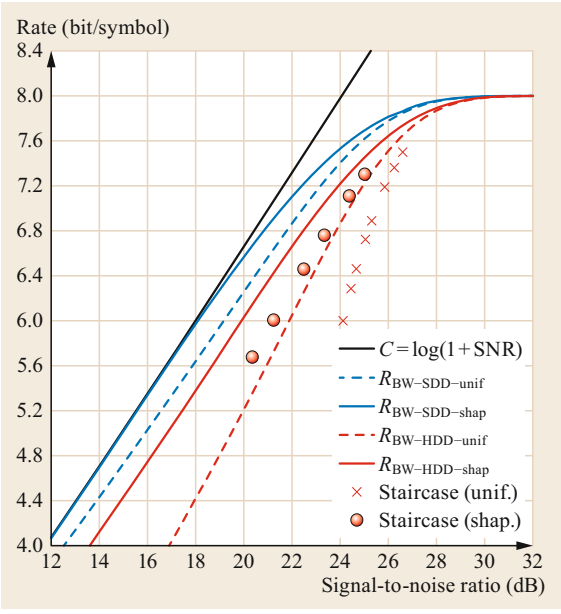

Fig. 7.50 Achievable rates for SDD and HDD with uniform signaling and shaping and performance of a probabilistically shaped CM scheme using staircase codes and comparison with a BICM system using a staircase code and conventional, uniform signaling. 256-QAM, AWGN channel

7.7 Evaluating Forward Error Correction Performance in Transmission Experiments

The design of many optical communication systems often requires the heavy use of transmission experiments to verify models, assumptions, and complete systems. This is largely due to the absence of a rigorous and widely accepted channel model that includes all the effects and impairments of transceivers and optical fibers. Furthermore, in contrast to wireless communications, for example, the fiber-optic communication channel is rather static, enabling relatively easy reproducibility of the experimental results.

Early transmission experiments required specialized hardware such as pattern generators, leading to some constraints on the data to be transmitted. With the absence of ADCs in early optical communication systems, HDD was the dominant decoding method until about 2012 and the advent of commercial systems with SDD [7.252]. Focusing on HDD, a standard solution in system experiments in the 10 and 40 Gbit/s era was to count the bit errors at the receiver (e.g., using a specialized hardware error counter) and to compare this so-called *pre-FEC BER* with the average error-correcting performance of an FEC code with HDD over the BSC. The receiver often consisted of a simple photodiode followed by a high-speed flipflop to sample the photodiode output. This approach assumes that the transmission channel is more or less stationary or is made stationary by a sufficiently large interleaver (to remove, e.g., burst errors). The pre-FEC BER at which the target post-FEC BER was obtained is commonly referred to as the *pre-FEC BER threshold*.

With the advent of ADCs and coherent optical communications, SDD became feasible and quickly became the state-of-the-art decoding scheme in many optical communication systems, especially long-haul and submarine communications. Despite the use of SDD and the absence of a BSC model, the use of a pre-FEC BER threshold was still prevalent in the field for many years. It was first recognized in [7.253] that the pre-FEC BER threshold was not a good performance predictor in systems with differentially detected QPSK followed by an FEC code with SDD. Such systems were dominant in early coherent systems due to a large amount of phase slip from neighboring OOK WDM channels. The authors of [7.253] suggested using a performance prediction threshold that had a better information theoretical foundation and is related to the *achievable rate* of the system (see Sect. 7.2), in that case the MI between code bits and differential detector output.

As coherent optical communication systems matured, and with the introduction of new high-speed digital-to-analog converters (DACs), higher-order modulation formats [7.254], sometimes in combination with probabilistic shaping [7.255], became the state-of-the-art technology for increasing the spectral efficiency of such systems. In transmission experiments, the pre-FEC BER was still often used as threshold despite the fact that the pair $(\mathrm{BER}_{\mathrm{in}}, \mathrm{BER}_{\mathrm{out}})$ does not necessarily fully characterize an FEC code with SDD when the channel, including modulation format, DSP, and quantization, is subject to change. Thus, as previously advocated in [7.253], the authors in [7.256, 257] suggested the use of an information-theoretic measure closely related to the channel and CM scheme utilized. With BICM being the pragmatic choice of CM, this information-theoretic measure is the achievable rate $R_{\mathrm{SDD\text{-}BW}}$ of bit-wise SDD given in (7.8). This quantity is often called GMI, which originates from the theory of mismatched decoding, i.e., the use of a suboptimal decoder [7.87, 88], and is a lower bound of the achievable rate. For BICM, it was shown in [7.97] that the GMI equals the achievable rate $R_{\mathrm{SDD\text{-}BW}}$ ((7.7)–(7.8)). This motivated the authors of [7.256] to refer to $R_{\mathrm{SDD\text{-}BW}}$ as GMI. The term GMI is now ubiquitously used in the field of fiber-optic communications as a proxy for $R_{\mathrm{SDD\text{-}BW}}$. We would like to emphasize here that the GMI is a much broader concept that can be used in a much more general way, and hence we prefer to use the term $R_{\mathrm{SDD\text{-}BW}}$ to denote the achievable rate of BICM.

The authors of [7.256] suggested characterizing a certain FEC code by a pair of achievable rate and output BER $(R_{\mathrm{in}}, \mathrm{BER}_{\mathrm{out}})$ (e.g., $(R_{\mathrm{SDD\text{-}BW}}, \mathrm{BER}_{\mathrm{out}})$), and showed by means of an example based on LDPC codes that this is a fairly good assumption when changing the modulation format but leaving the channel fixed. In [7.258, 259], these results were extended to the case of nonbinary FEC with SDD (i.e., using the pair $(R_{\mathrm{SDD\text{-}SW}}, \mathrm{BER}_{\mathrm{out}})$), another CM scheme that has been promoted for use in fiber-optic communications. At the same time, in [7.259, 260], the use of thresholds as performance predictor in general was questioned, as all threshold-based methods rely on the *universality* of FEC codes, which should be closely checked before employing a threshold-based method.

In this section, we discuss the universality of FEC schemes, introduce the threshold-based performance estimation approach, and discuss the most common thresholds and how to use them in practice. Finally, we show how to best avoid pitfalls of thresholds and how to include FEC in transmission experiments, which gives the most accurate estimates.

7.7.1 Threshold-Based Forward Error Correction Performance Prediction

While thresholds are a perfectly fine tool for predicting the performance of some FEC schemes with HDD (under some stationarity assumptions), the use of FEC schemes with SDD together with varying modulation formats and transmission links requires more caution. This is because SDD relies on knowledge of the probabilistic channel model (Fig. 7.1), which is subject to change in the latter scenarios.

Forward Error Correction Universality

When assessing and comparing the performance of different modulation formats and transmission scenarios (e.g., fiber types, modulators, converters) based on *thresholds*, it is important to understand the concept of FEC *universality*. An FEC code and decoder pair is said to be *universal* if its performance of the code (measured in terms of post-FEC BER or symbol error rate (SER)) does not depend on the channel, provided that the CM scheme is fixed and the achievable rate of the channel is fixed.

When we refer to *the channel*, we consider the whole transmission chain between the FEC encoder output $\boldsymbol{x}$ and the decoder LLR input $\boldsymbol{l}$, including modulation and demodulation, LLR computation, DSP, ADCs and DACs, optical transmission, filtering, and amplification including noise. We say that the channel changes if any of the components in the chain between $\boldsymbol{x}$ and $\boldsymbol{l}$ changes. This can be for instance the noise spectrum or the OSNR, but also the modulation format or the DSP algorithms. However, we assume that the CM scheme (e.g., BICM) is fixed, as it determines the type of threshold to be used.

Unfortunately, not much is known about the universality of practical coding schemes. It is conjectured that many LDPC codes used in practice are approximately universal [7.261], and some LDPC code ensembles (under some relatively mild conditions) have been shown to be universal in the limit of asymptotically large block lengths [7.262]. Guidelines for designing LDPC codes that show good universality properties are highlighted for instance in [7.263]. The class of SC-LDPC codes has also been shown to be asymptotically universal [7.76]. However, the conditions for achieving this asymptotic universality are relatively stringent, and do not allow much to be said about the universality in the non-asymptotic regime, i.e., for finite batch size n_b, finite coupling width w, and finite replication factor L. Polar codes (see Sect. 7.4.3) are examples of *nonuniversal* codes: a polar code needs to be redesigned for every different channel. It is worth pointing out, however, that there exists a modification that renders them universal [7.264]. Unfortunately, the required block length to achieve the same performance becomes considerably larger, limiting the practical application of this scheme.

Although most LDPC codes used in practice are asymptotically universal, we wish to emphasize that practical, finite-length realizations of codes may only be approximately universal. For instance, [7.261, Fig. 3] reveals that the performance of some LDPC codes at a BER of 10^{-4} differs significantly for different channels. This difference is expected to be even larger at very low BERs because of the different slopes of the curves in the waterfall region.

In the following, we define universality of FEC schemes as in [7.263], with the help of Fig. 7.51.

Definition 7.11 FEC Universality

As BICM is ubiquitously used as a CM scheme in fiber-optic communications, we assume BICM and bit-wise SDD. Consider an FEC encoder that generates a codeword consisting of n bits. We transmit these bits over two different communication channels with different (memoryless) channel transition PDFs: channel 1 with PDF $p_{Y_1|X_1}(y_1|x_1)$ and channel 2 with PDF $p_{Y_2|X_2}(y_2|x_2)$. Both channels have *identical* achievable rate $R_{\text{SDD-BW}}$. A fraction γn of the bits is transmitted over channel 1, while the remaining $(1-\gamma)n$ bits are transmitted over channel 2, where $\gamma \in [0, 1]$ such that γn is an integer. We say that a code is *universal* for channels 1 and 2 if the post-FEC BER is independent of γ.

We can extend this definition to i channels (having the same achievable rate) and say that a code is universal if the post-FEC BER is independent of the fraction of bits transmitted per channel and the channels.

In many practical cases, we generally do not experience any issue with universality, as most often the only change made to the channel is a change in the modulation format, while the underlying fiber and noise model

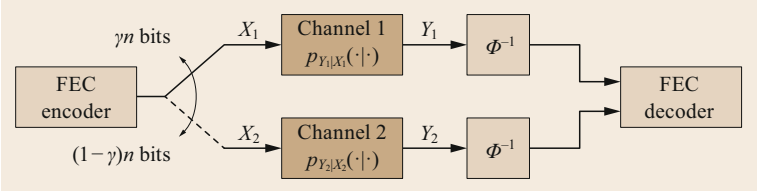

Fig. 7.51 Definition of universality of FEC schemes according to [7.263]. Channels 1 and 2 have the same achievable rate

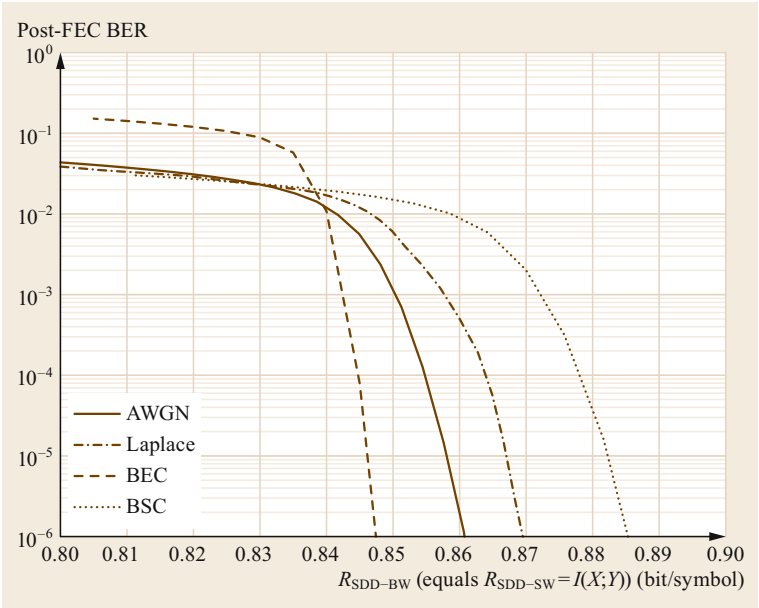

Fig. 7.52 Illustration of the non-universality of an LDPC code with scaled min-sum decoding

remain relatively constant. The common fiber-optic transmission with coherent reception and no in-line dispersion compensation can be accurately modeled as an AWGN channel. In this case, the codes are approximately universal [7.256, 257, 259], and the achievable rate threshold can serve as an accurate prediction. In some cases, however, the changes to the channel can be more drastic. For example, instead of coherent detection, we could use a simple direct detection (DD) scheme that can lead to significantly different noise distributions. On the other hand, the presence of in-line dispersion compensation might lead to significantly different channel statistics that cannot be easily modeled by AWGN.

In [7.259], the impact of a more drastic change in the channel on code universality was shown for the case of CM with nonbinary LDPC codes: a severe quantization was added at the channel output, and the performance (in terms of gap relative to the achievable rate) of the nonbinary LDPC decoder changed significantly in that case. In the following, we illustrate the concept of non-universality of a common FEC code/decoder by means of two different examples.

In the first example, we consider a regular QC-LDPC code of rate $R = 4/5$ with parameters $d_\mathrm{v} = 3$, $d_\mathrm{c} = 15$, $S = 128$, and $n = 38\,400$. We use this code to transmit codewords over four different channels: the previously introduced binary-input AWGN channel, the BSC, the BEC, and the binary-input Laplace channel. The BEC is a channel with binary input $\mathcal{X} = \{0, 1\}$ and ternary output alphabet $\mathcal{Y} = \{0, ?, 1\}$. The channel transition probabilities are $P_{Y|X}(0|0) = 1-\epsilon$, $P_{Y|X}(?|0) = \epsilon$, $P_{Y|X}(1|0) = 0$, and by symmetry, $P_{Y|X}(1|1) = 1-\epsilon$ and $P_{Y|X}(?|1) = \epsilon$. The channel output is either erased (?) with probability ϵ, or equal to the transmitted bit with probability $1-\epsilon$. The binary-input Laplace channel adds noise (per real dimension) according to the Laplacian distribution

$$p_{Y|X}(y|x) = \frac{1}{2b}\exp\left(-\frac{|y-x|}{b}\right) \quad \text{with } b = \frac{1}{2\sqrt{E_\mathrm{s}/N_0}}\,. \tag{7.94}$$

The channel parameters are configured such that all four channels have the same achievable rate $R_{\mathrm{SDD\text{-}BW}}$ (which for this example is equivalent to $R_{\mathrm{SDD\text{-}SW}}$, as the channel input is binary). After transmission over the channel, we compute LLRs using the true respective channel PDF, i.e., the receiver is matched to the channel. We consider a layered decoder employing the scaled min-sum decoding rule ($\alpha = 0.75$) as described in Sect. 7.4.1 with 10 decoding iterations. The simulation results are shown in Fig. 7.52. We observe not only different behavior of the codes, but also different slopes. Because of the different slopes, the difference will be even larger at low BERs. This offset can be attributed to the fact that the LDPC code utilized is not exactly universal and the code length is relatively small, which is an effect that was also observed in [7.261]. Note that if we are allowed to increase the code length and optimize the degree distribution, as highlighted for instance in [7.263], and use the non-simplified CN update rule (instead of the min-sum simplification),

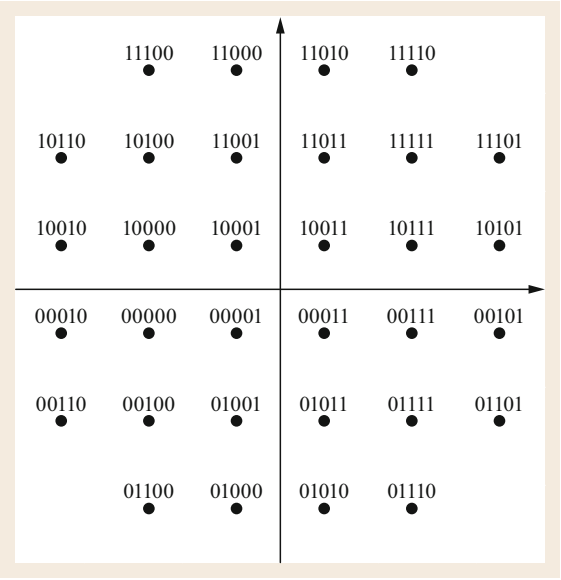

Fig. 7.53 32-QAM constellation with bit mapping maximizing $R_{\text{SDD-BW}}$

the performance prediction becomes more accurate again.

Another example is highlighted in [7.253, Fig. 3], where the authors compare a wide range of different WDM systems consisting of either only coherent 100 Gbit/s channels, or of a mix between coherent and OOK channels. Different fiber types are also used. It is shown that the achievable rate (in that case $R_{\text{SDD-SW}}$) serves as a better predictor than the pre-FEC BER, but itself also fails to accurately predict the performance due to changing channel characteristics. We illustrate the lack of universality with another example [7.260]. In this example, we use BICM together with five different constellations: QPSK, 8-QAM (as in [7.259, Fig. 3, C_3]), 16-QAM, 32-QAM (with the optimized bit labeling shown in Fig. 7.53), and 64-QAM. We consider transmission over both the AWGN and the Laplace channels using the same code as for the example in Fig. 7.52, and at the receiver employ scaled min-sum decoding ($\alpha = 0.75$) with 10 decoding iterations. The results in terms of normalized $R_{\text{SDD-BW}}/m$ are shown in Fig. 7.54. We can clearly see that even in the case of an AWGN channel, the GMI is only an approximately good threshold of the performance, but if the channel law changes (e.g., a Laplace channel is used), the thresholding effect is compromised, and a significantly higher value of $R_{\text{SDD-BW}}$ is required for decoding. This could lead to significantly misleading conclusions, e.g., in terms of reach prediction.

We hence conclude that performance predictors based on the achievable rate should be used with caution. They can still give rough first-order estimates of the decoding performance, even if we introduce drastic changes into the channel (e.g., a strong quantization, moving from dispersion-uncompensated to dispersion-compensated links, or even from coherent transmission to direct detection systems). Thresholds should therefore be used only to quickly assess the performance and to determine the range of fine measurements. We can improve the accuracy if the channel used to compute the threshold is fairly close to the actual channel of the

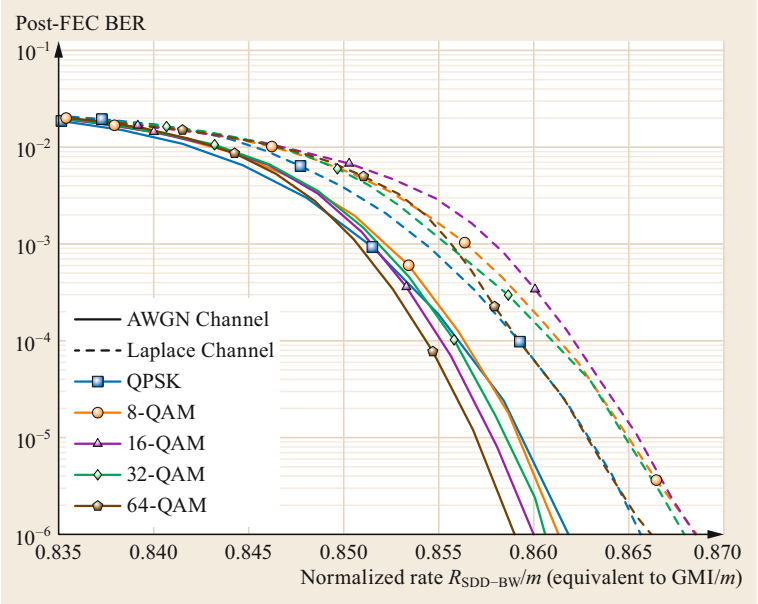

Fig. 7.54 Illustration of the non-universality with different modulation formats and BICM

system. However, in all cases, actual decoding mimicking as closely as possible the true FEC should be used.

Summary of Performance Prediction Thresholds and Usage Guidelines

In this section, we present some of the thresholds that are commonly used today, provide guidelines for their usage, and discuss some potential pitfalls. We assume that a transmission experiment has been carried out and that for a particular setup, we have a measurement consisting of N_M data points (x_κ, y_κ) that are given as the original transmit sequence $x_\kappa \in \mathbb{C}$ and the corresponding received sequence $y_\kappa \in \mathbb{C}$, both consisting of complex modulation symbols. To keep exposition simple, we do not consider 4-D constellation symbols (e.g., dual-polarization modulation formats), but assume an independent treatment of both polarizations. The computation of the achievable rate for 4-D constellations has been addressed in [7.265]. We further assume that both sequences are aligned and that eventual phase jumps have been taken care of (e.g., using pilot symbols). The sequence recovery can be performed either by cross-correlating some or all of the received symbols with the transmit symbols or, if a pseudo-random binary sequence (PRBS) is transmitted, by utilizing a simple PRBS synchronization algorithm.

Pre-FEC SER. The pre-FEC SER is perhaps the easiest to compute directly from the experimental measurement database. First, we require a demodulation function. Often, when the channel is Gaussian-like, the nearest-neighbor demodulator (also called Euclidean distance demodulator) is used. The nearest-neighbor demodulator computes estimates of the transmit sequence as

$$\hat{x}_\kappa = \arg\min_{s\in\mathcal{X}} \|y_\kappa - s\|^2 \,. \tag{7.95}$$

Note that the Euclidean distance rule is only optimal for Gaussian noise and should be modified accordingly if the channel behaves differently (e.g., when strong phase noise is present). Using the estimated symbol sequence $\hat{\boldsymbol{x}}$, the pre-FER SER is estimated as

$$\mathrm{SER}_{\mathrm{pre}} = \frac{1}{N_M} \sum_{\kappa=1}^{N_M} \mathbb{1}_{\{\hat{x}_\kappa \neq x_\kappa\}} \,. \tag{7.96}$$

The Pre-FEC SER should be used only as a threshold in particular cases, e.g., when symbol-wise HDD is used and the constellation size is matched to the symbol size of the code. In this case, for a fixed constellation size M, the achievable rate $R_{\text{HDD-SW}}$ given by (7.15) is directly linked to the symbol error probability (therein denoted δ), to which the SER converges as $N_M \to \infty$, and has no further dependence on the modulation format (except its size M).

Pre-FEC BER. The pre-FEC BER was once the most widespread threshold function and still is for FEC schemes with bit-wise HDD. Unfortunately, in many experimental publications, it is not explicitly stated how the pre-FEC BER is computed. Especially if higher-order constellations are used, different computation rules can lead to (slightly) different results.

The computation of the pre-FEC BER is only marginally more complicated than the computation of the pre-FEC SER. Possibly the easiest method is to start from the estimated symbols $\hat{x}_\kappa$, computed using (7.95), and to use these to recover the bit patterns by applying the binary labeling function $\mathsf{L}(\hat{x}_\kappa)$, assuming *implicitly* the use of BICM as CM technique. We denote by $\mathsf{L}(\hat{x}_\kappa) = (\hat{b}_\kappa^{(1)}, \ldots, \hat{b}_\kappa^{(m)})$ the bits that are assigned to the modulation symbol $\hat{x}_\kappa$, and similarly, we denote by $\mathsf{L}(x_\kappa) = (b_\kappa^{(1)}, \ldots, b_\kappa^{(m)})$ the transmit bits associated with x_κ. The pre-FEC BER $\mathrm{BER}_{\mathrm{pre}}$ is then given by

$$\mathrm{BER}_{\mathrm{pre}} = \frac{1}{mN_M} \sum_{\kappa=1}^{N_M} \sum_{i=1}^{m} \mathbb{1}_{\{b_\kappa^{(i)} \neq \hat{b}_\kappa^{(i)}\}} \,. \tag{7.97}$$

An alternative method for computing the pre-FEC BER is to compare the sign of the LLR $l_\kappa^{(i)}$ given by the bit-wise demodulator Φ^{-1} with the transmit bit sequence. The two approaches lead to different results. However, for most practical cases and constellations, the differences are negligible.

The pre-FEC BER should be used *only* if bit-wise HDD is utilized and the channel is sufficiently interleaved to remove all burst errors. In this case, the achievable rate $R_{\text{HDD-BW}}$ is directly linked to the average bit error probability (therein denoted $\bar{\epsilon}$), of which the pre-FEC BER is an estimate. The pre-FEC BER threshold can be used in some circumstances with SDD, but only if the FEC that is evaluated has been thoroughly simulated with a model that is sufficiently close to the experimental setup (e.g., using the same modulation format, quantization, fiber model, neighboring channel setup). Only in this case is the use of pre-FEC BER legitimate. Given the effort required to set up such an involved simulation, it may be easier to include the FEC code directly in the experiment.

Generalized Mutual Information. In the field of fiber-optic communications, the use of the GMI as decoding threshold has become dominant in the recent years. We would like to point out again that the notion of GMI is a much broader concept, introduced as

a bound on the achievable rate for mismatched decoding [7.87, 88]. In the case of BICM, the GMI equals the achievable rate $R_{\text{SDD-BW}}$. Hence, the term GMI is often used in a somewhat inaccurate way, interchangeably with the achievable rate of BICM.

For computing the GMI, we assume that all constellation symbols are equiprobable. There are multiple ways to compute the GMI [7.266]. We give here the one that we believe is easiest. In a first step, we use the bit-wise demodulator Φ^{-1} given by (7.93) to compute m LLRs per received symbol, i.e., $\Phi^{-1}(y_\kappa) = (l_\kappa^{(1)}, \ldots, l_\kappa^{(m)})$. Similarly, we compute the corresponding bit patterns of the transmit sequence using $\mathsf{L}(x_\kappa) = (b_\kappa^{(1)}, \ldots, b_\kappa^{(m)})$. The *bit-wise* GMI threshold can then be computed directly from the LLRs as

$$\text{GMI}_{\text{SDD-BW}} = \underbrace{\log_2 |\mathcal{X}|}_{=m} - \frac{1}{N_M} \inf_{s\geq 0} \sum_{i=1}^{m} \sum_{\kappa=1}^{N_m} \log_2\left(1 + \mathrm{e}^{s(-1)^{b_\kappa^{(i)}} l_\kappa^{(i)}}\right). \tag{7.98}$$

The computation includes a minimization (inf) over the variable $s \geq 0$. When the computation of the LLRs (7.93) is carried out using *exactly* the same channel PDF $p_{Y_i|B_i^{(j)}}(y_i|b_i^{(j)})$ that was used for transmission (e.g., in a simulation), the minimum is obtained for $s = 1$, and the minimization does not need to be carried out. In any other case, due to the unimodality of the objective function, the minimization can be easily carried out using, for example, the golden section search or built-in minimization functions of numerical software packages (e.g., `fminbnd` of MATLAB®).

The threshold $\text{GMI}_{\text{SDD-BW}}$ is an estimate of the achievable rate $R_{\text{SDD-BW}}$ and hence should be used *only* for FEC with bit-wise SDD (i.e., in the case of BICM) and if there is sufficient evidence that the code is approximately *universal* or, alternatively, if the GMI threshold of the code has been determined in a simulation mimicking sufficiently closely the transmission experiment, such that the code's lack of universality does not cause a difference.

PAS has recently become an attractive solution for realizing probabilistic constellation shaping and has found widespread use in optical communications. PAS is not a BICM scheme, but still uses a bit-wise demodulator Φ^{-1} that computes LLRs according to

$$l_i^{(j)} \triangleq \log\left(\frac{\sum_{x\in\mathcal{X}_0^{(j)}} p_{Y_i|\mathsf{X}_i}(y_i|x)P_X(x)}{\sum_{x\in\mathcal{X}_1^{(j)}} p_{Y_i|\mathsf{X}_i}(y_i|x)P_X(x)}\right), \tag{7.99}$$

with $P_X(x)$ being the prior distribution of using constellation symbol x. Applying the LLR $l_i^{(j)}$ given in (7.99) in (7.98) yields a value that we denote as $\bar{R}_{\text{SDD-BW}}$ and that was used in [7.267, Eq. (6)] to compute the so-called normalized generalized mutual information (NGMI), which has been shown to serve as a relatively accurate performance threshold. Note, however, that the NGMI should not be confused with the notion of GMI (despite the similarity in the name). For details regarding achievable rates of PAS, we refer the interested reader to [7.91].

Mutual Information. The estimation of the MI threshold $\text{MI}_{\text{SDD-SW}}$ can be subdivided into two steps. In a first step, we estimate the actual channel PDF $p_{Y|X}(y|x)$ as closely as possible neglecting potential memory effects. We denote the estimated channel PDF by $q_{Y|X}(y|x)$. The PDF can be modeled using kernel density estimators, histograms, and piecewise approximations, or using Gaussian mixture models (GMMs). In the latter case, using g mixtures, for every constellation symbol $\mathsf{X}_i \in \mathcal{X}$, the estimate is written as

$$q_{Y|X}(y|X = \mathsf{X}_i) = \sum_{j=1}^{g} w_{i,j} \mathcal{CN}(\mu_{i,j}, \sigma_{i,j}^2),$$
$$\text{with } \mathcal{CN}(\mu, \sigma^2) = \frac{1}{\pi\sigma^2} \exp\left(-\frac{\|y-\mu\|^2}{\sigma^2}\right), \tag{7.100}$$

i.e., $\mathcal{CN}(\mu, \sigma^2)$ is the complex, circularly symmetric Gaussian PDF with (complex) mean μ and variance σ^2. The PDF $q_{Y|X}$ is parameterized by Mg 4-tuples $(w_{i,j}, \text{Re}\{\mu_{i,j}\}, \text{Im}\{\mu_{i,j}\}, \sigma_{i,j}^2)$ that need to be estimated from the measurement. The $4Mg$ parameters of the model can be estimated for instance using the expectation-maximization (EM) algorithm or built-in estimators of numerical computing environments (e.g., `fitgmdist` of MATLAB®). The MI threshold can then be estimated in a similar way as the GMI

$$\text{MI}_{\text{SDD-SW}} = \frac{1}{N_m} \sup_{s\geq 0} \sum_{\kappa=1}^{N_m} \log_2\left(\frac{M\left[q_{Y|X}(y_\kappa|x_\kappa)\right]^s}{\sum_{x'\in\mathcal{X}}\left[q_{Y|X}(y_\kappa|x')\right]^s}\right). \tag{7.101}$$

The computation includes a maximization (sup) over the variable $s \geq 0$, which can be easily carried out due to the unimodality of the objective function. If $q_{Y|X}(y|x)$ matches the true channel PDF $p_{Y|X}(y|x)$, the maximum is obtained for $s = 1$.

Often, especially in dispersion-uncompensated coherent fiber-optic communications, the GMM is not necessary, and a 2-D Gaussian PDF approximates the

true channel PDF sufficiently well as predicted by the GN model [7.99, 100] and its extensions. Such a 2-D Gaussian PDF yields good estimates of the MI, neglecting any cross-polarization and memory effects. In some circumstances, a 4-D Gaussian PDF can also be used [7.259, 265]. In optical receivers, it is usually not feasible to implement the GMM of the noise, and a complex circularly symmetric Gaussian PDF is usually used as a simple estimate of the true PDF. In this case, we can use a GMI-like argument to compute the threshold

$$\mathrm{MI}_{\text{SDD-SW}} = \frac{1}{N_m} \sup_{s\geq 0} \sum_{\kappa=1}^{N_m} \log_2 \left(\frac{M \exp(-s\|y_\kappa - x_\kappa\|^2)}{\sum_{x'\in\mathcal{X}} \exp(-s\|y_\kappa - x'\|^2)} \right). \tag{7.102}$$

Note that the maximization (sup) over s implicitly estimates the variance of the Gaussian PDF as $\sigma^2 = s_{\max}^{-1}$ [7.259, Example 2].

The MI threshold $\mathrm{MI}_{\text{SDD-SW}}$, which approximates $R_{\text{SDD-SW}}$, should be used only in cases where $R_{\text{SDD-SW}}$ is actually an achievable rate of the transmission system. This includes the use of nonbinary codes, e.g., nonbinary LDPC codes matched to the modulation format as CM scheme, with SDD. The MI threshold can also be used when multilevel coding with multistage decoding is employed as CM scheme. However, the latter is an example of a nonuniversal CM scheme.

Note that in many cases, the values of $\mathrm{MI}_{\text{SDD-SW}}$ and $\mathrm{GMI}_{\text{SDD-BW}}$ are relatively close (e.g., BICM with square QAM constellations and Gray coding, and PAS [7.255]). In these cases, the GMI threshold $\mathrm{GMI}_{\text{SDD-BW}}$ can be replaced by $\mathrm{MI}_{\text{SDD-SW}}$ without losing too much accuracy. This has advantages, as the MI is often easier to compute in the experiment. Computing the MI does not require the implementation of a bit-wise demapper, nor does it need the definition of a bit mapping. The MI can be directly computed from the complex samples at the output of the transmission experiments. In [7.268], MI and GMI thresholds were compared for a field system based on PAS, and were found to be very close.

7.7.2 Implementing Forward Error Correction in Experiments

In view of the pitfalls inherent in the use of thresholds, especially when there is uncertainty as to the universality of the FEC and CM scheme used, we suggest including FEC in the transmission experiments. In particular, the use of offline DSP in modern transmission experiments facilitates the inclusion of at least a basic offline FEC decoding in the evaluation phase of the experiments. This is additionally made easy by the availability, for example, of integrated LDPC encoding and decoding routines in common computational software such as MATLAB®. Essentially, there are two main possibilities for including FEC with actual decoding in transmission experiments, which we discuss in the following.

Implementing Complete Encoding and Decoding

The closest approximation to the true system performance is achieved by implementing the complete physical layer including FEC encoding and decoding. For this, we use an encoder that generates codewords $\boldsymbol{c}$ (for instance using random information words $\boldsymbol{u}$) which are then fed to the transmitter. After reception, DSP is carried out, and following frame alignment, decoding can be performed. The recovered information words can be compared with the original information words to estimate the post-FEC BER. While this approach should be used whenever possible, it has some drawbacks:

- In some transmission experiments, no programmable DAC is available, and the transmit sequence cannot be freely chosen, but is fixed and limited to some PRBS. In other cases, the memory depth of the DAC may be limited, such that a whole codeword cannot fit into the memory (especially if long SC-LDPC codes with large replication factor L are chosen).
- It is often possible that the code design will not yet be completed when transmission experiments are carried out, and the code designers would like to use the results of the transmission experiment to estimate channel characteristics in order to best adapt their code to the channel. This chicken-and-egg problem requires other approaches.

In both cases, we need to decouple the transmission experiment from the evaluation of the FEC performance. This is highlighted in what follows.

Implementing Decoding Using a Database of Measurements

In [7.269], the authors suggested reusing a database of measurements to evaluate the performance of multiple FEC schemes. Essentially the same method was later proposed in [7.270], which however requires a modification of the decoder and introduces some extra interleaving to enlarge the set of sequences, neglecting possible memory effects.

In the following, we describe the method reported in [7.269] that integrates the evaluation of FEC into the

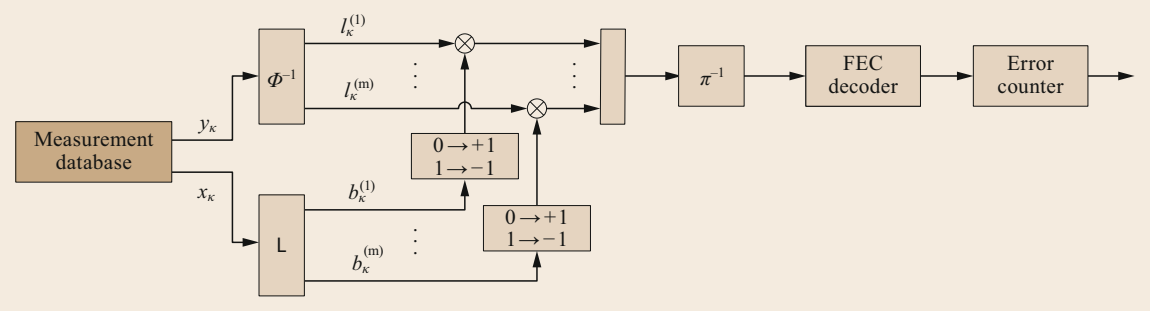

Fig. 7.55 Evaluating FEC performance from measurements for a BICM-based CM system

receiver processing chain in order to evaluate the performance of different codes. This method is based on the fact that the post-FEC BER performance of most practically employed FEC codes and, most importantly, their decoders, does *not* depend on the transmitted codeword, but only on the noise pattern. This property holds for LDPC and SC-LDPC codes together with the decoders that we introduced in Sect. 7.4 (see [7.111, Chap. 4] for a detailed discussion).

Our method is based on channel adapters introduced in [7.271] for analyzing CM schemes. In order to devise a strategy for performance assessment, we assume that the coding scheme to be tested generates one (or several) valid codewords. For simplicity, if linear codes are used, we can use the all-zero codeword $\boldsymbol{c} = (0, 0, \ldots, 0)$, which belongs to any linear code.

We explain the method for the case with BICM as CM scheme, but we stress that the method can be easily extended to other CM schemes (e.g., PAS) as well. The method is illustrated in Fig. 7.55. The first step of the method consists in generating an equivalent bitstream of length mN_M corresponding to the transmit sequence from the experimental database by

$$\begin{aligned} &\boldsymbol{b} = (\boldsymbol{b}_1, \boldsymbol{b}_2, \ldots, \boldsymbol{b}_{N_M}), \\ &\quad \text{with } \boldsymbol{b}_\kappa = (b_\kappa^{(1)}, \ldots, b_\kappa^{(m)}) = \mathsf{L}(x_\kappa)\,. \end{aligned} \tag{7.103}$$

Similarly, we compute a sequence of LLRs for the received samples y_k,

$$\begin{aligned} &\boldsymbol{l} = (\boldsymbol{l}_1, \boldsymbol{l}_2, \ldots, \boldsymbol{l}_{N_M}), \\ &\quad \text{with } \boldsymbol{l}_\kappa = (l_\kappa^{(1)}, \ldots, l_\kappa^{(m)}) = \Phi^{-1}(y_\kappa)\,. \end{aligned} \tag{7.104}$$

Using both sequences, we generate a set of equivalent LLRs, corresponding to the transmission of the all-zero codeword as

$$\begin{aligned} \tilde{\boldsymbol{l}} &= (\tilde{\boldsymbol{l}}_1, \ldots, \tilde{\boldsymbol{l}}_{N_M}) \\ &\quad \text{with } \tilde{\boldsymbol{l}}_\kappa = \left(\tilde{l}_\kappa^{(1)}, \ldots, \tilde{l}_\kappa^{(m)}\right) \\ &\qquad = \left((-1)^{b_\kappa^{(1)}} l_\kappa^{(1)}, \ldots, (-1)^{b_\kappa^{(m)}} \tilde{l}_\kappa^{(m)}\right). \end{aligned} \tag{7.105}$$

This approach corresponds to transmitting the all-zero codeword $\boldsymbol{c}$, which is scrambled using a (time-varying, data-dependent) binary scrambler. This scrambler generates, by modulo-2 addition (i.e., XOR) of a scrambling sequence, the desired transmit bit sequence $\boldsymbol{b}$. This sequence corresponds to the sequence which, after modulation, yields the transmitted symbol sequence used in the experiment.

The sequence $\tilde{\boldsymbol{l}} = (\tilde{l}_1, \ldots, \tilde{l}_{mN_M})$ now consists of mN_M LLRs that can be fed to an FEC decoder. If $mN_M \gg n$, with n being the codeword length, we can partition the sequence $\tilde{\boldsymbol{l}}$ into subsequences of length n, by selecting $\tilde{n} \triangleq \lceil n/m \rceil$ consecutive vectors $\tilde{\boldsymbol{l}}_i$ and permuting the resulting sequence of LLRs with a de-interleaver π^{-1}. Note that in BICM with LDPC codes, interleaving is sometimes not explicitly carried out but assumed to be implicitly part of the code. However, when QC-LDPC codes are used, care must be taken, and we advise the reader to always explicitly carry out interleaving. The de-interleaved vectors are then fed into the FEC decoder, $f_{\text{FEC,dec}}$, which outputs a binary sequence corresponding to the estimated codeword $\hat{\boldsymbol{c}}$. The post-FEC BER BER_{post} is then obtained by counting the errors after decoding a sufficiently large number of such frames.

Often, the number of possible measurements is not large enough to obtain sufficiently accurate post-FEC BER estimates. In this case, we can extend the estimation using the interleaver method proposed in [7.270]. However, note that this method assumes that at the receiver, long interleaving across multiple codewords is carried out, breaking all correlation between neighboring symbols that arise due to the interplay of chromatic dispersion and fiber nonlinearities. Such a long interleaving will mask any nonstationary effects and may thus lead to overly optimistic performance estimates. Short burst errors, which can be caused for instance by DSP algorithms that cannot track phase or polarization changes during transmission, and cause uncorrectable blocks (UCBs), will not be captured by such an approach. Our advice is therefore to record sufficiently

long sequences and treat the sequences like a continuous bitstream.

7.7.3 Performance Example

To experimentally verify the proposed method, we consider a system using 8-QAM together with BICM. We reuse the measurement database that was used in [7.259] to evaluate nonbinary LDPC codes. We use two 8-QAM constellations $\mathcal{X}_1$ and $\mathcal{X}_2$, shown in Fig. 7.56b and c, together with the bit labeling that maximizes the GMI [7.272]. For illustration purposes, we use three quasi-cyclic regular LDPC codes with rates 0.8, 0.85, and 0.9 (corresponding to FEC overheads of $\approx 25\%$, 18%, and 11%, respectively) with VN degree $d_v = 3$, CN degree $d_c \in \{15, 20, 30\}$, and lifting factor $S = 128$. Each code has length $n = 38\,400$, i.e., 12 800 8-QAM symbols are always mapped to one LDPC codeword. Decoding takes place using $I = 10$ iterations with a layered scaled min-sum decoder ($\alpha = 0.75$). We first test the performance of the three LDPC codes in an AWGN channel. To this end, we first calculate $R_{\text{SDD-BW}}$ for the two constellations $\mathcal{X}_1$ and $\mathcal{X}_2$ as a function of E_s/N_0. This is achieved, for example, by applying the estimator given in (7.98) to the results of a simulation over an AWGN channel.

In Fig. 7.56a, we show the post-FEC BER as a function of $R_{\text{SDD-BW}}$. Changing the constellation for a given code can be interpreted as changing the equivalent channel. We see that the codes act approximately universally, and their performance only marginally depends on the chosen constellation. For a post-FEC BER of 10^{-4} (horizontal line), we find the equivalent achievable rate thresholds T_R for each rate.

To validate the AWGN results in Fig. 7.56a, we now consider a coherent fiber-optic communication system based on dual-polarization transmission at a symbol rate of 41.6 Gbaud. First, symbol sequences corresponding to constellation $\mathcal{X}_1$ are generated and tested using a high-speed DAC in a back-to-back configuration. A root-raised cosine pulse shaping signal (roll-off factor 0.1) is generated as described in [7.272], and two code rates ($R = 0.8$ and $R = 0.85$) are chosen, giving net data rates of approximately 200 and 212 Gbit/s, respectively.

The empirical achievable rate estimates $\text{GMI}_{\text{SDD-BW}}$, computed using (7.98), are shown as a function of the OSNR in Fig. 7.57a. We also show the GMI thresholds $T_{0.8} = 2.57$ and $T_{0.85} = 2.69$. These thresholds are then used to determine equivalent OSNR thresholds (vertical lines). The measured data are then used to perform LDPC code decoding using the method described in Sect. 7.7.2. The obtained results are shown in Fig. 7.57b by solid markers. Additionally, from the estimated achievable rate values, we interpolate the estimated post-FEC BER values using the AWGN simulation results from Fig. 7.56a, which are given by the thin dotted lines. We observe an agreement between the predicted post-FEC BER and actual post-FEC BER. However, we also note that the performance of the actual decoding deviates from the prediction, especially at low error rates. This is mostly due to some non-stationarity of the measurements, with some frames that are more affected by the noise than others and cannot be reliably decoded.

In order to show that the proposed method also works for a transmission over a link, we apply the method to a transmission experiment using both constellations

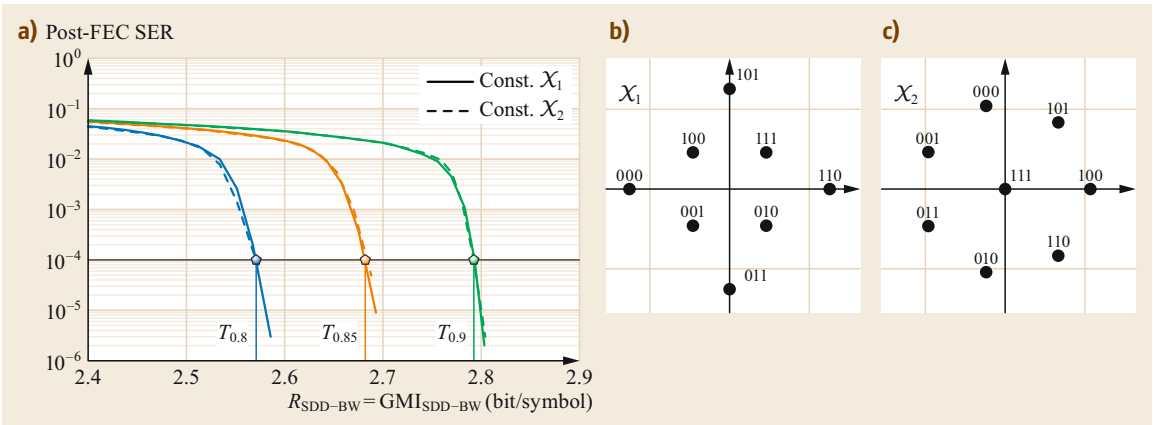

Fig. 7.56a–c AWGN simulation results of regular LDPC codes of rates $R \in \{0.8, 0.85, 0.9\}$ with $d_v = 3$ and $d_c \in \{15, 20, 30\}$ with layered normalized min-sum decoding ($\alpha = 0.75$) and $I = 10$ decoding iterations **(a)**. X_1 and X_2 over a recirculating loop, described in detail in [7.273]. We recapitulate the experimental setup in the following. The transmission testbed consists of one narrow-linewidth laser under test at 1545.72 nm, and additionally 63 loading channels spaced by 50 GHz. The output of the laser under test is sent into a dual-polarization I/Q modulator driven by a pair of DACs operating at 65 Gsamples/s. Multiple delayed-decorrelated sequences of 2^{15} bits are used to generate the multilevel drive signals. Pilot symbols and a sequence for frame synchronization are additionally inserted.

The symbol sequences are oversampled by a factor of ≈ 1.56 and pulse-shaped by a root-raised cosine function with roll-off of 0.1. The load channels are separated into odd and even sets of channels and modulated independently with the same constellation as the channel under test using separate I/Q modulators. Odd and even sets are then polarization-multiplexed by dividing, decorrelating, and recombining through a polarization beam combiner with an approximate delay of 10 ns. The test channel and the loading channels are passed into separate low-speed (< 10 Hz) polarization scramblers and spectrally combined through a wavelength-selective switch (WSS). The resulting multiplex is boosted through a single-stage EDFA and sent into the recirculating loop. The loop consists of four 100 km-long dispersion-uncompensated spans of standard single-mode fiber with hybrid Raman–EDFA optical repeaters to compensate for the fiber loss. The Raman pre-amplifier is designed to provide ≈ 10 dB on–off gain. Loop-synchronous polarization scrambling is used, and power equalization is performed by a 50 GHz-grid WSS inserted at the end of the loop.

At the receiver side, the channel under test is selected by a tunable filter and sent into a dual-polarization coherent receiver feeding four balanced photodiodes. Their electrical signals are sampled at 80 Gsamples/s by a real-time digital oscilloscope with 33 GHz electrical bandwidth. For each measurement, five different sets of 20 µs are stored. The received samples are processed offline by a DSP, including chromatic dispersion compensation, polarization demultiplexing by a 25 tap $T/2$ spaced butterfly equalizer with blind adaptation based on a multi-modulus algorithm, frequency recovery using the fourth and seventh power (depending on the constellation) periodogram, and phase recovery using the blind phase search algorithm. In the latter, equally spaced test phases in the interval $[-\pi/4; \pi/4]$ (constellation X_1) or in the interval $[-\pi/7; \pi/7]$ (constellation X_2) are used with correspondingly modified phase unwrapping.

We consider transmission over a distance of 3200 km, corresponding to eight round trips in the recirculating loop. Figure 7.58a shows the estimated $\mathrm{GMI}_{\mathrm{SDD\text{-}BW}}$ as a function of the input power P_{in} per WDM channel [7.273, Fig. 3a]. Additionally, we show the achievable rate thresholds T_R for $R \in \{0.8, 0.85, 0.9\}$. The thresholds give us the region of launch powers at which reliable transmission is possible. To be precise, whenever the estimated achievable rate lies above the threshold T_R, it means that transmission with a post-FEC BER below 10^{-4} is possible. For example, consider the horizontal line in Fig. 7.58a corresponding to $T_{0.9}$. We can see that with constellation X_2, we are just barely above the line for $P_{\mathrm{in}} \in \{-2\,\mathrm{dBm}, -1\,\mathrm{dBm}\}$, which means that decoding is also

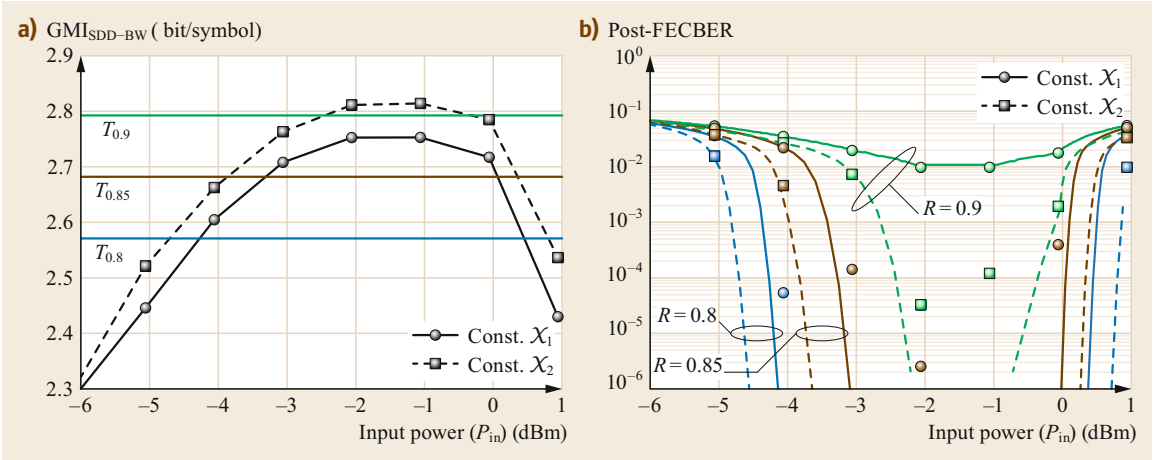

Fig. 7.58a,b Transmission results. Estimated GMI$_{SDD-BW}$ for two constellations $\mathcal{X}_1$ and $\mathcal{X}_2$ together with thresholds to achieve a post-FEC BER of 10^{-4} with LDPC codes ($d_v = 3$, $d_c \in \{15, 20, 30\}$, rates $R \in \{0.8, 0.85, 0.9\}$) with layered scaled-min-sum decoding ($\alpha = 0.75$) **(a)** and interpolated post-FEC BER (from AWGN simulations with the same setup as in Fig. 7.54) together with actual decoding given by markers **(b)**

only barely possible. Contrarily, with constellation $\mathcal{X}_1$, we do not cross the line, and reliable decoding is not possible.

In Fig. 7.58b, we use the simulation results of Fig. 7.56a to estimate the post-FEC performance of the transmission system by interpolation. The interpolated curves are given by the solid (constellation $\mathcal{X}_1$) and dash-dotted (constellation $\mathcal{X}_2$) lines. Additionally, we carried out actual decoding using the LDPC codes introduced before and the method of Sect. 7.7.2. The post-FEC BER results after decoding are given by the solid markers in the figure. We can see that the estimates from interpolation match the actual decoding performance, especially for high BERs. However, we see a deviation at low BERs around 10^{-4}, which is caused by non-stationarity in the measurements. For instance, at P_{in} of -1 dB, a burst caused by the DSP not following the polarization rotation quickly enough occured. The average GMI$_{SDD-BW}$ was still below the threshold. However, the burst causes a frame that cannot be decoded by the LDPC decoder and hence yields a post-FEC BER above 10^{-4}.

7.8 Conclusion and Outlook

A vast body of research on FEC exists today, spanning over seven decades. For most of the classical communication channels, coding schemes that asymptotically achieve the theoretical capacity limits are already available. There also exist very powerful coding schemes that yield excellent performance for short block lengths. Surprisingly, however, despite being a relatively old field, and notwithstanding the enormous successes achieved over the past decades, coding is still a very vibrant research topic. One of the main reasons is that it transcends the classical transmission problem. Today, coding plays a crucial role in myriad applications, from distributed storage, caching and computing, to privacy and post-quantum cryptography. We are convinced that coding will continue to be an indispensable tool for future applications, many of which we cannot even envisage, and expertise and frontline research in this area will certainly be necessary.

For the classical data transmission problem, while most of the major theoretical breakthroughs and code constructions are probably behind us, there are still important open challenges to be addressed. This is particularly true in the area of optical communications, which poses severe constraints in terms of complexity, throughput, and power consumption. For example, finding the best scheme yielding the highest coding gains under heavy complexity constraints, and having a highly parallelizable, efficient decoder hardware architecture enabling high data throughput, remains a very challenging engineering task.

Future research on FEC for optical communications will likely focus on low-complexity coding schemes and

[a] Extrapolated from software verification down to 10^{-12}
[b] Extrapolated from FPGA verification down to 10^{-13}
[c] Extrapolated from FPGA verification down to 10^{-14}
[d] The LDPC super FEC allows lower latency due to lower block length than other codes for HDD defined in [7.46] at a cost of a lower NCG
[e] The extra NCG compared with staircase codes is mostly due to the use of an improved decoding algorithm, which however doubles the memory usage. Without this algorithm, the NCG is similar to that of staircase codes
[f] Extrapolated from software verification. System overhead larger due to extra required stuffing bits
[g] Performance evaluated only for a simplified SDD with 4-level channel output quantization
[h] Concatenated Hamming code and staircase code, optimized for SDD with low power consumption
[i] Outer code not implemented and assuming ideal interleaving between inner and outer code

decoding algorithms that allow us to approach capacity limits, and we believe that the most interesting contributions will lie in this area. Two promising research lines in this direction are soft-aided decoding algorithms for product-like codes [7.223, 224] (see also Sect. 7.5.8) and hybrid HDD/SDD schemes, where an outer hard-decision FEC (a staircase code) is concatenated with an inner soft-decision FEC (typically a low-density parity-check code) [7.221, 222]. The latter schemes are now emerging in standards for low-complexity short-reach optical communications [7.280].

To conclude the chapter, we present to the reader an overview of some state-of-the-art FEC schemes that have been proposed for use in optical communications and whose error rate performance has been evaluated down to a BER of 10^{-15} or extrapolated from a reasonably close value. In Table 7.5, we provide a selection of popular and recently proposed FEC schemes for both HDD and SDD. Besides the achievable NCG, we also provide the pre-FEC BER threshold, $\mathrm{BER_{pre}}$, and the GMI threshold, $\mathrm{GMI_{SDD\text{-}BW}}$, if SDD is employed. In the case of SDD, $\mathrm{BER_{pre}}$ is computed assuming BPSK modulation over the AWGN channel. However, we would like to point out (see also Sect. 7.7) that it is not necessarily a good metric for performance estimation, which is why it is given in gray font. The achievable NCGs of the schemes from Table 7.5 are also visualized in Fig. 7.59.

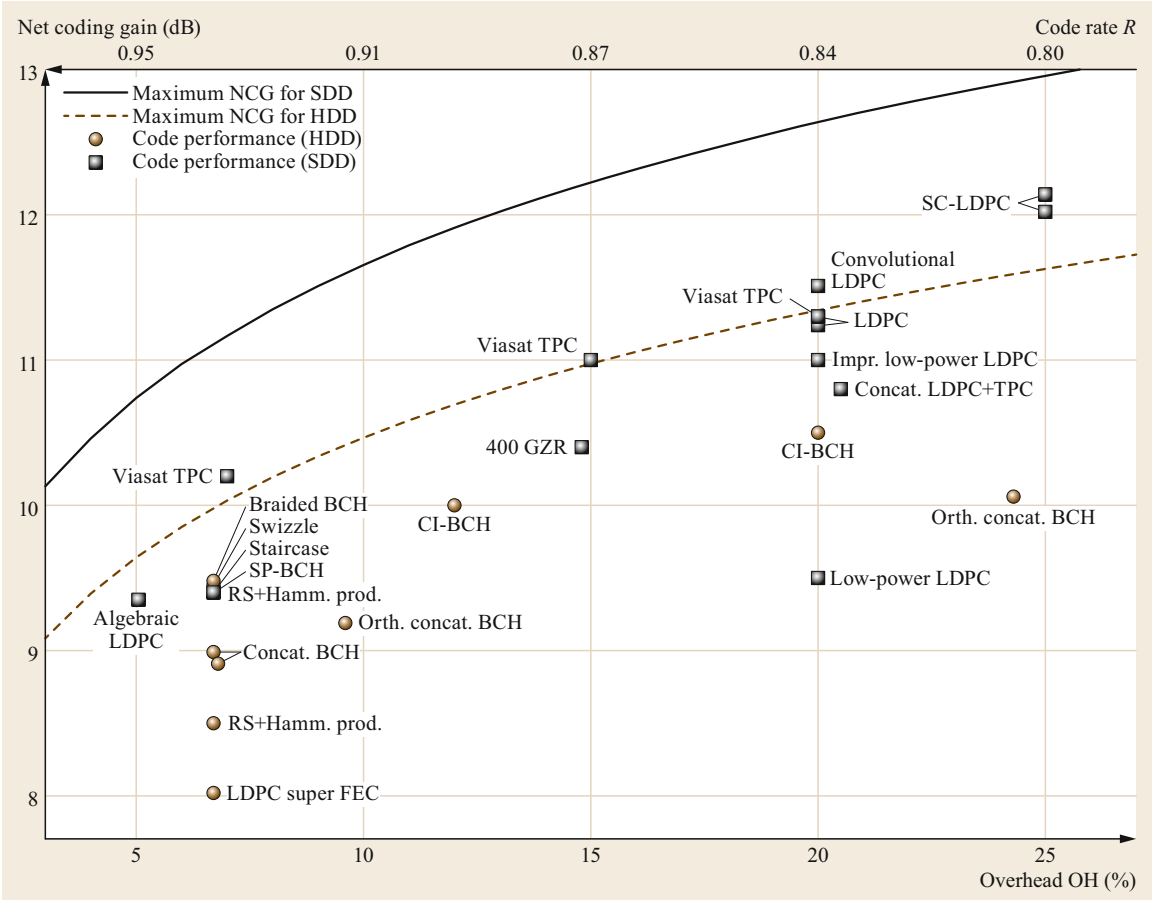

Fig. 7.59 Illustration of NCGs (at an output BER of 10^{-15}) obtained by different state-of-the-art FEC schemes with HDD and SDD taken from Tab. 7.5

Acknowledgments. Laurent Schmalen would like to acknowledge the support of Sebastian Cammerer (University of Stuttgart) for providing the polar coding simulation results shown in Fig. 7.24, Rafael Rios–Müller (Nokia Bell Labs) for carrying out the experiments used in Sect. 7.7.3, and Detlef Suikat and Detlef Rösener for programming the FPGA platform used in Sect. 7.4.5.

Alexandre Graell i Amat

Dept. of Electrical Engineering
Chalmers University of Technology
Gothenburg, Sweden
alexandre.graell@chalmers.se

Alexandre Graell i Amat received his PhD from Politecnico di Torino, Italy, in 2004. He is currently a professor at the Department of Electrical Engineering of Chalmers University of Technology, Sweden. His research interests are in the field of coding theory and its application to distributed storage and computing, privacy, and fiber-optic communications.

Laurent Schmalen

Communications Engineering Lab (CEL)
Karlsruhe Institute of Technology (KIT)
Karlsruhe, Germany
laurent.schmalen@kit.edu

Laurent Schmalen received his PhD from RWTH Aachen University in Germany in 2011. Until 2019, he worked as a researcher and Department Head at Nokia Bell Labs in Stuttgart, Germany. He is now a professor at Karlsruhe Institute of Technology (KIT). His work focuses on forward error correcting codes, digital modulation schemes, and machine learning algorithms for high-speed data transmission.

8. Optical Node Architectures

Brandon Collings, Mark Filer

This chapter provides an overview of prominent optical network node architectures beginning with basic nonwavelength channel reconfigurable nodes through to the most advanced reconfigurable node configurations. The generic functionality of an optical network node is summarized as it pertains to network performance (Sect. 8.1), functionality and network topology, including characteristics such as colorless, directionless and contentionless switching and flexible spectrum channel definition. A variety of node architectures are then described in detail (Sect. 8.2), highlighting the capabilities and flexibilities these architectures provide and what the key devices necessary to construct each node architecture are and their attributes. A general overview of how the performance of the overall network depends upon the various node architectures and the implementing devices (Sect. 8.3), including the addition of optical noise, optical filtering and optical channel crosstalk is provided, followed by a description of general approaches to optically monitoring and validating the optical signals traversing the node. Finally, a summary of general forward-looking trends for reconfigurable optical network nodes is provided.

Optical communication in essence involves the transportation of optical, data-carrying signals between two desired locations separated by a physical distance, generally over optical fiber, in order to provide communication of that data between those two locations. Optical communication networking, however, refers to an optical transportation infrastructure that provides optical communication between multitudes of separate locations using a common infrastructure over which those optical data-carrying signals propagate. In practice, this common infrastructure generally consists of a network of optical nodes located at traffic communication end-points and interconnected by optical fibers. Leveraging such a common infrastructure provides economic advantages as a large number of communication links can be supported between diverse locations by that infrastructure. In addition, an operational advantage is generally further achieved as additional communication links can be introduced onto that network over time as the demand arises, providing the network operator the ability to grow the overall traffic-carrying capability of their network in alignment with their needs. As traffic capacity growth patterns are generally difficult to accurately predict, network operators are generally interested in an optical network infrastructure that provides them the ability to flexibly and efficiently support the introduction of new communication links generally between any pairs of nodes within the network as the need arises and with minimal restrictions from already deployed traffic. This maximizes the growth lifetime of the network and consequently the utility of the network infrastructure investment they have already made.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_8

8.1 Generalized Functions of an Optical Node

The base functionality of an optical network node is to direct each optical signal entering that node to its prescribed and respective exit direction from that node, which may include directing one or more signals to local transceivers to terminate those particular links or directing it to continue through the network node along a prescribed fiber route as depicted in Fig. 8.1. However, and as will be described in this chapter, the extent to which the optical channels can be routed independently and dynamically depends greatly upon the hardware and network management software used to implement the node and the network. The simplest implementations, in which channels are routed through the node and are terminated locally, is essentially permanently decided during the design and initial deployment of the network infrastructure. Such nodes are identified as nonreconfigurable. Intermediately advanced node implementations provide the ability to independently select during the deployment process how each new channel is routed through the node or whether it is locally terminated. This level of reconfigurable flexibility, while requiring greater hardware complexity within the node, provides the ability for the network operator to introduce new capacity onto the network when and where the demand arises, thereby extending the growth lifetime of the network. Such network nodes with the capability to reconfigure how signals are routed within the nodes through management software control are collectively referred to as reconfigurable optical add/drop multiplexer (ROADM) nodes. Finally, highly advanced ROADM node implementations provide the ability to independently and dynamically modify how deployed and active channels are routed through the node through network management software control and without any modifications to the physical configuration or interconnections within the node or network. This level of flexibility provides the network operator the ability to efficiently, reliably and perhaps automatically make adjustments and optimizations to the network while the network is operating in order to improve the efficiency of the network's utilization, to reroute traffic around faulted hardware or fibers, or to dynamically align the deployed capacity levels to time-dependent demand requirements, further extending the growth lifetime and increasing the overall service delivery efficiency of the network infrastructure.

This chapter will describe the dominant optical communication network ROADM node implementations, beginning with a general example of a nonreconfigurable node, progressing through examples of less complex and less flexible ROADM node implementations to the most flexible and dynamic ROADM node implementations. This will include highlighting which aspects of signal routing flexibility are enabled, how that flexibility is physically implemented, and what performance or device characteristics are required to ensure the desired minimum performance capabilities. This chapter will also describe how other important network node functions are implemented, such as optical amplification, channel presence detection, channel monitoring, channel protection and power equalization.

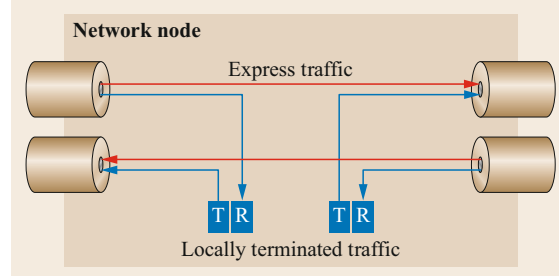

Fig. 8.1 General depiction of an optical network node (T = transmitter, R = receiver)

8.2 General Configuration and Functionality of a ROADM Node

Optical network nodes are generally located at the convergence of multiple pairs of fibers originating from one or more remote locations. These fiber pairs carry the optical wavelength signals that enter and leave the node along respective fibers of each pair. Generally each fiber carries signals propagating unidirectionally. Therefore each fiber pair comprises a bidirectional communication link along that respective physical route, each transporting signal traffic to and from adjacent nodes within the network. Each fiber pair converging upon a network node, and the equipment dedicated to managing the channels entering and exiting the node through those fibers, is described as a *degree* of that node. In a ring network, each node consists of a 2-degree node with each degree respectively connecting that node to the two adjacent nodes (Fig. 8.2).

The general function of a 2-degree node is to control and dictate if each of the optical wavelengths entering each degree will either traverse through the node, from one degree to the other and continue on to the next node within the network, or be routed to a local transceiver to terminate that link at that node. This wavelength signal routing can be implemented at the granularity of each independent wavelength or at a coarser granularity of groups of wavelength channels.

As shown in Fig. 8.2, 2-degree node implementations generally consist of separate hardware configurations comprising each degree. Each configuration includes both the hardware to manage the wavelengths entering/exiting the node through that respective degree, as well as the group of transceivers that terminate/originate selected wavelength traffic that enters/leaves through that same degree. This physical separation of hardware between each degree is intentional as it prevents failure of any hardware element within one degree from impacting the viability of the traffic terminating within the other degree. A typical approach for transporting critical, high-value traffic consists of transporting duplicate copies of that traffic along fully separate and physically diverse routes within the network. This is implemented by utilizing separate transceivers in each degree and routing the bidirectional signal pairs from each transceiver through the physically separate degrees as well as through diverse physical routes within the network to the remote location. Therefore, any single hardware or fiber failure will only impair one of these two (bidirectional) connections and the operational viability of the other (bidirectional) connection will not be impacted, enabling that critical traffic to continue to be transported to the remote location. In general, an electronic switch platform duplicates the traffic within each link endpoint node and provides a copy to both transponders. That same switch platform receives the inbound traffic from both transceivers and selects the healthier traffic to forward out of the node to the network user, providing nearly continuous connectivity despite any single hardware or fiber fault (Fig. 8.3).

Nodes with more than two degrees enable the creation of networks with more complex optical mesh topologies (Fig. 8.4). Such optical nodes are naturally more complicated to implement as wavelength signals entering each degree, if not terminated at a local transceiver, can be routed to one of the other multiple degrees to continue through the network. Similar to a 2-degree node, the hardware of each degree is implemented separately, with each degree containing a complement of transceivers adding/dropping wavelength traffic entering the node through that respective degree. Therefore, a failure in the functionality within

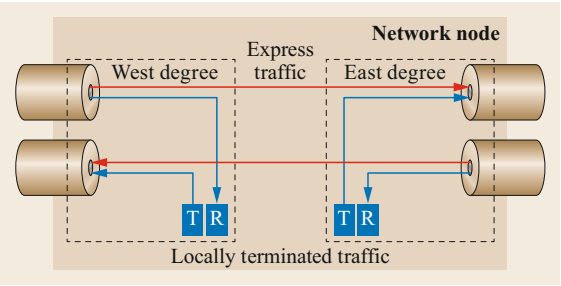

Fig. 8.2 General depiction of an optical network node highlighting East and West degree demarcations

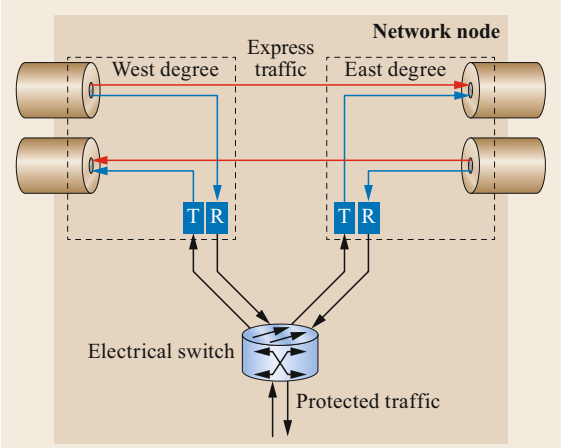

Fig. 8.3 General depiction of an optical network node implementing 1 + 1 protection using dual transceivers over diverse fiber routes

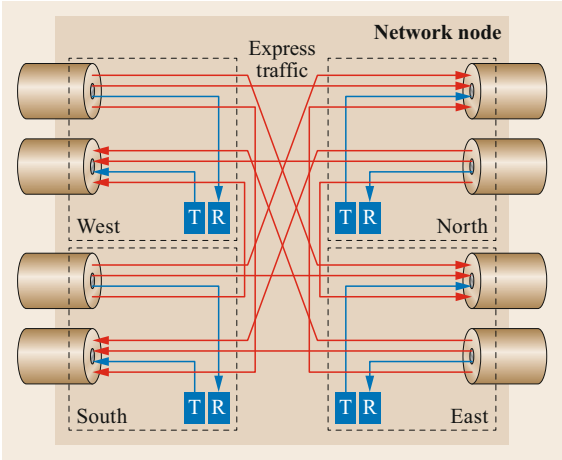

Fig. 8.4 General depiction of a 4-degree node with separate degrees

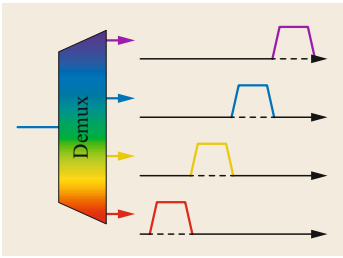

Fig. 8.5 General functionality of an optical demultiplexer (Demux)

any degree does not impact the viability of any of the other traffic within the node passing through any of the other degrees and thus, critical traffic can be diversely routed through the network and its viability will not be significantly impacted by a single fiber or hardware failure.

In order to extract a single wavelength channel from an ensemble of wavelengths (and conversely in order to insert a single channel into an ensemble of wavelengths), the hardware within each degree must be capable of optically demultiplexing (and multiplexing) each single desired wavelength in order to provide only that single extracted wavelength to a transceiver's receiver (Fig. 8.5). Conversely, each degree must be capable of optically multiplexing channels originating at multiple transceivers local to that degree together, along with other wavelength signals from other degrees, onto a single fiber in preparation to launch that ensemble onto the outbound transmission fiber.

As the transceivers are all located locally within each degree along with dedicated optical wavelength multiplexing and demultiplexing capabilities, each transceiver is said to be *directional* given each transceiver is inflexibly connected to the corresponding fiber route of that degree (Fig. 8.4).

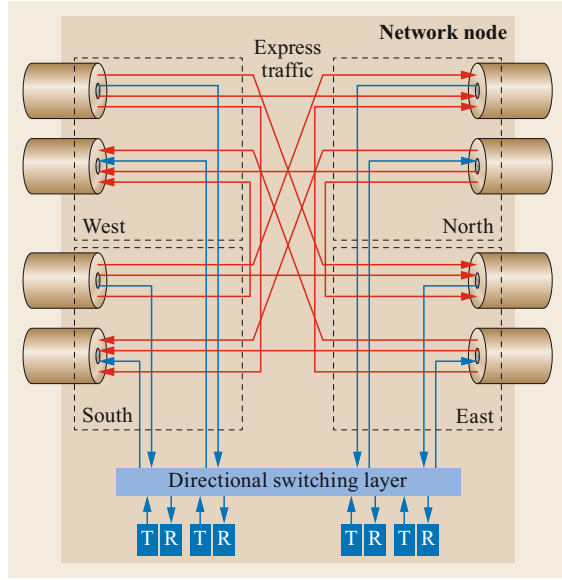

Fig. 8.6 General depiction of a 4-degree node with directionless transceivers

The flexibility of how wavelength channels are physically routed within the network can be enhanced by removing this fiber route inflexibility of which the transceiver's signal can utilize immediately adjacent to the termination node. This requires the transceivers to be physically located separately from the degrees, and an optical switching functionality is introduced between each of those transceivers and each of the node degrees (Fig. 8.6). In this configuration, each transceiver is said to be *directionless* as it can transmit/receive its respective wavelength channel through any degree, and thus fiber route of the node, by selecting the proper configuration of that intermediate switching functionality through the management control software.

When implementing directionless multiplexed/demultiplexed ports, typically multiple multiplexing/demultiplexing modules are deployed so that two diverse and independent paths can be established to carry critical traffic. With this configuration, any single hardware failure cannot impair both the performance and connectivity of the signals along these diverse routes.

The process of optically multiplexing/demultiplexing wavelength channels into/from the full group of channels is said to be *colored* if the multiplexing/demultiplexing add/drop ports that connect to each transceiver permanently support a single particular wavelength channel (Fig. 8.5). In this case, the transceiver, even if it possesses wavelength tunability, must be tuned to that specific channel of that add/drop port in which it is connected in order for that signal to pass through the multiplexer/demultiplexer.

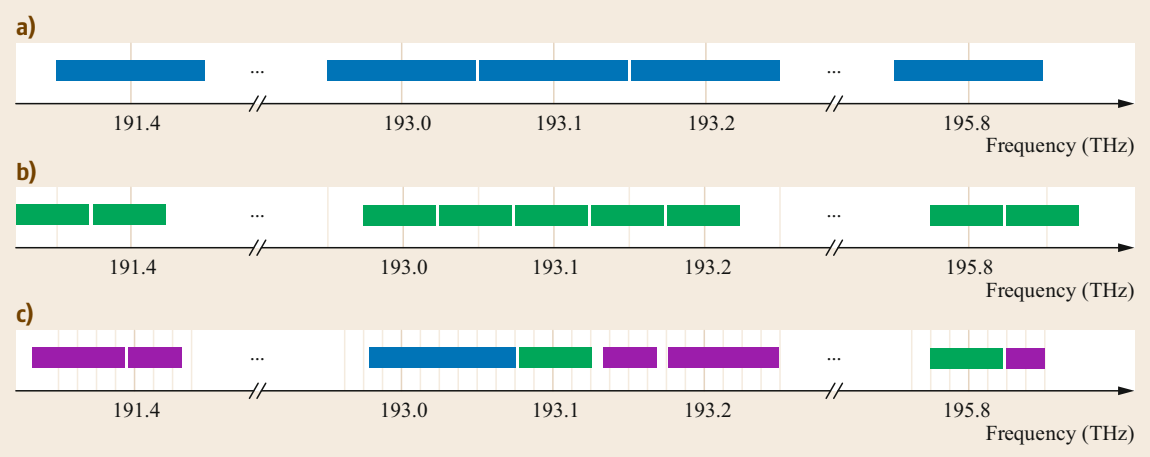

Fig. 8.7a–c Wavelength channel definition for **(a)** 100 GHz fixed wavelength grid, **(b)** 50 GHz fixed wavelength grid, and **(c)** an example of a flex spectrum channel assignment

Therefore, there is no flexibility to alter the operating wavelength of that transceiver without physically disconnecting it from the multiplexer/demultiplexer and reconnecting it to the add/drop port pair associated with the desired new operating wavelength channel. Given a manual intervention of disconnecting and reconnecting the transceiver in order to change the wavelength of operation takes time to manually plan and execute, and errors can be made, such modifications to in-service wavelengths are generally not an operational consideration.

The ability to flexibility modify the operating wavelength is provided by *colorless* multiplexers/demultiplexers, which allow the operating wavelength of the colorless add/drop ports to be specified to any available wavelength channel using the network management control plane. Therefore, the desired operating wavelength channel can be selected after the transceiver is deployed, and the operating wavelength can be modified entirely through the network management software without the need to physically disconnect and reconnect the transceiver.

For a multiplexing/demultiplexing module implementing both directionless and colorless multiplexing/demultiplexing, the module is said to be *contentionless* if the same wavelength channel can be provisioned between separate node degrees and independent respective transceivers (Fig. 8.6). Naturally, if a wavelength channel is already in operation within a given degree, a second independent signal at that same wavelength cannot be routed to that same degree even with a contentionless multiplexer/demultiplexer, as two signals at the same wavelength cannot be carried within a single node degree or fiber. Contentionless multiplexing/demultiplexing simply introduces additional flexibility that can be leveraged by a tunable transceiver, thereby providing greater flexibility to grow and optimize the network traffic.

Since the introduction of dense wavelength division multiplexing (DWDM), the available amplified spectrum has been segmented into optical channels defined by the International Telecommunication Union (ITU) spec G.694.1 [8.1] with channels spaced by 100 or 50 GHz and centered on defined optical frequencies (Fig. 8.7). For each defined channel, the actual usable bandwidth depends upon the quality and quantity of all passband filtering that signal experiences during multiplexing, network wavelength routing and demultiplexing, such that the effective bandwidth is always less than the full defined width of the channel. Despite this, the available bandwidth within a 50 GHz defined wavelength channel has historically been sufficient for optical signals with baud rates below roughly 35 GBd. However, as transceiver technology progresses and optical signal baud rates have continued to increase, the ability to implement wavelength channels with flexibly defined widths and central wavelengths in order to accommodate wider signal bandwidths has emerged (Fig. 8.7). This mode of highly flexible channel definition is commonly referred to *flexible spectrum* or *flexible grid*. The ITU has introduced a finer granularity frequency grid definition [8.1], which allows the definition of channel widths with a granularity of 12.5 GHz and central wavelengths tied to a defined frequency grid. However, some optical systems support channel edge definition with a finer granularity and with an arbitrary total width and center. Note that such systems are equivalently able to support the conventionally defined 50 GHz channel grid if desired. Implementing the flexible grid capability re-

quires that all wavelength-specific elements within the node support the necessary flexible spectrum characteristics, including wavelength multiplexing/demultiplexing, network wavelength management filtering, optical spectrum monitoring, transceiver tunable lasers and network management software.

8.3 General Performance Requirements of a ROADM Node

The general primary functions of a ROADM node are to manage wavelength routing and to amplify signal strengths for propagation and error-free reception. ROADM node design and comprising hardware components thus strive to accomplish these primary functions while imparting the least amount of degradation or distortion of the optical signals in order to enable their respective maximum total propagation distance and avoid costly reception and optical signal regeneration.

The process of optical amplification includes the addition of unwanted optical noise, which can impair the ability to successfully receive and extract the digital information encoded within a signal (Chap. 3). Therefore, typically within a ROADM node, all signals entering the node are immediately amplified so that the least amount of optical noise is added to the signal during that amplification (Fig. 8.8). Generally, following that amplification the wavelength signals are then independently directed to their respective destinations, such as expressed through the network to another degree, or directed towards a local transceiver to be terminated. The wavelength management function generally introduces significant loss to the signals such that, following that function, further amplification is required so that the signals have the desired power levels to exit a degree and be launched onto a transmission fiber (Fig. 8.8). Therefore, in order to minimize the noise added to the signals by this outbound amplification and extend the potential optical transmission range, minimizing the total insertion loss of the wavelength management function is desired and can have a significant influence upon the node architecture and device design, as will be described later in this chapter.

For network efficiency, it is highly desirable to be able to use any unoccupied wavelength channel between two end-point nodes independent of how that wavelength channel is utilized elsewhere in the network. This ability requires that the wavelength management devices provide sufficient blocking and isolation of signals from each other during the process of routing and filtering wavelength channels. Unwanted signal power improperly leaking from one area of the network to another and mixing with an active signal can distort that signal and limit its propagation distance [8.2]. Therefore, minimizing the potential sources of this interference is a critical consideration in the node architecture and in conjunction with the capabilities of the devices that implement that architecture. This will be apparent in the node architectures detailed in this chapter.

Other signal degrading effects must be managed and minimized as part of the ROADM node design and implementation. In particular, additional potential sources of distortion generally include minimizing the accumulation of polarization-dependent loss, polarization mode dispersion, chromatic dispersion and multipath interference. Mitigating these impairments typically involves leveraging optical devices within the node that are intentionally designed with minimal levels of these impairments.

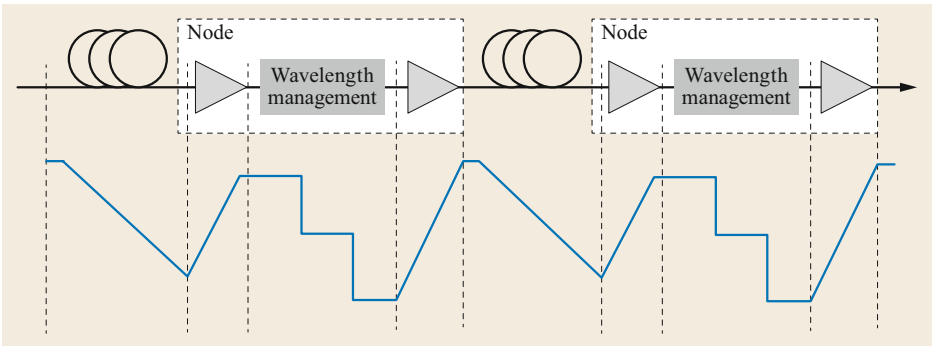

Fig. 8.8 Illustrative channel power (*blue line*) during propagation through fiber spans and optical network nodes

8.4 2-degree Fixed Optical Add/Drop Multiplexer (OADM) Node

The simplest implementation from a hardware perspective of optical add/drop functionality at a node junction is realized by a 2-degree fixed optical add/drop multiplexer (fixed OADM, or FOADM) configuration. It provides the minimum functionality to achieve local adding/dropping or express pass-through of wavelength traffic at that node. Any channels that are not added/dropped at the node are by definition expressed through the node. Historically, there have been a variety of implementations of a fixed OADM topology, but the three most common approaches are to utilize:

1. Individual wavelength multiplexing/demultiplexing filters placed in series, which extract/add the desired channel from/to the remainder of the channel spectrum that passes optically through the node (Fig. 8.9a).
2. Band demultiplexer/multiplexers placed in series, which extract/add a contiguous segment of wavelength channels from/to the remaining channel spectrum that passes optically through the node (Fig. 8.9b).
3. Full demultiplexers/multiplexers with local add/drop paths connected to colocated optical transceivers (Fig. 8.9c) and express wavelengths created by individual optical connections between same-channel demultiplexer outputs and multiplexer inputs.

The first approach utilizing individual add/drop filters relies upon thin-film filter (TFF) technology, which is inherently colored and tied to a fixed ITU grid. As mentioned, each TFF module is a three-port device with a common, express, and single-channel port. On the ingress side, the full spectrum of signals enters, and the desired channel is wavelength-demultiplexed to a receiver, while the rest of the spectrum is reflected and passed through (the reverse occurs for the add function). To realize additional add/drop channels, multiple TFF devices are cascaded in series (Fig. 8.9a). An obvious drawback of this approach is that the insertion loss to the express channels increases linearly with each TFF added in series, and so there is typically a practical upper bound for the number of devices that can be cascaded (i.e., the number of channels that can be added/dropped) at a node. Additionally, the insertion loss for each individual added/dropped channel is different. This is particularly problematic during multiplexing as the transmitted power levels into fiber of the multiplexed and expressed channels can be highly nonuniform.

The third approach using full multiplexer/demultiplexer devices alleviates some of these drawbacks (Fig. 8.9c). Any number of channels may be added/dropped at a given node without impacting the insertion loss of the add, drop, or express path. Express path channels are achieved by simply interconnecting demultiplexer outputs to multiplexer inputs with individual patch cables. Added/dropped channels are implemented by directly connecting local transceivers to the proper multiplex/demultiplex ports. As these devices are typically implemented with arrayed waveguide grating (AWG) devices, the insertion losses do not significantly depend upon the number of channels being locally added/dropped. Transmitted power levels into fiber are uniform, although some consideration may need to be made to equalize the add signals to the express signals.

These approaches have the advantage of being relatively low loss (particularly the first and second approaches when a small number of channels are added/dropped at a node), inexpensive, and compact. However, in addition to the drawbacks mentioned above, perhaps the largest disadvantage is that there is no flexibility in these approaches – the network topology must be fully defined at deployment. Should the desire to augment or reconfigure the add/drop capacity at the node arise, significant manual intervention is required, including manual rearrangement of optical interconnections within the node, and for the first and second approaches the addition of new hardware and full interruption of all expressed traffic. Alluded to above, matching channel power levels between express and add/drop channels is also problematic since the loss of individual channel paths depends on number of TFFs and the position of that channel's TFF within the cascade. This must be mitigated through a very manual process of placing appropriately valued attenuators on the transceiver transmitter based upon a measured spectral uniformity at each node. A transceiver equipped with a variable optical attenuator (VOA) on the transmitter can alleviate the complication of using manual attenuators, but the resulting power levels must still be set and manually measured by a trained technician. Lastly, inherent to these implementations is an inability to achieve any type of true mesh networking at the optical layer – ingress signals must be terminated, electronically switched, and regenerated to achieve degrees greater than two.

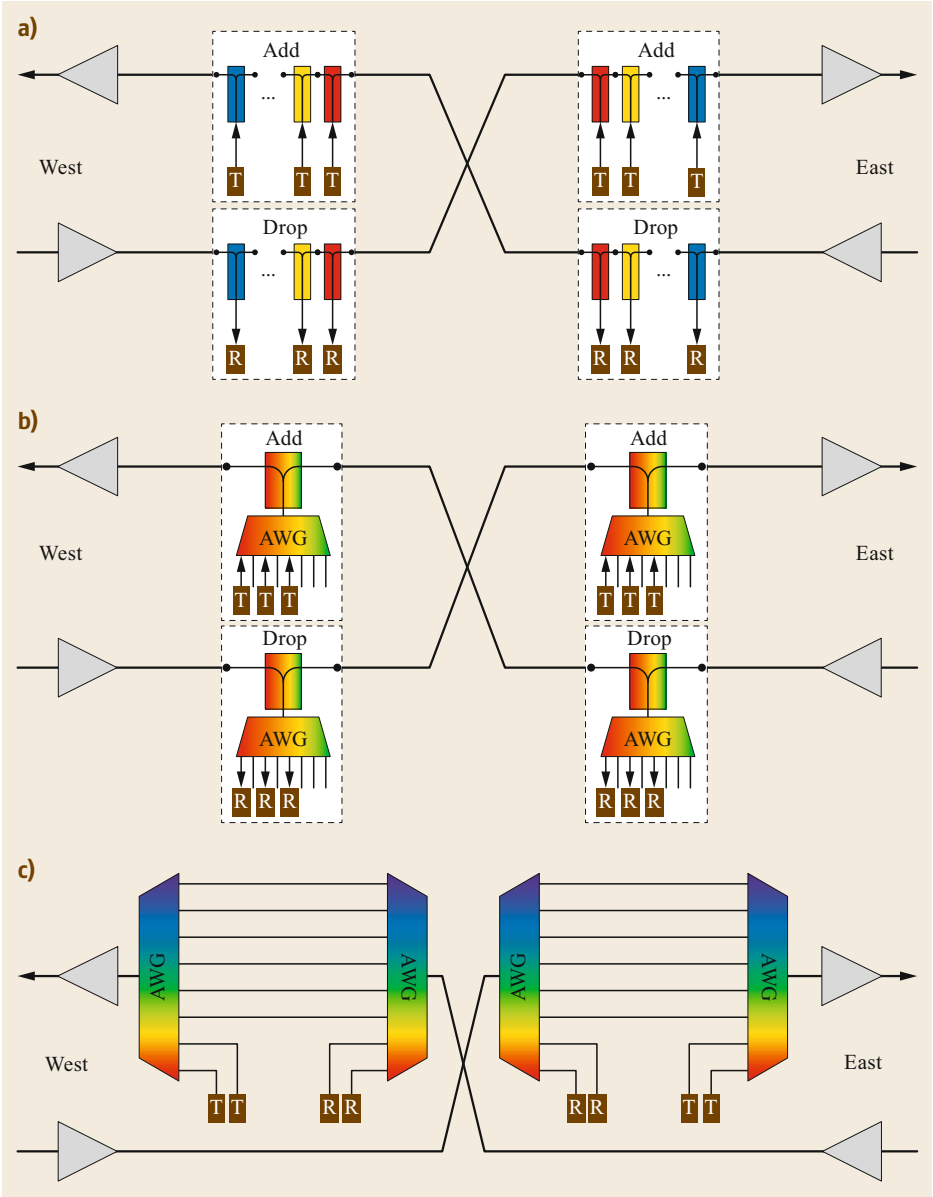

Fig. 8.9a–c FOADM implementations – **(a)** individual wavelength demultiplexers/multiplexers using TFFs, **(b)** band demultiplexer/multiplexer and **(c)** full spectrum demultiplexer/multiplexer with local add/drop (T = transmitter, R = receiver)

8.5 2-degree ROADM Node

In order to improve upon some of the drawbacks inherent to the fixed OADM architectures described above, as the enabling technologies became available optical network system suppliers began offering reconfigurable solutions. Early ROADM implementations address only 2-degree nodes and provide some automated ability to block individual channels from passing from one degree to the other. A copy of all channels entering the node are routed to a demultiplexing AWG so that if a channel is desired to be dropped at this node, a receiver may be connected to the proper drop port. If a channel is dropped, the signal for that channel is blocked from reaching the opposite degree, thus allowing that wavelength channel to be reused with an independent channel in the other degree.

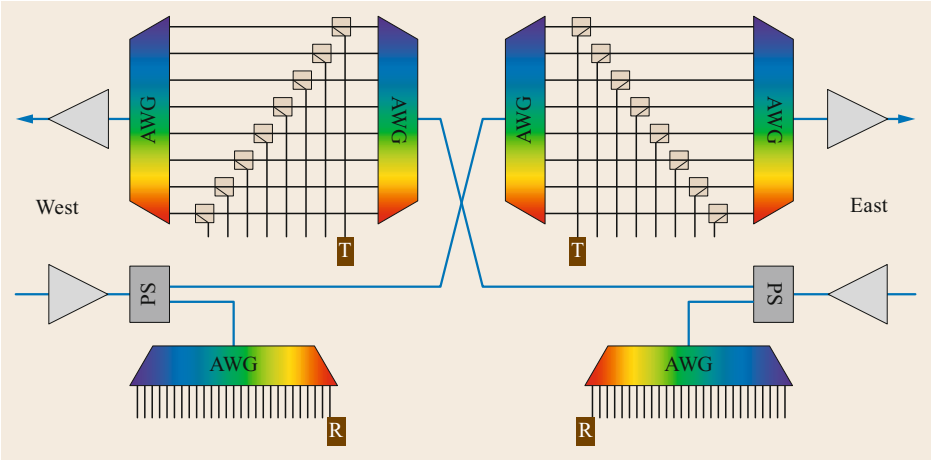

Fig. 8.10 iPLC-based 2-degree ROADM (PS = power splitter)

In general, there are two basic approaches taken, depending on the technology employed. One approach leverages integrated planar lightwave circuit (iPLC) technology and integrates a pair of AWGs and a 2×1 switch between each same wavelength pair of single-channel ports (Fig. 8.10). A third AWG could be integrated within each degree to provide the demultiplexing function. This approach addresses the primary shortcoming of the previous nonreconfigurable topologies in that every wavelength channel could independently be configured to be locally added/dropped or expressed entirely through the management software control without any physical intervention. This allows new channels to be flexibly provisioned quickly and dependably. In addition, this technology allows convenient integration of VOAs within each of the channel add paths for independent channel power equalization. This equalization can be fully automated with the inclusion of optical channel monitors (OCMs) with this configuration.

An alternative variant of a 2-degree ROADM architecture leverages a wavelength blocker (WB), a 2-port device with the ability to independently attenuate and block each wavelength channel. The general functionality of a WB is represented in Fig. 8.11 where all channels entering the device on a single input fiber are separated by wavelength channel, individually and independently attenuated or fully blocked, and then multiplexed to exit the device all on the same output fiber.

This node architecture is illustrated in Fig. 8.12 and is quite similar to the iPLC node architecture (Fig. 8.10). The WB is located on the optical connection between each of the two degrees such that if a wavelength channel is not provisioned to be expressed through the node, the WB fully attenuates that signal so that wavelength channel can be reused by an independent transceiver in the opposite degree (if desired). Similar to the iPLC approach, a separate AWG is used for demultiplexing all channels in each degree. However, with the WB architecture, a second AWG is needed to multiplex all locally added channels in each degree. Individual channel power equalization is accomplished using per-channel VOAs within the multiplexing AWG or by variable attenuation within the WB.

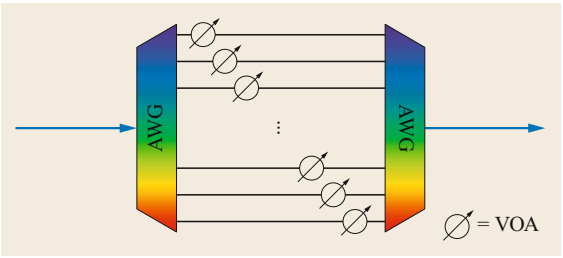

Fig. 8.11 Functional representation of a wavelength blocker (WB)

An enhancement to the 2-degree WB-based node architecture is implemented by replacing the WB and power combiner functionality with a 2×1 wavelength selective switch (WSS) device. A general representation of the functionality of a 2×1 WSS device is shown in Fig. 8.13 (note the optical functionality is fully equivalent independent of in which direction the light is passing) [8.3–6].

In this node configuration (Fig. 8.14), the node ingress signal is amplified and duplicated, with one copy routed to the opposite degree to support express traffic and the other sent to a demultiplexing AWG where the individual drop channels are connected to corresponding transceiver receivers. The express traffic enters one port of the two (or more) WSS ports while the output of an add multiplexer AWG is connected to the other WSS input port. The WSS device is then

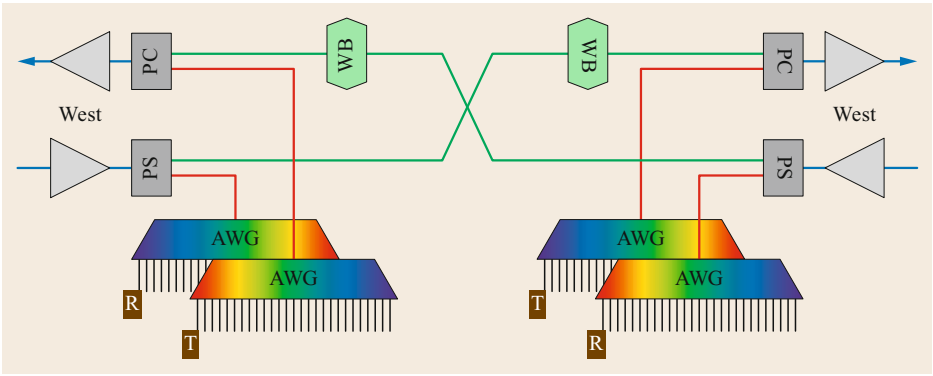

Fig. 8.12 WB-based 2-degree ROADM node (PS = power splitter, PC = power coupler, WB = wavelength blocker)

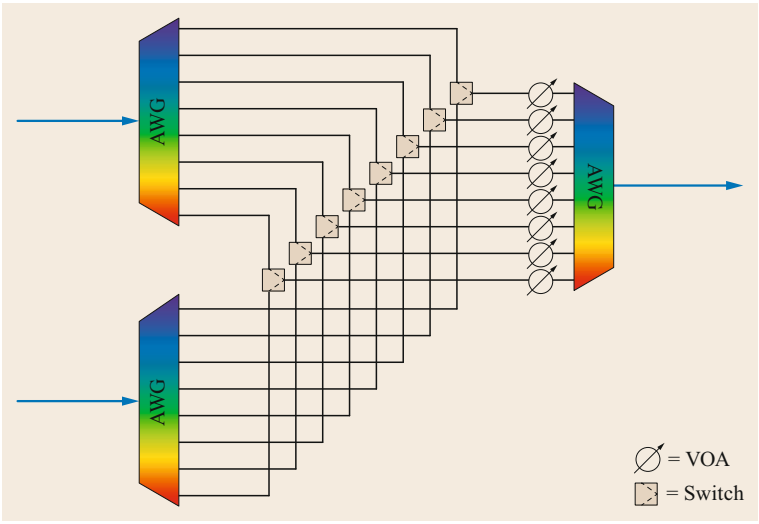

Fig. 8.13 Representation of the principle functionality of the wavelength selective switch (WSS). Note that practical WSS devices are not constructed from the elements as shown

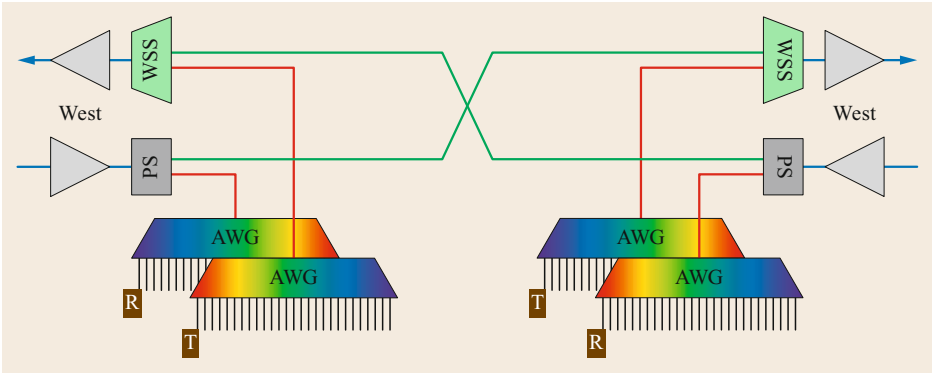

Fig. 8.14 General node architecture for a 2-degree WSS-based ROADM

configured to route any locally added signal from the add port of the WSS to the common port, which provides the collection of output signals to exit that degree. Similarly, it is also configured to route any selected express signals to the common output port. Since the express input of the WSS is receiving the full complement of channels entering the opposing node, the WSS is responsible for selecting only the desired express channels provisioned to pass through to the output, and blocking all others. For this reason, this configuration is known as broadcast-and-select.

Several advantages are immediately apparent compared to fixed OADM architectures. Foremost, this implementation gives the ability to add/drop wave-

lengths independently and programmatically, which in the former case, always requires early detailed topology planning, with very disruptive and error-prone requirements in making changes or augmentations. However, due to the colored and directional nature of this implementation, this flexibility can only be exploited during initial channel provisioning. Once a channel is deployed, generally any alteration requires significant manual intervention and subsequently such modifications are rarely implemented. Another advantage is the fact that add/express channels' power levels can be equalized in an automated fashion, as again, modern ROADM nodes are typically deployed with integrated OCM devices. Due to the broadcast nature of this configuration as implemented with the passive splitter, the express optical signals only encounter a single WSS bandpass per channel at each node. This reduces the amount of bandwidth narrowing the signal experiences, which leads to reduced transmission penalty at the receiver [8.7]. The presence of a colored multiplexer on the add path and a demultiplexer on the drop path minimize the effects of adjacent channel crosstalk and make this architecture ideally suited for direct-detect optical receivers.

8.6 2- to 8-degree Broadcast-and-select Colored and Directional ROADM Node

By utilizing WSSs with port counts beyond $N = 2$ as a building block, topologies with higher degrees of connectivity and flexibility are realized, enabling optical mesh networking. The next evolution of ROADM node architectures commonly featured 1×4, 1×5, 1×8 or 1×9 WSSs, providing up to eight additional degrees of connectivity at a given node. The configuration for the N-degree ROADM is identical to the 2-degree ROADM of the previous section, except now the broadcast power splitter on the drop path is a $1 \times N$ and the *select* WSS on the add path is an $N \times 1$, as pictured in Fig. 8.15. The additional splitter outputs and WSS inputs are used to interconnect other degrees. Local add and drop is achieved with multiplexer/demultiplexer units such as the AWGs discussed earlier. As with the 2-degree ROADM, this implementation is inherently colored with wavelength channels operating on the fixed ITU 50 or 100 GHz grid.

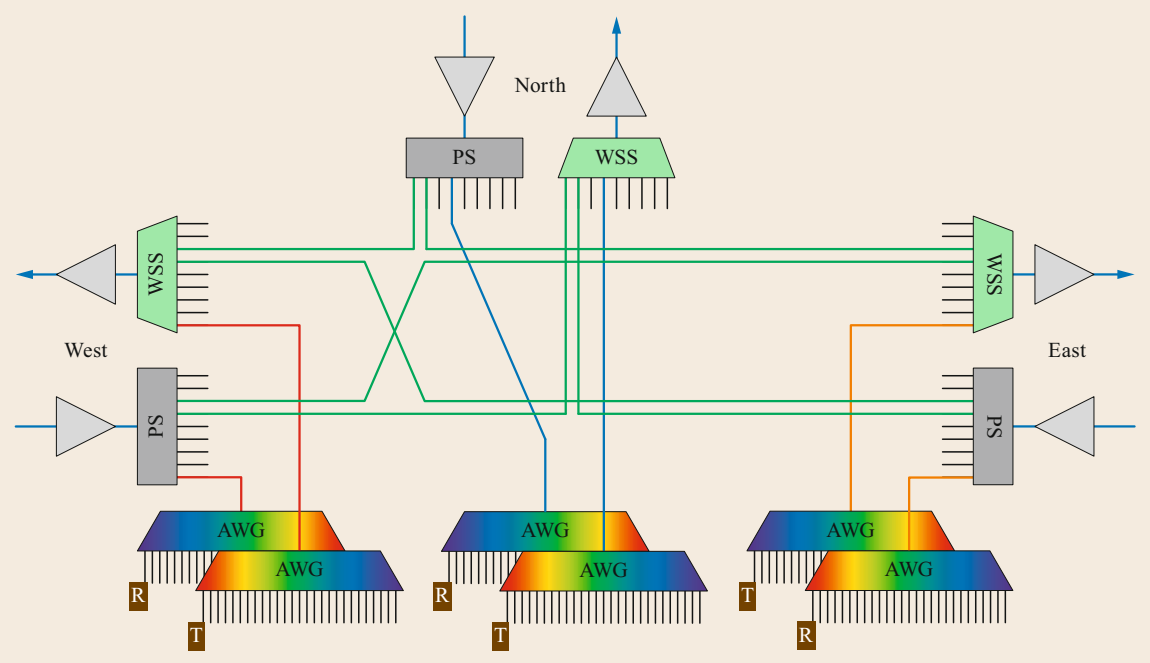

Fig. 8.15 General node architecture for a 3-degree broadcast-and-select node with AWG-based colored/directional add/drop

Fig. 8.15 shows a 3-degree application with local add/drop per degree. The *directional* nature of the topology is apparent, where a multiplexer/demultiplexer pair is located within each degree.

As with the 2-degree broadcast-and-select WSS-based ROADM, the user still has the flexibility to add/drop wavelengths independently, although due to the colored nature of the multiplexer/demultiplexer units, this flexibility can practically only be utilized during initial provisioning or in combination with manually reconnecting a transceiver to a different add/drop port. Additionally, intermediate ROADM nodes can, in principle, dynamically reroute wavelengths to adjacent degrees without any physical intervention. Although the corresponding wavelengths at the terminal nodes would need to be manually reconfigured to transmit/receive the rerouted channels, it alleviates the requirement for manual intervention at the intermediate sites. Other advantages inherited from the 2-degree broadcast-and-select WSS architecture include integrated power monitoring on the add and express paths, single WSS filter passed per node, and per-channel filtering provided by the colored multiplexer/demultiplexer on the add/drop paths.

One challenging aspect of any multidegree broadcast-and-select-based ROADM topology is that for a given direction, a single WSS device must provide sufficient optical isolation across all of its ports to prevent any optical distortion of a provisioned wavelength arising from interference from signal power from insufficiently suppressed signals at that same wavelength

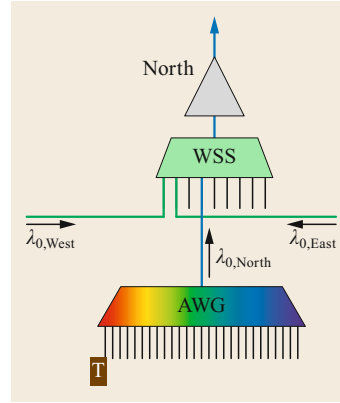

Fig. 8.16 Isolation requirements of broadcast-and-select architectures

channel [8.8]. This requirement can be understood using the system shown in Fig. 8.15. Assume an optical source with wavelength λ_0 is being added to the North direction. In principle, that same wavelength λ_0 could be propagating into the node from both the East and West degrees from adjacent nodes, and either expressed between these directions, or each dropped at the East and West terminal AWGs. Regardless, due to the broadcast nature of broadcast-and-select ROADMs' splitters, nominally powered signals with wavelength λ_0 are also present at two additional North WSS input ports ($\lambda_{0,East}$ and $\lambda_{0,West}$). This situation for the North WSS is captured in Fig. 8.16, which must be able to sufficiently block the unwanted λ_0 signals from the East and West degrees such that the λ_0 signal propagating northward experiences no interference [8.9].

8.7 2- to 8-degree Broadcast-and-select, Colorless and Directionless ROADM Node

The broadcast-and-select architecture shown in the previous section supports mesh network nodes and flexible wavelength configuration between degrees at each node. However, as indicated, all transceivers are located within a particular degree and consequently have no directional flexibility. Implementing directionless transceivers provides the network operator an additional level of flexibility to reprovision existing wavelengths along new routes, including modifying the route used directly adjacent to both the terminating nodes. Similarly, including colorless multiplexing/demultiplexing capability further increases reprovisioning flexibility by allowing the selection of a new wavelength channel. This route and wavelength reprovisioning flexibility provides a greater number of options for that signal to be routed between two network nodes and thus a great probability that a wavelength and route combination can be available despite the existing population of other channels already operating within the network.

To implement directionless multiplexing/demultiplexing, each transceiver signal must be able to be configured to enter/exit the node from any degree. Therefore, they cannot be physically located within any specific degree. One approach is to utilize the general broadcast-and-select degree structure as the switching stage between the array of transceivers and all of the degrees (as shown in Fig. 8.17). In this node construction, a complete copy of the incoming signals entering each degree is provided to the colorless and directionless (CD) multiplexer/demultiplexer module, in the same manner that a copy is also provided to all other node degrees. All these copies are provided to the M inputs of an $M \times 1$ WSS, which then only allows those wavelength channels intended to be demultiplexed and

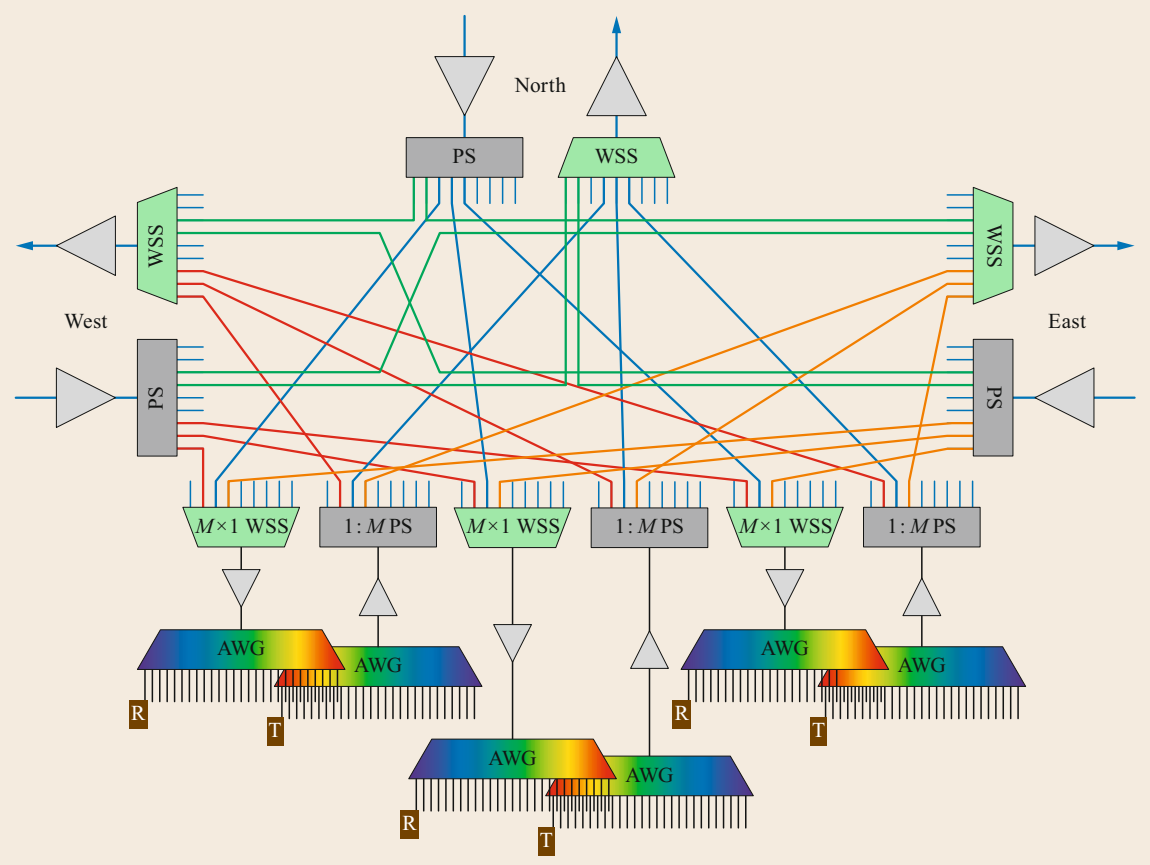

Fig. 8.17 General node architecture for a 3-degree broadcast-and-select node with AWG-based CD add/drop

received by the transceivers connected to that CD module. All other wavelength signals must be blocked by the WSS so that none interfere with those express wavelengths. Note this is the same function that the $M \times 1$ WSS performs in the node degrees [8.2, 5].

To demultiplex the signals and provide them to the individual transceivers, the common port of the $M \times 1$ WSS is connected to a demultiplexing element such as an AWG (Fig. 8.17) for colored demultiplexing or a $1 \times n$ WSS (Fig. 8.18) for filtered colorless demultiplexing. In both cases, the AWG or the $1 \times n$ WSS optically filter and suppress all wavelength signals except for the particular channel to be received by the respective receiver. This prevents any interference from other wavelength channels within receivers that are sensitive to total optical signal power.

With the advent and use of coherent transmission technology [8.10], colorless wavelength demultiplexing can be significantly simplified as coherent receivers have the inherent ability of limiting their sensitivity to optical signal power existing within a very narrow wavelength range [8.11, 12]. In general, coherent receivers operate by optically mixing the incoming signal (or collection of a multitude of signals) with a powerful, locally generated, narrow-linewidth continuous-wave signal and then limiting a detection to only the resulting baseband signal within a narrow radio frequency (RF) range determined by the baud rate of the encoded signal [8.13–15]. Thus, the coherent receiver's sensitivity predominantly lies within the narrow wavelength region about the wavelength of the respective local oscillator and signal power outside of this wavelength region is nominally ignored. Therefore, this capability allows the coherent receiver to select and suitably receive a single channel from a multitude of incident wavelength channels [8.16, 17]. This capability allows for the removal of optical filtering of unwanted channels at a receiver, thereby significantly simplifying the demultiplexing requirements. As shown in Fig. 8.19, the AWG or WSS element can be replaced with a $1 : n$ power splitter to provide colorless demultiplexing (assuming all receivers are suitable coherent receivers capable of isolating a desired channel from a multitude of n channels). Due to the combined insertion loss

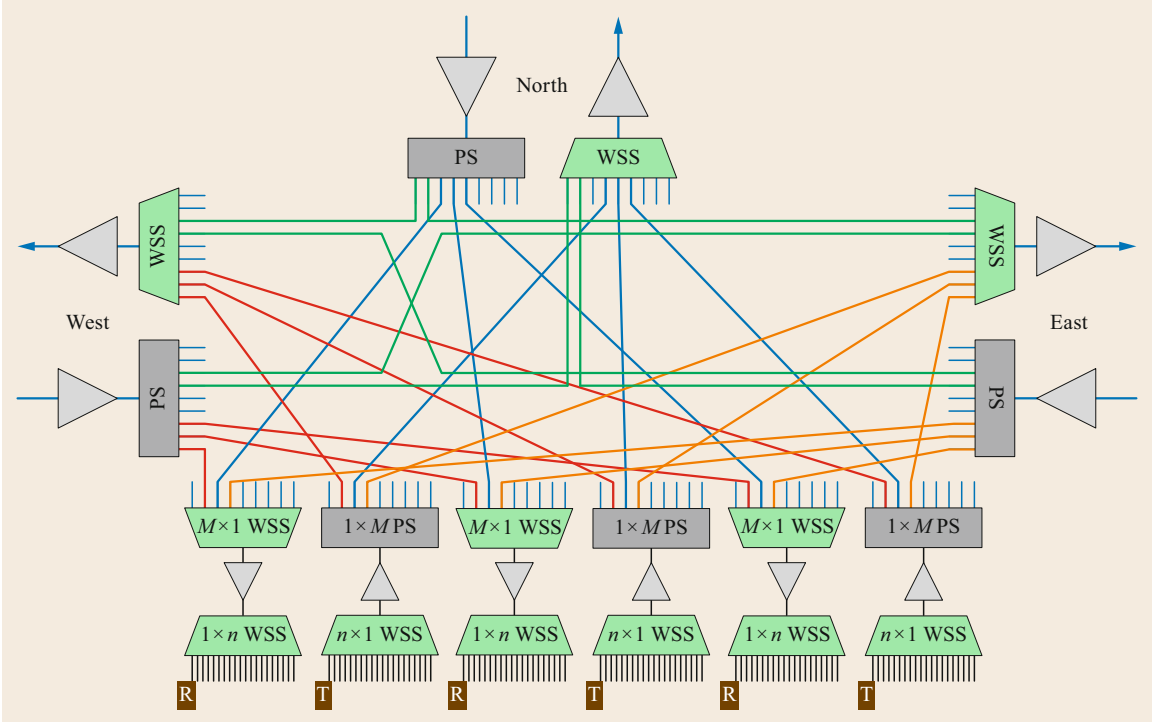

Fig. 8.18 General node architecture for a 3-degree broadcast-and-select node with WSS-based CD add/drop

of the WSS and the AWG, power splitter or WSS demultiplexer, optical amplification is generally required between the WSS and AWG, WSS or power splitter as shown in Figs. 8.17–8.19.

For multiplexing, a similar AWG structure is used for colored multiplexing of the individual signals. These combined signals are then split M ways with a copy routed to each of the degrees, much like the routing between node degrees (Fig. 8.17). The WSS within each degree then will pass only those channels which are provisioned to leave the node through that respective degree. All other channels must be sufficiently blocked to avoid any interference with other channels that are correctly exiting the WSS and the degree. Similar to the demultiplexing configuration, the insertion loss of the AWG and power splitter generally requires the inclusion of an optical amplifier.

To implement filtered colorless multiplexing, a $1 \times n$ WSS is used to passively multiplex n channels onto a single fiber. As with colored multiplexing, this combination of channels is then split M ways to each degree (Fig. 8.18). Alternatively, unfiltered colorless multiplexing is implemented using a $n:1$ power combiner to multiplex n channels together, which are then split M ways (Fig. 8.19).

In both multiplexing and demultiplexing portions of the CD structure, all the signals pass through a single fiber between the $1 \times M$ element facing the degrees and the $1 \times n$ element facing the transceivers. Therefore, this approach possesses wavelength contention within each CD structure such that only a single signal at any wavelength channel from any degree can be provisioned through each respective CD structure. Note that multiple CD structures can be deployed such that each channel can be deployed multiple times through independent degrees. However, when wavelength contention arises for a given transceiver, overcoming that contention requires that the transceiver be physically disconnected and reconnected to a different CD structure where that desired wavelength is available. Therefore, given this need for physical intervention, any wavelength contention is practically only avoidable during the deployment process of a new transceiver and wavelength contention is not avoidable during dynamic or automated channel restoration or reprovisioning activities.

Generally a minimum of two structures are implemented to enable two redundant paths for protected channels. However, as each structure requires a respective port on the WSS within every degree as well as an additional copy of the channels entering each node, significantly increasing the number of CD structures within a node possesses practical limitations.

Within the unfiltered colorless configurations shown in Fig. 8.19, the scale of the $1:n$ power splitter

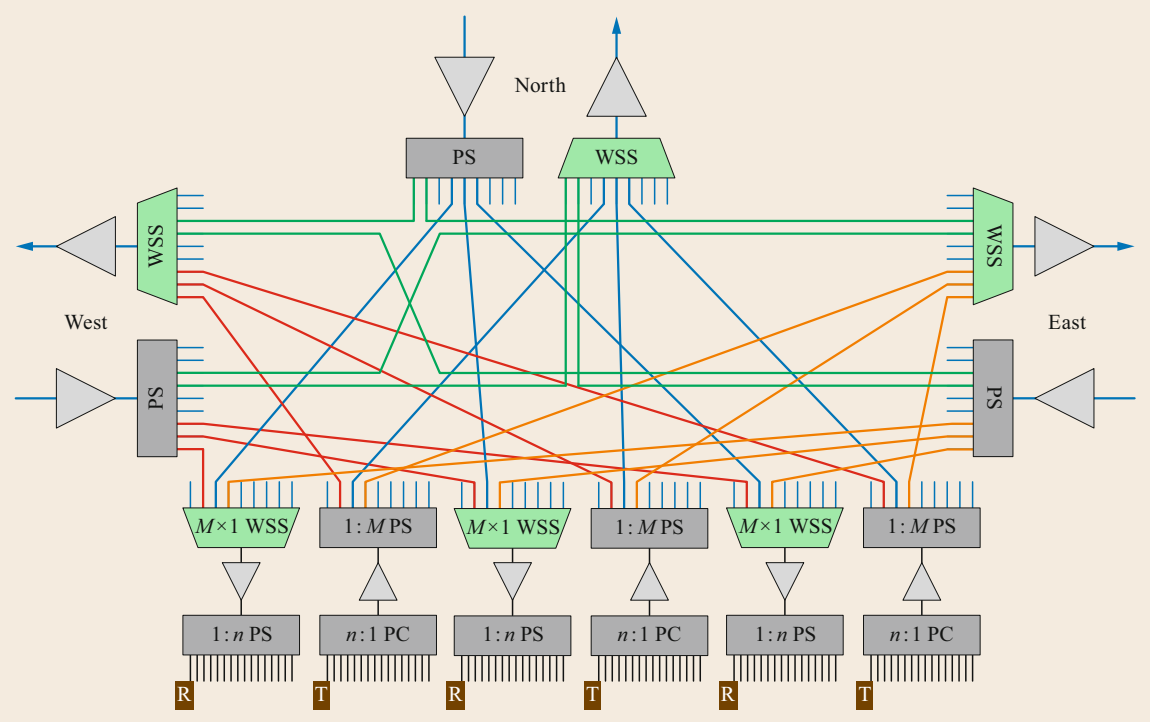

Fig. 8.19 General node architecture for a 3-degree broadcast-and-select node with power splitter and power coupler-based CD add/drop

and coupler determines the number of add/drop ports provided within each CD structure. The ability to increase the number of ports on these splitters/couplers generally depends upon three factors. The first is the need to sufficiently overcome the loss of these passive devices. The second is the limit of the number of channels the coherent receiver can tolerate while adequately isolating the desired channel (typically this limit is due more to limited power dynamic range during mild power transient events). The third limit is the accumulation of out-of-signal-band noise as the channels are combined by the passive coupler as illustrated in Fig. 8.20 [8.18]. This accumulated noise will overlap and interfere with signals and can degrade performance. The accumulation and impact of this noise also directly depends upon the amount of noise produced by the transceivers. In practice, the limit for the number of power splitting/combining ports is around 16 for both coherent receiver dynamic range as well as for noise accumulation within the combiner (assuming a transceiver emitting a signal with a 40 dB Tx_OSNR specification) [8.6].

For unfiltered colorless multiplexing/demultiplexing, the number of add/drop ports within a CD structure can be increased by implementing a second layer of wavelength management as shown in Fig. 8.21. In the

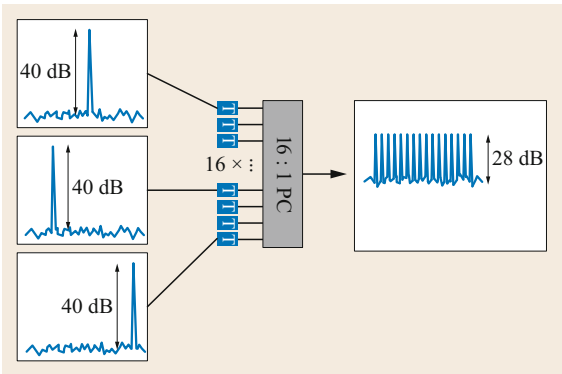

Fig. 8.20 Accumulation of out-of-band signal noise through a power coupler assuming transceivers with a 40 dB Tx_OSNR specification resulting in a potential for a 28 dB OSNR after the passive combination

demultiplexing direction, the common output of the $1 \times M$ WSS is connected to the common port of a second $1 \times n$ WSS. Each WSS output is then connected to a $1 : n$ power splitter. As the WSS is only directing those wavelength signals that are to be received following the power splitter, and blocking all others, the number of signals presented to each coherent receiver is limited to n. Therefore, the total number of add/drop ports

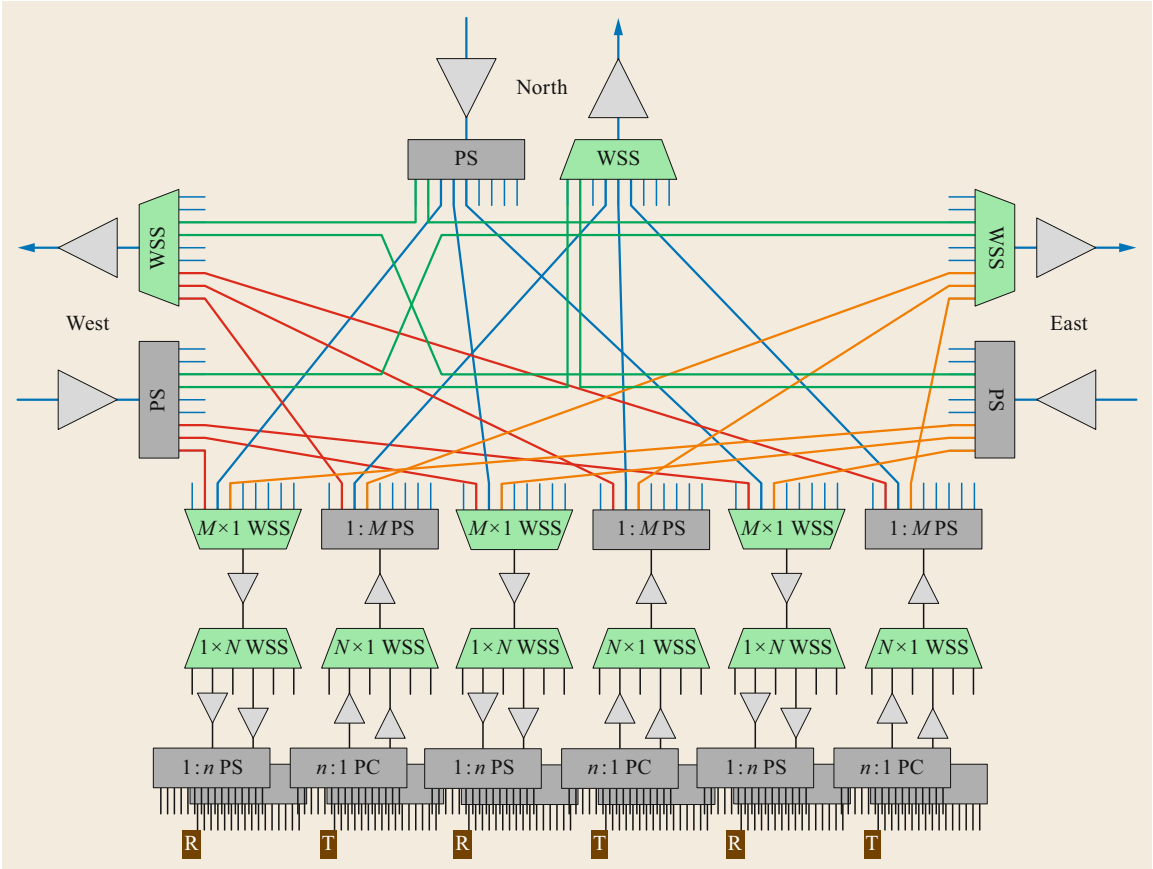

Fig. 8.21 General node architecture for a 3-degree broadcast-and-select node with WSS-based CD add/drop and expansion power splitter and power coupler demultiplexing and multiplexing

that can be supported within each CD structure can be increased N-fold, nominally without significant degradation in performance [8.19, 20]. A similar structure is used in the multiplexing direction (Fig. 8.21). Here the $1 \times N$ WSS is blocking any noise outside the active wavelength signal bands and thus practically eliminates any accumulation of noise outside of those active signal wavelengths bands.

These broadcast-and-select CD architectures have the advantage that they utilize the single $1 \times M$ WSS arrangement within each degree, a simpler arrangement generally with lower implementation cost, and they essentially reuse this same arrangement within the CD structure. Also, operators can deploy networks with a combination of non-CD multiplexing/demultiplexing in some nodes and CD multiplexing/demultiplexing in others.

However, these architectures require a dedicated WSS and splitter port for each CD structure within each degree, in addition to the WSS and splitter ports needed for each other node degree. Therefore, a 4-degree node with four CD structures requires a 1×7 WSS and a $1:7$ power splitter within each degree. An 8-degree node with maximum of eight CD structures requires a 1×15 WSS and a $1:15$ power splitter within each degree. Due to the finite signal isolation provided by practical WSS devices as well as the increased loss introduced by larger power splitters, performance degradation arising from accumulated interference from incompletely blocked signals [8.2] and increased amplification requirements respectively places practical constraints on the size of the WSS and power splitter that can be utilized within each degree. Thus, the number of degrees that can be implemented within a node using the broadcast-and-select approach with CD multiplexing/demultiplexing is practically limited to a number between four and eight, depending upon the desired design maximum number of CD structures [8.20].

8.8 4- to 16-degree Route-and-select, Colorless and Directionless ROADM Node

To address the need to support nodes with more than four degrees with full CD multiplexing/demultiplexing and without performance compromise due to signal distortion, a node architecture is introduced where the broadcasting function within each degree is replaced with the wavelength routing function of a WSS. This architecture is shown in Fig. 8.22 and is generally referred to as a route-and-select architecture. By using a WSS instead of a power splitter, only those wavelength channels which are provisioned to be routed to each respective degree are allowed to pass to that degree. Those that are not provisioned to a respective degree are blocked. Therefore, wavelength signals must pass through two WSS devices (one within the inbound degree and one within the outbound degree) before they are present on an outbound fiber where signal interference would occur and the blocking capability of both WSS devices is aggregated to prevent undesired signals from propagating where they should not. This combined blocking approach has the practical advantage that the isolation capability provided by each WSS need only be half of the total of what is needed to prevent accumulated signal distortion [8.18, 20]. Relaxing the required isolation within a WSS simplifies the ability to design WSS devices with higher port counts, smaller physical dimensions, as well as two independent WSS devices in a single package [8.20]. Additional advantages of this arrangement include reduced insertion loss through the routing WSS relative to a power splitter of the same port count (which reduces the amount of optical amplification needed, which improves performance) [8.20] and the provision of filtering of unwanted signals provided to the CD structure [8.20].

To implement CD demultiplexing within a route-and-select architecture with perhaps limited isolation within the WSSs in each degree, a broadcasting function or power-combing function within the CD add/drop structure may result in unwanted crosstalk between channels of the same wavelength. Therefore, a routing function is generally used within the CD structure as shown in Fig. 8.22. In this approach, the CD add/drop structure is not contentionless given the unitary fiber connection between the $M \times 1$ and $1 \times N$ WSS. Similar to the approach shown in Fig. 8.21, $1 : n$ power splitters and $n : 1$ power couplers are connected to the multichannel outputs of each of the N WSS ports to expand

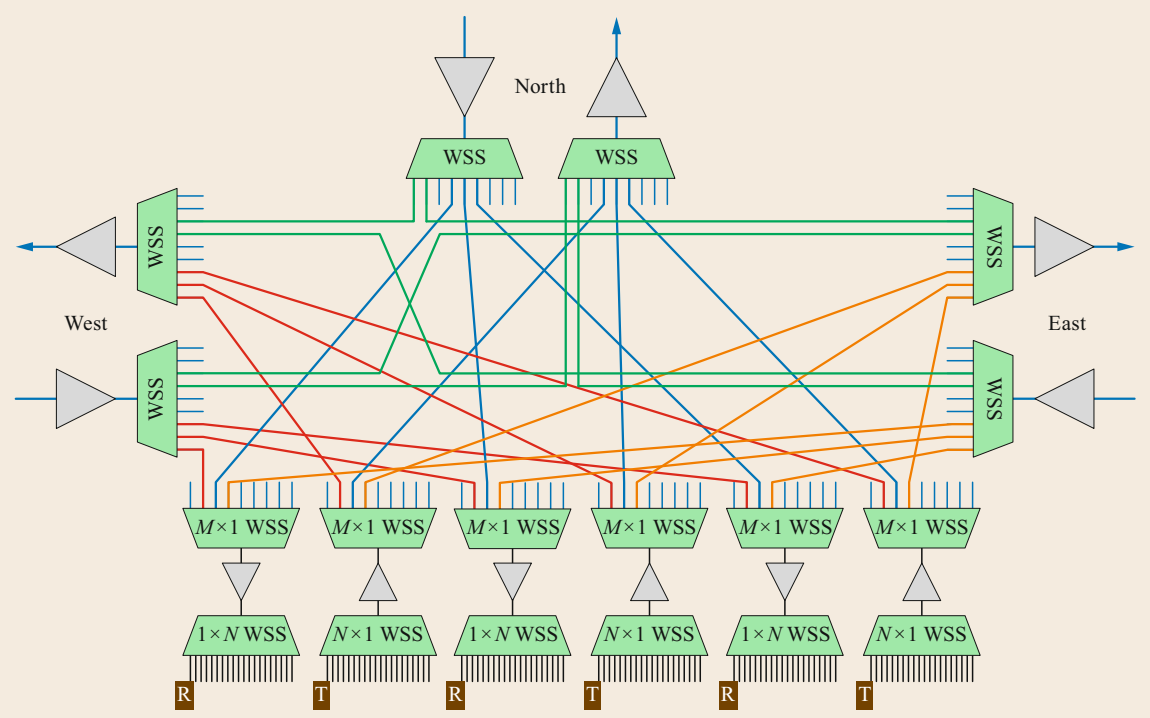

Fig. 8.22 General node architecture for a 3-degree route-and-select node with back-to-back $M \times 1$ and $1 \times N$ WSSs providing CD add/drop

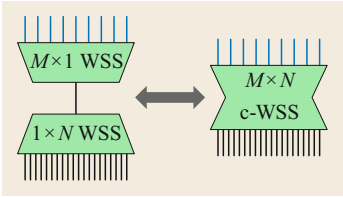

Fig. 8.23 Representation of the principle functionality of a wavelength-contentioned $M \times N$ WSS device ($M \times N$ c-WSS)

each WSS port into n ports supporting n transceivers, where each transceiver receives an independent channel.

The function of the back-to-back $M \times 1$ and $1 \times N$ WSSs (shown in Fig. 8.22) can be more efficiently accomplished by use of an integrated wavelength-contentioned $M \times N$ WSS device [8.21]. The functionality of a contentioned $M \times N$ WSS is shown in Fig. 8.23. The same device can function as a multiplexer or demultiplexer. The architecture utilizing the contentioned $M \times N$ WSS is shown in Fig. 8.24 [8.20]. This approach has the advantages that the contentioned $M \times N$ WSS has nominally the same physical form factor and insertion loss as a single $1 \times N$ WSS and it provides a more compact overall solution and removes the need for the additional amplifier located between the common ports of the $1 \times M$ and $1 \times N$ WSSs.

This architecture, with the availability of 1×20 WSSs within the degrees and 16×5 wavelength-contentioned WSSs within the CD structure enables the construction of practical 16-degree nodes, which support up to five CD structures, each of which can support the full complement of C-band channels (i.e., ninety-six 50 GHz wide wavelength channels). While this scale of node and add/drop is generally sufficient for the majority of network nodes, additional CD structures can be accommodated by adding a second layer of 1×20 WSSs attached to each degree WSS to provide additional ports in which to connect up to 20 additional CD structures. These expansion WSSs can be added after the initial five CD structures are deployed and without interrupting any service already deployed within the node, thus allowing the network operator the confidence to be able to expand any node to its maximum of 16 degrees but also with the flexibility to only need to deploy this expansion equipment once the need is identified for any given node.

Unfortunately, due to the construction of the wavelength-contentioned $M \times N$ WSS device (at time of this printing), when provisioning a connection between one of the M ports and one of the N ports, one or more unwanted connections between other M and other N ports can be made [8.22]. This characteristic is not a concern for the architecture shown in Fig. 8.25 because the degree WSS provides some blocking of all unwanted

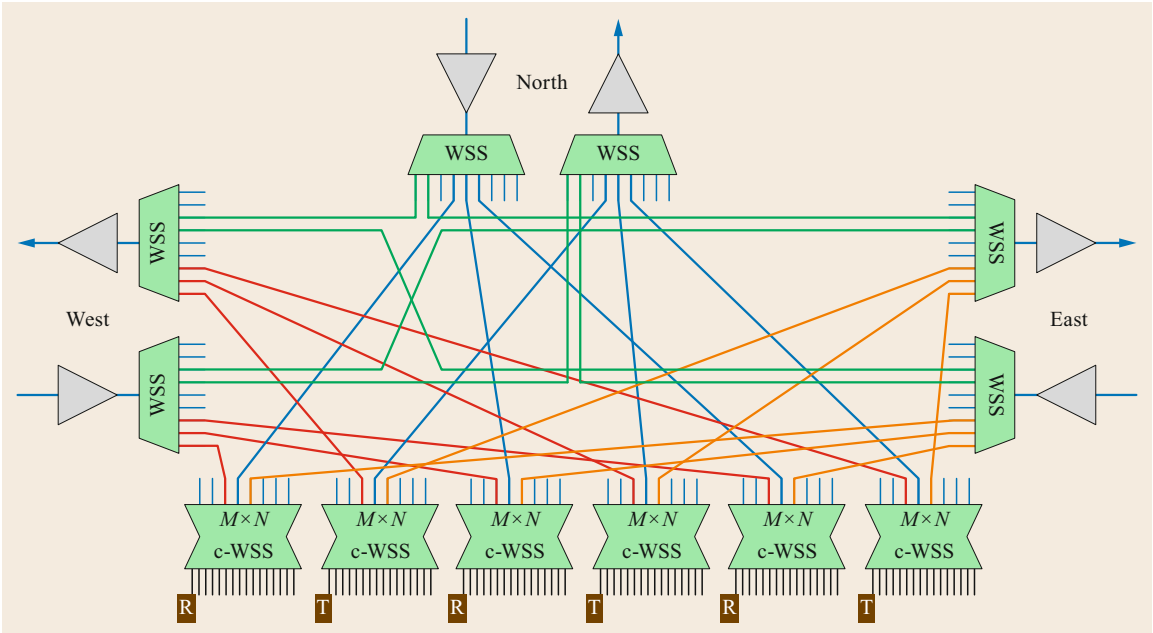

Fig. 8.24 General node architecture for a 3-degree route-and-select node with wavelength-contentioned $M \times N$ WSS-based CD add/drop

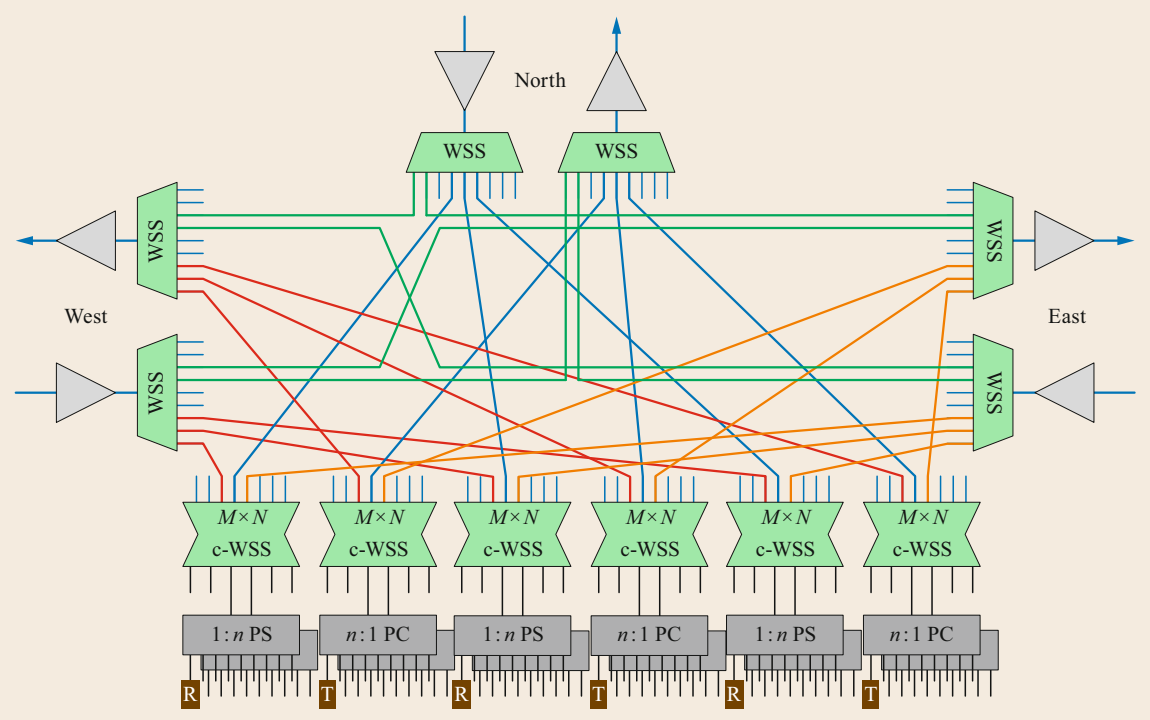

Fig. 8.25 General node architecture for a 3-degree route-and-select node with CD add/drop based upon a contentioned $M \times N$ WSS ($M \times N$ c-WSS) and expansion power splitter (PS) and power coupler (PC) demultiplexing and multiplexing

wavelength signals headed to the CD $M \times N$ WSS and if that mostly blocked, low-power signal were to reach a coherent transceiver it would not interfere with that receiver's ability to receive its desired signal. However, this characteristic does present a performance problem for using the wavelength-contentioned $M \times N$ WSS as a functional replacement for the back-to-back WSS architecture, given the potential for lower power signals to reach a direct detect receiver and have sufficient power level to potentially degrade its performance.

8.9 4- to 16-degree Route-and-select, Colorless, Directionless and Contentionless ROADM Node

The impact of wavelength contention within CD multiplexing/demultiplexing dominantly affects dynamic and automated wavelength reprovisioning and restoration activities and the level of the impact strongly depends upon the overall network architecture and the network utilization percentage [8.22, 23]. As network automation and optimization increases, the interest level is increasing in removing the multiplexing/demultiplexing wavelength-contention limitation simply to gain greater flexibility and utility from operators' ROADM networks. Therefore, networks providing colorless, directionless and contentionless (CDC) multiplexing/demultiplexing are currently increasingly being developed and deployed.

The first generation of CDC multiplexing/demultiplexing implementation utilizes the route-and-select architecture within the node degrees in conjunction with generally multiple subtending CDC multiplexing/demultiplexing structures incorporating a pair of $M \times N$ multicast switches (MCSs) (Fig. 8.26). The basic functionality of an $M \times N$ MCS is shown in Fig. 8.27. Each signal input into each of the M inputs is broadcast to N selection switches, each $M \times 1$ in dimension, such that any signal input into the $M \times N$ WSS can be routed to any of the N outputs without any wavelength contention. However, each of the N outputs will contain the full complement of wavelength signals that was directed to that input from the degree WSS as the MCS

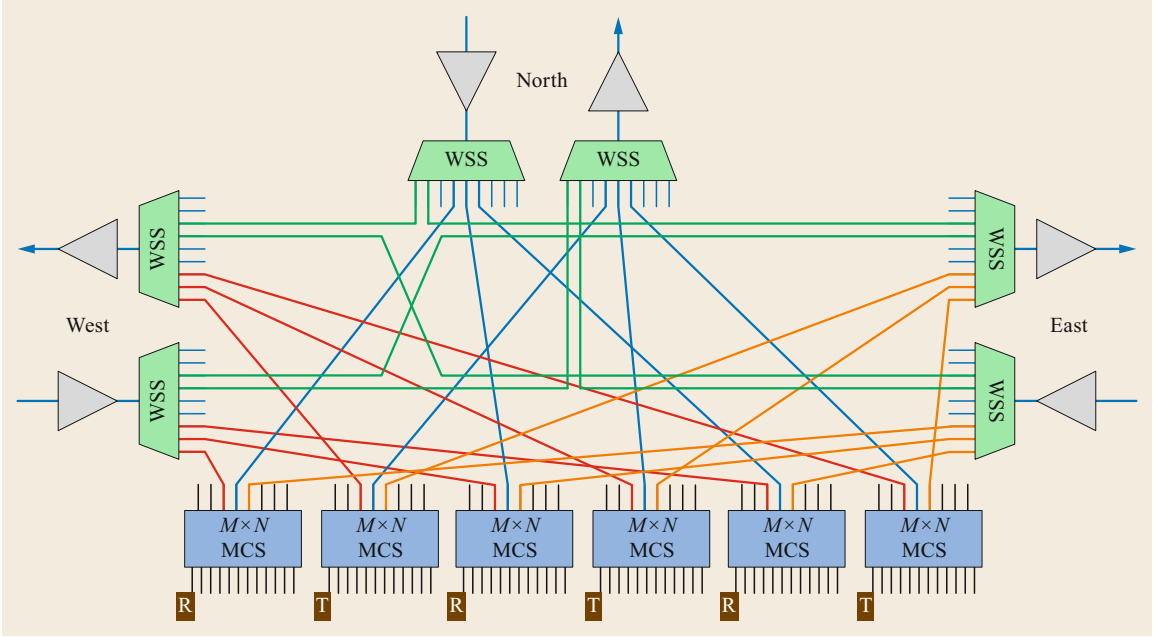

Fig. 8.26 General node architecture for a 3-degree route-and-select node with MCS-based CDC add/drop

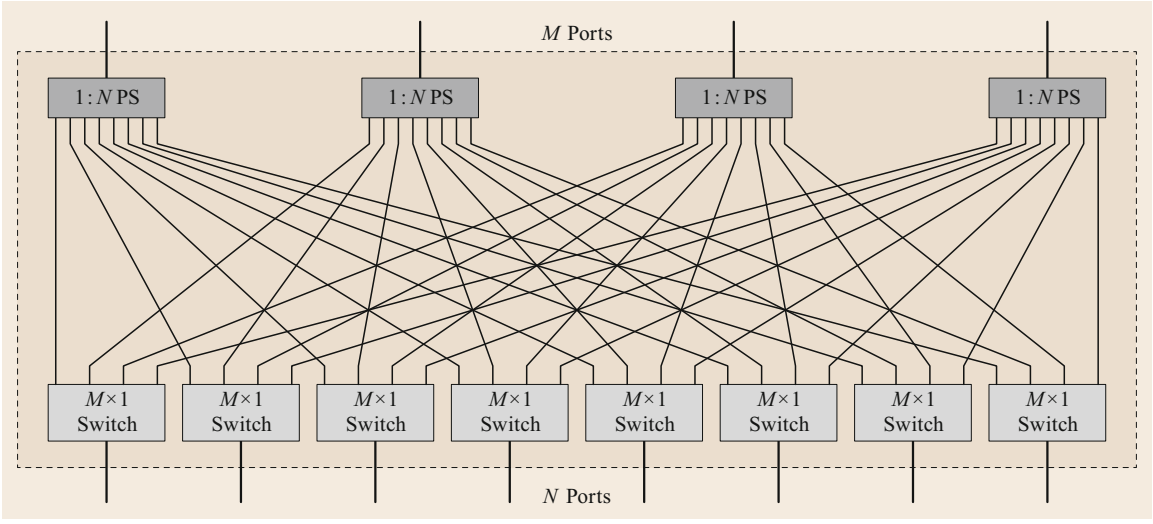

Fig. 8.27 Representation of the principle functionality of an $M \times N$ MCS device (PS = power splitter)

contains no wavelength filtering capabilities. Therefore, if multiple transceivers connected to the MCS receive separate independent wavelength channels from the same degree, all of those wavelength signals from that degree will be present at each respective receiver provisioned to receive one of those channels. The WSS within the degree performs the critical function of limiting the total number of wavelength signals directed to each MCS. Finally, unless individual tunable filters capable of isolating only the desired channel are implemented after the MCS, MCS-based demultiplexing is only compatible with coherent detection.

Multiplexing for CDC is accomplished with the same MCS structure, only with all optical signals propagating in the reverse direction (Fig. 8.26). Each $M \times 1$ switch directs the incoming signal to a respective $N : 1$ power combiner associated with the desired node degree where that signal is combined with all other signals directed to that same degree. As the MCS does not possess any wavelength filtering, all out-of-band noise

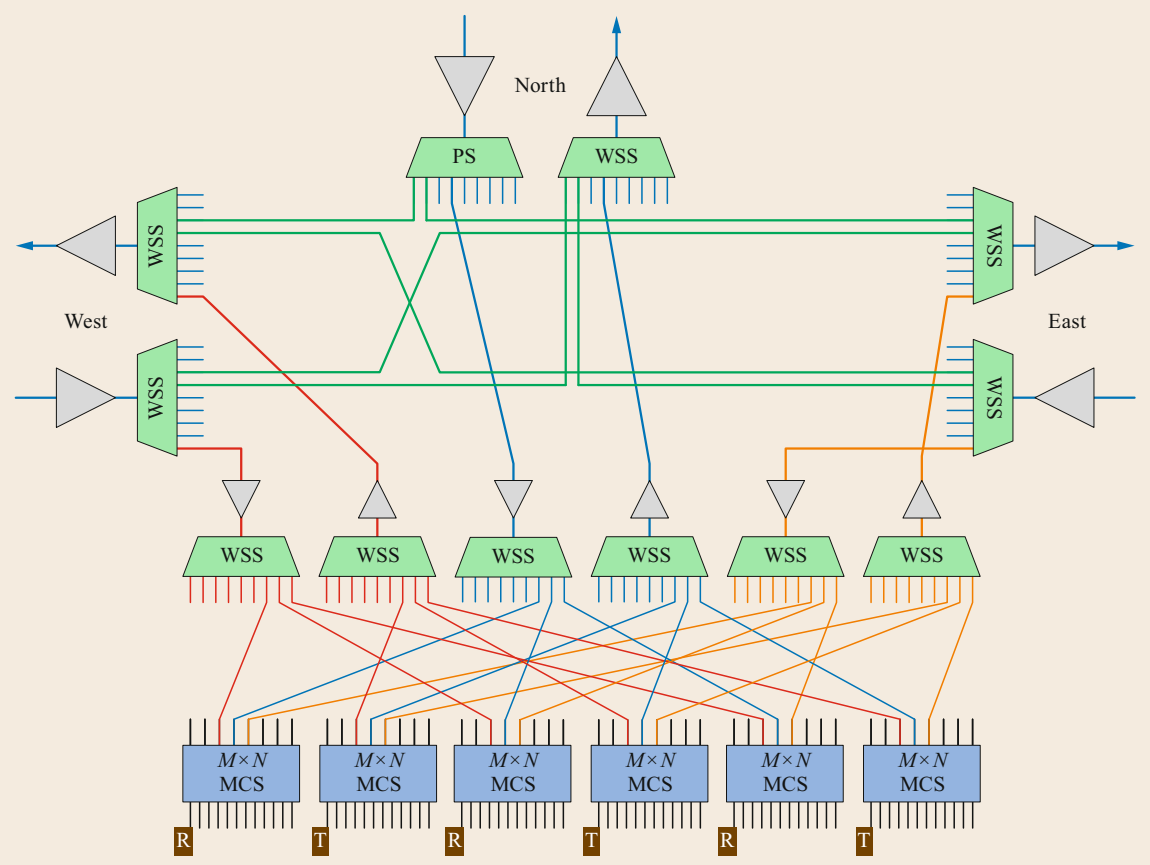

Fig. 8.28 General node architecture for a 3-degree route-and-select node with MCS-based CDC expansion WSS

generated by the transmitters will be combined within the MCS, which places a minimum requirement on the Tx_OSNR specification of the transmitters so that the reach performance of those aggregated signals is not meaningfully degraded. The impact of this noise aggregation from the transmitters as well as from the amplifier array is limited to only those channels from that respective MCS given the degree WSS will block all optical noise not spectrally located within the channel passbands of those active channels.

As the MCS construction is based upon power splitting/combining, the insertion loss through the device fundamentally depends upon N, the number of transceiver ports, with additional loss attributed to the implementation of the selection switch as well as additional device losses. Generally, for MCS devices where N is larger than four to eight, the total combined loss of the degree WSS and the MCS results in insufficient power at the respective receiver, thus requiring the inclusion of optical amplification located between the WSS and the MCS. Given the M input, this requires an M-wide optical amplifier array where each amplifier is capable of supplying enough output power to amplify N wavelength signals that can be distributed in any configuration across the C-band and must minimize gain excursion during any transient power fluctuation events of some or all channels.

In the multiplexing direction, a similar situation triggers the need for the inclusion of an M-wide optical amplifier array between the MCS and the degree WSSs, again with each multichannel amplifier capable of an output power sufficient to amplify N wavelength signals.

For each node, generally a minimum of two CDC structures is implemented to ensure redundancy for critical traffic. In order to increase the total number of wavelengths added/dropped within a node, additional CDC structures must be added, with each CDC structure requiring a connection to a port on every WSS within the node. Currently, MCS dimensions favor N not exceeding 16, given a larger number of ports could increase the MCS insertion loss such that an undesirably large output power is needed within the demultiplexer amplifier array, the maximum number of wavelength signals po-

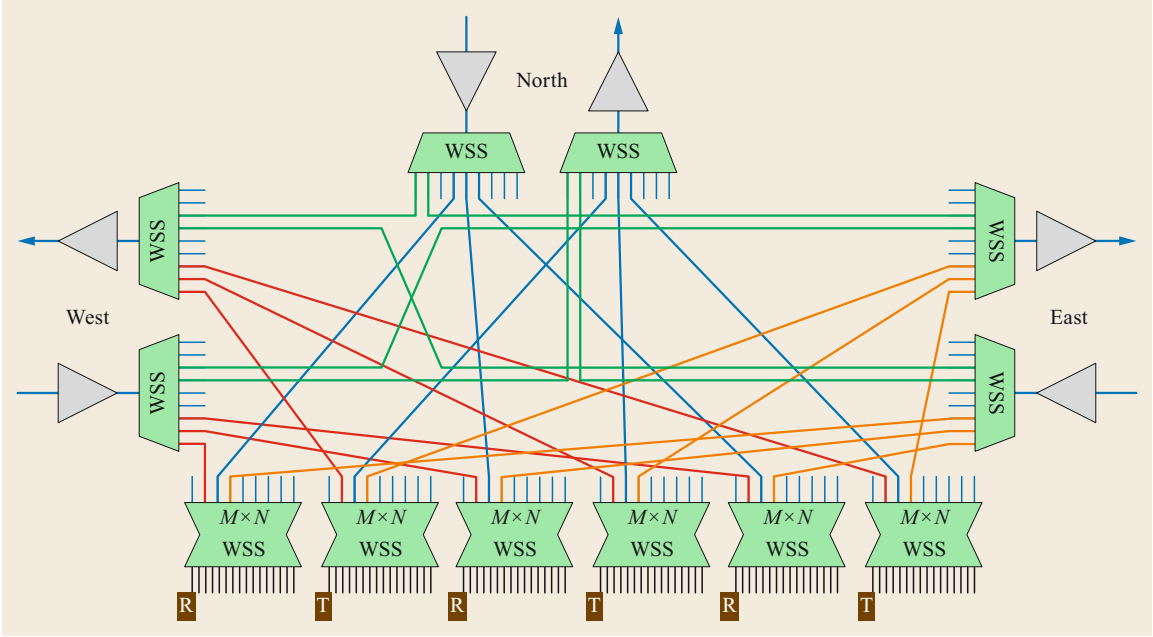

Fig. 8.29 General node architecture for a 3-degree route-and-select node with $M \times N$ WSS-based CDC add/drop

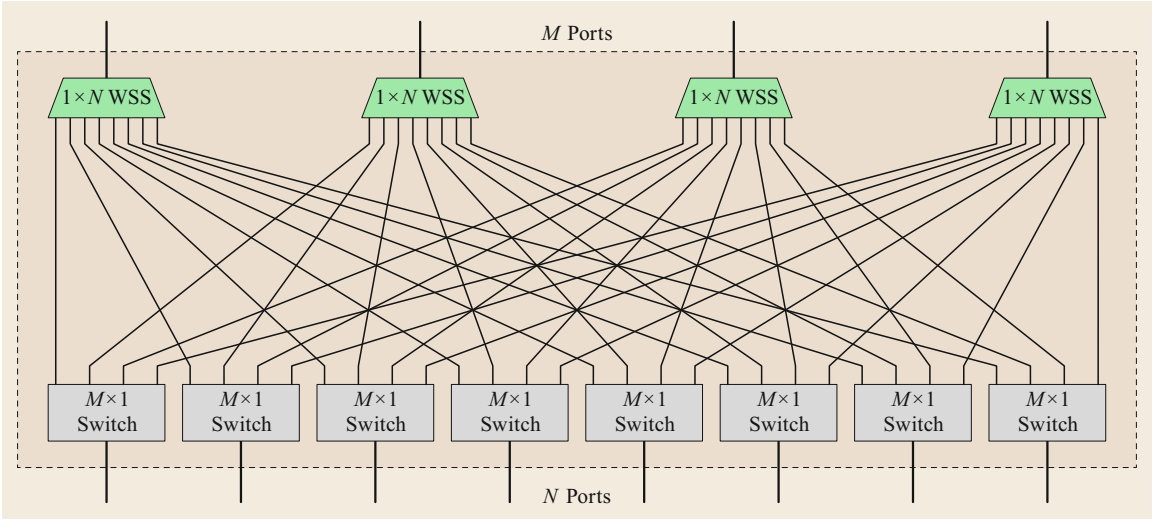

Fig. 8.30 Representation of the principle functionality of a contentionless $M \times N$ WSS device

tentially incident onto a coherent receiver is excessive, and/or the amount of out-of-band transmitter noise accumulated within the MCS is excessive.

To accommodate up to 16 degrees as well as a significant total number of add/drop ports within a degree, node WSSs with port counts exceeding 32 ports are utilized. Additional WSS ports for more CDC structures can be provided by deploying an expansion WSS in the same manner as illustrated in Fig. 8.28.

A subsequent alternative approach to CDC multiplexing/demultiplexing that address a number of the perceived shortcomings of the MCS implementation, particularly for larger nodes, is the wavelength-contentionless $M \times N$ WSS [8.24] (Fig. 8.29). This device has the ability to independently route any wavelength signal between any of the M input ports to any of the N output ports without any dependence upon how any of the other wavelength signals are routed (excluding routing two of the same wavelength signals to the same port) (Fig. 8.30).

As the contentionless $M \times N$ WSS device is based upon wavelength routing and not power splitting, the

insertion loss is not fundamentally dependent upon the port count on either the M or N dimension. Therefore, if the insertion loss of the device can be sufficiently low, no amplification array is necessary within the CDC structure, leading to a simplified CDC structure. With limited insertion loss dependence, both the degree (M) and add/drop port count (N) can be increased without a fundamental increase in insertion loss, allowing the number of degrees and add/drop ports supported by a contention to increase without requiring an amplification array. This scalability enables more ports per CDC structure and thus requires fewer node WSS ports for a given total number of add/drop ports.

The contentionless $M \times N$ WSS possesses flex-spectrum wavelength filtering such that only the wavelength bands routed to a port are allowed to pass with all other portions of the spectrum significantly blocked. This provides advantages in that only the desired channel need be routed to each receiver, which can improve the receiver's ability to receive that channel. Similarly, any out-of-band transmitter noise will be suppressed within the contentionless $M \times N$ WSS such that the Tx_OSNR specifications on the transceivers can be relaxed without performance degradation and independent of the number of add ports (N).

8.10 Reach and Performance Dependencies

Reduction of insertion loss is a primary goal of any optical network design. The attenuation of signals passing through a ROADM node is compensated by amplifiers, which increase signal power at the cost of added noise (Chap. 3). Accumulation of noise throughout the optical link leads to a reduction in optical signal to noise ratio (OSNR) and limits the maximum propagation distance of optical signals. Hence, there is a desire to reduce the loss and the amplification requirements throughout an optical network.

The loss of a ROADM node depends on the node architecture and the optical components that are utilized. The loss of a power splitter and coupler scales with the number of ports, whereas the loss of a WSS generally does not increase linearly with port count. However, a WSS has a higher excess insertion loss than a coupler. Therefore, a 16-degree route-and-select ROADM node employing 20-port WSS modules can possess a higher total loss than 2-degree ROADMs using a simple splitter and a 2×1 WSS architecture. However, that same 20-port route-and-select node can have less total loss than an 8-degree broadcast-and-select node. Additionally, the ROADM performs wavelength channel power equalization by reducing the power on all wavelengths to the lowest channel power within the spectrum. The difference in power between the average channel power and the lowest channel power, and the accuracy in power setting, should also be considered as contributors to the total node loss [8.25].

In general, on either side of the ROADM's broadcast and/or switching elements sits an inbound erbium-doped fiber amplifier (EDFA) (commonly referred to as a preamplifier) and an outbound EDFA (referred to as a postamplifier) (Fig. 8.31). The purpose of the preamplifier is to compensate for the fiber loss of the preceding span, typically with the gain, noise figure, and maximum output power optimized to compensate for high losses and channel power targets suitable for the ROADM's drop structure. The postamplifier compensates for the node loss, including equalization gain margins, with gain, noise figure, and power optimized to achieve channel power targets well suited for fiber propagation with minimal nonlinear impact. For long-haul networks, the preamplifier may be augmented with counterpropagating Raman in order to reduce the effective noise figure of the node (Chap. 3).

In typical metro networks, the intranode loss is usually higher than the fiber span loss because of the limited distances needed to interconnect a metropolitan area. Most of the OSNR degradation is induced by the postamplifier, which in turn is a function of the ROADM loss. Maximum reach is therefore typically more dependent upon the total number of nodes than it is on fiber span lengths. In contrast, in long-haul networks, amplifier-only non-ROADM nodes occur with much greater frequency, and OSNR degradation is dominated by the fiber loss-compensating amplifier-only nodes. Maximum reach is therefore largely related to length of fiber spans and fiber type than it is to the total number of ROADM nodes.

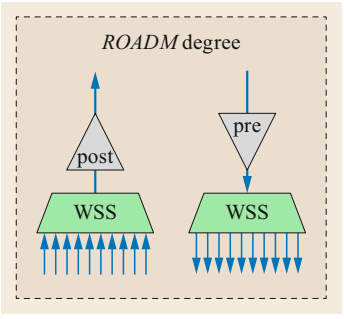

Fig. 8.31 Pre- and postamplifier positioning at a ROADM node

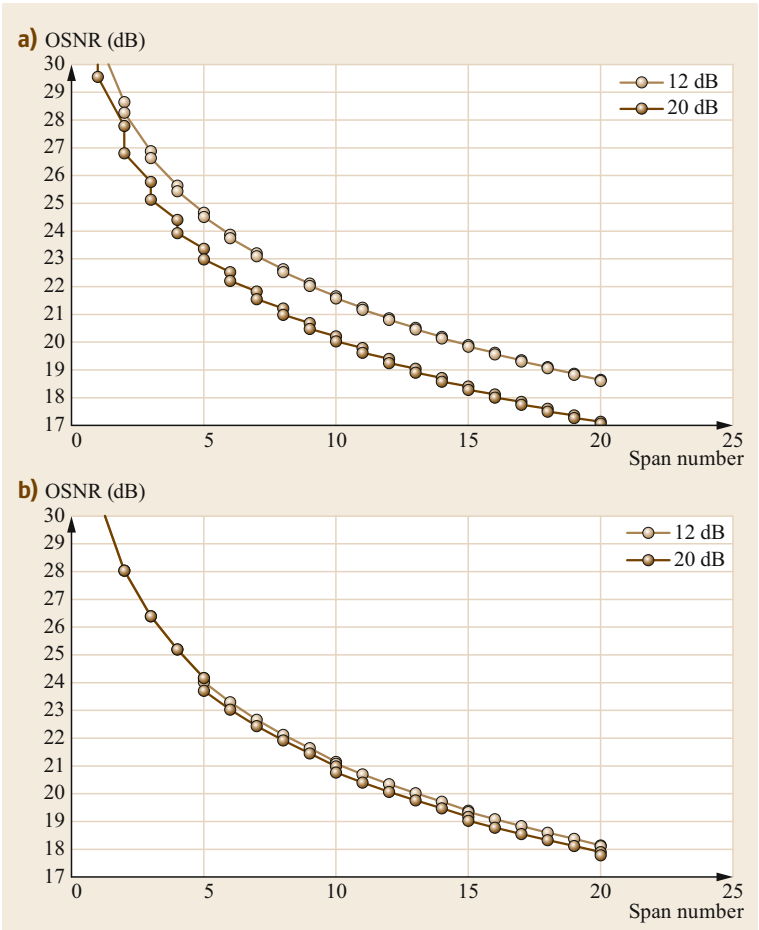

Fig. 8.32a,b Examples of OSNR degradation for **(a)** metro and **(b)** long-haul representative networks

To highlight the impact of ROADM design (particularly insertion loss) on overall system performance, a case study of a 96-channel, highly meshed metro network with ROADMs after every span is compared to one of a long-haul network with fewer, infrequent ROADMs placed primarily for periodic channel power equalization. Each example network is analyzed for two cases of total ROADM loss: 12 and 20 dB. The 12 dB node could correspond to a simple 2-degree ROADM, while the 20 dB could represent a higher-loss broadcast-and-select 8-degree ROADM. Each node is assumed to have an EDFA preamplifier and an EDFA postamplifier to compensate fiber span and node loss, as discussed above. The amplifiers are assumed to have noise figure values that are a function of gain; the preamplifiers optimized for lower noise figures at higher gain values, and higher available gain range, than the postamplifiers. The fiber span loss is assumed to be 16 dB for the metro example and 24 dB for the long haul.

The reduction in OSNR with span number is illustrated in Fig. 8.32a, b for the metro and long-haul cases respectively. As expected, a much larger ROADM loss dependency on the delivered OSNR can be seen in the metro case (a) compared to the long-haul case (b). After 20 nodes, the delivered OSNR for the metro example is about 1.5 dB lower for ROADMs with 20 dB loss versus 12 dB loss (about a 30% reduction). Viewed another way, if an optical transceiver requires an OSNR of 19 dB for error-free operation (e.g., 200 Gb/s 16QAM [8.26]), with 12 dB ROADMs the signal could achieve transmission over 19 spans, but with 20 dB ROADMs, it would be limited to 13 spans. In contrast, because the ROADMs are so infrequent, in the long-haul network the OSNR difference after 20 spans is only about 0.3 dB between the 12 and 20 dB cases. Considering the same 19 dB OSNR example, a reduction in maximum reach of only one span (from 16 to 15 spans) is observed.

8.11 WSS Bandpass Filtering and Implications

Another impairment requiring consideration in ROADM-enabled networks originates from the filtering of the optical signals as they pass through multiple WSS devices. As signals independently propagate through the network, neighboring channels may be added or dropped at nodes along a signal's route to its destination. As these neighboring channels get added or dropped, an optical bandpass filtering effect is applied to the signal of interest. An example of such a filter shape can be seen in Fig. 8.33a, which shows the WSS insertion loss as a function of frequency, assuming neighboring channels have been filtered out on either side of the center channel. As more ROADM nodes are cascaded for a given signal, there is the potential for the signal to experience an increasing amount of total filtering with each successive ROADM node. Figure 8.33b shows the cascaded filter bandwidth as a function of number of WSSs traversed. When considering that a signal passes through two WSSs in a route-and-select ROADM node, the number of potential WSSs traversed can grow quite large. This cascading of optical bandpass filtering can lead to narrowing of the transmitted optical signal – an impairment difficult to equalize within the receiver. Particularly for modern optical networks, which employ high-bitrate optical sources with Nyquist signaling (allowing channel spacing at intervals slightly higher than the baud rate), this is problematic and can lead to high transmission penalties after relatively few devices [8.27, 28].

The implications of this potential distortion source as transceiver technologies move towards higher baud rates and subsequently wider optical signals has motivated ROADM node designers to adopt statistical modeling of bandpass narrowing in engineering specifications and design rules, and WSS designers to develop higher-resolution WSS devices with sharper filter passband shapes.

During earlier ROADM node designs and deployments, state-of-the-art transponder technology generally employed on-off keying at 10 Gb/s, and chan-

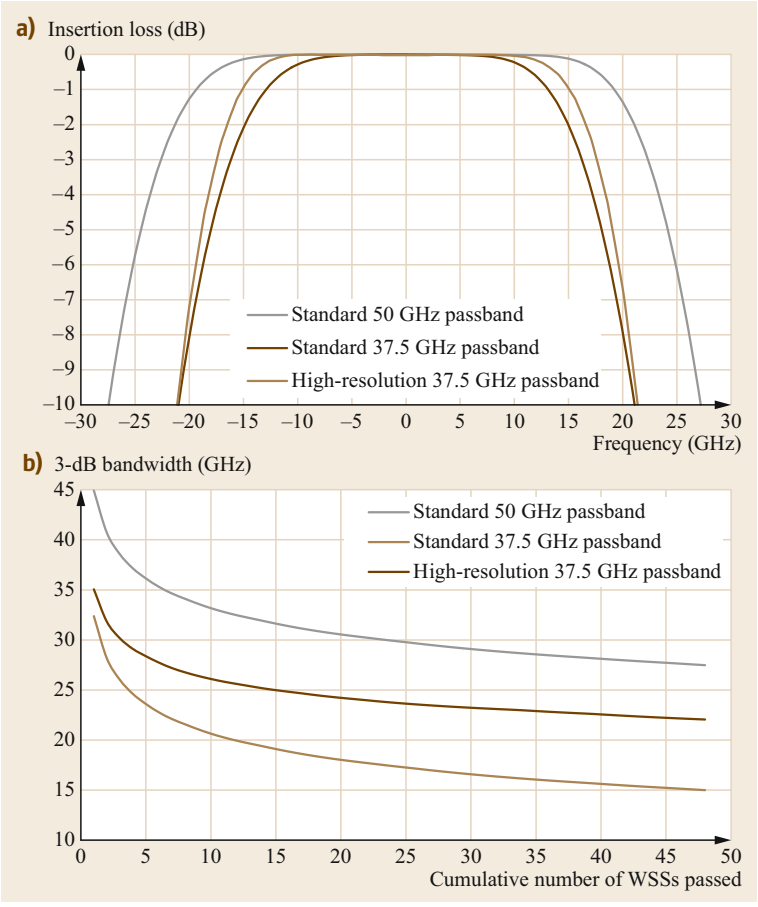

Fig. 8.33 **(a)** Example insertion loss channel passband for 50 GHz channel of a standard quality WSS and channel passbands of a 37.5 GHz channel for a standard (*blue*) and high-resolution (*green*) WSS. **(b)** Cumulative channel passband after a cascade of a given number of respective WSSs

nel spacing was typically 50 or 100 GHz such that the spectral occupancy of the signals was much narrower than the cumulative passband filtering created by the cascaded WSSs. Specifying WSS devices in terms of a simple center frequency and minimum passband width was typical, and penalties incurred due to filtering were negligible. As transceiver signal bandwidths have approached that of the channel spacing, WSS device manufacturers' and optical network system suppliers' handling of specifications and engineering rules evolved accordingly. Rather than using the minimum specifications for the WSS passbands to determine the cumulative WSS passband width, given the large number of WSSs a signal potentially experiences, a statistical approach has widely been adopted to model the cumulative passband width of a cascade of ROADM nodes. It has been found that for WSSs with sharper passband filter shapes, the cumulative bandpass filter width decreases sublinearly and the net bandwidth variation in a ROADM cascade (due to variations among individual WSSs in the cascade) decreases rapidly with increasing number of ROADMs [8.7]. This has allowed ROADM networks designs to accommodate higher baud rate signals without costly hardware, network topology, or reach implications.

The second implication has been the general improvement in WSS device technology providing higher-resolution WSS designs, which enable sharper filter shapes without significant compromises in physical size or cost. The curves in Fig. 8.33 labeled *high-resolution* show the impact of such design improvements.

8.12 Performance Monitoring and Wavelength Connection Validation

In the discussions above, it was assumed that the ability to perform monitoring of the incoming and outgoing optical signals is provided within the ROADM node. Optical signal monitoring is a critical capability as it provides both the information needed for the system to automatically control various automated control features (such as channel power equalization), and provides validation and visibility into the network characteristics at remote locations, allowing technicians such visibility entirely though the management software.

8.12.1 Optical Channel Monitoring

The ability to measure optical power is essential to the ability to perform channel presence detection, per-channel and spectral power equalization, spectral pre-emphasis, early detection of performance degradation, and fault troubleshooting. A ROADM node design very typically implements optical channel monitoring capability using low-percentage optical taps on all node ingress and egress ports providing a measurement of power versus frequency of the optical signals that enter and leave the node (similar to what an externally connected optical spectrum analyzer would provide). Early OCMs provided measurements of channel power levels integrated over the full 50 or 100 GHz channels. However, with the advent of flexible grid systems and Nyquist signaling, OCM requirements have evolved to provide subchannel granularity measurements (e.g., sub-6.25 GHz resolution) and report power spectral density (PSD, typically dBm/Hz). Given the measurements from the OCM are generally the primary information source from which automated functional control is determined, more frequent measurements can accelerate the frequency in which these controls can operate. This can translate into more rapid wavelength provisioning, reprovisioning following a fault, and more effective power transient suppression. OCM scanning speeds on the order of hundreds of milliseconds are typically currently desired for these applications.

8.12.2 Connection Validation and Wavelength Activation

Due to the large number of physical connections that are required between discrete elements or modules within an advanced ROADM node, operators desire the ability to automatically detect and validate that connections have been properly made, ensuring that the ROADM node is fibered properly and with the expected losses. A simple form of validation includes using low-percentage optical taps connected to a photodiode at strategic locations within the node, which can detect a low dither frequency unique to each transceiver. Another approach can include injecting a dedicated test signal at a reserved wavelength and then verifying that signal is detected by filtered tap-photodiodes at the proper locations within the node. A third approach leverages an extra test port on the WSSs to implement an optical loopback function for a prescribed wavelength channel in order to provide transceiver connection validation within various domains of the ROADM node, including within the CDC multiplexing/demul-

tiplexing as well as within the full node degree. This aids in troubleshooting initial deployments and turn-up, in identifying sources of network faults during ongoing operations and allows for self-calibration of optical transponders before turn-up to ensure optimal performance.

8.13 Looking Forward

The chapter above describes node architectures generally aimed at supporting up to 16 degrees, whereas the industry is currently developing designs to support beyond 16 degrees. Similarly, current network implementations are optimized around supporting transceivers that operate a single-wavelength signal within a channel. To keep pace with the needed increase in capacities [8.29], it is expected that the industry will eventually shift to transceivers that utilize multiple wavelength signals tightly spaced together so that they are treated as a single, wide channel [8.30]. While requiring the ability to support flexible spectrum, which most modern ROADM networks already support, these channels will possess higher total power levels due to the presence of multiple wavelengths. This is likely to force some modifications to existing CD and CDC networks, which may be engineered for lower total power levels per channel. This impact may not drive strong modifications to the ROADM node degree architecture, but may drive design choices where amplification is avoided given these higher power levels, such as using the contentionless $M \times N$ WSS for CDC multiplexing/demultiplexing (Fig. 8.29), which does not incorporate amplification in comparison to the MCS-based approach, which does (Fig. 8.26).

He holds B.Sc. and M.Sc. degrees in electrical engineering from the Georgia Institute of Technology in Atlanta, GA.

9. Fiber Nonlinearity and Optical System Performance

Alberto Bononi, Ronen Dar, Marco Secondini, Paolo Serena, Pierluigi Poggiolini

This chapter aims to provide a comprehensive picture of the impact of fiber nonlinear effects on modern coherent wavelength division multiplexing (WDM) systems' performance. First, the main nonlinearity models currently available are introduced and discussed in depth. Then, various specific aspects are addressed, such as the interplay of polarization mode dispersion (PMD)/polarization dependent loss (PDL) and nonlinearity, or the dependence of nonlinear effects on modulation format. The important topic of nonlinear effects mitigation is then dealt with. Finally, system performance metrics and capacity are discussed extensively, as to how they are fundamentally influenced and limited by fiber nonlinearity.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_9

Optical propagation within an optical fiber involves complex linear and nonlinear interactions among traveling optical signals, which manifest themselves as intersymbol and interchannel interference among the digital data. To shed light on such effects, a large number of analytical, numerical, and experimental investigations have been carried out. Scientific modeling is an essential tool for any investigation as a way to make it easier to understand and reproduce experimentally observed results. Models help system designers in predicting the behavior of an optical network and show their greatest effectiveness in their ability to isolate subsets of test conditions that are not easily obtainable otherwise.

The main aim of this chapter is to review the most important models for performance prediction in optical fibers, to point out their strengths and weaknesses, and to provide both theoretical background and practical indications on their use.

9.1 Modeling the Optical Fiber

Any model captures part of the reality at a given abstraction level, and hence each model can always be generalized to a more complete model able to explain the previous one, at the cost of increased complexity. Usually, in science the most complete models are local models, i.e., general descriptions of what happens at each space coordinate. Such models are usually written in terms of differential equations. In many cases, such equations cannot be solved exactly, nevertheless they contain all the information about the evolution of the signal of interest. In optical fiber propagation, the reference model is the nonlinear Schrödinger equation (NLSE), which is a partial differential equation that describes the local behavior of a propagating electromagnetic wave [9.1]. In optical communications, an electromagnetic wave is typically written as $A(z,t) \times \exp[\mathrm{j}(\omega t - \beta z)]$. Such notation describes a wave of amplitude $|A|$, phase $\arg[A]$, propagating at frequency $f = \omega/(2\pi)$ at phase velocity ω/β in the z-direction; $A\,(z,t)$ is assumed to be *slowly varying*, in both time t and distance z, with respect to the faster oscillating exponential factor. Henceforth, for compactness, we will omit to explicitly indicate the t and z-dependence of A.

In its simplest form, the NLSE can be written as [9.1]

$$\frac{\partial A}{\partial z} = -\frac{\alpha_\mathrm{p}}{2}A + \mathrm{j}\frac{\beta_2}{2}\frac{\partial^2 A}{\partial t^2} - \mathrm{j}\gamma\,|A|^2 A\,. \tag{9.1}$$

The first term on the right-hand side in (9.1) causes the wave to experience a *power loss* at a rate set by α_p. The small value of α_P in silica compared to copper cable has been one of the greatest achievements of optical communications, celebrated by awarding the Nobel prize to the pioneering studies made by Sir Charles Kao.

The second term in (9.1) expresses dispersion in the time domain t. To understand the implications of dispersion we should first generalize the basic idea of the plane wave. The reader familiar with the Fourier transform should not be surprised that the true electromagnetic field propagating within an optical fiber can be described by a superposition of waves. However, such waves travel at different speeds with a group velocity dispersion (GVD) proportional to β_2. This is the implication of the second term on the right-hand side of (9.1), which is usually best understood in the frequency domain as a term in quadrature with the signal and proportional to the square of the frequency. As a result, GVD alone on a global scale manifests as a pure phase shift in the frequency domain. GVD makes the different waves making up the signal reach the receiver at different times, so that their sum is different than what it was at the transmitter. The result is signal distortion, generally referred to as intersymbol interference at the receiver. This problem was eventually solved by means of optical or electronic dispersion compensation.

The third term in (9.1) is a nonlinear term, i.e., a contribution for which the superposition principle no longer holds. It is called the nonlinear Kerr effect [9.1, 2]. As a consequence, because of nonlinearity, the traveling waves interact. We observe that nonlinearity is weighed by a factor $|A|^2$, hence proportional to the *power* of the propagating signal. We thus expect the nonlinear effect to be relevant only at high power. This observation is reminiscent of the idea of the Taylor series in mathematics, where any well-behaved function is linear in a small neighborhood of a given value. In this case, we could say that the fiber is linear close to the zero value of the amplitude A. It is worth noting, though, that from a naive similarity with the Taylor series, one would expect a nonlinear quadratic term, whereas the nonlinear Kerr term in (9.1) is *cubic* in A. The reason for the cubic behavior is strictly related to the odd symmetry of the silica molecule [9.1].

The nonlinear Kerr term in (9.1) is a memoryless effect since it impacts the propagating signal at the present time only. This is clearly unrealistic, since any physical effect has some memory. However, this assumption is justified by the extremely small time lag

over which nonlinearity occurs, of the order of femtoseconds.

There is a very interesting duality between the nonlinear Kerr effect in the time domain and dispersion in the frequency domain. For instance, GVD alone does not make different frequencies interact, as for any linear time-invariant effect, while it creates intersymbol interference in the time domain; the opposite occurs for nonlinearity, where different times do not interact, while different frequencies do. Moreover, while GVD acts in quadrature with the signal in the frequency domain, the same occurs for the nonlinear Kerr effect, but in the time domain. Hence, for similar arguments, both effects manifest as phase rotations: GVD in the frequency domain and the nonlinear Kerr effect in the time domain. The latter is generally called self-phase modulation (SPM).

Modeling nonlinearity has been one of the greatest challenges of the last decades because of the complexity of the problem. Thanks to the similarity between the propagation of optical waves in optical fibers and that of water waves in the sea, it is helpful to visualize nonlinearity by the waves' interaction in a heavy sea. The chaotic behavior of such interaction itself explains the difficulty of undoing it at the receiver, as well as that of the difficulty of a full statistical description.

Linear and nonlinear effects are experienced both by the information signal but also by the unavoidably propagating noise, generally introduced by optical amplifiers in the form of amplified spontaneous emission (ASE).

To understand the implications of ASE let us ignore nonlinear effects for a moment. At the receiver we know how to compensate for dispersion, thus we are left with the problem of noise cumulated along the link. The solution appears simple: increase power to make noise negligible with respect to the information signal. Figure 9.1 sketches this idea by showing the typical behavior of the receiver signal-to-noise ratio (SNR) versus signal power, at the output of a fiber transmission link. The SNR is a typical quality-of-transmission parameter, as we will discuss more in detail later in this chapter. In the absence of nonlinear effects, the SNR would grow indefinitely for increasing power, see the dashed line *linear asymptote* in Fig. 9.1. However, this ceases to hold when nonlinearity enters the game. The typical behavior of SNR versus power is depicted in Fig. 9.1 by a solid line. In the figure, we observe that an *optimal power* exists, corresponding to the maximum achievable SNR. Beyond the optimal power the SNR drops, with a slope which is actually steeper than the slope of increase at small power [9.3, 4].

We thus recognize two asymptotic behaviors at small/high powers, which in agreement with the previous discussion define what we call the ASE-limited region and the nonlinearity-limited region, respectively.

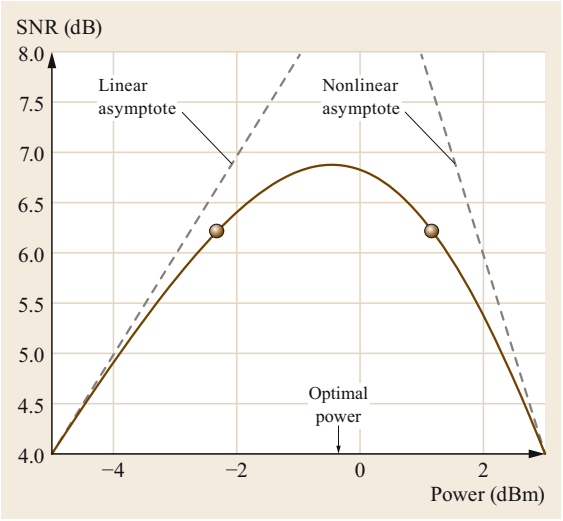

Fig. 9.1 Example of behavior SNR versus power after a fiber-optic link

The optimal power of Fig. 9.1 refers to a link of a given length. We may ask what happens by increasing the link length. In this scenario, both the linear and the nonlinear asymptotes run lower, because of more accumulated ASE and nonlinearity along transmission. If we fix a reference SNR, which may be the threshold of the forward-error correcting code under use, we can identify two power values, one in the ASE-dominated regime and one in the nonlinearity-dominated regime. Such values are sketched in Fig. 9.1 at a fixed distance, and in Fig. 9.2 at all distances up to the maximum distance, or *maximum reach* (MR), at which they merge into a single power value.

In this chapter, we discuss some models that are able to describe such important features as the optimal power and the reach with good approximation. Of course, their knowledge is of great importance in the study, design, and even realtime management of optical networks, a topic that will be covered in Sect. 9.10.3.

The NLSE can be further generalized. So far, we have described the electromagnetic wave in terms of its amplitude, frequency, and propagation constant. However, if this wave collides with an electron along propagation, such an electron starts oscillating around a preferred direction. The information about this direction has not been accounted for, so far. We thus need to accept that our signal wave is described by a *vector*. When such a direction matters for the investigation of propagation, we say that the optical fiber shows *birefringence*. Such vectors can be fully described by two components. The scalar impairments, such as loss and

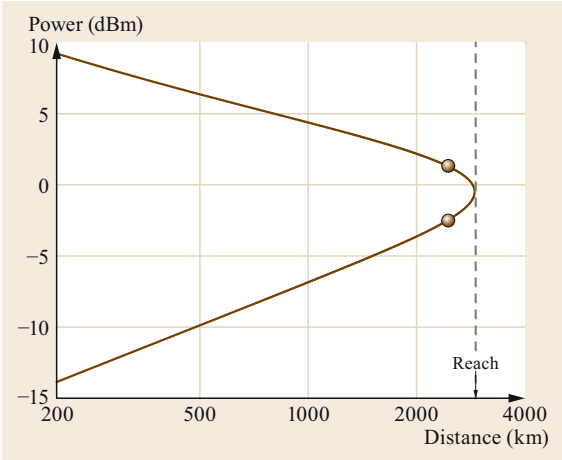

Fig. 9.2 Example of contour levels at fixed SNR. The lower part is set by accumulation of ASE, and the higher part is set by accumulation of nonlinearity. The reach is the maximum distance for the given SNR

dispersion, become matrices in the presence of birefringence.

The implications of the vector nature of the waves will be described more in detail in Sect. 9.9.3. In essence, the nonlinear term of the NLSE becomes more complex [9.2, 5, 6]. However, it is possible to simplify it with reasonable approximations, based on the following argument.

The two components of the wave, from now on referred to as *polarizations*, experience different propagation constants. Such a difference is the main manifestation of fiber birefringence. Because of it, the two polarizations periodically phase shift and return in phase after the so-called *beat length* [9.7]. For typical telecom fibers, the beat length is of the order of meters, a length scale usually much smaller than the length scale over which nonlinearity induces significant changes in the wave. We are, thus, justified to average out such fast phase variations.

The result yields an isotropic nonlinear effect, which turns the scalar nonlinear term $\gamma |A|^2 A$ into $\gamma(8/9)||\boldsymbol{A}||^2\boldsymbol{A}$, where $\boldsymbol{A} = \left[A_x, A_y\right]$ is the vector containing the amplitudes of the two polarizations in the fiber, while $||\boldsymbol{A}||^2$ is the overall power of the wave. The factor $8/9$ is the net result of the averaging. The corresponding equation is referred to as the *Manakov equation* [9.8, 9].

The Manakov equation is currently the most widely used signal-propagation equation, the starting point for the derivation of most analytical models quantifying the system impact of nonlinearity. This chapter will mostly focus on such analytical models. However, another approach is also possible for system study and design.

It is based on the brute-force numerical integration of the signal propagation equation, be it the NLSE, the Manakov equation, or more complex ones. While analytical modeling has recently gained widespread adoption, numerical integration is, and will likely be, a mainstay of system studies. One of the main reasons is that, as mentioned above, all analytical models are based on assumptions and approximations, and must be validated. System simulation, by means of direct numerical integration of the propagation equations and Monte-Carlo system performance estimation, provides an indispensable tool for model validation. In addition, nonconventional system setups may fall outside the scope of models and necessarily need numerical integration. Because of the key role of system simulations, the next section is devoted to this topic.

9.2 Fiber Propagation: Numerical Methods

The NLSE (9.1) introduced in Sect. 9.1 has no general closed-form solution. While some approximated analytical solutions (discussed in Sect. 9.3.1) are available and are widely used for modeling purposes, the accurate simulation of optical fiber systems largely relies on numerical methods.

Over the years, several different numerical methods have been developed to solve the NLSE and its generalizations, based on different approaches for the discretization of the time and space variables, such as classical explicit and implicit finite difference methods and pseudospectral methods (see, for instance, [9.1, 10] and references therein). Among them, the split-step Fourier method (SSFM) [9.11, 12] has largely prevailed due to its simplicity, flexibility (it can be easily extended to include other propagation effects and system elements), numerical stability, and computational efficiency [9.10], becoming the method of reference in the optical fiber community [9.1].

The key idea behind the SSFM is that of dividing the propagation along a link of length L into M steps of length $h = L/M$, over which the effects of the linear and nonlinear parts of the equation are split (hence, the attribute *split step*). Equation (9.1) is rewritten in the simple general form

$$\frac{\partial A}{\partial z} = (\mathcal{L} + \mathcal{N})A \,, \tag{9.2}$$

where the operators $\mathcal{L} = \mathrm{j}(\beta_2/2)(\partial^2/\partial t^2)$ and $\mathcal{N} = -\alpha_\mathrm{p}/2 - \mathrm{j}\gamma\,|A|^2$ represent the linear and nonlinear parts of the equation, respectively [9.13]. (Although fiber attenuation is a linear effect and should naturally be included in the linear operator $\mathcal{L}$, moving it into the nonlinear operator $\mathcal{N}$ makes the resulting SSFM more accurate [9.13].)

The propagation over a step of length h can be formally approximated as

$$A(z+h,t) \cong \exp\left[\int_z^{z+h} \mathcal{N}(\zeta)\mathrm{d}\zeta\right] \exp(h\mathcal{L})A(z,t)\ . \tag{9.3}$$

The approximation (9.3) is particularly convenient, as the separate effects of the linear and nonlinear operators can be easily expressed in closed form, the former in the frequency domain (hence the attribute *Fourier*) and the latter in the time domain.

The algorithm operates on a discrete-time representation of the propagating waveform $A(z,t)$. Assuming a sampling time T_s and a total duration $T = NT_\mathrm{s}$, the signal at distance $z = kh$ (i.e., after k propagation steps) is represented by the vector $\boldsymbol{A}_k = (A_{k,1}, \ldots, A_{k,N})$, with $A_{k,i} = A(kh, iT_\mathrm{s})$. Transformations from time to the frequency domain and back are based on the direct and inverse discrete Fourier transforms, which are efficiently computed by the fast Fourier transform (FFT) algorithm. This entails assuming periodic boundary conditions both in time and frequency, with periods T and $B = 1/T_\mathrm{s}$, respectively. Therefore, when selecting T and B, special care must be taken to ensure that they are sufficiently wider than the actual continuous-time signal duration and (two-sided) bandwidth, respectively, to avoid time and frequency aliasing [9.14]. In the basic implementation of the algorithm, the input vector $\boldsymbol{A}_0$ is propagated through the M fiber sections according to the scheme in Fig. 9.3. In particular, the propagation through the k-th section of the fiber consists of the following four operations:

1. Computation of the FFT of $\boldsymbol{A}_{k-1}$ to obtain the frequency-domain vector $\tilde{\boldsymbol{A}}_k = (\tilde{A}_{k,1}, \ldots, \tilde{A}_{k,N})$.
2. A linear step to compute the vector $\tilde{\boldsymbol{A}}'_k = (\tilde{A}'_{k,1}, \ldots, \tilde{A}'_{k,N})$ according to

$$\tilde{A}'_{k,i} = \tilde{A}_{k,i}\mathrm{e}^{-\mathrm{j}2\pi^2\beta_2 f_i^2 h}, \quad i = 1, \ldots, N\,, \tag{9.4}$$

   where f_i is the frequency of the i-th component
3. Computation of the inverse FFT (IFFT) of $\tilde{\boldsymbol{A}}'_k$ to obtain the time-domain vector $\boldsymbol{A}'_k = (A'_{k,1}, \ldots, A'_{k,N})$.
4. Nonlinear step to compute the vector $\boldsymbol{A}_k = (A_{k,1}, \ldots, A_{k,N})$ according to

$$A_{k,i} = A'_{k,i}\mathrm{e}^{-\alpha_\mathrm{p}h/2}\mathrm{e}^{-\mathrm{j}\gamma h_\mathrm{eff}|A'_{k,i}|^2}, \quad i = 1, \ldots, N\,, \tag{9.5}$$

   where $h_\mathrm{eff} = (1 - \mathrm{e}^{-\alpha_\mathrm{p}h})/\alpha_\mathrm{p}$ is the effective length of the step, which accounts for the dependence of the nonlinear operator on the propagation variable due to the attenuation.

The algorithm complexity is $O(N \log N)$ for FFTs and $O(N)$ for (9.4) and (9.5). The actual number of operations depends on the specific implementation of the algorithm and will be briefly discussed in Sect. 9.11.1. The algorithm can be extended to the Manakov equation for dual-polarization signals by replacing signal samples with two-element vector samples (each element representing a polarization component). All the operations described should then be applied to both polarizations, interpreting the squared modulus $|A'_{k,i}|^2$ in (9.5) as the squared norm $\|A'_{k,i}\|^2$ of the vector sample.

Since the linear and nonlinear operators in (9.2) do not commute, (9.3) is only an approximation. However, an argument based on the Baker–Campbell–Hausdorff formula ensures that the local error induced by (9.3) is of the order of h^2, such that the global error accumulated at the output of the link is of the order of h, i.e., it decreases linearly with the number of steps M. A more accurate approximation can be obtained by using (9.3) for half the step and applying the operators in reverse order for the other half, such that error terms of the order of h^2 cancel out. This results in a symmetric version of the algorithm that is based on the approximation

$$A(z+h) \cong \exp\left(\frac{h}{2}\mathcal{L}\right) \exp\left[\int_z^{z+h} \mathcal{N}(\zeta)\mathrm{d}\zeta\right] \times \exp\left(\frac{h}{2}\mathcal{L}\right) A(z) \tag{9.6}$$

and has local and global errors of the order of h^3 and h^2, respectively. The adjacent linear steps of two consecutive sections can be merged into a single linear step of length h. Therefore, the symmetric algorithm is almost equal to the basic one depicted in Fig. 9.3—but for halving the length of the first linear step and for adding one more linear steps of length $h/2$ after the last section—and achieves a higher accuracy with a negligible increase of complexity.

The accuracy and complexity of the algorithm can be traded off by selecting the step size h, which can

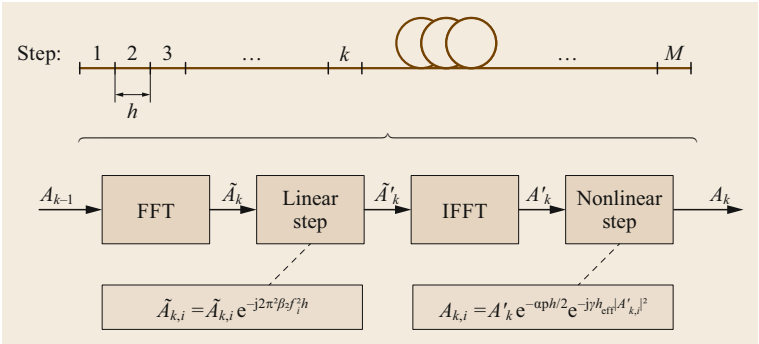

Fig. 9.3 Basic implementation of the SSFM algorithm

also be adaptively changed along the link to increase the accuracy for a fixed complexity. Some possible criteria for the selection of the step size, as well as a strategy for its adaptation based on the local error, are discussed and compared in [9.15]. A simple strategy for the adaptation of the step size based on the global error is presented in [9.16].

When processing a very long sequence of samples, the overlap-and-save technique is typically employed to minimize the complexity of the algorithm and keep its latency within reasonable limits [9.14]. The input sequence of samples is thus divided into several overlapping blocks of length N, which are separately processed according to the algorithm in Fig. 9.3. The output sequence is eventually reconstructed by concatenating the output blocks and discarding the overlapping samples.

The number of overlapping samples should be at least equal to the overall memory N_{m} of the fiber-optic channel, which depends on the maximum dispersion experienced during propagation. In a dispersion-uncompensated link of total length L, assuming a constant dispersion parameter β_2, the channel memory can be approximated as $N_{\text{m}} \cong 2\pi|\beta_2|B^2L$ [9.17].

9.3 Fiber Propagation: Analytical Perturbation Modeling

The absence of closed-form solutions of the NLSE, except for peculiar cases, stimulated the search for approximated analytical solutions. Among the plethora of methods that mathematics can provide, perturbation theory [9.18, 19] has been the most widely used in approximating the NLSE.

9.3.1 Perturbation Methods

The basic idea of perturbation theory is to identify a term in a differential equation that is expected to be a small disturbance to the exact solution of the equation, i.e., it is a perturbation. Most of the time, the small perturbative term is weighed by a parameter, which represents a key variable for perturbation theory. If such a parameter is not clearly visible, one can always multiply the perturbative term by a coefficient ϵ, apply the perturbation theory, and finally set $\epsilon = 1$.

Once the small perturbation and its related parameter ϵ, which is based on physical intuition, are identified, one can use math to properly approximate the solution for small ϵ. The idea is to write the unknown exact solution of the differential equation as a Taylor series in ϵ. In the NLSE case, we identify the nonlinear Kerr effect as the small perturbation and γ as the corresponding small parameter [9.20–22]. We, thus, search the solution of the NLSE as a Taylor series with respect to γ

$$A(z,t) \cong A_0(z,t) + A_1(z,t)\gamma + \dots \,.$$

We do not know $A(z,t)$, but due to perturbation theory we can evaluate $A_n(z,t)$ for all integers $n \geq 1$. They can be evaluated recursively by solving the following differential equations [9.18]

$$\frac{\partial A_n}{\partial z} = \mathcal{L}A_n + \mathcal{N}(A_{n-1}) \,. \tag{9.7}$$

At a closer look we note that such differential equations are linear, with a forcing term $\mathcal{N}(A_{n-1})$. Each of them can, thus, be solved exactly once we know the solution at the previous order.

Although we can truncate the Taylor series up to any order, all A_n with $n \geq 2$ are extremely complex and, with very few exceptions, the NLSE has typically been approximated to first order in γ. Incidentally, the NLSE is a well-behaved differential equation and setting $\gamma =$

0 does not cause divergence problems, so that we say that we have a regular perturbation (RP) solution [9.18]. We are then mainly interested in RP1, i.e., in RP up to γ^1.

The first-order perturbative term in the frequency domain takes the following general expression [9.19, 20, 23, 24]

$$\tilde{A}_1(z,f) = \iint_{-\infty}^{\infty} \eta(f_1,f_2,f) \times \tilde{A}(0,f+f_1)\tilde{A}(0,f+f_2)\tilde{A}^*(0,f+f_1+f_2)\mathrm{d}f_1\mathrm{d}f_2 \,, \tag{9.8}$$

where $\eta(f_1,f_2,f)$ is the fiber kernel and contains all the main properties of the link. From a numerical point of view, the RP solution (9.8) does not yield significant speed-up with respect to the numerical solution provided by SSFM. However, its main interest lies in providing an end-to-end analytical solution that can be statistically manipulated, as we will see in the following sections. Alternatively, the RP1 solution can be expressed as a propagating perturbative term along the distance, the implications of which will be discussed in Sect. 9.6.

For the NLSE, the RP has been showed to coincide with the Volterra series expansion [9.23]. Nevertheless, the physical intuition behind RP is of great help in suggesting ways to improve the solution. First, it has been shown that even in the presence of dispersion part of the perturbation is in quadrature with the unperturbed signal. Therefore, besides observing amplitude distortion at the receiver, we do have phase distortion that we generally categorize as SPM and XPM. Even if SPM and XPM are small phase distortions, they may induce a significant low-frequency contribution that is usually removed by the carrier-phase estimator (CPE) in the coherent detection, or by the photodiode in the direct detection. The basic RP solution (9.8) is *unaware* of such observations, and, thus, its basic expression (9.8) often fails to be satisfactorily accurate. Special tricks to remove such problems are, thus, necessary to improve the range of validity of the RP1 approximation.

A first improvement is to search the perturbation in the reference system of the *average nonlinear phase rotation*, yielding the enhanced RP (eRP) method [9.23]. For first-order eRP, the approximated solution of the NLSE is

$$A(z,t) \cong (A_0 + \gamma A_1)\, \mathrm{e}^{-\mathrm{j}\Phi_{\mathrm{NL}}} \,,$$

where Φ_{NL} is the average nonlinear phase cumulated along the link. For instance, for a single span of effective length L_{eff} and nonlinear length L_{NL}, it is $\Phi_{\mathrm{NL}} = \gamma L_{\mathrm{NL}}/L_{\mathrm{eff}}$. This approach corresponds to perturbing a modified NLSE with average power P removed in the nonlinear term, i.e., with $\mathcal{N}(A) = -\mathrm{j}\gamma(|A|^2 - P)A$ [9.25]. In Sects. 9.4, 9.5, and 9.6, we will calculate and discuss the variance of the perturbation in the eRP reference system.

Another improvement to RP is the logarithmic perturbation (LP), where the perturbation is searched in a logarithmic domain [9.26]. At first order for $A_0 \neq 0$, we have

$$A(z,t) \cong A_0 \mathrm{e}^{\gamma \frac{A_1}{A_0}} \,.$$

LP coincides with the exact solution of NLSE in the limit of zero dispersive effect, where the nonlinear Kerr effect is a pure phase rotation. With GVD the exponent in LP is a complex number, hence it does not manifest itself just as a phase rotation. This class of models will be discussed in Sect. 9.7.

9.4 From FWM to GN and EGN Models

In this section, two of the most well-known and widely used nonlinearity models, the GN and EGN model, will be introduced by deriving them from the basic Kerr-related nonlinear fiber effect called four-wave mixing (FWM). Historically, this is one of the ways in which these models have been derived, and perhaps it is one of the most intuitive. Interestingly, this FWM-based derivation can be shown to be equivalent to the first-order eRP solution described in [9.27] Sect. 9.3.1.

In the end, although some of the details will have to be skipped, the reader should gain a rather detailed appreciation of the derivation procedure, of the inner structure of these models, and a general understanding of how fiber nonlinear effects can be described in terms of the interaction of many discrete signal spectral components with one-another.

The GN model was actually derived several times, in slightly different versions, over the years. The earliest instance dates back to 1993 [9.28], where an FWM-based derivation was used. Though limited to single-polarization, ideal-lossless fiber and a rectangular overall WDM spectrum, the equations in [9.28] essentially coincide with those of the incoherent GN model or the iGN model (Sect. 9.4.7).

Later, in 2003, it was shown in [9.29] that results similar to [9.28] could also be derived using a different perturbation approach, earlier proposed in [9.30]. Similar equations were also independently derived in [9.24] using truncated Volterra series in the frequency domain, as introduced in [9.20].

Subsequently (2008–2010), a derivation approach based again on FWM was used in [9.31, 32] to derive a GN model version limited to optical OFDM. A similar approach was independently exploited in 2010–2011 to address not just OFDM, but all WDM systems [9.33–35]. The derivation yielded the frequency-continuous, dual-polarization integral GN model formula, which is currently considered the reference formula for the model (called GNRF, or GN model reference formula). The name *GN model* was first introduced in [9.34].

Detailed rederivations of the GN model were published in [9.27, 36], based on different methods. Both independently confirmed the GN model equations and provided substantial extensions and insightful generalizations. Various follow-up papers have been published since, providing further extensions, as well as closed-form approximate solutions of the integral GN model formula, for instance, [9.37–41].

More recently, based on a better understanding of the features and limitations of the GN model, an improved model called the *enhanced* GN model (or EGN model) has been proposed. For references and a detailed discussion of the EGN model, see Sect. 9.4.8.

9.4.1 Kerr Nonlinearity and Spectral Line Signals

We consider a signal $E(f)$, made up of Q spectral *lines*, ideally Dirac's deltas, written as

$$E(f) = \sum_{q=1}^{Q} \zeta_q \delta(f - f_q) \,, \tag{9.9}$$

where the ζ_qs are the complex amplitudes of each one of the lines. On such spectrally delta-like signals, fiber Kerr nonlinearity (Sect. 9.1) acts mainly through the FWM effect.

The literature on FWM is vast. A comprehensive treatment can be found in [9.1]. In the next few paragraphs, we are going to recall only what is strictly needed for our purposes.

When $E(f)$ is propagated along a stretch of optical fiber, then *each* set of *three* out of the Q signal lines in (9.9), say those located at frequencies f_k, f_m and f_n, generates a FWM contribution in the form of a *fourth* spectral line at frequency

$$f_{\mathrm{FWM}}^{(i)} = f_k + f_m - f_n \,, \tag{9.10}$$

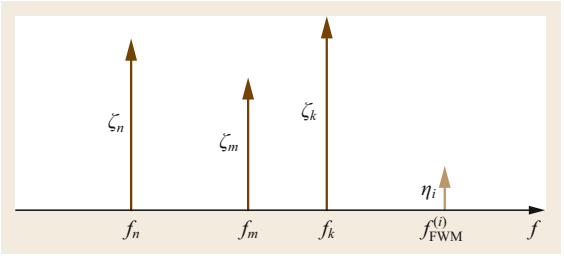

Fig. 9.4 Generation of a FWM spectral line at frequency $f_{\mathrm{FWM}}^{(i)} = (f_m - f_n + f_k)$ due to Kerr nonlinearity acting upon the signal spectral lines at frequencies f_m, f_n, and f_k, called *pumps*

as shown in Fig. 9.4. Note that k, m, n run each independently over $\{1 \dots Q\}$ and, therefore, there are Q^3 possible triples (k, m, n). We use the index i to identify each one of these triples, through the notation $(k, m, n)_i$, where i runs over $1 \dots Q^3$. A given triple $(k, m, n)_i$ may actually generate a FWM line at the same frequency as the FWM line generated by another triple $(k', m', n')_{i'}$. That is, it can be that: $f_{\mathrm{FWM}}^{(i)} = f_{\mathrm{FWM}}^{(i')}$. The reason is that it is possible that $(f_k + f_m - f_n) = (f_{k'} + f_{m'} - f_{n'})$, even though $(k, m, n)_i \neq (k', m', n')_{i'}$.

We now write the FWM generation formulas for a single stretch of fiber. An FWM spectral line generated by the triple $(k, m, n)_i$ at a specific frequency $f_{\mathrm{FWM}}^{(i)}$ can be written as

$$E_i(z, f) = \eta_i(z) \delta(f - f_{\mathrm{FWM}}^{(i)}) \,. \tag{9.11}$$

Its complex amplitude η_i grows along the fiber, depending on several parameters, including the power of the signal spectral lines, their relative spectral position, fiber dispersion, loss, and the strength of the Kerr nonlinearity of that fiber.

Significantly, such a growth law takes on a relatively simple form, provided that the so-called undepleted pump assumption (UPA) can be made. Such terminology stems from the fact that the signal lines in (9.9) are called *pumps* according to jargon inherited from physics. The UPA consists of this. Due to energy conservation, the FWM-generated spectral lines draw their growing power from the *pumps*, whose power is, therefore, *depleted*. However, if the overall power of the generated FWM lines is small versus the pumps' power, then the pumps can be assumed unperturbed, or *undepleted*. It can be shown that the UPA is equivalent to what is called a *first-order regular perturbation* (RP1) approach to finding the solution of the NLSE (Sect. 9.3.1).

We assume that the FWM amplitude value at the start of the fiber, $z = 0$, is equal to zero, so that $\eta_i(0) = 0$. Then, using the single-polarization NLSE, under the

UPA, the FWM line amplitude η_i can be shown to be

$$\eta_i(z) = -\mathrm{j}\zeta_m\zeta_n^*\zeta_k \times \mathrm{e}^{\int_0^z \kappa(f_{\mathrm{FWM}}^{(i)},z')\mathrm{d}z'} \times \int_0^z \gamma(z')\mathrm{e}^{\int_0^{z'}[-\kappa(f_{\mathrm{FWM}}^{(i)},z'')+\kappa(f_m,z'')+\kappa^*(f_n,z'')+\kappa(f_k,z'')]\mathrm{d}z''}\mathrm{d}z' , \tag{9.12}$$

where

$$\kappa(f,z) = -\mathrm{j}\beta(f,z) - \alpha(f,z) + g(f,z) . \tag{9.13}$$

Note that this equation can handle all-order dispersion through $\beta(f,z)$, as well as frequency-dependent distributed gain or loss along the fiber through $g(f,z)$ and $\alpha(f,z)$, respectively, g and α both being positive numbers by definition.

The overall FWM created by the signal of (9.9) at the location z along the fiber is actually given by the superposition of all the individually generated FWM contributions, that is,

$$E_{\mathrm{FWM}}(z,f) = \sum_i \eta_i(z)\delta(f - f_{\mathrm{FWM}}^{(i)}) . \tag{9.14}$$

Focusing on the quite typical case of a *homogenous* stretch of fiber, whereby γ is a constant versus the spatial coordinate z, one can rewrite (9.12) in the compact form

$$\eta_i(z) = -\mathrm{j}\gamma\zeta_k\zeta_m\zeta_n^* H(f_{\mathrm{FWM}}^{(i)},z)L_{\mathrm{eff}}(z,\bar{f}_i)\mu(z,\bar{f}_i) , \tag{9.15}$$

where $\bar{f}_i = (f_k,f_m,f_n)$ is shorthand for the i-th triple of frequencies from (9.4) generating a FWM line at $f_{\mathrm{FWM}}^{(i)}$ as per (9.10), and

$$H(f,z) = \mathrm{e}^{\int_0^z \kappa(f,z')\mathrm{d}z'} , \tag{9.16}$$

is the *linear fiber transfer function* at a generic frequency f, from the fiber start till the length z. In addition,

$$L_{\mathrm{eff}}(z,\bar{f}_i) = \int_0^z \mathrm{e}^{\int_0^{z'}\mathrm{Re}\{-\kappa(f_{\mathrm{FWM}}^{(i)},z'')+\kappa(f_m,z'')+\kappa^*(f_n,z'')+\kappa(f_k,z'')\}\mathrm{d}z''}\mathrm{d}z' , \tag{9.17}$$

$$\mu(z,\bar{f}_i) = L_{\mathrm{eff}}^{-1}(z,\bar{f}_i) \times \int_0^z \mathrm{e}^{\int_0^{z'}[-\kappa(f_{\mathrm{FWM}}^{(i)},z'')+\kappa(f_m,z'')+\kappa^*(f_n,z'')+\kappa(f_k,z'')]\mathrm{d}z''}\mathrm{d}z' , \tag{9.18}$$

where $\mathrm{Re}\{\cdot\}$ means the *real part*.

Equation (9.15) shows that the amplitude of the i-th generated FWM line, η_i, is proportional to the factors L_{eff} and μ. The former is called the *effective length* of the fiber. It is a *real and positive* number, with units of length. It can be thought of as the length of the fiber as *felt* by FWM generation. In a perfectly lossless fiber, it coincides with the actual physical length of the fiber, that is, $L_{\mathrm{eff}} = z$. In a lossy fiber, it is shorter than z. Note that when *both* loss and distributed gain are present, the result of (9.17) can be either shorter or longer than z, depending on their balance.

The quantity μ is the so-called *FWM efficiency*, and it accounts for the critically important effect of dispersion on FWM generation. If there is no dispersion, i.e., if $\beta(f)$ is a constant versus f, then it can be immediately seen from (9.18) that $\mu = 1$. If *any* amount of dispersion is present instead, then $|\mu| < 1$. This shows that dispersion is a mitigator of FWM and, in general, of nonlinearity, an important concept that we will return to later in the chapter.

Equations (9.15)–(9.18) constitute an analytical solution to the NLSE in the FWM framework, potentially providing a powerful tool for the derivation of nonlinearity models. In practice, for this to be the case, two conditions must be met: (i) that the propagation problem is within the validity range of RP1, and (ii) that the signal of interest, which is sent into the fiber, can be described as a set of spectral lines like (9.9), so that the FWM formalism can be applied.

As for (i), this condition is typically well verified in modern fiber telecom systems. We will later actually transition from RP1 to eRP1 (see Sect. 9.3.1 for the definition of eRP), which further extends the range of validity of the solution. Regarding (ii), the question is whether actual data signals just can be put in the form (9.9). In the following, we briefly address this latter aspect.

Actual physical transmitted signals (henceforth *data signals*), which we will denote by $E_{\mathrm{S}}(t)$, have the following features: they are finite-energy, limited-peak-power signals of finite bandwidth $[f_l,f_h]$ and finite duration $[t_l,t_h]$. This is, of course, true also for WDM signals consisting of multiple channels. In the WDM case, $[f_l,f_h]$ would represent the overall WDM comb optical bandwidth. Signals with these features can always be Fourier transformed. Formally, $E_{\mathrm{S}}(f) = \mathrm{F}\{E_{\mathrm{S}}(t)\}$, where $\mathrm{F}\{\cdot\}$ is the Fourier transform. In general, though, $E_{\mathrm{S}}(f)$ *would not be* in the form of (9.9); it could contain some spectral lines but would typically consist mainly of a continuous spectrum. However, given *any* signal with the above features as $E_{\mathrm{S}}(t)$, the *periodic signal* built by simply repeating it at regular inter-

vals T_0

$$E_{\mathrm{S}}^{\mathrm{per}}(t) = \sum_{q=-\infty}^{\infty} E_{\mathrm{S}}(t - qT_0) \tag{9.19}$$

acquires a *pure line spectrum* whose expression is

$$E_{\mathrm{S}}^{\mathrm{per}}(f) = \sum_{q=q_l}^{q_h} \zeta_q \, \delta(f - qf_0) \, , \tag{9.20}$$

where $f_0 = 1/T_0$ and $\zeta_q = f_0 E_{\mathrm{S}}(qf_0)$. The summation index q would ideally run over $[-\infty, \infty]$ but $E_{\mathrm{S}}(f)$ is band limited by assumption to $[f_l, f_h]$. This curtails q within $q_l = \min\{q : qf_0 > f_l\}$ and $q_h = \max\{q : qf_0 < f_h\}$. In conclusion, the signal of (9.20) is of the form (9.9) and, therefore, the FWM formalism can be applied to it.

Concerns may arise whether the periodization performed in (9.19) may lead to undesired consequences or loss of generality. There are subtleties to be heeded, such as signal continuity issues at the edges of each period, but the answer is that no loss of generality is incurred.

Note that (9.20) is actually more constrained than (9.9), because the spectral lines in (9.20) are not arbitrarily located in frequency, but rather lie on a *grid of fixed pitch* f_0. Due to this, without any loss of generality, we can from now on identify the frequencies f_k, f_m, and f_n in (9.10) as kf_0, mf_0, and nf_0, respectively. When this is inserted into (9.10), it can be seen that all generated FWM contributions $f_{\mathrm{FWM}}^{(i)}$ forcedly lie *on the same frequency grid* qf_0 where the periodized signal spectral lines also lie, with q

$$q = (k + m - n) \, . \tag{9.21}$$

For notational compactness, we then define $\{i\}_q$ as the set of all the indices i that identify triples $(k, m, n)_i$ that produce an FWM line *at the same frequency* qf_0, according to (9.10). In formulas

$$\{i\}_q = \{i \, : \, f_{\mathrm{FWM}}^{(i)} = qf_0\} \, . \tag{9.22}$$

This could be rephrased by saying that the index q identifies the class of equivalence $\{i\}_q$ of all possible triples $(k, m, n)_i$ that produce an FWM spectral line at the *same frequency* qf_0. Assuming that we are looking at a single span of fiber of length L_s, then the total signal, including both data signal and FWM, at the end of the span is given by

$$E_{\mathrm{tot}}(f, L_{\mathrm{s}}) = E_{\mathrm{S}}(f, L_{\mathrm{s}}) + E_{\mathrm{FWM}}(f, L_{\mathrm{s}}) \, , \tag{9.23}$$

where

$$E_{\mathrm{S}}(f, L_{\mathrm{s}}) = \sum_{q=q_l}^{q_h} \zeta_q(L_{\mathrm{s}}) \delta(f - qf_0) \, , \tag{9.24}$$

$$E_{\mathrm{FWM}}(f, L_{\mathrm{s}}) = \sum_{q} \sum_{\{i\}_q} \eta_i(L_{\mathrm{s}}) \delta(f - qf_0) \, . \tag{9.25}$$

The factors $\zeta_q(L_{\mathrm{s}})$ are the data signal spectral line amplitudes from (9.20), linearly propagated to the end of the span according to

$$\zeta_q(L_{\mathrm{s}}) = \zeta_q \times H(f_q, L_s) \, , \tag{9.26}$$

and H is the fiber linear transfer function defined in (9.16).

9.4.2 Multispan Links

Extending the previous equations to *multiple spans* requires that the UPA be augmented by two related assumptions.

One is that the total FWM at the end of a multispan link can be expressed as the sum of the FWM generated in each generic n-th span. The other is that the signal that generates FWM in the n-th span consists of just the data signal spectral lines injected at the input of the overall link, then linearly propagated to the input of the n-th span.

These assumptions neglect the fact that, at the input of each successive span, besides the data signal, there is also the FWM produced in the previous spans, as well as ASE noise. This approximation is viable provided that, at any point along the link, the data signal power can be assumed to be much larger than the accumulated FWM and ASE power. In practice, this is typically the case because otherwise, if the data signal power was comparable to either the ASE or FWM power, the data signal would be too degraded for successful reception to take place. This argument fails only for systems that can operate at quite low optical signal-to-noise ratio (OSNR) values. Indicatively, no significant effect of co-propagating ASE or FWM are observed down to about 10 dB OSNR [9.42, 43]. A clear impact can be observed at about 5 dB OSNR where, indicatively, about 10% maximum reach decrease is found between considering co-propagating ASE and FWM versus not considering them. In this section, we neglect this aspect, which is discussed in more detail in Sect. 9.9.1.

Analytically, (9.15) can then be modified as follows, to provide η_i at the end of the link (i.e., at L_{end}), which

we call η_i^{e}

$$\eta_i^{\mathrm{e}} = -\mathrm{j}\zeta_k\zeta_m\zeta_n^* \sum_{n_\mathrm{s}=1}^{N_\mathrm{s}} \mathbf{H}(\bar{f}_i; 1, n_\mathrm{s}-1) \times \gamma(n_\mathrm{s}) L_\mathrm{eff}(\bar{f}_i; n_\mathrm{s}) \mu(\bar{f}_i; n_\mathrm{s}) H(f_\mathrm{FWM}^{(i)}; n_\mathrm{s}, N_\mathrm{s}) \,, \tag{9.27}$$

where the fiber transfer function $H(f_\mathrm{FWM}^{(i)}; n_\mathrm{s}, N_\mathrm{s})$ linearly propagates the i-th FWM line from where it is generated, i.e., the n_s-th span, to the last span N_s; H can be found by cascading its single-span version (9.16) along the link. The factor $\mathbf{H}(\bar{f}_i; 1, n_\mathrm{s}-1)$ is shorthand for the product of the three transfer functions that propagate linearly the three pumps from the first span to the end of the $(n_\mathrm{s}-1)$-th span, that is,

$$\mathbf{H}(\bar{f}_i; 1, n_\mathrm{s}-1) = H(f_k; 1, n_\mathrm{s}-1) H(f_m; 1, n_\mathrm{s}-1) H^*(f_n; 1, n_\mathrm{s}-1) \,, \tag{9.28}$$

The notation $L_\mathrm{eff}(\bar{f}_i; n_\mathrm{s})$ indicates the effective length calculated for the n_s-th span alone, relative to the i-th triple $(k, m, n)_i$. It is found by using (9.17) in the local span length coordinate, which runs from 0 to the span length $L_\mathrm{s}^{(n_\mathrm{s})}$, and setting $z = L_\mathrm{s}^{(n_\mathrm{s})}$. Similarly for $\mu(\bar{f}_i; n_\mathrm{s})$ with (9.18). Finally, the summation in (9.27) sums the overall FWM produced in each span, then linearly propagated to the end of the link.

We could then use (9.22)–(9.25) to express the overall data and FWM signals at the end of the multispan link. We will do this in Sect. 9.4.4 after dealing with dual-polarization propagation.

9.4.3 Dual Polarization

Actual fibers carry two polarizations. Nonlinear propagation in dual polarization (DP) obeys a set of two stochastically-coupled nonlinear differential equations, called dual-polarization NLSE (DP-NLSE) [9.1]. The stochastic nature of the coupling is due to the random birefringence of the fiber. However, as pointed out in Sect. 9.1, in typical telecom fibers, it is possible to average the DP-NLSE over the spatial evolution of random birefringence, obtaining the so-called Manakov equation (ME) [9.8, 44, 45]. The ME provides a very effective means of modeling DP nonlinear propagation and is very widely used in analytical modeling and simulations.

To address DP-FWM, we first redefine the *pump* amplitudes ζ_q in (9.9) as DP quantities

$$\zeta_q = \zeta_{\hat{x},q}\hat{x} + \zeta_{\hat{y},q}\hat{y} \,, \tag{9.29}$$

where $\zeta_{\hat{x},q}, \zeta_{\hat{y},q}$ are the $\hat{x}$ and $\hat{y}$ pump components, respectively. Then, according to the ME, quite remarkably all of the previously shown formulas remain *unchanged*, with the exception of the substitution of the scalar quantity $\zeta_k\zeta_m\zeta_n^*$, in (9.27), with the Jones vector (in the $\hat{x}$ and $\hat{y}$ basis) appearing in square brackets below

$$\eta_i^{\mathrm{e}} = -\mathrm{j}\frac{8}{9} \begin{bmatrix} (\zeta_k^{\hat{x}}\zeta_m^{\hat{x}}\zeta_n^{\hat{x}*} + \zeta_k^{\hat{x}}\zeta_m^{\hat{y}}\zeta_n^{\hat{y}*}) \\ (\zeta_k^{\hat{y}}\zeta_m^{\hat{y}}\zeta_n^{\hat{y}*} + \zeta_k^{\hat{y}}\zeta_m^{\hat{x}}\zeta_n^{\hat{x}*}) \end{bmatrix} \sum_{n_\mathrm{s}=1}^{N_\mathrm{s}} L_\mathrm{eff}(\bar{f}_i; n_\mathrm{s}) \times \gamma(n_\mathrm{s}) \mu(\bar{f}_i; n_\mathrm{s}) \mathbf{H}(\bar{f}_i; 1, n_\mathrm{s}-1) H(f_\mathrm{FWM}^{(i)}; n_\mathrm{s}, N_\mathrm{s}) \,. \tag{9.30}$$

Note, in particular, that L_eff, μ, $\mathbf{H}$, and H are *scalar quantities* and are unaffected by DP. Of course, as a result of the above substitution, the FWM amplitudes η_i^{e} acquire a DP nature too, that is, $\eta_i^{\mathrm{e}} = \eta_{\hat{x},i}^{\mathrm{e}}\hat{x} + \eta_{\hat{y},i}^{\mathrm{e}}\hat{y}$.

9.4.4 The Statistical Modeling Approach

The shown analytical FWM formalism lends itself to the derivation of *statistical models*, which are potentially more powerful design/analysis tools than brute-force numerical NLSE or ME integration and Monte-Carlo performance estimation.

We focus on the *end of the link*, identified as L_end. In agreement with system-related literature, we call the Kerr-induced nonlinear disturbance at this location *nonlinear interference*, or NLI, replacing the *FWM* acronym, that is,

$$E_\mathrm{NLI}(f) = E_\mathrm{FWM}(f, L_\mathrm{end}) \,. \tag{9.31}$$

The formula for E_NLI at L_end is then, similarly to (9.25),

$$E_\mathrm{NLI}(f) = \sum_q \sum_{\{i\}_q} \eta_i^{\mathrm{e}} \delta(f - qf_0) \,. \tag{9.32}$$

In essence, the *statistical approach* (SA) consists of viewing the η_i^{e} as random variables (RVs), so that the overall NLI disturbance field (9.32) becomes a random process (RPR), whose statistical features can be studied to assess its impact on data signal detection. Note that the η_i^{e} are *not* RVs if transmission of a *specific* fully-defined data signal takes place. They become RVs if transmission of *random* data signals is assumed. Then, by statistical manipulation, one can extract the average features of NLI over *all possible* data signals, which is the great advantage of the SA over any Monte-Carlo strategy.

In this section, we focus on the GN/EGN class of models. These models aim at finding the *power spectral density* (PSD) of $E_\mathrm{NLI}(f)$, which we will call $G_\mathrm{NLI}(f)$

(typically in [W/Hz]). The reason for the focus on this quantity is that the impact of NLI noise on system performance, typically expressed in terms of a degraded estimated OSNR, can be found based on $G_{\mathrm{NLI}}(f)$. Other indicators can then be estimated based on such OSNR, such as BER, MI, and GMI, to different accuracy.

For convenience, we first define a new RV that is the sum of all the FWM amplitudes *contributing to the same* NLI *line at frequency* (qf_0)

$$\nu_q^{\mathrm{e}} = \sum_{\{i\}_q} \eta_i^{\mathrm{e}} \,. \tag{9.33}$$

Given (9.32) and (9.33), $G_{\mathrm{NLI}}(f)$ is then directly found as

$$G_{\mathrm{NLI}}(f) = \sum_q \mathrm{E}\{|\,\nu_q^{\mathrm{e}}\,|^2\}\delta(f-qf_0) \,. \tag{9.34}$$

To carry out the calculation of $\mathrm{E}\{|\,\nu_q^{\mathrm{e}}\,|^2\}$, with reference to (9.30) and (9.33), we define the *data signal factor*

$$\mathbf{S}_i = \begin{bmatrix} (\zeta_k^{\hat{x}}\zeta_m^{\hat{x}}\zeta_n^{\hat{x}*} + \zeta_k^{\hat{x}}\zeta_m^{\hat{y}}\zeta_n^{\hat{y}*}) \\ (\zeta_k^{\hat{y}}\zeta_m^{\hat{y}}\zeta_n^{\hat{x}*} + \zeta_k^{\hat{y}}\zeta_m^{\hat{x}}\zeta_n^{\hat{x}*}) \end{bmatrix} \tag{9.35}$$

and the *link factor*

$$\begin{aligned} \mathrm{LK}_i = -\mathrm{j}\frac{8}{9}\sum_{n_{\mathrm{s}}=1}^{N_{\mathrm{s}}} & \gamma(n_{\mathrm{s}})L_{\mathrm{eff}}(\bar{f}_i;n_{\mathrm{s}})\mu(\bar{f}_i;n_{\mathrm{s}}) \\ & \times \mathbf{H}(\bar{f}_i;1,n_{\mathrm{s}}-1)H(f_{\mathrm{FWM}}^{(i)};n_{\mathrm{s}},N_{\mathrm{s}}) \,. \end{aligned} \tag{9.36}$$

This way, we can compactly write $\nu_q^{\mathrm{e}} = \sum_{\{i\}_q} \mathrm{S}_i\,\mathrm{LK}_i$. We then have

$$\begin{aligned} \mathrm{E}\{|\nu_q^{\mathrm{e}}|^2\} &= \mathrm{E}\left\{\left(\sum_{\{i\}_q}\mathrm{S}_i\,\mathrm{LK}_i\right)^{\mathsf{T}*}\sum_{\{i'\}_q}\mathrm{S}_{i'}\mathrm{LK}_{i'}\right\} \\ &= \sum_{\{i\}_q}\sum_{\{i'\}_q}\mathrm{E}\{\mathrm{S}_i^{\mathsf{T}*}\mathrm{S}_{i'}\}\mathrm{LK}_i^*\mathrm{LK}_{i'} \,, \end{aligned} \tag{9.37}$$

where the superscript T means *transpose*. Note that the link factor, apart from normalizations, is the same quantity appearing as η in (9.8), which provides a clue that the FWM formalism with the UPA is equivalent to the RP1 approach (Sect. 9.3.1).

Equation (9.37) is at the core of both the GN and EGN models. It shows that the SA reduces to the evaluation of the expectation $\mathrm{E}\{\mathrm{S}_i^{\mathsf{T}*}\mathrm{S}_{i'}\}$, since $\mathrm{LK}_i\mathrm{LK}_{i'}^*$ is completely deterministic and is even available in closed-form in various relevant cases. Note also from (9.35) that S_i *depends only on the data signal at the input of the fiber* and not on the link features, which are instead confined within LK_i.

Despite its apparent compactness, (9.37) does not typically generate simple results. The reason is that the RVs ζ_q, which are the amplitudes of the overall WDM data signal spectral lines in (9.20), interact nonlinearly in (9.37) giving rise to complex sixth-order moments, which generate a large number of terms. Only under drastic simplifying assumptions or special circumstances (9.37) and, as a result, the NLI spectrum (9.34), take on simple forms. This is the case of the GN model, which we introduce next.

9.4.5 The GN Model

The complexity hidden within (9.37) simplifies drastically provided that certain approximations are made. Such approximations give rise to the so-called GN model. They are as follows.

It is assumed that the ζ_qs in (9.9) are *statistically independent* (SI) *zero-mean complex circular jointly-Gaussian* RV. As for their variances $\sigma_{\zeta_q}^2$, they directly relate to the average PSD of the periodized data signal of (9.20), which is given by

$$G_{\mathrm{S}}^{\mathrm{per}}(f) = \sum_{q=q_l}^{q_h} \sigma_{\zeta_q}^2\,\delta(f-q\,f_0) \,. \tag{9.38}$$

Then, a logical choice is to assume that the $\sigma_{\zeta_q}^2$ are such that $G_{\mathrm{S}}^{\mathrm{per}}(f)$ tends to follow the average PSD of the *aperiodic* data signal, $G_{\mathrm{S}}(f)$. This is obtained by imposing

$$\sigma_{\zeta_q}^2 = f_0 \times G_{\mathrm{S}}(q\,f_0) \,, \tag{9.39}$$

where the multiplying constant f_0 adjusts dimensions and also ensures signal power consistency. This way, $G_{\mathrm{S}}^{\mathrm{per}}(f)$ and $G_{\mathrm{S}}(f)$ relate as in the pictorial example of Fig. 9.5.

A key point is whether the main assumptions made so far are reasonable and accurate. As has already been stated, the signal periodization of (9.19) is of no concern. In addition, in Sect. 9.4.5, we will actually show that it can be removed. The PSD matching of (9.39), depicted in Fig. 9.5, is not problematic either. The zero-mean complex circular Gaussian distribution assumption for each one of the ζ_q, *individually*, is also actually quite accurate. What, in general, is *not* accurate, is the assumption that the ζ_q are SI. In fact, assuming conventional memoryless modulation, with independent symbols and standard PM-QAM constellations, the ζ_q *are not independent* within each single WDM channel. Also, their dependence is not straightforward, since,

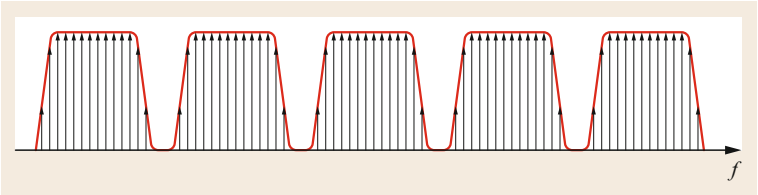

Fig. 9.5 *Solid red line*: an example of the PSD $G_{\mathrm{S}}(f)$ of a five-channel aperiodic WDM transmission signal. *Black arrows*: Dirac's deltas making up the PSD $G_{\mathrm{S}}^{\mathrm{per}}(f)$ of the periodized transmission signal (9.38), according to (9.39)

even though they are individually Gaussian, they are not jointly-Gaussian.

The GN model *neglects* the statistical dependence of the ζ_q within each WDM channel, and this approximation can be expected to generate some error, which we will discuss later on. On the other hand, it allows for extremely simple handling of the average $\mathrm{E}\{\mathrm{S}_i^{\mathsf{T}*}\mathrm{S}_{i'}\}$. The very compact result, which can be obtained through Isserlis's theorem, is

$$\begin{aligned}\mathrm{E}\{\mathrm{S}_i^{\mathsf{T}*}\mathrm{S}_{i'}\} &= \frac{3}{4}\sigma_{\zeta_k}^2\sigma_{\zeta_m}^2\sigma_{\zeta_n}^2\delta_{ii'} \\ &= \frac{3}{4}f_0^3 G_{\mathrm{S}}(kf_0)G_{\mathrm{S}}(mf_0)G_{\mathrm{S}}(nf_0)\delta_{ii'}\ . \end{aligned} \tag{9.40}$$

It should be mentioned that (9.40) is valid when the three indices k, m, n of the i-th triple are *all different*. Using it when this is not the case introduces an approximation, which is, however, of vanishing impact for decreasing f_0. We consequently assume that a small-enough f_0 is chosen. Interestingly, it can be shown that by introducing such approximation, and assuming a small-enough f_0 to make it accurate, the result tends to the better eRP perturbation approach rather than RP. See Sect. 9.3.1 for details on eRP versus RP.

Once (9.40) is plugged into (9.37), Kronecker's delta $\delta_{ii'}$ reduces the double summation to a single one. As a result, the power carried by the NLI spectral line at frequency (qf_0) is given by

$$\begin{aligned}\mathrm{E}\{|\nu_q^{\mathrm{e}}|^2\} = &\frac{16}{27}f_0^3 \\ &\times \sum_{\{i\}_q} G_{\mathrm{S}}(kf_0)G_{\mathrm{S}}(mf_0)G_{\mathrm{S}}(nf_0)\,|\mathrm{LK}_i|^2\ . \end{aligned} \tag{9.41}$$

We must now make explicit the implicit indexing system used in (9.41), defined in (9.22), and write equivalently but *explicitly*

$$\begin{aligned}\mathrm{E}\{|\nu_q^{\mathrm{e}}|^2\} = &\frac{16}{27}f_0^3 \sum_{k=q_l}^{q_h}\sum_{m=q_l}^{q_h} \left|\mathrm{LK}_{km(k+m-q)}\right|^2 \\ &\times G_{\mathrm{S}}(kf_0)G_{\mathrm{S}}(mf_0)G_{\mathrm{S}}([k+m-q]f_0)\ , \end{aligned} \tag{9.42}$$

where the relation $n = (k+m-q)$, derived from (9.21), was used. The link factor LK_{kmn} is now written as

$$\begin{aligned}\mathrm{LK}_{kmn} = -\mathrm{j}\sum_{n_{\mathrm{s}}=1}^{N_{\mathrm{s}}} &\gamma(n_{\mathrm{s}})L_{\mathrm{eff}}(kf_0, mf_0, nf_0; n_{\mathrm{s}}) \\ &\times \mu(kf_0, mf_0, nf_0; n_{\mathrm{s}})H(qf_0; n_{\mathrm{s}}, N_{\mathrm{s}}) \\ &\times \mathbf{H}(kf_0, mf_0, nf_0; 1, n_{\mathrm{s}}-1)\ . \end{aligned} \tag{9.43}$$

Equations (9.42) and (9.43), together with (9.34), provide *a general frequency-discrete* GN *model equation set*. These formulas could be directly used to calculate the PSD of NLI by executing the indicated summations numerically. However, a *frequency-continuous* set of formulas can be derived from them.

Continuous Frequency

It is possible to recast the GN model in integral form by going from discrete to continuous frequency. This is also useful because in certain cases it allows analytical closed-form solutions to be obtained.

The procedure consists of lengthening the periodicity T_0 of the data signal in (9.20). In the limit of $T_0 \to \infty$, that is, of the data signal effectively becoming aperiodic and infinitely extended in time, then also $f_0 \to 0$, and through rather straightforward mathematical manipulation, the *frequency continuous* GN *model* is found. The PSD of NLI is given by

$$\begin{aligned}G_{\mathrm{NLI}}(f) = \frac{16}{27}\int_{f_l}^{f_h}\int_{f_l}^{f_h} &G_{\mathrm{S}}(f_1)G_{\mathrm{S}}(f_2)G_{\mathrm{S}}(f_1+f_2-f) \\ &\times |\mathrm{LK}(f_1,f_2,f_1+f_2-f)|^2\,\mathrm{d}f_1\mathrm{d}f_2\ , \end{aligned} \tag{9.44}$$

$$\begin{aligned}\mathrm{LK}(f_1,f_2,f_3) = -\mathrm{j}\sum_{n_{\mathrm{s}}=1}^{N_{\mathrm{s}}} &\gamma(n_{\mathrm{s}})L_{\mathrm{eff}}[(f_1,f_2,f_3); n_{\mathrm{s}}] \\ &\times \mu[(f_1,f_2,f_3); n_{\mathrm{s}}] \\ &\times H(f_1+f_2-f_3; n_{\mathrm{s}}, N_{\mathrm{s}}) \\ &\times \mathbf{H}[(f_1,f_2,f_3); 1, n_{\mathrm{s}}-1]\ . \end{aligned} \tag{9.45}$$

For the readers' convenience, below we replace the shorthand forms appearing in (9.45) with their definitions, and include certain elements, such as lumped gain/loss and possible dispersion-compensating units (DCUs) that have not been explicitly introduced so far.

The result is

$$\begin{aligned}\mathrm{LK}(f_1,f_2,f_3) &= -\mathrm{j}\sum_{n_s=1}^{N_s}\gamma_{n_s}\\ &\times\int_0^{L_s^{(n_s)}} \mathrm{e}^{\int_0^{z'}[\kappa_{n_s}(f_1,z'')+\kappa_{n_s}^*(f_3,z'')+\kappa_{n_s}(f_2,z'')-\kappa_{n_s}(f_1+f_2-f_3,z'')]\mathrm{d}z''}\mathrm{d}z'\\ &\times\prod_{p=n_s}^{N_s}\Gamma_p^{1/2}(f_1+f_2-f_3)\mathrm{e}^{\int_0^{L_s^{(p)}}\kappa_p(f_1+f_2-f_3,z)\mathrm{d}z}\\ &\quad\times\mathrm{e}^{-\mathrm{j}\beta_{\mathrm{DCU}}^{(p)}(f_1+f_2-f_3)}\\ &\times\prod_{p=1}^{n_s-1}[\Gamma_p(f_1)\Gamma_p(f_2)\Gamma_p(f_3)]^{\frac{1}{2}}\\ &\quad\times\mathrm{e}^{\int_0^{L_s^{(p)}}[\kappa_p(f_1,z)+\kappa_p(f_2,z)+\kappa_p^*(f_3,z)]\mathrm{d}z}\\ &\quad\times\mathrm{e}^{-\mathrm{j}[\beta_{\mathrm{DCU}}^{(p)}(f_1)+\beta_{\mathrm{DCU}}^{(p)}(f_2)-\beta_{\mathrm{DCU}}^{(p)}(f_3)]}\,, \end{aligned}\tag{9.46}$$

where Γ_p is lumped power gain/loss and $\beta_{\mathrm{DCU}}^{(p)}(f)$ is the effect of a DCU element, both located at the end of the p-th span. The quantity κ_p is the complex propagation constant, defined in (9.13), for the p-th span. Equation (9.46) is quite general, as it can handle both distributed and lumped loss/gain, also frequency dependent, as well as the possible presence of DCUs.

9.4.6 Noteworthy Link Factors

In this section, we focus on closed forms or simplified forms for the LK factor, which can be found for various cases of interest. LK is a function of the frequencies of the three *pumps* generating a FWM contribution. This dependence can be cast in the discrete framework of (9.42)–(9.43) through the indices k,m,n or in the continuous framework of (9.44)–(9.45) using frequencies f_1,f_2,f_3. We use the latter, but it is possible to convert from one to the other through the direct substitutions: $f_1=kf_0, f_2=mf_0, f_3=nf_0$.

Transparent and Uniform Link with Lumped Amplification

A *transparent span* is such that its optical gain equals its loss exactly, from the input of that span to the input of the next span. A *transparent link* is one where every span is transparent. A link is *uniform if all spans are identical*.

Under the assumptions of a transparent and uniform link, (9.45) takes on the closed form

$$\begin{aligned}\mathrm{LK}(f_1,f_2,f_3) &= -\mathrm{j}N_s\gamma L_{\mathrm{eff}}(f_1,f_2,f_3)\mu(f_1,f_2,f_3)\\ &\times\mathrm{e}^{-\mathrm{j}N_sL_s\beta(f_1+f_2-f_3)}\mathrm{e}^{\mathrm{j}\frac{\beta_{123}}{2}(N_s-1)L_s}D\left(L_s\frac{\beta_{123}}{2},N_s\right),\end{aligned}\tag{9.47}$$

where the dependence of L_{eff} and μ on n_s was removed, since they are identical for all spans, and we use the shorthand

$$\beta_{123}=\beta(f_1+f_2-f_3)-\beta(f_1)-\beta(f_2)+\beta(f_3)\,;\tag{9.48}$$

$D(x,N)=[\sin(Nx/2)]/[N\sin(x/2)]$ is the periodic-sinc Dirichlet function of order N [9.46].

If we further assume that the fiber loss coefficient α is frequency independent and that lumped (nondistributed) frequency-independent amplification is used, with the amplifier placed at the end of each span, then L_{eff} and μ simplify to

$$L_{\mathrm{eff}}=\frac{1-\mathrm{e}^{-2\alpha L_s}}{2\alpha}\,,\tag{9.49}$$

$$\mu(f_1,f_2,f_3)=\frac{1}{L_{\mathrm{eff}}}\times\frac{1-\mathrm{e}^{-2\alpha L_s}\mathrm{e}^{\mathrm{j}\beta_{123}L_s}}{2\alpha-\mathrm{j}\beta_{123}}\,.\tag{9.50}$$

Note that quite often β is accounted for through the so-called β_2 and β_3 coefficients, as

$$\beta(f)=2\pi^2\beta_2f^2+\frac{4}{3}\pi^3\beta_3f^3\,.\tag{9.51}$$

If so, (9.48) is rewritten as

$$\beta_{123}=4\pi^2(f_1-f_3)(f_2-f_3)[\beta_2+\pi\beta_3(f_1+f_2)]\,.\tag{9.52}$$

The Uniform Lossless Link

Lossless links are often used in research papers as a limiting case of ideal distributed amplification. A uniform lossless link with no DCUs can actually be viewed as a single span, whose length is that of the whole link. Using (9.17), (9.18), with $\alpha=0$, $g=0$ and integration length $z=L_{\mathrm{tot}}$, where L_{tot} is the whole link length, we have that $L_{\mathrm{eff}}=L_{\mathrm{tot}}$ and

$$\mu(f_1,f_2,f_3)=\mathrm{e}^{\mathrm{j}\beta_{123}\frac{L_{\mathrm{tot}}}{2}}\mathrm{Sinc}\left(\frac{\beta_{123}L_{\mathrm{tot}}}{2}\right),\tag{9.53}$$

where $\mathrm{Sinc}(x)=\sin(x)/x$. Using these results, the link factor becomes

$$\mathrm{LK}(f_1,f_2,f_3)=-\mathrm{j}\gamma L_{\mathrm{tot}}\mu(f_1,f_2,f_3)\mathrm{e}^{-\mathrm{j}\beta(f_1+f_2-f_3)L_{\mathrm{tot}}}\,.\tag{9.54}$$

If β is expressed as (9.51), then (9.52) allows us to modify (9.53)–(9.54) accordingly.

Note that there are substantial differences between the link factor of a uniform and transparent lossy multispan link (9.47) and a lossless one (9.54). Indeed, nonlinearity presents strongly different features in the two setups, so a lossless link should never be used as an approximation of a lossy one in practical system studies.

The Uniform Transparent Link with Undepleted Backward-Pumped Raman Amplification

Raman amplification has become a key staple of modern coherent terrestrial links, where it can provide equivalent noise-figure *gains* on the order of 4–6 dB. Equation (9.45) is capable of handling any distributed gain profile, and, therefore, Raman amplification too, but it would typically require numerical integration of (9.17) and (9.18), and, in general, the evaluation of LK would be quite involved.

A closed-form expression for LK is available provided that the following simplifying assumptions and approximations are made: the link is uniform and transparent; gain is due to a single counter-propagating Raman pump; the Raman pump is *undepleted*; Raman gain and fiber loss are frequency independent. Note that the Raman gain need not balance exactly fiber loss; however, we assume transparency, so either lumped loss or lumped gain are assumed to be present at the end of each span to bring the total span gain/loss to balance, from which $|H(f;n_s,N_s)|=1$, for any n_s.

The distributed (field) gain due to a single undepleted backward-propagating Raman pump at a location z within a span whose local spatial coordinate is $z\in[0,L_s]$, is

$$g(z)=C_R P_{R_0}\frac{e^{2\alpha_R z}}{2}\,, \tag{9.55}$$

where C_R is the Raman gain coefficient $1/(\mathrm{W\,km})$, α_R $(1/\mathrm{km})$ is the (field) attenuation of the fiber at the Raman pump frequency, and P_{R_0} is the power of the pump at $z=0$, i.e., at the start of the span. Note that, since the pump is injected at the end of the span and propagates backwards, its power profile actually grows exponentially in the forward direction, as shown by (9.55). The calculations are fully reported in [9.37], and the relevant results are

$$L_{\mathrm{eff}}=\frac{e^{-\frac{C_R P_{R_0}}{2\alpha_R}}}{2\alpha_R}\times\left(-\frac{C_R P_{R_0}}{2\alpha_R}\right)^{\frac{\alpha}{\alpha_R}}\times\left[\Gamma\left(-\frac{\alpha}{\alpha_R},-\frac{C_R P_{R_0}}{2\alpha_R}\right)-\Gamma\left(-\frac{\alpha}{\alpha_R},-\frac{C_R P_R}{2\alpha_R}\right)\right], \tag{9.56}$$

$$\mu(f_1,f_2,f_3)=\frac{e^{-\frac{C_R P_{R_0}}{2\alpha_R}}}{2\alpha_R L_{\mathrm{eff}}}\left(-\frac{C_R P_{R_0}}{2\alpha_R}\right)^{\frac{2\alpha-j\beta_{123}}{2\alpha_R}}\times\left[\Gamma\left(-\frac{2\alpha-j\beta_{123}}{2\alpha_R},-\frac{C_R P_{R_0}}{2\alpha_R}\right)-\Gamma\left(-\frac{2\alpha-j\beta_{123}}{2\alpha_R},-\frac{C_R P_R}{2\alpha_R}\right)\right], \tag{9.57}$$

where $P_R=P_{R_0}e^{2\alpha_R L_s}$ is the power of the pump as it is injected at the end of the span, and

$$\Gamma(x,y)=\int_y^\infty w^{x-1}e^{-w}\,dw$$

is the *upper incomplete* Gamma function. Here too, if β is expressed as (9.51), then (9.52) allows us to modify (9.57) accordingly. The overall expression of LK is still (9.47).

9.4.7 The Incoherent GN Model

Among the assumptions leading to the GN model, there is the premise that the NLI, generated by FWM in each span, adds up at the *field* level at the end of the link, that is,

$$E_{\mathrm{NLI}}^{\mathrm{end}}(f)=\sum_{n_s=1}^{N_s}E_{\mathrm{NLI}}^{(n_s)}(f)\,. \tag{9.58}$$

Equations (9.44) and (9.45) were derived accordingly. A possible alternative assumption is that NLI adds up in *power* at the end of the link, that is,

$$G_{\mathrm{NLI}}^{\mathrm{end}}(f)=\sum_{n_s=1}^{N_s}G_{\mathrm{NLI}}^{(n_s)}(f)\,. \tag{9.59}$$

This assumption is called the *incoherent accumulation approximation* or IAA. The GN model version that uses it is the *incoherent* GN *model*, or iGN model. The iGN model equations are (9.44) and the following (replacing (9.45))

$$|\mathrm{LK}(f_1,f_2,f_3)|^2=\sum_{n_s=1}^{N_s}|\gamma(n_s)L_{\mathrm{eff}}((f_1,f_2,f_3);n_s)\mu((f_1,f_2,f_3);n_s)|^2\times|H(f_1+f_2-f_3;n_s,N_s)\mathbf{H}((f_1,f_2,f_3);1,n_s-1)|^2\,. \tag{9.60}$$

The IAA is a rather drastic approximation. On the other hand, (9.59) brings about substantial simplification, which is greatly advantageous in the practical use of the GN model. There are three main aspects in which it helps.

First, if the GN model is evaluated by numerical integration of (9.44) and (9.45), the $|\mathrm{LK}|^2$ factor typically turns out to be very rapidly oscillating versus the integration variables, requiring a fine integration grid or

sophisticated integration strategies [9.37]. This can be appreciated by looking, for instance, at a closed-form LK, such as for the transparent and uniform link, where the Dirichlet function in (9.47) has a rapidly oscillatory behavior. Such behavior is due to the phase interference of the NLI contributions from different spans, occurring at the end of the link (see Fig. 21 in [9.37]). If the IAA is made, then this interference does not occur and, in the example in question, the Dirichlet function factor disappears altogether.

Secondly, the simplified analytical form of the LK factor makes it easier to find fully closed-form solutions for the overall NLI PSD $G_{\mathrm{NLI}}(f)$, see Sect. 9.4.10.

Thirdly, (9.59) makes it easy to assess NLI within complex reconfigurable networks, because the computation of NLI within each span, as well as the optimization of certain aspects such as launch power, become dependent only on span-local features. NLI is then easily propagated from that span on, by accounting only for loss and gain along the path. This was recognized early on and has developed, among others, into the LOGO network optimization and control strategy [9.47–49], which is currently in use in physical-layer-aware optical networking products of some vendors.

Of course, the above advantages would be moot if the IAA induced too large errors. However, despite the drastic nature of the IAA, the results of the iGN versus the GN model are typically quite close. In fact, in many cases, the iGN model appears more accurate than the GN model, due to the fortuitous circumstance that the error due to the Gaussian data signal assumption made by the GN model partially cancels out the error induced by the IAA. This aspect was studied in detail in [9.41] (Sects. III-D and V-D) and in [9.50]. It is also dealt with in the next section (Sect. 9.4.7).

GN Model Accuracy and Validity Range

For theoretical reasons,the discussion of which can be found in the rich literature on the topic, such as [9.25, 51–55], the GN model approximations tend to work well and produce accurate results when:

(1) The symbol rate is large
(2) Fiber dispersion is large
(3) Loss per span is not too small
(4) Amplification is prevalently lumped
(5) The number of traversed spans is sufficiently large.

In agreement with the above, the GN model has shown excellent predictive capability in ultra-long-haul (ULH) submarine transmission over PSCF at large symbol rates. Various level of inaccuracy have instead been found, for instance, over very low dispersion fibers, at low symbol rates, with short reach (1–3 spans). Note, though, that the model is rather robust in the sense that, typically, several of the above conditions must be simultaneously or severely violated in order to see large errors in NLI prediction by the model. Also, the GN model error is *always* towards underestimating system performance, i.e., it is always conservative. Such underestimation error is typically in the range −5 to −20% of maximum reach.

Several dedicated GN model test and validation studies have been carried out over the years, both simulative and experimental. Examples of the experimental ones are [9.49, 56–62], where the GN model consistently proved quite accurate. Two of these experiments were specifically designed to test the model over different fiber types [9.56, 60]. In particular, the latter addressed seven quite different fiber types. A massive ULH experiment [9.57] showed a very good accuracy of GN model predictions for a 106-channel system at 30 GBaud channel rate, with PM-16QAM transmission, over 10 290 km, with and without ideal DBP.

Regarding simulative tests, a great many papers have been published. A recent broad study [9.50] addressed a very wide range of scenarios, including five QAM formats (from PM-QPSK to PM-64QAM) at 32 GBaud, three fibers (NZ-DSF, SMF, PSCF), three channel spacings (33.6, 27.5 and 50 GHz), and two span lengths (60 and 100 km). Mixed Raman/EDFA amplification was also addressed. The range of maximum reach (MR) probed spanned from 200 to 10 000 km. Criteria (1)–(5) above were confirmed, and a gradual error increase was found when such criteria were departed from. Along similar lines, two newer studies [9.63, 64] have explored the realm of high symbol rates (from 64 to 512 GBaud), showing quite compellingly that, as symbol rates go up, the GN model becomes more accurate. We will come back to this aspect after introducing the EGN model in the next section.

Here, in Fig. 9.6a, we provide an original set of results where we focused on 15-channel systems operating at the next-generation industry-standard symbol-rate of 64 GBaud. The test was run on either single-mode-fiber (SMF) or a challenging nonzero dispersion-shifted-fiber (NZDSF) with high nonlinearity coefficient and very low dispersion. Six QAM formats were tested, from PM-8QAM to PM-256QAM, with three different spacings. The detailed system data are reported in the figure caption. MR at optimum launch power is shown, found based on reaching a target minimum generalized mutual information (GMI) equal to 87% of each format entropy, corresponding to about 15% FEC coding overhead. For instance, the entropy of PM-32QAM is 10 bit/symbol, and the target GMI was set to $0.87 \times 10 = 8.7$ bit/symbol. The abscissa is the net system

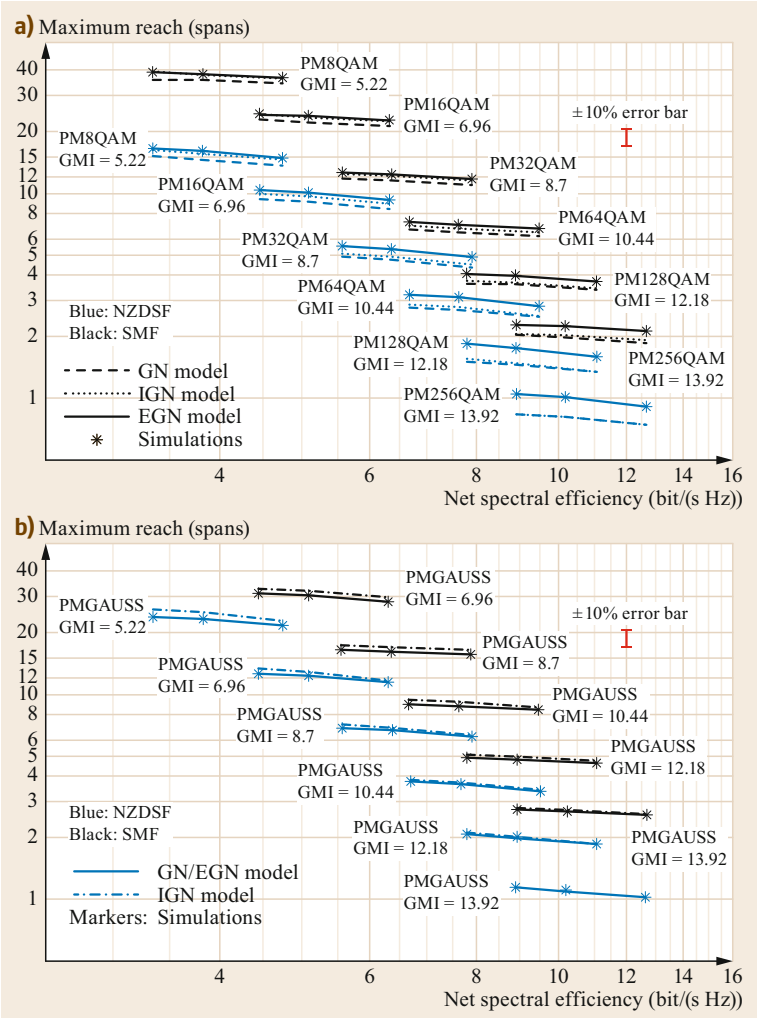

Fig. 9.6a,b System maximum reach (MR) in number of spans, versus net spectral efficiency. *Asterisks* are simulation results, *lines* are analytical predictions using the GN model, incoherent GN model, and EGN model (see legends). Results are shown in *blue* for NZDSF and in *black* for SMF. System data: the span length is 100 km, EDFA noise figure 6 dB, symbol rate $R_s = 64$ GBaud, 15 channels, the tested channel is the center one. For each format the target GMI (for PM-QAM) or MI (for PM-Gaussian) is shown. The abscissa was calculated as $\mathrm{GMI} \times R_s/\Delta f$, MI replacing GMI for PM-Gaussian. Three channel spacings Δf were used for each format: 76.2, 87.5, and 100 GHz. The error bars indicate ±10% error interval. Fibers were: SMF, $D = 16.7$ ps/(nm km), $\alpha = 0.21$ dB/km, $\gamma = 1.3$ 1/(W km); NZDSF, $D = 2.0$ ps/(nm km), $\alpha = 0.22$ dB/km, $\gamma = 1.77$ 1/(W km)

spectral efficiency in bit/(s Hz), calculated as shown in the caption.

Figure 9.6a confirms that the GN model always underestimates MR, in the SMF case by 7% for PM-8QAM, up to 17% for PM-256QAM. This larger error is due to the very short reach of PM-256QAM (1 span), severely violating condition (5). Errors are somewhat larger in the case of the NZDSF (which violates condition (2)), again especially at short reach (violating (2) and (5) together). The incoherent GN model is better overall, for the reasons explained at the end of Sect. 9.4.7.

In summary, the GN model and its incoherent version provide a low-complexity, conservative tool for the estimation of system performance across a very wide range of system scenarios. As we will later show, it also lends itself to the derivation of fully-closed form approximate solutions. These aspects justify its success and widespread use. Later, we will also show that the possible adoption of Gaussian-shaped constellation for optical transmission may actually provide a renewed boost to the use of the GN model.

9.4.8 The EGN Model

As mentioned above, the GN model loses accuracy when criteria (1)–(5) are violated. Also, because of the Gaussian data signal assumption, it does not account for certain nonlinearity features, such as the dependence of NLI generation on the modulation format. These problems were recognized early on [9.51–53], and in [9.53] a procedure was proposed by which the GN model could be modified to avoid them. In [9.65], the so-called *EGN model* was fully derived following up on the procedure introduced in [9.53]. Extended calculation details are reported in [9.66].

Both the GN and the EGN model descend from (9.37). They differ as to the *result of the expectation* $\mathrm{E}\{\mathrm{S}_i^{\mathrm{T}*}\mathrm{S}_{i'}\}$, where S_i is given by (9.35). This is because the RV's ζ_n, which make up S_i, are assumed SI for the GN model, whereas in the EGN model their statistical dependence is taken into account. As a consequence, the sixth-order moments of the ζ_n, which appear within $\mathrm{E}\{\mathrm{S}_i^{\mathrm{T}*}\mathrm{S}_{i'}\}$, yield a much more complex result than (9.40). When such a result is put into (9.37), and the transition from discrete frequency to continuous frequency is made (Sect. 9.4.5), not just one, as in the GN model case, but a total of *12* integral terms are generated, each with different integrand functions and different integration domains.

Interestingly, one of these integral terms *corresponds to the GN model itself*, so that it is possible to write the EGN model as

$$G_{\mathrm{NLI}}^{\mathrm{EGN}}(f) = G_{\mathrm{NLI}}^{\mathrm{GN}}(f) - G_{\mathrm{NLI}}^{\mathrm{corr}}(f)\,, \tag{9.61}$$

where $G_{\mathrm{NLI}}^{\mathrm{GN}}(f)$ is the GN model term and $G_{\mathrm{NLI}}^{\mathrm{corr}}(f)$ collects the other 11 integral terms. It can be thought of as a *correction* that originates from the statistical dependence of the ζ_n, not taken into account in $G_{\mathrm{NLI}}^{\mathrm{GN}}(f)$. Incidentally, such statistical dependence changes depending on the modulation format, so while $G_{\mathrm{NLI}}^{\mathrm{GN}}(f)$ is format independent, $G_{\mathrm{NLI}}^{\mathrm{corr}}(f)$ is not. Note also that $G_{\mathrm{NLI}}^{\mathrm{corr}}(f)$ is intentionally presented with a minus sign in (9.61) to stress the fact that the EGN correction typically *decreases* NLI. In fact, it *always* decreases NLI if PM-QAM signals are assumed, and this explains the feature observed of $G_{\mathrm{NLI}}^{\mathrm{GN}}(f)$ always overestimating NLI.

A complete version of the quite complex EGN model formulas is reported in [9.65, 67]. We will not reproduce them here for lack of space. We will focus instead on an approximate *reduced* EGN model in Sect. 9.4.8, *The Reduced EGN Model*.

EGN Model Accuracy

The EGN model accuracy has been extensively investigated simulatively (see for instance [9.50, 63, 64]). The results have consistently shown that the accuracy of the EGN model is excellent, even when one or more of the conditions (1)–(5), which are critical for the GN model (see the beginning of Sect. 9.4.7), are not met. As we did for the GN model, in Fig. 9.6a we show a collection of tests on QAM systems operating at 64 GBaud, over SMF and NZDSF, with 100 km spans (see Sect. 9.4.7 and the caption of Fig. 9.6a for setup details). The very remarkable feature of the plot is the flawless coincidence of the EGN model MR prediction with the simulation results, across all system configurations, MR values, channel spacings, and fibers.

Note that the star markers in Fig. 9.6a are simulations that use a receiver that is optimum in AWGN and *makes no attempt* at mitigating the component of NLI, which can be classified as *nonlinear phase noise* (NLPN). Such an NLI component turns out to be correlated over time, to an extent that roughly grows as the accumulated dispersion along the link and as the symbol rate squared. If enough time correlation is present, NLPN can be removed by means of relatively simple carrier-phase estimation (CPE) algorithms, and a somewhat better performance than predicted by the EGN model can be achieved. This aspect is discussed extensively in [9.50, 63, 64] and is dealt with in Sect. 9.5.2 of this chapter.

The Reduced EGN Model

The EGN model is very accurate but quite complex. On the other hand, in virtually all cases of practical interest, very good accuracy is still achieved by using the so-called EGN-SCI-X1 [9.67] approximation, which we call here *reduced EGN model*. It consists of neglecting those EGN model terms whose contribution is typically the smallest. The remaining terms are still substantially more complex, as a whole, than the GN model, but about only 1/3 as complex as the complete EGN model. With reference to Fig. 9.6a, the curves of the reduced EGN model would be completely superimposed to those of the EGN model (less than 1% MR difference), in all cases presented there.

To deal with the EGN model, we have to introduce a different notation from that used for the GN model in (9.44). The reason is that the term $G_{\mathrm{NLI}}^{\mathrm{corr}}(f)$, cannot be expressed in terms of the WDM signal PSD. Rather, the Fourier transforms of the individual WDM channel *pulses* are called into play. Please refer to Appendix 9.B for a detailed list of symbol definitions.

The overall WDM data signal is written in the time domain as

$$s_{\mathrm{WDM}}(t) = \sum_{n_{\mathrm{ch}}=1}^{N_{\mathrm{ch}}} \sum_{r} (a_{x,n_{\mathrm{ch}}}^{r}\hat{x} + a_{y,n_{\mathrm{ch}}}^{r}\hat{y}) \times s_{n_{\mathrm{ch}}}(t - rT_{n_{\mathrm{ch}}})\mathrm{e}^{\mathrm{j}2\pi f_{n_{\mathrm{ch}}}t}\,. \tag{9.62}$$

The $a_{x,n_{\mathrm{ch}}}^{r}$ and $a_{y,n_{\mathrm{ch}}}^{r}$ are the symbols sent on the $\hat{x}$ and $\hat{y}$ polarizations in the r signaling time slot, on the n_{ch} the WDM channel. We then assume that all quantities are normalized, so that the power carried by each WDM channel is given by

$$P_{n_{\mathrm{ch}}} = \mathrm{E}\{|a_{x,n_{\mathrm{ch}}}^{r}|^2 + |a_{y,n_{\mathrm{ch}}}^{r}|^2\}\,. \tag{9.63}$$

Table 9.1 Exact values of Φ and Ψ parameters

Format	Φ	Ψ
PM-BPSK	1	−4
PM-QPSK	1	−4
PM-8QAM	2/3	−2
PM-16QAM	17/25	−52/25
PM-QPSK	69/100	−211/100
PM-64QAM	13/21	−5548/3087
PM-128	1105/1681	−135044/68921
PM-256	257/425	−12532/7225
PM-∞-QAM	3/5	−12/7
PM-Gaussian	0	0

We also define the following quantities related to the fourth and sixth moments of the channel symbols

$$\Phi = 2 - \frac{\mathrm{E}\{|a|^4\}}{\mathrm{E}^2\{|a|^2\}}\,,$$
$$\Psi = -\frac{\mathrm{E}\{|a|^6\}}{\mathrm{E}^3\{|a|^2\}} + 9\frac{\mathrm{E}\{|a|^4\}}{\mathrm{E}^2\{|a|^2\}} - 12\,, \tag{9.64}$$

where a is any of the $a^r_{x,n_{\mathrm{ch}}}$ or of the $a^r_{y,n_{\mathrm{ch}}}$, which are assumed to all be identically distributed. The exact values of Φ and Ψ for the most commonly-used constellations are shown in Table 9.1. They vary substantially among low-cardinality constellations, whereas they change little among high-cardinality ones. We also report the limit values for a QAM constellation made up of infinitely many signal points, uniformly distributed within a square region whose center is the origin (the PM-∞-QAM entry in Table 9.1). Note that the values for PM-64QAM are already very close to such a limit.

To compute the GN model contribution $G^{\mathrm{GN}}_{\mathrm{NLI}}(f)$ according to the signal notation introduced above, (9.44) can still be used, with the substitution

$$G_{\mathrm{S}}(f) = \sum_{n_{\mathrm{ch}}=1}^{N_{\mathrm{ch}}} P_{n_{\mathrm{ch}}} R_{n_{\mathrm{ch}}} \, |\tilde{s}_{n_{\mathrm{ch}}}(f)|^2 \;, \tag{9.65}$$

where $\tilde{s}_{n_{\mathrm{ch}}}(f) = \mathrm{F}\{s_{n_{\mathrm{ch}}}(t)\mathrm{e}^{\mathrm{j}2\pi f_{n_{\mathrm{ch}}}t}\}$. Regarding the correction term $G^{\mathrm{corr}}_{\mathrm{NLI}}(f)$, its overall expression for the *reduced* EGN model is

$$G^{\mathrm{corr}}_{\mathrm{NLI}}(f) = P^3_{m_{\mathrm{c}}}\left[\Phi_{m_{\mathrm{c}}}\rho^{m_{\mathrm{c}}}_{\mathrm{SCI}}(f) + \Psi_{m_{\mathrm{c}}}\tau^{m_{\mathrm{c}}}_{\mathrm{SCI}}(f)\right] + P_{m_{\mathrm{c}}}\sum_{\substack{n_{\mathrm{ch}}=1\\ n_{\mathrm{ch}}\neq m_{\mathrm{c}}}}^{N_{\mathrm{ch}}} P^2_{n_{\mathrm{ch}}}\Phi_{n_{\mathrm{ch}}}\rho^{n_{\mathrm{ch}}}_{\mathrm{X1}}(f)\,, \tag{9.66}$$

where we have assumed that the channel under test (CUT) is the m_{c}-th channel, *not necessarily* the center channel in the WDM comb.

The terms in (9.66) bearing the subscript SCI (self-channel interference) are EGN correction terms to the NLI produced by the CUT onto itself. Their expression is

$$\begin{aligned}\rho^{m_{\mathrm{c}}}_{\mathrm{SCI}}(f) = \frac{80}{81}R^2_m \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_1 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_2 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f'_2 \\ \times |\tilde{s}_{m_{\mathrm{c}}}(f_1)|^2\tilde{s}_{m_{\mathrm{c}}}(f_2)\tilde{s}^*_{m_{\mathrm{c}}}(f'_2)\tilde{s}^*_{m_{\mathrm{c}}}(f_1+f_2-f) \\ \times \tilde{s}_{m_{\mathrm{c}}}(f_1+f'_2-f) \\ \times \mathrm{LK}(f_1,f_2,f_1+f_2-f)\mathrm{LK}^*(f_1,f'_2,f_1+f'_2-f) \\ + \frac{16}{81}R^2_{m_{\mathrm{c}}} \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_1 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_2 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f'_2 \\ \times |\tilde{s}_{m_{\mathrm{c}}}(f_1+f_2-f)|^2\tilde{s}_{m_{\mathrm{c}}}(f_1)\tilde{s}_{m_{\mathrm{c}}}(f_2) \\ \times \tilde{s}^*_{m_{\mathrm{c}}}(f_1+f_2-f'_2)\tilde{s}^*_{m_{\mathrm{c}}}(f'_2) \\ \times \mathrm{LK}(f_1,f_2,f_1+f_2-f) \\ \times \mathrm{LK}^*(f_1+f_2-f'_2,f'_2,f_1+f_2-f)\,,\end{aligned} \tag{9.67}$$

$$\begin{aligned}\tau^{m_{\mathrm{c}}}_{\mathrm{SCI}}(f) = \frac{16}{81}R_{m_{\mathrm{c}}} \\ \times \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_1 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_2 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f'_1 \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f'_2 \\ \times \tilde{s}_{m_{\mathrm{c}}}(f_1)\tilde{s}_{m_{\mathrm{c}}}(f_2)\tilde{s}^*_{m_{\mathrm{c}}}(f_1+f_2-f) \\ \times \tilde{s}^*_{m_{\mathrm{c}}}(f'_1)\tilde{s}^*_{m_{\mathrm{c}}}(f'_2)\tilde{s}_{m_{\mathrm{c}}}(f'_1+f'_2-f) \\ \times \mathrm{LK}(f_1,f_2,f_1+f_2-f)\mathrm{LK}^*(f'_1,f'_2,f'_1+f'_2-f)\,,\end{aligned} \tag{9.68}$$

where the integration limits were made explicit and correspond to the frequency interval occupied by the CUT, i.e.,

$$f \in \left[f_{m_{\mathrm{c}}} - \frac{B_{m_{\mathrm{c}}}}{2}, f_{m_{\mathrm{c}}} + \frac{B_{m_{\mathrm{c}}}}{2}\right]. \tag{9.69}$$

The terms in (9.66) bearing the subscript *X1* are EGN correction terms to the NLI produced by *XPM* (cross-phase modulation) or, according to a different taxonomy [9.37], due to *XCI* (cross-channel interference). Their expression is

$$\begin{aligned}\rho^{n_{\mathrm{ch}}}_{\mathrm{X1}}(f) = \frac{80}{81}R_{m_{\mathrm{c}}}R_{n_{\mathrm{ch}}} \\ \times \int_{f_{m_{\mathrm{c}}}-B_{m_{\mathrm{c}}}/2}^{f_{m_{\mathrm{c}}}+B_{m_{\mathrm{c}}}/2}\mathrm{d}f_1 \int_{f_{n_{\mathrm{ch}}}-B_{n_{\mathrm{ch}}}/2}^{f_{n_{\mathrm{ch}}}+B_{n_{\mathrm{ch}}}/2}\mathrm{d}f_2 \int_{f_{n_{\mathrm{ch}}}-B_{n_{\mathrm{ch}}}/2}^{f_{n_{\mathrm{ch}}}+B_{n_{\mathrm{ch}}}/2}\mathrm{d}f'_2 \\ \times |\tilde{s}_{m_{\mathrm{c}}}(f_1)|^2\tilde{s}_{n_{\mathrm{ch}}}(f_2)\tilde{s}^*_{n_{\mathrm{ch}}}(f'_2) \\ \times \tilde{s}^*_{n_{\mathrm{ch}}}(f_1+f_2-f)\tilde{s}_{n_{\mathrm{ch}}}(f_1+f'_2-f) \\ \times \mathrm{LK}(f_1,f_2,f_1+f_2-f)\mathrm{LK}^*(f_1,f'_2,f_1+f'_2-f)\,,\end{aligned} \tag{9.70}$$

where the integration limits were made explicit and correspond to either the frequency interval occupied by the CUT as written in (9.69) or by the generic n_{ch}-th WDM channel

$$f \in [f_{n_{\mathrm{ch}}} - \frac{B_{n_{\mathrm{ch}}}}{2}, f_{n_{\mathrm{ch}}} + \frac{B_{n_{\mathrm{ch}}}}{2}] \,. \tag{9.71}$$

9.4.9 Gaussian-Shaped Constellations

If a *PM-Gaussian* constellation is used, then all the factors Φ and Ψ in (9.66) are zero, according to Table 9.1. This implies $G_{\mathrm{NLI}}^{\mathrm{corr}}(f) = 0$ or, equivalently, $G_{\mathrm{NLI}}^{\mathrm{EGN}}(f) = G_{\mathrm{NLI}}^{\mathrm{GN}}(f)$.

Given the current rapidly growing interest in Gaussian-shaped constellations (GSCs), this is an important result. To check it, we ran the sample test set of Fig. 9.6a using an ideal GCS, taking as target MIs the values of GMI of the six QAM systems in Fig. 9.6a. The results are shown in Fig. 9.6b. Simulations agree very well with the GN/EGN curve. Therefore, if systems using GSCs earned widespread adoption, NLI modeling complexity would reduce to that of the GN model, but EGN model accuracy should be expected. This circumstance might help in the design and real-time handling of future physical-layer-aware networks based on GCSs. A specifically devoted paper was recently published on this topic, combining it with future ultra-high symbol rates [9.64]. As a caveat, GSCs are known to generate more NLPN than QAM constellations. For a discussion of the possible impact of this aspect on modeling and for more information on how simulations involving GSCs can be performed, see [9.64].

9.4.10 GN Model Closed-Form Approximate Solutions

In some cases, approximate closed-form solutions (ACFSs) can be found not just for the link factor, as shown in Sect. 9.4.6, but for the overall NLI PSD $G_{\mathrm{NLI}}(f)$, for either the GN or the EGN model. Several ACFSs have been proposed, among them [9.27, 37–41, 67, 68]. Being approximate solutions, each one has specific limitations that must be taken into account.

For the EGN model, however, only one ACFS is currently available, consisting of an asymptotic form (in the number of spans) of the correction term $G_{\mathrm{NLI}}^{\mathrm{corr}}(f)$. It was proposed in [9.68] and then upgraded in [9.67, 69]. Though effective, it only works well for relatively long links.

Instead, several ACFSs have been found for the GN model. A very accurate GN model ACFS is available for transparent and uniform systems using an ideal Nyquist-WDM comb (zero roll-off and channel spacing equal to the symbol rate). It was originally derived in [9.37] and consists of (9.7), (9.13), and (9.23) in that paper, combined.

An extension to non-Nyquist systems, for identical channels with uniform channel spacing, was also proposed in [9.37] ((9.7), (9.15) and unnumbered formula after (9.23)). Its accuracy is quite good for narrow channel spacing but may degrade for large channel spacing.

An ACFS not requiring either transparency, uniformity, or identical, equally-spaced channels, and therefore of great potential usefulness, was reported in [9.41]. Such a formula is quite general, but it approximates the iGN model, rather than GN, i.e., it assumes *incoherent NLI accumulation* (Sect. 9.4.7). On the other hand, the results from the literature [9.50, 63, 64] as well as Fig. 9.6, show the iGN model to be close to the GN model in most practical situations, including that of GSC-based systems (Fig. 9.6b). Two more assumptions are made, which were needed in the derivation: the channels have approximately rectangular PSD (that is, very small roll-off) and span loss is at least 7 dB, with greater than 10 dB being the optimal condition. Also, this ACFS provides an estimate of $G_{\mathrm{NLI}}(f)$ at the *center* of any one of the WDM channels. For the purpose of system performance assessment, it is then necessary to assume that $G_{\mathrm{NLI}}(f)$ is flat over the channel of interest. This *local white noise* assumption was studied in [9.37] and [9.41] and was shown to typically induce a small error. The formula is

$$\begin{aligned} G_{\mathrm{NLI}}(f_{i_{\mathrm{ch}}}) = {} & \frac{16}{27} \sum_{n_{\mathrm{s}}=1}^{N_{\mathrm{s}}} \gamma_{n_{\mathrm{s}}}^2 L_{\mathrm{eff},n_{\mathrm{s}}}^2 \\ & \times \prod_{p=1}^{n_{\mathrm{s}}-1} \Gamma_p^3 \mathrm{e}^{-6\alpha_p L_{\mathrm{s}}^{(p)}} \times \prod_{p=n_{\mathrm{s}}}^{N_{\mathrm{s}}} \Gamma_p \mathrm{e}^{-2\alpha_p L_{\mathrm{s}}^{(p)}} \\ & \times \sum_{n_{\mathrm{ch}}=1}^{N_{\mathrm{ch}}} G_{\mathrm{S}}^2(f_{n_{\mathrm{ch}}}) G_{\mathrm{S}}(f_{i_{\mathrm{ch}}}) \times (2 - \delta_{n_{\mathrm{ch}} i_{\mathrm{ch}}}) \times \Theta_{n_{\mathrm{ch}} i_{\mathrm{ch}} n_{\mathrm{s}}} \,, \end{aligned} \tag{9.72}$$

where $G_{\mathrm{NLI}}(f_{i_{\mathrm{ch}}})$ is the NLI PSD at the center frequency $f_{i_{\mathrm{ch}}}$ of the i_{ch}-th channel of the comb; $G_{\mathrm{S}}(f_{n_{\mathrm{ch}}})$ and $G_{\mathrm{S}}(f_{i_{\mathrm{ch}}})$ are the PSDs of the WDM data signal at the center frequency of the n_{ch}-th and i_{ch}-th channels, respectively; $\delta_{n_{\mathrm{ch}} i_{\mathrm{ch}}}$ is Kronecker's delta, i.e., it is one if $n_{\mathrm{ch}} = i_{\mathrm{ch}}$ and zero otherwise; finally, Θ is

$$\begin{aligned} & \Theta_{n_{\mathrm{ch}} i_{\mathrm{ch}} n_{\mathrm{s}}} \\ & \approx \frac{\operatorname{asinh}\left[\pi^2 (2\alpha_{n_{\mathrm{s}}})^{-1} |\beta_{2,n_{\mathrm{s}}}| f_{n_{\mathrm{ch}}} - f_{i_{\mathrm{ch}}} + \frac{B_{n_{\mathrm{ch}}}}{2} B_{i_{\mathrm{ch}}}\right]}{4\pi (2\alpha_{n_{\mathrm{s}}})^{-1} |\beta_{2,n_{\mathrm{s}}}|} \\ & \quad - \frac{\operatorname{asinh}\left[\pi^2 (2\alpha_{n_{\mathrm{s}}})^{-1} |\beta_{2,n_{\mathrm{s}}}| f_{n_{\mathrm{ch}}} - f_{i_{\mathrm{ch}}} - \frac{B_{n_{\mathrm{ch}}}}{2} B_{i_{\mathrm{ch}}}\right]}{4\pi (2\alpha_{n_{\mathrm{s}}})^{-1} |\beta_{2,n_{\mathrm{s}}}|}, \\ & \qquad n_{\mathrm{ch}} \neq i_{\mathrm{ch}} \end{aligned} \tag{9.73}$$

$$\Theta_{i_{\rm ch}i_{\rm ch}n_{\rm s}} \approx \frac{\operatorname{asinh}\left[\frac{\pi^2}{2}|\beta_{2,n_{\rm s}}|(2\alpha_{n_{\rm s}})^{-1}B_{i_{\rm ch}}^2\right]}{2\pi|\beta_{2,n_{\rm s}}|(2\alpha_{n_{\rm s}})^{-1}},$$
$$n_{\rm ch} = i_{\rm ch}\,, \tag{9.74}$$

where $B_{n_{\rm ch}}$ and $B_{i_{\rm ch}}$ are the bandwidth of the $n_{\rm ch}$-th and $i_{\rm ch}$-th channels, respectively. Note that the formula can be easily upgraded to support lumped frequency-dependent gain or loss, as well as to allow us to account for the drop-off and join-in of channels at any of the span starts.

Regarding accuracy, the typical absolute error between the predictions of (9.72)–(9.74) versus numerical integration of the iGN model is typically 2–3% of MR, making it a valuable tool for real-time system appraisal.

While this chapter was being finalized, two GN/iGN model ACFS were proposed, which upgrade (9.72)–(9.74) to also support dispersion slope through β_3, frequency-dependent loss and interchannel stimulated Raman scattering [9.70, 71]. They represent substantial progress, since they make it possible to analyze ultra-broadband systems, such as (C+L)-band ones. Due to their closed form, they could potentially become effective tools for real-time physical-layer-aware management of fully-loaded reconfigurable optical networks.

Closed-Form NLI Modeling and Raman Amplification

In previous sections, the GN and EGN general expressions (9.44)–(9.46) were provided in such a form that they can support arbitrary and possibly frequency-dependent amplification.

One overall ACFS is currently available for the GN model assuming *ideal distributed* amplification, i.e., with $\alpha(z) = g(z)$ at each point along the link, and ideal Nyquist-WDM transmission. It is (9.24) in [9.37], but of course this represents a completely ideal reference scenario.

An exact closed form was provided for the LK factor in Sect. 9.4.6, under simplifying assumptions (undepleted backward-propagating pump, frequency-flat gain). By means of various simplifications and approximations of the LK term and of the integration procedure, an ACFS for frequency-independent Raman amplification was proposed in [9.72] and extensively tested with good results. In [9.73, 74], the LK factor was approximated in suitable ways such that subsequent simplified numerical integration was possible, even in the most general case of depleted-pump and frequency-dependent Raman amplification.

It should also be pointed out that, as shown extensively in [9.50], provided that Raman amplification is backward-pumped and provides gain which is at least 6 dB lower than fiber loss, then its effect on NLI generation is small. In practice, it is possible to neglect it, incurring only about 2–3% MR estimation error. This result is significant, since in many practical cases Raman amplification complies with the above condition, as part of the span loss is compensated for by Raman amplification and part by an EDFA placed at the end of the span. This is called *hybrid Raman-EDFA amplification* and currently represents the typical solution employed in terrestrial (new or refurbished) links. In such cases, the effect of Raman on NLI generation can essentially be ignored.

9.5 Time-Domain Perturbative Model

In this section, we explore a perturbation-based *time-domain* model [9.75], describing the way in which data symbols transmitted into the optical fiber are perturbed by the nonlinearity of the fiber. This approach is alternative to the frequency-domain FWM approach described in the previous section. While it leads to similar results to the EGN model, it also permits us to predict statistical correlations between different temporal NLI symbols and to discern among different types of NLI. In particular, it allows to single out and characterize its so-called PPRN components (phase and polarization rotation noise).

In the following, we ignore nonlinear perturbations generated by the presence of co-propagating ASE noise and focus on SPM perturbations caused by the symbols transmitted over the channel of interest, as well as on XPM and FWM perturbations caused by the data symbols transmitted over neighboring interfering WDM channels.

In the framework of first-order perturbation analysis, the symbols received after ideal dispersion compensation can be written as

$$\boldsymbol{r}_n = \boldsymbol{a}_n + \Delta\boldsymbol{a}_n\,, \tag{9.75}$$

where the two-element column vectors $\boldsymbol{a}_n$ and $\boldsymbol{r}_n$ represent the transmitted and received polarization multiplexed data symbols of the channel of interest in the n-th time slot. The two-element data vector $\Delta\boldsymbol{a}_n$ corresponds to the first-order nonlinear perturbation. The various signal-induced contributions to $\Delta\boldsymbol{a}_n$ can be categorized as resulting from SPM, XPM, and FWM.

Their time-domain representation is given by [9.53, 75]

$$\Delta \boldsymbol{a}_n^{\mathrm{SPM}} = \sum_{l,k,m} \boldsymbol{a}_{n+l} \boldsymbol{a}_{n+k}^{\dagger} \boldsymbol{a}_{n+m} S_{l,k,m}, \tag{9.76}$$

$$\Delta \boldsymbol{a}_n^{\mathrm{XPM}} = \sum_{l,k,m,j} \left(\boldsymbol{b}_{n+k,j}^{\dagger} \boldsymbol{b}_{n+m,j} \mathbf{I} + \boldsymbol{b}_{n+m,j} \boldsymbol{b}_{n+k,j}^{\dagger} \right) \times \boldsymbol{a}_{n+l} X_{l,k,m}(\Omega_j), \tag{9.77}$$

$$\Delta \boldsymbol{a}_n^{\mathrm{FWM}} = \sum_{\substack{l,k,m \\ j_1,j_2,j_3}} \boldsymbol{b}_{n+l,j_1} \boldsymbol{b}_{n+k,j_2}^{\dagger} \boldsymbol{b}_{n+m,j_1} \times F_{l,k,m}(\Omega_{j_1}, \Omega_{j_2}, \Omega_{j_3}) , \tag{9.78}$$

where $\boldsymbol{b}_{n,j}$ represents the two-element data vector transmitted in the n-th time slot over the j-th interfering WDM channel, having a frequency separation of Ω_j from the channel of interest. The FWM kernels $F_{l,k,m}(\Omega_{j_1}, \Omega_{j_2}, \Omega_{j_3})$ satisfy

$$F_{l,k,m}(\Omega_{j_1}, \Omega_{j_2}, \Omega_{j_3}) = \mathrm{j}\gamma \frac{8}{9} \int_0^L \int f(z) s_0^*(z,t) \times s_{\Omega_{j_1}}(z, t - lT) s_{\Omega_{j_2}}^*(z, t - kT) s_{\Omega_{j_3}}(z, t - mT) \mathrm{d}z \mathrm{d}t , \tag{9.79}$$

where γ is the nonlinear coefficient of the fiber, L and $f(z)$ are the length and power profile of the link, T is the symbol time duration, and where $s_{\Omega}(z,t)$ represents the dispersed waveform of the pulse transmitted over a WDM channel spaced by Ω from the channel of interest, when reaching point z along the fiber. The SPM and XPM kernels are given by $S_{l,k,m} = F_{l,k,m}(0,0,0)$ and $X_{l,k,m}(\Omega) = F_{l,k,m}(0,\Omega,\Omega)$, respectively. We note that in cases where the channel spacing is sufficiently low, there are additional XPM contributions that do not appear in (9.77) and that involve interactions between three data-vectors from the closest interfering channel or interactions between two data vectors from the channel of interest and a single data vector from the closest interfering channels.

9.5.1 XPM Time-Varying ISI Representation

The effect of XPM on the received data symbols of the channel of interest can be described as time-varying ISI [9.76, 77]. This can be viewed by rewriting (9.77) as

$$\Delta \boldsymbol{a}_n^{\mathrm{XPM}} = \sum_h \mathbf{H}_l^{(n)} \boldsymbol{a}_{n+l} , \tag{9.80}$$

where the 2×2 ISI matrices are given by

$$\mathbf{H}_l^{(n)} = \sum_{k,m,j} \left(\boldsymbol{b}_{k+n,j}^{\dagger} \boldsymbol{b}_{m+n,j} \mathbf{I} + \boldsymbol{b}_{m+n,j} \boldsymbol{b}_{k+n,j}^{\dagger} \right) X_{l,k,m}(\Omega_j) . \tag{9.81}$$

Assuming that the data symbols transmitted over the interfering channels are unknown at the transmitter and receiver implies that the ISI matrices $\mathbf{H}_l^{(n)}$ are unknown as well. The summation over k and m in (9.81) implies that the set of data vectors $\boldsymbol{b}_{n,j}$ contributing to $\mathbf{H}_l^{(n)}$ changes with n and, hence, the ISI matrices vary with time, as indicated by the superscript (n). In highly dispersive systems a large number of data vectors $\boldsymbol{b}_{n,j}$ may participate in the summation of (9.81), implying that the ISI matrices $\mathbf{H}_l^{(n)}$ change slowly with n. The temporal correlation of these ISI matrices is further discussed in Sect. 9.5.4.

9.5.2 Nonlinear Phase and Polarization Rotation

The zeroth-order XPM contribution $\mathbf{H}_0^{(n)} \boldsymbol{a}_n$ possesses some interesting and unique properties that have important implications on the statistical properties of NLIN and on its mitigation [9.53, 55, 75]. As shown in [9.55] and in the Appendix of [9.78], its effect can be written as

$$\boldsymbol{a}_n + \mathbf{H}_0^{(n)} \boldsymbol{a}_n = \begin{pmatrix} \mathrm{e}^{\mathrm{j}\theta_n^{(x)}} & \mathrm{j}h_n \\ \mathrm{j}h_n^* & \mathrm{e}^{\mathrm{j}\theta_n^{(y)}} \end{pmatrix} \begin{pmatrix} a_n^{(x)} \\ a_n^{(y)} \end{pmatrix} , \tag{9.82}$$

where $a_n^{(x)}$ and $a_n^{(y)}$ are the two elements of the data vector $\boldsymbol{a}_n$, and where $\theta_n^{(x)}$, $\theta_n^{(y)}$ and h_n are given by

$$\theta_n^{(x)} = \gamma \frac{8}{9} \sum_{k,m,j} \left(2 b_{n+k,j}^{(x)*} b_{n+m,j}^{(x)} + b_{n+k,j}^{(y)*} b_{n+m,j}^{(y)} \right) \times X_{0,k,m}(\Omega_j) , \tag{9.83}$$

$$\theta_n^{(y)} = \gamma \frac{8}{9} \sum_{k,m,j} \left(2 b_{n+k,j}^{(y)*} b_{n+m,j}^{(y)} + b_{n+k,j}^{(x)*} b_{n+m,j}^{(x)} \right) \times X_{0,k,m}(\Omega_j) , \tag{9.84}$$

$$h_n = \gamma \frac{8}{9} \sum_{k,m,j} b_{n+k,j}^{(y)*} b_{n+m,j}^{(x)} X_{0,k,m}(\Omega_j) , \tag{9.85}$$

with $b_{n,j}^{(x)}$ and $b_{n,j}^{(y)}$ representing the two elements of $\boldsymbol{b}_{n,j}$.

The zeroth-order XPM contribution can, therefore, be viewed as inducing independent phase noise in each polarization, as well as polarization crosstalk, which is known also as cross polarization modulation (XpolM). Another important observation that arises from (9.82)–(9.84) is that nonlinear phase noise has a strong dependence on the modulation format [9.53, 75]. This

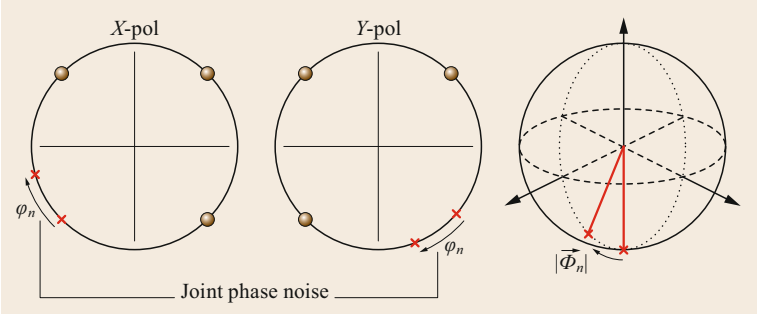

Fig. 9.7 Phase and polarization-rotation noise (PPRN) in QPSK transmission

dependence results from the fact that the terms with $k = m$ in (9.83) and (9.84) are proportional to $|b^{(x)}_{n+m,j}|^2$ and $|b^{(y)}_{n+m,j}|^2$. For constant-modulus formats, these terms are fixed for any n, implying that they induce a constant phase shift for all received data symbols (i.e., only rotating the entire received constellation). On the other hand, when amplitude modulation is introduced to the data symbols, $|b^{(x)}_{n+m,j}|^2$ and $|b^{(y)}_{n+m,j}|^2$ change with n, and $\theta^{(x)}_n$ and $\theta^{(y)}_n$ vary with time. This is why nonlinear phase noise is relatively small in systems using QPSK but significantly larger in systems employing higher-order QAM formats [9.53]. Note however, that even for constant-modulus formats, polarization crosstalk (through ih_n) can be very important.

The effect of the zeroth-order XPM contribution on the dual-polarization signal can be also described as phase and polarization rotation noise. Using the power series expansion of matrix exponentials [9.79, 80], (9.82)–(9.85) can be written as [9.55]

$$\boldsymbol{a}_n + \mathbf{H}_0^{(n)}\boldsymbol{a}_n = \mathrm{e}^{\mathrm{j}\varphi_n}\mathrm{e}^{\mathrm{j}\boldsymbol{\Phi}_n}\boldsymbol{a}_n\,, \tag{9.86}$$

where the term $\exp(\mathrm{j}\varphi_n)$ induces phase-noise and is given by

$$\varphi_n = \gamma\frac{4}{3}\sum_{k,m,j}\boldsymbol{b}^{\dagger}_{n+k,j}\boldsymbol{b}_{n+m,j}X_{0,k,m}(\Omega_j)\,, \tag{9.87}$$

and where the matrix exponential $\exp(\mathrm{j}\boldsymbol{\Phi}_n)$ induces polarization rotation noise and is given by

$$\boldsymbol{\Phi}_n = \gamma\frac{8}{9}\sum_{k,m,j}\left(\boldsymbol{b}_{n+m,j}\boldsymbol{b}^{\dagger}_{n+k,j} - \frac{1}{2}\boldsymbol{b}^{\dagger}_{n+k,j}\boldsymbol{b}_{n+m,j}\mathbf{I}\right) \times X_{0,k,m}(\Omega_j)\,. \tag{9.88}$$

Figure 9.7 visualizes the two contributions of the zeroth-order XPM effect. The phase-noise part $\mathrm{e}^{\mathrm{j}\varphi_n}$ rotates the two polarizations together by a common angle φ_n equal to the average of $\theta^{(x)}_n$ and $\theta^{(y)}_n$, whereas the polarization-state rotation $\exp(\mathrm{j}\boldsymbol{\Phi}_n)$ causes the Stokes vector representing $\boldsymbol{a}_n$ on the Poincaré sphere [9.80] to rotate about $\boldsymbol{\Phi}_n$, the Stokes vector of $\boldsymbol{\Phi}_n$, at an angle equal to its length $|\boldsymbol{\Phi}_n|$. This motivates the term *phase and polarization-rotation noise* (PPRN) to denote the zeroth-order XPM contribution. Furthermore, the PPRN description captures the unitarity of the zeroth-order XPM effect, which does not impair the norm of the transmitted dual-polarization data vector $\boldsymbol{a}^{\dagger}_n\boldsymbol{a}_n$.

9.5.3 Variance of PPRN and Higher-Order XPM Terms

In what follows, we examine the relative importance of the various XPM contributions by examining their individual contribution to the overall XPM variance. The predictions are based on the calculations of [9.81] (also shown in the Appendix of [9.78]), which were shown to be in excellent agreement with split-step simulations. The calculations assume polarization-multiplexed transmission of statistically independent data symbols, isotropically symmetric in their phase space and are given here, for simplicity of notation, for perfect Nyquist pulses with zero roll-off. The dependence of XPM on the roll-off factor is typically small but may become significant for roll-off factors larger than ≈ 0.2. We refer the interested reader to Appendix B of [9.81] for further information on how to modify the formulas below to account for nonzero roll-off factors.

The variance of XPM contributions can be written as $P_0P^2_{\mathrm{int}}\chi_{\mathrm{XPM}}$, where P_0 and P_{int} are the average launch power of the channel of interest and the interfering channel. Following the assumptions before, the various XPM terms are uncorrelated, and the XPM nonlinear coefficient, χ_{XPM}, can be written as [9.81]

$$\chi_{\mathrm{XPM}} = \sum_l \chi^{(l)}_{\mathrm{XPM}} = \sum_l \chi^{(l)}_{\mathrm{XPM},1} + \left(\frac{\langle|b|^4\rangle}{\langle|b|^2\rangle^2} - 2\right)\chi^{(l)}_{\mathrm{XPM},2}\,, \tag{9.89}$$

where b represents a single data symbol transmitted over one of the polarizations of the interfering channel, and where the angled brackets denote statistical averaging. The term $\langle|b|^4\rangle/\langle|b|^2\rangle^2$ accounts for the dependence of XPM on the fourth-order moment of the interfering data symbols.

The contribution of the l-th XPM term $\mathbf{H}_l^{(n)}\boldsymbol{a}_{n+l}$ to the overall XPM variance is, therefore, given by $P_0 P_{\mathrm{INT}}^2 \chi_{\mathrm{XPM}}^{(l)}$, where the coefficients $\chi_{\mathrm{XPM},1}^{(l)}$ and $\chi_{\mathrm{XPM},2}^{(l)}$ are given in [9.81]

$$\chi_{\mathrm{XPM},1}^{(l)} = \frac{32}{27}\frac{\gamma^2}{T^2}\sum_j \int \rho_j(\omega_1,\omega_2,\omega_3)\rho_j^*(\omega_4,\omega_2,\omega_3) \times \mathrm{e}^{\mathrm{j}(\omega_1-\omega_4)lT}\frac{\mathrm{d}^4\omega}{(2\pi)^4},$$

$$\chi_{\mathrm{XPM},2}^{(l)} = \frac{80}{81}\frac{\gamma^2}{T}\sum_j \int \rho_j(\omega_1,\omega_2,\omega_3)\rho_j^*(\omega_4,\omega_5,\omega_6) \times \mathrm{e}^{\mathrm{j}(\omega_1-\omega_4)lT}\frac{\mathrm{d}^5\omega}{(2\pi)^5}, \tag{9.90}$$

with $\omega_6 = \omega_5 - \omega_2 + \omega_3$. The kernels $\rho_j(\omega_1,\omega_2,\omega_3)$ are given by

$$\rho_j(\omega_1,\omega_2,\omega_3) = \tilde{s}_0^*(\omega_1-\omega_2+\omega_3)\tilde{s}_0(\omega_1)\tilde{s}_j^*(\omega_2)\tilde{s}_j(\omega_3) \times \int_0^L f(z)\mathrm{e}^{\mathrm{j}(\omega_1-\omega_2-\Omega_j)(\omega_2-\omega_3)\beta''z}\mathrm{d}z, \tag{9.91}$$

where β'' is the dispersion coefficient of the fiber, and where $\tilde{s}_0(\omega)$ and $\tilde{s}_j(\omega)$ represent the baseband spectral shape of the transmitted pulses from the channel of interest and the j-th interfering channel.

In Fig. 9.8 we examine the significance of the various XPM contributions in standard 16-QAM WDM systems with 100 km spans, 115 32 Gbaud channels, and 37.5 GHz channel spacing. We plot the variance of the various XPM contributions $\mathbf{H}_l^{(n)}\boldsymbol{a}_{n+l}$ normalized by the variance of the zeroth-order XPM contribution $\mathbf{H}_0^{(n)}\boldsymbol{a}_n$. Evidently, the PPRN contribution has the most pronounced effect whereas the significance of the XPM terms $\mathbf{H}_l^{(n)}\boldsymbol{a}_{n+l}$ with $|l|>0$ decreases monotonically with $|l|$.

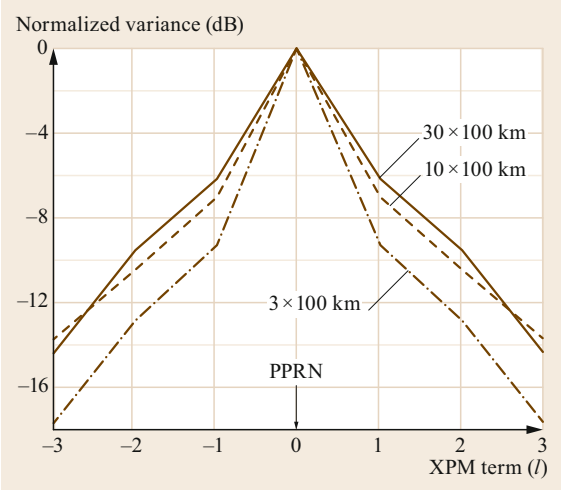

Fig. 9.8 Variance of the various XPM terms normalized by the variance of the zeroth-order XPM term (PPRN) for fully-loaded 115-channel transmission using 16-QAM

9.5.4 Temporal Correlations

An important observation regarding the ISI form of XPM is the fact that the ISI matrices $\mathbf{H}_l^{(n)}$ change slowly with n, as the matrix elements are the result of a summation over a significant number of interfering symbols, see (9.81). Following the assumptions of Sect. 9.5.3, the temporal autocorrelation function of the diagonal elements of $\mathbf{H}_l^{(n)}$ is given in [9.81]

$$R_{\mathrm{diag}}^{(l)}(s) = R_{\mathrm{diag},1}^{(l)}(s) + \left(\frac{\langle|b|^4\rangle}{\langle|b|^2\rangle^2} - 2\right)R_{\mathrm{diag},2}^{(l)}(s), \tag{9.92}$$

where

$$R_{\mathrm{diag},1}^{(l)}(s) = \frac{80}{81}\frac{\gamma^2}{T^2}\sum_j \int \rho_j(\omega_1,\omega_2,\omega_3)\rho_j^*(\omega_4,\omega_2,\omega_3) \times \mathrm{e}^{\mathrm{j}(\omega_1-\omega_4)lT}\mathrm{e}^{\mathrm{j}(\omega_2-\omega_3)sT}\frac{\mathrm{d}^4\omega}{(2\pi)^4},$$

$$R_{\mathrm{diag},2}^{(l)}(s) = \frac{80}{81}\frac{\gamma^2}{T}\sum_j \int \rho_j(\omega_1,\omega_2,\omega_3)\rho_j^*(\omega_4,\omega_5,\omega_6) \times \mathrm{e}^{\mathrm{j}(\omega_1-\omega_4)lT}\mathrm{e}^{\mathrm{j}(\omega_2-\omega_3)sT}\frac{\mathrm{d}^5\omega}{(2\pi)^5}, \tag{9.93}$$

with $\omega_6 = \omega_5 - \omega_2 + \omega_3$. The temporal autocorrelation function of the off-diagonal elements of $\mathbf{H}_l^{(n)}$ is given in [9.81]

$$R_{\mathrm{off-diag}}^{(l)}(s) = \frac{1}{5}R_{\mathrm{diag},1}^{(l)}(s). \tag{9.94}$$

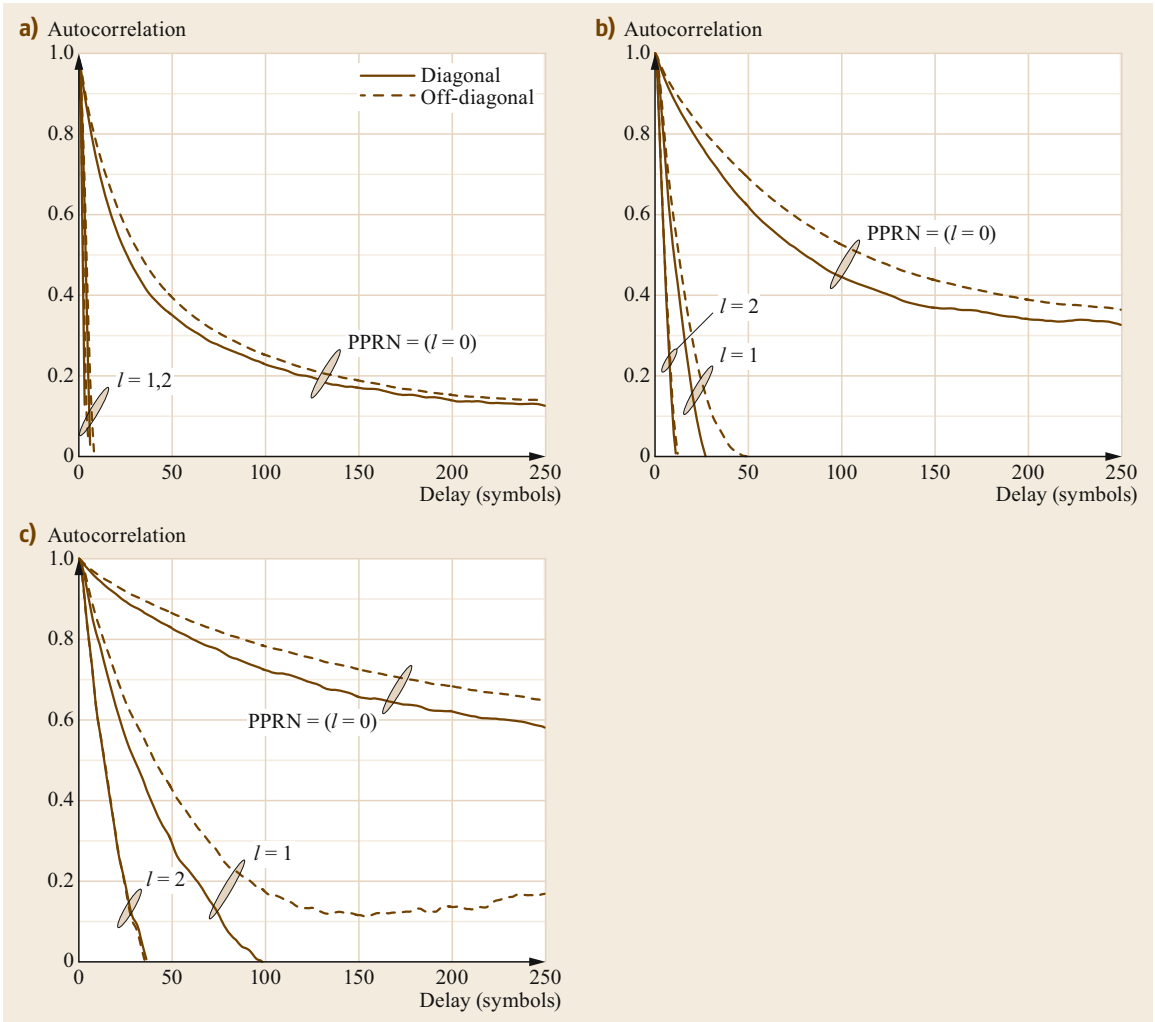

Fig. 9.9a–c Autocorrelation of the diagonal (*solid*) and off-diagonal (*dashed*) elements of $\mathbf{H}_l^{(n)}$ for $l = 0, 1, 2$ in 16-QAM fully loaded systems with 115 channels. The diagonal and off-diagonal elements of $\mathbf{H}_0^{(n)}$ induce nonlinear phase-noise and polarization crosstalk. **(a)** 3×100 km; **(b)** 10×100 km; **(c)** 30×100 km

In Fig. 9.9, we show the autocorrelation function of the diagonal and off-diagonal elements of $\mathbf{H}_l^{(n)}$ for $l = 0, 1, 2$, considering 16-QAM transmission, 100 km spans, and standard fully loaded systems with 115 32 Gbaud channels and 37.5 GHz channel spacing. The correlations of the higher-order XPM terms quickly drop to zero, even in systems operating over a 3000 km link. The correlations of nonlinear PPRN ($l = 0$), however, are relatively long, of the order of tens of symbols. These results are aligned with numerical simulations [9.82–85] and experimental measurements [9.86, 87] verifying the long temporal correlations of the phase-noise contribution of PPRN (diagonal elements with $l = 0$), as well as with the numerical [9.83, 84] and experimental [9.88, 89] verification of the long temporal correlations of the polarization crosstalk contribution of PPRN (off-diagonal elements with $l = 0$).

Regarding the specific system impact of PPRN and NLPN, see Sect. 9.9.2.

9.5.5 Pulse Collision Theory

The time-domain model further provides insights into how the various NLI contributions are formed. By examining the optical field of the transmitted signal as a collection of temporal pulses transmitted from multiple WDM channels, one can characterize and analyze

the different nonlinear interactions between the transmitted pulses as they propagate through the optical fiber.

In particular, in the limits of first-order perturbation analysis, the interactions can be classified as collisions between two pulses, three pulses, and four pulses; these collisions can be either complete, or incomplete. A rigorous and comprehensive analysis of the various types of collisions is provided in [9.55]. Each type of collision is shown to have its unique signature, and the overall nature of NLI is determined by the relative significance of the various collisions in a given WDM transmission. The most important contributions to NLI are shown to follow from two-pulse and four-pulse collisions. Two-pulse collisions generate NLI in the form of PPRN, whereas four-pulse collisions generate complex circular ISI noise. In addition, two-pulse collisions are shown to have a strong dependence on the modulation format of the interfering WDM channels and to be most pronounced when the collision is complete, whereas four-pulse collisions are shown to be modulation-format independent and to be strongest when the collision is incomplete. The theory further shows that in short optical links with lumped amplification, and links with perfect distributed amplification, NLI tends to be dominated by PPRN contributions generated by two-pulse collisions; in long links with lumped amplification, the importance of four-pulse collisions increases, and NLI becomes more complex circular with reduced dependence on modulation format.

9.6 Spatially-Resolved Perturbative Models and Their Applications

The perturbative method discussed in Sects. 9.3.1 and 9.4 shows the perturbation as a double integral in the frequency domain, weighted by the kernel function. Strictly speaking, each frequency of the signal is perturbed by all possible FWM combinations, and the kernel represents their efficiency.

This picture is a global input/output description of the whole optical link, and it is of great interest for the system perspective as shown in several sections of this chapter. Nevertheless, it is of interest to relate such a global scale description to a local scale at a given coordinate. Such a relation highlights several physical connections that may help to understand the perturbative models and to search for novel applications of perturbation theory in nonlinear optical communications.

The local description of the perturbation is the dynamical model expressed by the differential equation (9.7). We find it particularly interesting to solve it by following the numerical split-step idea, much as we did for the NLSE with the SSFM. The corresponding block diagram is shown in Fig. 9.10 [9.23, 25, 90]. For the sake of comparison, we also show the SSFM method in Fig. 9.10.

The RP1 solution is the sum of the unperturbed and the first-order perturbation. The unperturbed term, by definition, has been discretized by the concatenation of linear blocks only, here indicated by the letter L. Each linear block thus summarizes linear effects such as attenuation, GVD, etc., into an infinitesimal step h.

The perturbation is, indeed, the result of many contributions, each represented by a branch in the block diagram. In such paths we find nonlinear blocks, which implement the input/output relation $N(A) = -\mathrm{j}\gamma|A|^2Ah$. We note that, since the received perturbation is linear in γ, the electric field, according to RP1, while traveling along the link can cross only one nonlinear block from input to output. However, such a nonlinearity can appear anywhere, hence the reason for the final sum creating the perturbative term as a sort of multipath interference.

The idea can be iterated, creating higher-order RP schemes [9.91]. For instance, RP2 can be emulated by considering all possible combinations of two nonlinear blocks within the discretized distance grid. The SSFM algorithm can be viewed as an RP∞ method implemented in a clever way, where the nonlinear block is substituted by the SPM operator $N(A) = \mathrm{e}^{-\mathrm{j}\gamma|A|^2h}$.

In Fig. 9.10, we refer to RP1 as parallel RP1 because of its parallel nature, which is not the case of SSFM whose serial structure is unavoidable. Besides the physical intuition, such a parallel structure might find some advantages in numerical implementation when a high degree of parallelization is available [9.92].

We can exploit the RP1 diagram to derive a spatially-resolved GN model [9.25, 27]. Our target is the variance of the output perturbation γA_1, and more generally its autocorrelation function. Since the output perturbation is the sum of many contributions (Fig. 9.10) to get our target we need the cross-correlation among any two generic paths forming the perturbation [9.27, 93]. Let us focus on two such paths, the ones where the nonlinearity appears after s and z km, respectively. See Fig. 9.10 for reference and for the main definitions of variables.

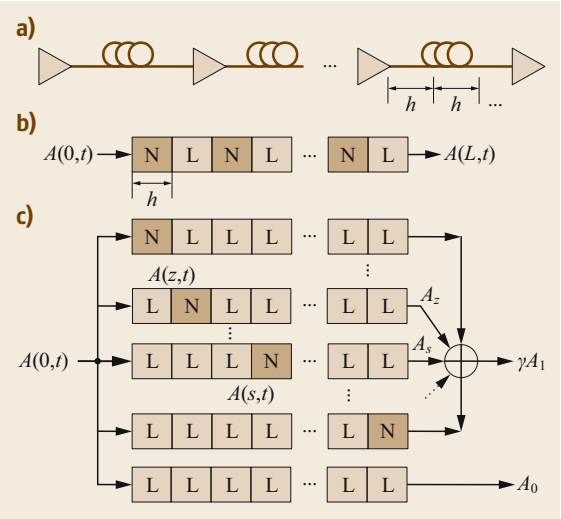

Fig. 9.10 (a) Physical link, (b) its corresponding standard SSFM model, and (c) its parallel RP1 model

The common input to such paths is a linear digital modulated signal $A(z=0,t)$, with t time. In case of interest, such a signal is actually a cyclo-stationary stochastic process, i.e., its statistical properties vary cyclically in time with a period equal to the symbol time. However, we believe that the signal can be safely treated as stationary. This claim finds its ground in the observation that we are planning to work with dispersion uncompensated links where the strong interference induced by dispersion likely removes higher order cyclo-stationary effects, and because we mainly focus on sinc-like pulses such that the signal is almost stationary already at the fiber input.

In this framework, if we know the cross-correlation function of the outgoing fields from the nonlinear blocks, here called $R_{zs}^{(\mathrm{out})}(\tau)$, with τ the time lag, the cross-correlation of the received fields on such paths can be found by using basic linear system theory [9.94]. In detail, the cross-correlation between A_z and A_s at the output coordinate L is related to $R_{zs}^{(\mathrm{out})}(\tau)$ by

$$\mathbb{E}[A_z(t+\tau)A_s^*(t)] = h_{zL}(\tau) \otimes h_{sL}^*(-\tau) \otimes R_{zs}^{(\mathrm{out})}(\tau) \,,$$

with $\otimes$ denoting convolution and $h_{zL}(\tau)$ the impulse response of the filter accounting for all linear effects from coordinate z to output coordinate L. Such an expression can be efficiently evaluated in the frequency domain by working with power spectral densities.

With similar arguments, we can relate the autocorrelation function of the transmitted field $A(0,t)$ to the ingoing fields of the nonlinear blocks at coordinates z and s, respectively,

$$\begin{aligned} R_{zs}^{(\mathrm{in})} &\triangleq \mathbb{E}[A(z,t+\tau)A^*(s,t)] \\ &= h_{0z}(\tau) \otimes h_{0s}^*(-\tau) \otimes R_{00}(\tau) \,, \end{aligned} \tag{9.95}$$

with $R_{00}(\tau) = \mathbb{E}[A(0,t+\tau)A^*(0,t)]$. If we are able to relate $R_{zs}^{(\mathrm{out})}(\tau)$ to $R_{zs}^{(\mathrm{in})}(\tau)$, we therefore have a relation between the system input/output autocorrelation functions and, thus, our target can definitely be solved by summing, i.e., integrating, all such contributions.

Such a relation is possible in the special, yet relevant, case of $A(z,t)$ with Gaussian statistics at any coordinate [9.19]. If we get rid of the constant phase-shift term as in the eRP (Sect. 9.3.1), the relation takes a simple and elegant form [9.27]

$$R_{zs}^{(\mathrm{out})}(\tau) = 2\left|R_{zs}^{(\mathrm{in})}(\tau)\right|^2 R_{zs}^{(\mathrm{in})}(\tau) \,. \tag{9.96}$$

Such assumptions are exactly those of the GN model, whose spatially-resolved reference formula is, thus,

$$\tilde{S}_{\mathrm{GN}}(f) = \int_0^L \int_0^L \tilde{h}_{zL}(f)\tilde{h}_{sL}^*(f) \times \mathcal{F}\{R_{zs}^{(\mathrm{out})}(\tau)\}\mathrm{d}z\mathrm{d}s \,, \tag{9.97}$$

where $\tilde{S}_{\mathrm{GN}}(f)$ is the PSD of the received perturbation, i.e., the Fourier transform of the autocorrelation function. The variance of the nonlinear interference given by the GN model is simply the integral of this PSD.

Such a solution has several similarities with the basic RP idea adopted for the electric field. Strictly speaking, we are propagating the signal correlation function from input to output by performing first a linear operation according to (9.95), then the same first-order nonlinear perturbation identical to the one experienced by the electric field except for a factor 2, then again linear effects up to the output. The main difference is that while the field perturbation is the sum of many perturbative infinitesimal contributions, here we have to account for all possible pairs of cross-correlations, thus increasing the complexity to a double integration. However, it has been shown that the double integral can be reduced to a single integration by exploiting the exponential behavior of attenuation along the distance [9.27].

What about the general case of non-Gaussian statistics for the propagating signal? The previous idea can still be used by properly modifying (9.96). Now the cross-correlation of the signals outgoing the nonlinear blocks cannot be related just to the same cross-correlation between the inputs, but we have to account

for higher-order statistics because of the nonlinear transformation [9.75]. Since nonlinearity is cubic, the cross-correlation involves products of six random variables. Such random variables are the digital symbols of the modulation format under use. Among all possible combinations, many of them have zero average for classical modulation formats with uniform distribution and rotationally symmetric constellations. If we let a_k be the information symbol at time k, we are left with just three kinds of nonzero contributions to the cross-correlation: one involving $\{|a_k|^2|a_n|^2|a_l|^2\}$ with $k \neq n \neq l$, one with $\{|a_k|^4|a_n|^2\}$ with $k \neq n$, and one for $\{|a_k|^6\}$. The first partition is the biggest one and generates terms like the one in (9.96), since indexes are different and symbols independent. Hence, such a partition is the one accounted by the GN model. The other two partitions generate the higher-order contributions of the EGN model [9.65].

In summary, the cross-correlation $R_{zs}^{(\mathrm{out})}(\tau)$ can be related to the shape of the supporting pulse distorted by linear effects up to coordinate z, $p(z,t) \triangleq h_{0z}(t) \otimes p(0,t)$, by [9.25]

$$R_{zs}^{(\mathrm{out})}(\tau) = \underbrace{\frac{\mu_2^3}{T^3} 2|Q(z,s,\tau)|^2 Q(z,s,\tau)}_{\text{GN model}} + \frac{\mu_2 \kappa_{2;2}}{T^2}\left[4F_4(z,s,\tau) + Q_4(z,s,\tau)\right]Q(z,s,\tau) + \frac{\kappa_{3;3}}{T} Q_6(z,s,\tau)\,, \tag{9.98}$$

with $\kappa_{i;i}$ the i-th cumulant of transmission symbol ([9.25] Appendix B), $\mu_2 \triangleq \mathbb{E}[|a_k|^2]$, and

$$\begin{aligned} Q(z,s,\tau) &\triangleq p(z,\tau) \otimes p^*(s,-\tau)\,, \\ Q_4(z,s,\tau) &\triangleq p^2(z,\tau) \otimes (p^*(s,-\tau))^2\,, \\ F_4(z,s,\tau) &\triangleq |p(z,\tau)|^2 \otimes |p(s,-\tau)|^2\,, \\ Q_6(z,s,\tau) &\triangleq [|p(z,\tau)|^2 p(z,\tau)] \\ &\quad \otimes [|p(s,-\tau)|^2 p^*(s,-\tau)]\,. \end{aligned} \tag{9.99}$$

In particular, square M-QAM modulation with i.i.d. symbols has

$$\kappa_{2;2} = -\frac{3}{5}\frac{M+1}{M-1}\mu_2^2, \qquad \kappa_{3;3} = \frac{36}{21}\frac{M^3-1}{(M-1)^3}\mu_2^2\,.$$

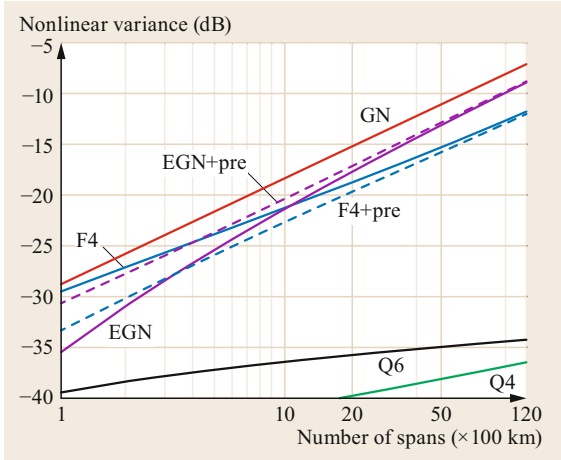

Fig. 9.11 Contributions to nonlinear interference variance (normalized to the cube of signal power P) versus the number of spans N_s. 133 PDM-QPSK channels ($R = 32$ Gbaud, $\Delta f = 37.5$ GHz) transmitted into a $N_s \times 100$ km SMF dispersion uncompensated link; F_4 and Q_4 contributions are plotted in absolute value, since they are actually negative. The impact of a precompensation of 8500 ps/nm on some terms is shown by a *dashed line*. Note that GN model overestimates the EGN prediction (after [9.25])

The expression for $R_{zs}^{(\mathrm{out})}(\tau)$ can finally be inserted in (9.97), and the PSD of the nonlinear interference can be evaluated by numerical integration. Please note that with Gaussian distributed symbols $\kappa_{i;i} = 0$, $i > 1$, so that (9.98) coincides with (9.96), since $R_{zs}^{(\mathrm{in})}(\tau) = (\mu_2/T)Q(z,s,\tau)$, for a digital signal with supporting pulse $p(0,t)$.

The EGN model can be read as an additive correction to the GN model. Although the EGN is more accurate, it is worth noting that, except for very peculiar modulation formats [9.52], the GN model gives a conservative overestimation. The previous derivation was for single channel in single polarization. Extensions to PDM and WDM are available [9.25].

The relative importance of each term forming the EGN model is shown in Fig. 9.11 for a specific example detailed in the figure caption. We observe the mentioned GN overestimation compared to the EGN model. The most important EGN correction is the one provided by the fourth-order correction F_4 [9.75]. Such a term is partially mitigated at short lengths by predistorting the signal with a precompensation fiber.

9.7 Multiplicative Models and Their Applications

We might wonder, at this point, whether the models introduced in the previous sections definitively solve the problem of modeling the optical fiber channel. For instance, the representation of NLI as AWGN provides a good accuracy in terms of performance evaluation (the EGN model, in particular) with a reasonably low complexity (the GN model, in particular). However, it also entails that NLI cannot be mitigated, which is not entirely correct. For instance, deterministic intrachannel nonlinear effects can be exactly compensated for by digital backpropagation (DBP) (Sect. 9.11.1). Moreover, as shown in Sect. 9.5, some NLI terms due to XPM are not independent of the signal and should be more properly interpreted as time-varying ISI, rather than noise. In general, this means that the accuracy of AWGN-like models in terms of performance evaluation does not necessarily correspond to an accurate and detailed characterization of the statistical properties of NLI (e.g., non-Gaussian statistics, temporal correlation, and so on). These properties are not particularly relevant to determine the performance of systems employing conventional symbol-by-symbol detection, but might be the key to devise improved detection and nonlinearity mitigation strategies—e.g., able to mitigate also interchannel nonlinearity and signal–noise interaction, or to perform DBP with a lower complexity. Research of alternative models for the optical-fiber channel is, hence, still in progress. Strictly connected with this topic, is the computation of channel capacity (discussed in Sect. 9.12), which entails an accurate knowledge of the channel and the use of the best possible modulation and detection strategy.

A possible approach is provided by the LP model, briefly introduced in Sect. 9.3.1, which falls within the broader class of *multiplicative models*. As opposed to *additive models*, which describe nonlinear effects by means of a noise-like additive term, multiplicative models describe nonlinear effects through a fading-like multiplicative term—a change of the channel characteristics that causes a distortion of the propagating signal. The latter approach is usually more complex than the former, but also closer to the underlying physics—the Kerr effect being a change of the refractive index induced by the propagating optical signal that causes a phase rotation of the signal itself.

The LP model was originally introduced in [9.26] (and generalized to all orders in [9.91]) to provide an analytical approximation of the signal at the output of a nonlinear dispersive fiber given the input signal. It was later combined with the RP model to investigate signal–noise interaction, providing a joint description of both parametric gain and nonlinear phase-noise effects [9.95]. It has been eventually applied to study interchannel nonlinearity in WDM systems, originating the frequency-resolved LP (FRLP) model [9.76, 96]. This last model and its applications will be briefly described in the sequel. The model has been developed for the single-polarization case, but the concept can be extended to dual polarization signals.

To investigate the impact of interchannel nonlinearity in WDM systems, it is convenient to divide the overall WDM signal into the channel-of-interest (COI) component, still referred to as $A(z,t)$, and the interfering channels (IC) component $A_w(z,t)$—resulting from the combination of all the other WDM channels. Expanding the nonlinear term of the NLSE (9.1) into its SPM, XPM, and FWM components (according to the role played by the COI and IC components) [9.1], and retaining only the XPM one, the equation can be rewritten as

$$\frac{\partial A}{\partial z} = \mathrm{j}\frac{\beta_2}{2}\frac{\partial^2 A}{\partial t^2} - 2\mathrm{j}\gamma|A_w|^2 A\,. \tag{9.100}$$

Equation (9.100) does not account for SPM, which can be compensated for by DBP (Sect. 9.11.1), and for FWM and signal–noise interaction, whose impact in WDM systems is usually negligible compared to XPM (this might not be the case when considering WDM channels with a low symbol rate). The evolution of A_w is, in turn, subject to nonlinear interference from A, such that we should also write an analogous equation for A_w, coupled to (9.100). However, in terms of the impact of A_w on A, the nonlinear evolution of A_w is a second-order effect. Thus, we will neglect it and assume that A_w evolves linearly and independently of A. In this case, (9.100) is a linear Schrödinger equation with a space and time-variant potential, whose solution can be formally expressed as

$$A(L,t) = \int_{-\infty}^{\infty} H_w(f,t)\tilde{A}(0,f)\mathrm{e}^{\mathrm{j}2\pi ft}\mathrm{d}f\,, \tag{9.101}$$

where $H_w(f,t)$ is a *time-variant* transfer function [9.97]. In mathematics, the solution for this kind of equation is typically given in terms of *Green's function* (or *propagator* in quantum mechanics), to which the time-variant transfer function is simply related by a Fourier transform.

The transfer function can be obtained from the FRLP model and expressed as [9.76, 96]

$$H_w(f,t) = \mathrm{e}^{-\mathrm{j}\theta(f,t)}\,, \tag{9.102}$$

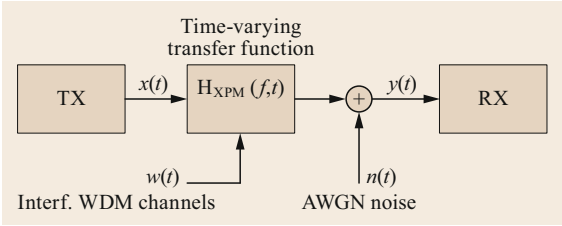

Fig. 9.12 Continuous-time FRLP model

where the XPM term $\theta(f,t)$ depends on the input IC signal $A_w(0,t)$ and on the link characteristics. Some general expressions for $\theta(f,t)$ and its statistics are provided in [9.76, 96].

Eventually, including the effect of amplifier noise, the overall system (from the COI standpoint) can be schematically modeled as in Fig. 9.12, in which $x(t) = A(0,t)$ is the transmitted signal, $y(t)$ the received signal, $H_w(f,t)$ the time-varying transfer function of the channel, which depends on the overall signal transmitted by the other channel users (the interfering channels) $w(t) = A_w(0,t)$, and $n(t)$ an AWGN term that accounts for the accumulated optical amplifier noise.

A key observation here is that all the neglected effects (e.g., FWM and signal–noise interaction) can eventually be reintroduced by properly increasing the power spectral density of the AWGN term, for instance, based on the calculations from the GN or EGN models or extracting the parameters from a numerical simulation. However, when modeling an effect as AWGN, we basically give up the possibility of mitigating it and make a worst-case assumption in terms of system performance. On the other hand, a more accurate modeling of the dominant XPM term may allow for its partial mitigation.

From the COI viewpoint, the model in Fig. 9.12 describes the nonlinear time-invariant optical fiber channel as a linear time-variant one. This apparent paradox is explained by the fact that channel nonlinearity is accounted for by the dependence of $H_w(f,t)$ on $w(t)$ [9.96]. However, assuming that $w(t)$ is unknown to both the transmitter and the receiver, such nonlinearity remains hidden, and the effect of $H_w(f,t)$ is simply perceived as a linear distortion. Moreover, since $w(t)$ depends on time, the channel transfer function $H_w(f,t)$ also depends on time.

The model in Fig. 9.12 is substantially that of a doubly-dispersive fading channel, often used in wireless communications, whose key features are the coherence time and bandwidth over which the channel remains strongly correlated [9.98]. This analogy may help to better understand the channel characteristics and behavior, as well as to devise improved transmission and detection strategies.

The coherence properties of the channel were studied in [9.99] and are illustrated by the contour plots in Fig. 9.13, which shows the correlation between the values $\theta(0,t)$ and $\theta(\Delta f, t+\tau)$ of the XPM term at two different times and frequencies inside the COI bandwidth, as a function of the delay τ and frequency separation Δf. The channel is assumed to be stationary in time but not in frequency, as the impact of the XPM term depends on the frequency distance from the interfering channels and varies inside the COI bandwidth. The correlation is analyzed by holding one frequency fixed in the middle of the COI bandwidth (conventionally set to $f = 0$), and letting the other vary inside the COI bandwidth. The scenarios considered refer to a Nyquist–WDM system with 50 GHz channel spacing and bandwidth, Gaussian symbols (a worst-case assumption in terms of XPM impact), and a 1000 km link of standard single-mode fiber with either ideal distributed amplification (IDA) (Fig. 9.13a) or 10×100 km lumped amplification (LA) (Fig. 9.13b). Only the XPM term generated by the couple of closest interfering channels (i.e., those located at $f = \pm 50$ GHz) is considered. The coherence is quite substantial in the IDA link, but significantly reduced in the LA link.

The FRLP model has been used to derive some closed-form expressions for the AIR with different modulation formats and a mismatched decoder optimized for the AWGN channel [9.96]. In this case, similar results could be obtained also with some additive models such as the RP or EGN models. However, the FRLP model can also be used to devise more efficient detection strategies that exploit the coherence properties of the channel and to derive some improved capacity bounds [9.82]. These issues will be discussed in greater detail in Sect. 9.12.

Equation (9.100) is also the starting point to derive other models and descriptions of interchannel nonlinearity. In [9.100, 101], Feynman path integrals and diagrammatic techniques are used to derive Green's function (propagator) of (9.100), from which the input–output channel statistics are obtained by assuming that the stochastic potential $|A_w|^2$ is a Gaussian process with short-ranged correlations in space and time—a more drastic approximation than the assumption of linear propagation of A_w done in deriving (9.102). The resulting model has been used to compute some capacity lower bounds for the optical fiber channel [9.100, 101].

Another approach to solve (9.100) is the *Magnus expansion*, a general method to derive approximate exponential representations of the solution of linear differential equations with varying coefficients [9.102]. The Magnus expansion provides a power series expansion for the corresponding exponent and, for this reason, is

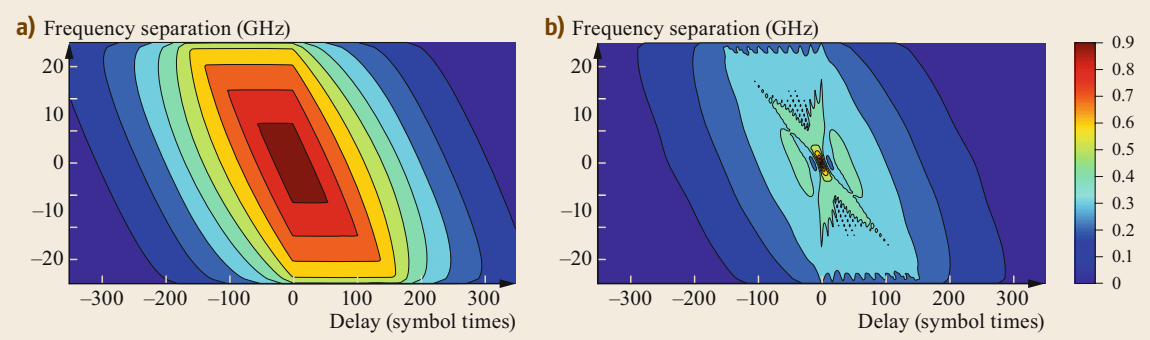

Fig. 9.13a,b XPM coherence: **(a)** IDA link; **(b)** 10×100 km LA link

sometimes referred to as time-dependent exponential perturbation theory. In optical-fiber communications, the Magnus expansion has already been employed to model linear effects such as polarization-mode dispersion and polarization-dependent loss [9.103], while its application to fiber nonlinearity has only been slightly touched [9.104]. When applied to (9.100), the Magnus expansion is quite accurate even at first order—in many cases more than the corresponding first-order RP, eRP, and LP expansions [9.104]—and has the desirable additional property of preserving at any order some important features of the original equation, such as its unitarity. These characteristics make it an interesting subject for future research.

9.8 Model-Specific Features

In this section, we try to provide a list of features of the various fiber nonlinearity models introduced so far, which make them attractive for certain applications. Carrying out a more comprehensive and comparative analysis of the models would be a difficult task, and we refrain from doing it. Some of the aspects mentioned here are dealt with in later sections, to which the reader should refer:

GN model: reasonable compromise between accuracy and complexity, very compact formula.

iGN model: for most systems, very good compromise between accuracy and complexity.

GN/iGN models: lend themselves to closed form solutions, some of which are extremely simple, yet rather accurate, such as for ideal Nyquist WDM with completely identical spans, helping establish fundamental limits; others are quite flexible (any comb, any link) but still fully closed form, very good for management of physical-layer aware optical networks.

EGN model: complete and accurate model in the frequency domain; computationally very complex; a reduced version exists, which is quite accurate and $1/3$ as complex, but complexity is still high. It does not allow us to accurately factor out PPRN, though it does allow us to approximately factor out NLPN by assuming constant-envelope transmission (i.e., assuming PM-QPSK-like parameters).

Time-domain model: very similar to the EGN model in terms of accuracy and complexity when predicting interference variance; also predicts nonlinear phase and polarization rotation noises (PPRN); predicts temporal correlations; describes nonlinear interference as an intersymbol interference (ISI), which can be used to examine and evaluate the performance of various ISI cancellation techniques; predicts the contribution of the various ISI terms.

Spatially-resolved model: alternative description of the EGN model; predicts temporal correlations of the optical nonlinear interference; focuses on nonlinear spatial interactions along the link, such as nonlinear signal–noise interaction; complexity grows with the system length.

FRLP model: represents NLI as a multiplicative distortion rather than as an additive noise; describes the channel through a time-varying transfer function; allows us to identify the NLPN component and calculate its correlation in time and frequency. These characteristics help devise improved detection and nonlinearity mitigation strategies. Closed-form solutions are available for simple system configurations (e.g., ideal Nyquist WDM).

9.9 Impact of Specific Effects on NL Modeling

Amplified spontaneous emission (ASE) noise interacts with the nonlinear Kerr effect along propagation. The result is generally referred to as nonlinear signal–noise interaction (NSNI). NSNI can be classified as an FWM process. However, it finds its own space in the literature because of the distinctive nature of some of the photons joining the FWM interaction, which come from a wide-band Gaussian distributed signal such as ASE.

9.9.1 Nonlinear Signal ASE Interaction

Initial studies on NSNI date back to investigations about the nonlinear interaction between a strong continuous-wave (CW) signal and wide-band noise [9.105, 106]. In such a case, only degenerate FWM yields significant NSNI, which motivated the use of small-signal analysis to analyze the effect. Results highlighted that an optical fiber can induce modulation instability (MI) depending on the dispersion sign. In particular, the white spectrum of noise may experience a gain (hence, the name modulation instability), which is maximum at the frequency $\sqrt{2\gamma P/|\beta_2|}$, with P the power of the strong CW [9.105].

Modulation instability has been exploited to build optical parametric amplifiers (OPA) [9.107]. OPA shows distinguished new features compared to existing optical amplifiers, such as adjustable gain spectra and center frequency, the possibility to work in phase sensitive mode with ideally zero noise figure, the possibility to perform phase conjugation and wavelength conversion [9.108]. However, OPA shows nontrivial problems such as gain-shape fluctuations and polarization dependence that have limited their applications in practice [9.108].

Besides the positive implications of NSNI in building optical amplifications, NSNI originating along the transmission fiber is generally a problem for the system performance. Initial studies showed that NSNI can induce strong phase noise, usually referred to as the Gordon and Mollenauer effect [9.109], whose impact has been shown to severely affect phase-modulated signals such as differential phase-shift keying (DPSK) transmissions [9.110]. A closed formula of the NSNI-induced phase noise variance and its main scaling properties was proposed in [9.109].

The phase noise induced by NSNI is a random variable whose exact probability density function was derived by *K.-P. Ho* in [9.111] in the absence of dispersive effects and before detection filters. The impact of dispersion is much more complex, such that the exact PDF is unknown but closed formulas exist for the NSNI variance due to intrachannel pulse XPM [9.112]. Small-signal analyses of NSNI in dispersive links were carried out in [9.113, 114] and in [9.115, 116], where they were referred to as parametric gain (PG).

ASE noise can be included in the GN and EGN models. Since ASE is inserted in the link along propagation, the spatially-resolved model of Fig. 9.10 is well suited to search for modifications to GN-based formulas [9.43].

Since ASE is Gaussian distributed, its dominant contribution appears as an enhancement of the GN part of the EGN formula (9.98). However, ASE impacts even the fourth-order nonlinear interference contribution proportional to $\kappa_{2;2}$.

One of the main implications of NSNI to GN model variance is that the NSNI nonlinear interference variance does not scale with the cube of the signal power, but with the square. This is not surprising, since the most dominant contribution to NSNI comes from FWM processes involving the beating of signal × signal × ASE [9.43, 117–119]. As a rule of thumb, numerical results showed that NSNI starts to impact the nonlinear interference variance at SNR smaller than 10 dB [9.42, 43].

Some formulas have been proposed in the literature to modify the GN model formula and account for NSNI. *Poggiolini* et al. proposed using the incoherent-GN formula by substituting the channel power at the input of fiber k with $P + P_{\mathrm{ASE}}k$, P being the transmitted power [9.42]. *Serena* ([9.43], eq. (10)) proposed correcting the cross-correlation between the nonlinear interference brought by two different spans by an ASE-dependent term. *Lavery* et al. [9.120] proposed weighting the NSNI accumulation coherence factor in a different way to the signal such that each ASE term contributes from its injection point in the link. *Ghazisaeidi* extended the theory of [9.75] by providing an efficient algorithm for NSNI variance computation [9.121].

NSNI is the fundamental limit to the performance in the presence of nonlinear equalization [9.43, 119–121], a feature that motivated the search of effective models of NSNI with the aim of finding the capacity of optical communication links. If we perturb the entire link, including digital backpropagation, we get the spatially resolved model of Fig. 9.14 [9.43]. We note that, without ASE, for any input/output branch, there is a branch with opposite parameters, such that the overall nonlinear interference is zero. However, with ASE, this symmetry is broken, such that a residual NSNI cannot be compensated for by a nonlinear equalizer. *Lavery*

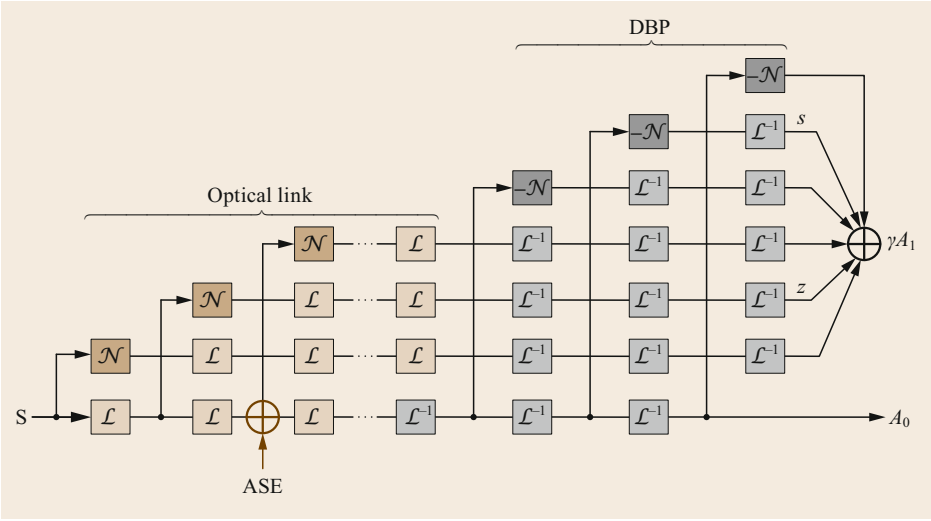

Fig. 9.14 First-order representation of an optical link including digital backpropagation (DBP) (after [9.43]). The paths labelled with s and z do not cancel out in the presence of the ASE source indicated

et al. [9.120] showed that the optimum is to equally split the nonlinear equalizer between transmitter and receiver sides.

9.9.2 System Impact of Nonlinear Phase and Polarization Noise

Section 9.5.2 provides the tools for accurate modeling of nonlinear phase and polarization noise (PPRN). These tools can then be used to assess the actual system impact of PPRN. As a relevant example, Fig. 9.15 shows the SNR gain that can be obtained by ideal removal of all interchannel PPRN. The plot is significant, since it addresses a realistic C-band fully populated 115-channel system, over SMF, with 100 km span length, at 32 GBaud. The SNR gain shown assumes that launch power is optimized to take the maximum advantage out of interchannel PPRN removal. Hence, the term *peak-SNR gain* is used ([9.78] for more details). Note that peak-SNR gain can also be interpreted, conversely, as the *impact* that PPRN has on the system. In other words, QPSK crossing the 0.5 dB line at five spans in Fig. 9.15 can be read as either a 0.5 dB potential gain if PPRN is removed or a 0.5 dB SNR degradation due specifically to PPRN.

Standard CPE (carrier-phase estimation) algorithms in the receiver DSP can mitigate the effect of PPRN, and in particular of its phase-noise component (NLPN). However, these algorithms typically leverage the time-correlation that such disturbances exhibit, quantified in Fig. 9.9. Unfortunately, where mitigation would be most needed, such as in short links according to Fig. 9.15, PPRN has short correlation time (Fig. 9.9), so that mitigation by standard CPE algorithms is only partially effective. PPRN can be almost completely removed in long links, where it exhibits long correlation times. There, though, its impact is relatively small, and the obtainable mitigation gain is limited.

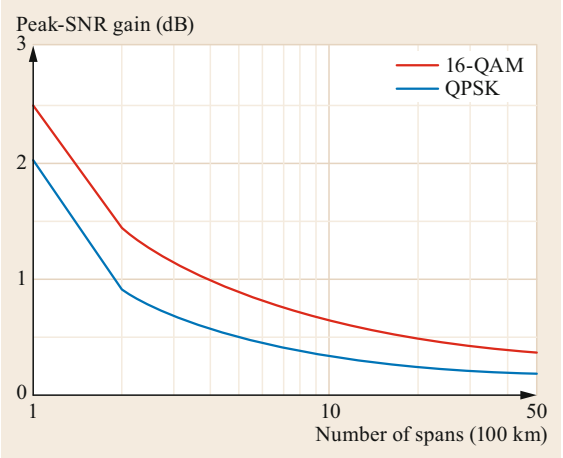

Fig. 9.15 Peak SNR gain resulting from perfect interchannel PPRN removal in fully loaded systems with 115 WDM channels at 32 GBaud. The detailed parameters used here are given by Table 2 in [9.78]. The Peak SNR gain is different between the maximum SNR, with and without interchannel PPRN. For more information on peak SNR gain, see [9.78], Sect. 4

This topic, however, is complex, and Fig. 9.15 only looks at one scenario. Many system features, such as fiber dispersion, distributed amplification, modulation format, etc., affect PPRN. For a comprehensive analysis and extensive references, see [9.78]. The symbol rate also affects PPRN. Recently, the scaling of the impact of NLPN versus *symbol rate* was studied, for instance, in [9.63, 64], using an approximate technique based on

the EGN model. The indication is that, when the symbol rate is increased, the variance of NLPN decreases and its correlation time increases. As a result, overall, its impact appears to decrease at higher symbol rates.

9.9.3 Joint Nonlinear and Polarization Effects, PMD/PDL

Although single-mode fibers support only one propagating mode, the resulting field is the superposition of two polarizations [9.7]. Each polarization can be independently modulated, and the resulting signal is generally referred to as polarization division multiplexing (PDM), also known as dual polarization (DP) or polarization multiplexing (PM). PDM is a simple technique to double the spectral efficiency and represents the starting point of more advanced techniques of spatial division multiplexing [9.122].

However, the two polarizations usually interact along propagation, thus generating polarization crosstalk at the receiver. The reason for such cross-coupling is related to perturbations to the ideal fiber structure, such as changes in the refractive index, non-circularity of the fiber, thermal stresses, variations in the core radius, irregularity at the core-cladding boundary, etc. Perturbations may be even deliberately introduced during fiber fabrication as a way to improve performance, as we will discuss later. All such stresses make the fiber anisotropic, i.e., they introduce birefringence.

As a result of birefringence, the polarizations may travel at different speeds, thus manifesting polarization-mode dispersion (PMD) [9.80]. A main implication of PMD is the end-to-end group delay spread between polarizations, called differential group delay (DGD). The problem is of particular concern in the presence of polarization coupling along transmission, because to undo the coupling at the receiver we must account for the memory introduced by DGD.

The accumulation of PMD along the distance depends on the correlation length over which mode coupling occurs, typically of about 100 m for SMF [9.7]. This way, a long-haul link operates in the strong coupling regime, whose random properties along distance eventually make the DGD a random variable, with Maxwellian statistics in the limit of correlation length approaching zero [9.123, 124]. Most importantly, the average DGD and the DGD standard deviation accumulate proportionally to the square root of the distance [9.9, 125]. This circumstance eases equalization of PMD. On the contrary, GVD has a much smaller randomness, such that it accumulates with a rate proportional to the distance.

For such reasons, short fiber correlation length is intentionally induced during fabrication by properly spinning the fiber [9.126]. Data sheets usually report the PMD coefficient η_{PMD}. Typical values are $0.32\,\mathrm{ps}/\sqrt{\mathrm{km}}$ for pre-1991 fibers, $0.13\,\mathrm{ps}/\sqrt{\mathrm{km}}$ for fibers installed in the period from 1992 to 1998, and $0.05\,\mathrm{ps}/\sqrt{\mathrm{km}}$ for post-1999 fibers [9.127]. For a fiber of length L, The average DGD $\overline{\tau}$ is related to the PMD coefficient by $\overline{\tau} = \eta_{\mathrm{PMD}}\sqrt{L}$, while the root mean square value of DGD is $\tau_{\mathrm{rms}} = \sqrt{(3\pi)/8}\,\overline{\tau}$ [9.124].

PMD is generally a problem in high symbol rate systems and must be properly equalized at the receiver side. Adaptive equalization is mandatory, since PMD varies in time on scales of the order of milliseconds. The problem is best solved with coherent detection where classical algorithms first developed for wireless communications have been successfully used. Some examples are the blind constant-modulus algorithm (CMA), the least mean squares (LMS) algorithm, and the data-aided least squares method [9.128].

Both birefringence and PMD play a role in the nonlinear regime. As mentioned in the introduction, the fast variations of birefringence with distance are usually averaged out as in the Manakov equation [9.9, 45]. In this scenario, the two polarization tributaries still interact nonlinearly along propagation through XPM, but they also interact through cross-polarization modulation (XPolM) [9.8, 9, 129–131]. XPolM is a generalization of the XPM phase rotation in the complex plane into a rotation in the three-dimensional space described by the Poincaré sphere. Now, it is the total power that is preserved; however, power can be exchanged between the polarization tributaries, thus creating nonlinear crosstalk. Contrary to PMD temporal variations, XPolM is rapidly varying in time, with temporal scales of the order of the walk-off between interacting channels. As a consequence, XPolM scattering manifests as a Brownian motion over the Poincaré sphere [9.130, 131], and its equalization is extremely challenging. XPolM has been shown to be one of the dominant nonlinear impairments in dispersion-managed PDM systems [9.132, 133].

PMD joins the polarization and nonlinear Kerr effect interactions [9.134]. The analysis is simplified in the strong coupling regime, where the reference model is the Manakov-PMD equation [9.45]. Numerical simulations and experiments [9.135, 136] showed that PMD helps improve the average performance of an optical link, provided that linear PMD is fully equalized at the receiver. The reason is that PMD is a dispersive effect, hence it decorrelates channels farther away than the PMD correlation bandwidth [9.137], thus mitigating the nonlinear interference accumulation along distance.

The numerical investigation of PMD in the nonlinear regime is particularly burdensome. To correctly

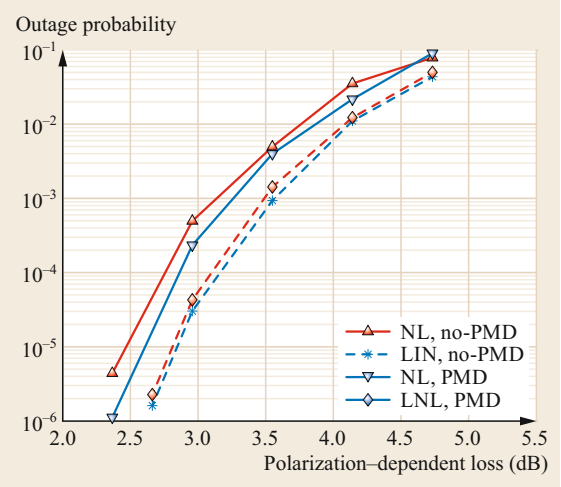

Fig. 9.16 Outage probability versus PDL. An outage event occurs when the Q-factor is smaller than 6.25 dB. *Dashed lines*: equivalent linear (LIN) model with the same average Q-factor as the in nonlinear (NL) propagation. PMD = $0.13\,\mathrm{ps}/\sqrt{\mathrm{km}}$ (after [9.138])

emulate the slow birefringence temporal variations it is mandatory to independently test many fiber realizations to find rare events that set the outage probability induced by PMD, i.e., the probability that the Q-factor is below a given threshold. Attempts to extend the GN model to include PMD are reported in [9.137].

Birefringence may also induce polarization-dependent loss (PDL), i.e., different energy losses for the two polarizations. PDL is mainly present in optical devices such as reconfigurable add-drop multiplexers (ROADM) or EDFA. PDL is expressed in international standards by [9.7]

$$\rho_{\mathrm{dB}} \triangleq 10\log_{10}\left(\frac{T_{\max}}{T_{\min}}\right),$$

where $T_{\max}$ and $T_{\min}$ are the maximum/minimum transmission powers after a PDL element. Typical values of ρ_{dB} are fractions of dB (e.g., 0.4 dB for a ROADM). The overall PDL cumulated along a link is a random variable, whose statistics can be evaluated by following similar methods as for DGD [9.139, 140].

PDL induces a penalty that is enhanced in a nonlinear regime by interaction with the nonlinear Kerr effect, thus increasing outage probability [9.141–143].

Figure 9.16 shows an example of outage probability estimated by numerical simulation in a 15-channel 32-Gbaud QPSK system, traveling in a 35×100 km, $D = 4\,\mathrm{ps}/(\mathrm{nm\,km})$, link at a power of 0.5 dBm and OSNR = 16.1 dB/0.1 nm [9.138]. PMD was either 0 or $0.13\,\mathrm{ps}/\sqrt{\mathrm{km}}$. Dashed lines show the result by an equivalent linear model, where the EDFA noise figure has been changed to get the same average Q-factor as in a nonlinear regime. The difference between the solid and the dashed lines is an indication that PMD/PDL interacted with nonlinearity along transmission.

9.10 Applications

The main outcome of the GN model is the received SNR. In the special, yet relevant, case of the additive white Gaussian noise (AWGN) channel with matched filter detection, the SNR can be converted into bit error rate (BER) by simple formulas, as shown in Appendix 9.A.

9.10.1 Which Performance Metric?

Usually, BER follows a complementary error function (erfc)-like behavior versus SNR, which does not suit a system designer that usually works on dB scales. For this reason, the Q-factor has been introduced. The Q-factor is a one-to-one relation with the BER in a reference system tracking the erfc transformation (Appendix 9.A). This way, the Q-factor coincides with the SNR in the relevant case of QPSK, and with 2·SNR for BPSK. For several other modulation formats, the relation is, luckily, almost linear with slope 1 on a dB/dB scale. Conversion graphs are available in Appendix 9.A.

Whatever the choice, BER or Q-factor, they are normally estimated before FEC decoding. The rationale is to associate a threshold to the FEC code and claim the post-FEC BER to be 0 if the pre-FEC BER is smaller than the threshold. For instance, the second generation hard-decision FEC (HD-FEC) standardized by ITU-T G.975.1 had a Q-factor threshold of 8.5 dB with an FEC overhead of 6.7%.

Nowadays, the trend is toward soft-decision FEC (SD-FEC) that can provide gains of about 1.5 dB with respect to hard-decision [9.144], or even more with iterative decoding. SD-FEC so far operate at overheads of ∼ 20% by exploiting soft decoding with advanced techniques such as low-density parity check codes (LDPC) or turbo product codes (TPC). However, it is worth noting that the higher complexity of SD-FEC may be an issue for some systems, thus HD-FEC with overhead

$\lesssim 15\%$ may be preferred for those applications where low power consumption is mandatory [9.144].

The idea of a FEC threshold works fine with binary HD-FEC and bit-interleaving, and thus BER works great in this scenario. However, it has been shown that it may fail with SD-FEC [9.145].

An alternative performance metric, more suited to SD-FEC, is the mutual information (MI). MI is a concept introduced in information theory to provide a measure of the *amount of information* obtained about one random variable through the knowledge of another random variable [9.146]. The concept of MI is strictly related to the concept of entropy, which provides a measure of unpredictability on average. For the continuous random variable Y with probability density function $p_Y(y)$, the entropy (more correctly, the differential entropy) is defined as

$$h(Y) \triangleq -\mathbb{E}[\log[p_Y(y)]] ,$$

with $\mathbb{E}[.]$ expectation. MI between two random variables X and Y is, thus, defined as

$$\mathrm{MI}(X, Y) \triangleq h(Y) - h(Y|X) , \qquad (9.103)$$

where $h(Y|X)$ is the conditional entropy, i.e., the entropy of Y conditioned to X averaged over all possible values of X. Hence, the computation of (9.103) requires knowledge of the conditional probability $p_{Y|X}(y|x)$.

MI is a relationship between two random variables. For channels with memory, we need to generalize the idea to stochastic processes, hence we should substitute MI with the information rate (IR) [9.146, 147]. Let $\mathbf{X}_N = (X_1, X_2, \ldots, X_n)$ and $\mathbf{Y}_N = (Y_1, Y_2, \ldots, Y_n)$ temporal sequences of the stochastic process $X(t)$ and $Y(t)$, respectively, from discrete time $t = 1$ to time $t = n$. The IR is defined as

$$I(\mathbf{X}_N, \mathbf{Y}_N) \triangleq \lim_{n\to\infty} \frac{1}{n}[h(\mathbf{Y}_N) - h(\mathbf{Y}_N|\mathbf{X}_N)] .$$

We are motivated to associate Y_k to the input of the soft decoder and X_k to the transmitted symbol. The GN model tells us that the AWGN channel is a good approximation of the true channel, and, thus, MI can be evaluated from the memoryless model $Y_k = X_k + n_k$, with n_k a complex Gaussian random variable. However, the true optical channel is different, not just in terms of different statistics but also because the optical channel exhibits memory, hence such a straightforward approach cannot exploit all the useful information [9.148, 149]. Nevertheless, the theory of mismatched decoding [9.150] shows that such MI is a lower bound to the maximum IR [9.147] constrained to the modulation format under use. An example of MI for QPSK modulation in AWGN [9.151] is reported in Fig. 9.17.

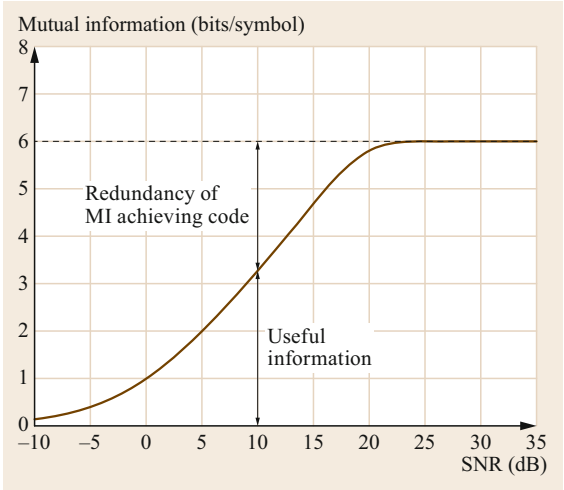

Fig. 9.17 MI of 64-QAM in AWGN. The error probability after FEC can be made arbitrarily small by a code having a redundancy of at least the indicated bits/symbol

In summary, if the soft-decoder has just the information provided by the GN model, i.e., it believes that noise is additive and Gaussian and knows its variance, we say that the corresponding MI described above is achievable, i.e., there exists a code for which error-free transmission is possible at MI bits/symbol. The redundancy of such best-code is reported, for example, in Fig. 9.17 for the reference case of SNR = 10 dB. Practical codes, able to exploit the information provided by the auxiliary channel, will need higher redundancies even if nowadays with LDPC and TPC the loss is very small.

We say that the AWGN channel approximation is an instance of an auxiliary channel of the true channel [9.147]. Other auxiliary channels are possible: the closer the auxiliary channel to the true channel, the tighter the lower bound to the maximum constrained IR. The capacity is the supremum among all possible modulation formats and symbols distributions.

MI is the relevant metric for symbol-wise receivers. However, optical communication systems often use bit-interleaved coded modulation (BICM) [9.152] whose noniterative implementation [9.153] simplifies decoding. For such schemes, the generalized mutual information (GMI) is better suited [9.145, 153]. The main difference with MI is that GMI depends on the bit-symbol mapping. If $X = (B_1 B_2 \ldots B_L)$ is the string of bits, $B_k \in (0, 1)$, corresponding to symbol X, GMI is defined as [9.153, 154]

$$\mathrm{GMI} \triangleq \sum_{k=1}^{L} \mathrm{MI}(B_k, Y) .$$

It is always GMI ≤ MI. For instance, for BPSK, it is GMI = MI because here bits ≡ symbols. QPSK is the composition of two BPSK in quadrature, hence with Gray coding and AWGN, each bit can be detected independently from the other by using the real/imaginary axis as a discriminating threshold. Hence, even for QPSK GMI = MI. In particular, $\mathrm{MI}_{\mathrm{QPSK}}(\mathrm{SNR}) = 2 \times \mathrm{MI}_{\mathrm{BPSK}}(\mathrm{SNR}/2)$.

For higher-order PSK and QAM modulation formats GMI < MI. The reason is that in these cases, the mentioned bit-independence in the detection rule is broken, and thus we can extract more information by using a symbol-wise detector rather than a bit-wise detector after bit interleaving.

For the AWGN channel the difference between GMI and MI is limited to fractions of bits (Appendix 9.A).

The debate about the most appropriate performance metric is still open. *Schmalen* et al. showed that with nonbinary FEC, MI is the right candidate [9.155]. *Cho* et al. showed that with probabilistic shaping, normalized GMI yields a better correlation with the post-FEC [9.156], while *Yoshida* et al. [9.157] proposed asymmetric information (ASI) as a better predictor in the nonlinear regime.

9.10.2 Maximum Reach and Optimum Launch Power

According to the perturbative description of the NLSE, the received SNR can be expressed by [9.3, 4]

$$\mathrm{SNR} = \frac{P}{\sigma^2_{\mathrm{ASE}} + \sigma^2_{\mathrm{NL}}}\,, \tag{9.104}$$

where P is the signal power, σ^2_{ASE} is the cumulative ASE power generated along the link, while σ^2_{NL} is the nonlinear interference variance. For a transparent N-span periodic link with optical amplifiers of noise figure F and gain G, it is $\sigma^2_{\mathrm{ASE}} = h\nu FGBN$, with h Planck's constant, ν the carrier frequency, and B the receiver bandwidth. According to GN model theory, $\sigma^2_{\mathrm{NL}} = \eta P^3$, where η is the unit-power nonlinear interference coefficient discussed in the previous sections.

Several interesting implications for system design can be inferred from (9.104). First, since ASE dominates the SNR at small powers, while nonlinear interference dominates at high powers, an optimal power exists (Fig. 9.1). Such a power is generally referred to as *nonlinear threshold* P_{NLT} and can be easily found by setting to zero $(\mathrm{dSNR})/(\mathrm{d}P)$, with the result

$$P_{\mathrm{NLT}} = \left(\frac{\sigma^2_{\mathrm{ASE}}}{2\eta}\right)^{1/3}.$$

By inverting such a relation, we find that $\sigma^2_{\mathrm{ASE}} = 2\eta P^3_{\mathrm{NLT}}$, i.e., at the optimal launched power, also known as the nonlinear threshold (NLT), ASE variance is twice the nonlinear interference variance. This important result tells us that at best power, the role of linear ASE noise is more important than the role of nonlinear distortions, such that it is better to put efforts into optimizing linear propagation rather than nonlinear propagation.

By substituting P_{NLT} into (9.104), we get the corresponding maximum SNR

$$\mathrm{SNR}_{\mathrm{NLT}} \triangleq \max(\mathrm{SNR}) = \frac{P_{\mathrm{NLT}}}{\frac{3}{2}\sigma^2_{\mathrm{ASE}}} = \frac{1}{\left[27\eta\left(\frac{h\nu FGBN}{2}\right)^2\right]^{\frac{1}{3}}}\,.$$

Besides these key ingredients to set up a connection, it is interesting to have a look at the SNR penalty with respect to linear impairments. By factoring out in (9.104) the SNR impaired by linear effects only, $\mathrm{SNR}_{\mathrm{lin}} = P/(\sigma^2_{\mathrm{ASE}})$, we can define such a penalty SP by

$$\mathrm{SP} \triangleq \frac{\mathrm{SNR}_{\mathrm{lin}}}{\mathrm{SNR}} = \frac{\sigma^2_{\mathrm{ASE}} + \sigma^2_{\mathrm{NL}}}{\sigma^2_{\mathrm{ASE}}}\,.$$

The interesting implication is that at best power P_{NLT}, the SNR penalty is always 3/2, whatever the value of σ^2_{ASE} and η, i.e., whatever the link for which the GN model assumptions work! Such a 3/2 factor is more conveniently expressed in dB by $10\log_{10} 3/2 \cong 1.76\,\mathrm{dB}$. Therefore, if our system works at power P_{NLT}, and we do not want to change such a power, at best we can improve the SNR by 1.76 dB with an ideal receiver able to exactly compensate for nonlinear impairments. Only by increasing the power can we improve the SNR by more than 1.76 dB by using a better receiver.

For the system designer used to work in dB, it is interesting to have a look at what happens by 3 dB changes in ASE and nonlinear interference power. We have

$$\sigma^{2'}_{\mathrm{ASE}} = \sigma^2_{\mathrm{ASE}} + 3\,\mathrm{dB} \Rightarrow \begin{cases} P'_{\mathrm{NLT}} = P_{\mathrm{NLT}} + 1\,\mathrm{dB} \\ \mathrm{SNR}'_{\mathrm{NLT}} = \mathrm{SNR}_{\mathrm{NLT}} - 2\,\mathrm{dB} \end{cases}$$

$$\eta' = \eta + 3\,\mathrm{dB} \Rightarrow \begin{cases} P'_{\mathrm{NLT}} = P_{\mathrm{NLT}} - 1\,\mathrm{dB} \\ \mathrm{SNR}'_{\mathrm{NLT}} = \mathrm{SNR}_{\mathrm{NLT}} - 1\,\mathrm{dB}\,. \end{cases}$$

Interestingly, a 3 dB change in ASE or nonlinear interference induces an absolute change of 1 dB in the nonlinear threshold.

The GN model can be used to infer the reach of the system at a given SNR, i.e., the maximum transmission distance ensuring the signal-to-noise ratio SNR at the receiver. Such an SNR can be, for instance, the SNR threshold of the FEC code under use. An example of signal power contour levels and their related reach is shown in Fig. 9.2. To estimate the reach we need to know how the ASE power and the nonlinear interference η scale with the number of spans N. The ASE power has a simple linear scaling $\sigma^2_{\mathrm{ASE}} = h\nu FGBN$. Experiments, numerical simulations, and theoretical models, indeed, suggest that the nonlinear interference follows the scaling law [9.41, 158, 159]

$$\eta = \eta_1 N^{1+\varepsilon} ,$$

where η_1 is the normalized nonlinear interference variance after one span, while ε is the coherence accumulation factor accounting for the superlinear accumulation of nonlinear effects along the distance. The presence of ε is due to correlations among the different paths creating the first-order perturbation (Fig. 9.10). In highly dispersive links, the strong dispersion makes the signal entering a given span almost uncorrelated with the signal entering a different span, hence we expect also the nonlinear interference to be almost uncorrelated span-by-span, such that the cumulative effect accounted by η scales linearly with distance, i.e., $\varepsilon \approx 0$. On the contrary, the accumulation factor is $0 < \varepsilon < 1$, with the extreme case of $\varepsilon = 1$ in fully-compensated dispersion-managed links. In dispersion-uncompensated links, it is typically $\varepsilon < 0.2$ [9.41, 159]; ϵ would be almost zero if only cross-channel nonlinearities were present, because the channel-walk-off decorrelates cross-nonlinear interference from span to span. An $\epsilon > 0$ is, thus, due to a significant single-channel nonlinearity. Therefore, single-channel nonlinearity grows faster with distance than cross-channel nonlinearity. This implies, for instance, that single-channel nonlinear equalizers become more effective at large propagation distances.

In this framework, the SNR is, thus, a function of three variables, σ^2_{ASE}, η_1 and ε. To get the reach, we thus need at least three measurements of power yielding the reference SNR at different distances. Based on the previous discussion, at the reach $N_0 \triangleq \max(N)$, the ASE variance is twice the nonlinear interference variance, hence the following identities hold

$$\mathrm{SNR} = \frac{P_0}{\frac{3}{2} h\nu FGBN_0} = \frac{P_0}{3\eta_1 N_0^{1+\varepsilon} P_0^3} ,$$

where P_0 is the signal power at the reach. The previous expression gives two equations in two variables (P_0, N_0), from which we get our target, the reach [9.159],

$$\mathrm{reach} \triangleq N_0 = \frac{1}{\left[(3\mathrm{SNR})^3 \eta_1 \left(\frac{h\nu FGB}{2}\right)^2\right]^{\frac{1}{3+\varepsilon}}} \quad (\mathrm{spans}) .$$

The reach is a function of the GN model key parameters η_1, ε, whose estimation is affected by errors. It is interesting to have a feeling of how reliable the formula of the reach is with variations of such parameters. Since it is preferable to work in dB scales, the following derivatives hold [9.159]

$$\frac{\partial N_0^{\mathrm{dB}}}{\partial \mathrm{SNR}^{\mathrm{dB}}} = -\frac{3}{3+\varepsilon}, \quad \frac{\partial N_0^{\mathrm{dB}}}{\partial F^{\mathrm{dB}}} = -\frac{2}{3+\varepsilon}, \quad \frac{\partial N_0^{\mathrm{dB}}}{\partial \eta_1^{\mathrm{dB}}} = -\frac{1}{3+\varepsilon} . \tag{9.105}$$

For instance, at $\varepsilon = 0$, an estimation error on η_1 of 1 dB translates into a reach error of 0.33 dB [9.41, 160].

Another key message from (9.105) is the following. To increase the reach we can play with i) the FEC by using a better code with a smaller SNR threshold, with ii) the optical link, for instance, by using better amplifiers with a smaller noise figure F, or with iii) the nonlinearity, for instance, by using a nonlinear equalizer to reduce η_1. Equation (9.105) tells us that such strategies are in order of effectiveness.

9.10.3 Modeling in Networks

The GN model has proved to be an invaluable analytical tool, able to explain the most important scaling laws and features of the new regime of highly-dispersed transmission entailed by dispersion-uncompensated links with coherent detection and electronic digital-signal processing. However, the GN model also finds one of its most practical uses in route selection in modern optical networks with quality-of-transmission (QoT) guarantees.

The dominant optical network paradigm is that of wavelength-routed optical networks (WRON), where a transparent optical channel (a light path) is established from source to destination on a fixed wavelength across multiple fiber links and optical switching nodes (Fig. 9.18). The most recent evolution of WRONs is that of elastic optical networks (EON) ([9.161, 162] and references therein), where bandwidth can be flexibly allocated to light paths with a granularity down to 6.25 GHz, due to coherent detection and smart wavelength-selective switches. Flexibility may also concern the modulation format and/or the forward error-correction (FEC) code of each light path at

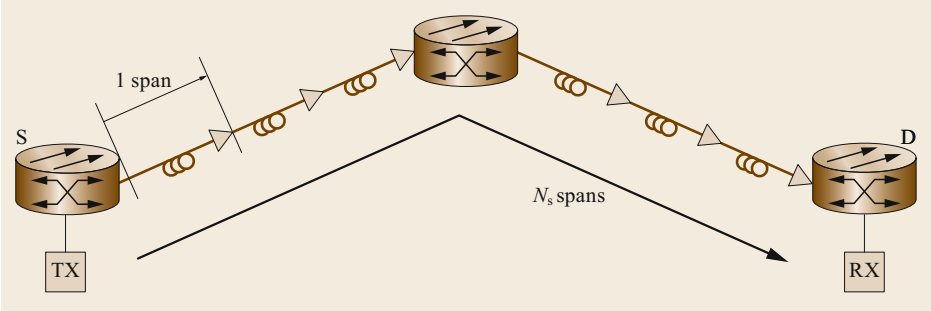

Fig. 9.18 Example of a selected light path from source (S) to destination (D) transmitted on a fixed wavelength across six spans, with two hops and three spans/hops

the transmitter in order to assure reaching the destination without intermediate regenerations. Electro-optical (EO) regenerations at intermediate nodes may, however, be necessary to both allow electrical multiplexing/demultiplexing onto the light path at intermediate nodes (*grooming*) and possibly to change the wavelength of the subsequent section of the light path in order to reduce wavelength blocking (WB). Reduction of WB through wavelength conversion has the beneficial effect of allowing an increase of network utilization (i.e., the fraction of wavelengths used in the network) and, thus, of network throughput, but at the moment it is still considered a too-costly option because of the cost of EO regenerations and is used with great care.

Initial efforts in dimensioning EONs when taking into account nonlinear propagation effects assumed a worst-case full-load scenario where all wavelengths in every fiber link are populated, and nonlinear effects are at their maximum [9.163]. Such a full-load assumption has the great advantage of simplifying the routing, modulation, and spectrum assignment (RMSA), since it decouples the propagation problem from the traffic-dependent linear and nonlinear interference. Hence, every modulation format has an optimal launch power spectral density and a maximum error-free transmission distance, known as the *reach*, and a simple comparison of the reach with the requested source-destination distance is enough to assess whether or not a connection is feasible without intermediate regeneration. The other major advantage of the full-load assumption is that of making existing light paths insensitive to the establishment of new connections, a fact that makes RMSA decisions fast even in a dynamic traffic scenario where connections my be established and released on short time scales.

The first RMSA algorithms were based on look-up tables containing the reach for every possible modulation format. The reach tables were evaluated offline by long statistical computations based on the split-step Fourier propagation method. Semi-analytical methods based on a single span propagation and tuning with variable residual input span dispersion were also proposed to speed up reach computations [9.93].

However, the fully analytical formulas afforded by the GN model quickly found their way into the RMSA design because they drastically speed up the calculation of the required received optical signal-to-noise ratio (OSNR) of a reference light path for a given modulation format, and thus the assessment of whether it is above its FEC threshold, and the connection is thus feasible.

In particular, the incoherent GN model treats the nonlinear interference terms generated at each span as if they were independent additive Gaussian noise, exactly as the optical noise from the amplifiers.

The first proposed use of the incoherent GN model in an EON scenario appeared in [9.47, 164], where the locally-optimal globally-optimal Nyquist (LOGON) strategy was introduced. It was there first observed that, when using the optimal power spectral density at full load, the reach at any load is never larger than $3/2$ of the full-load reach. This still is the major theoretical justification for using the apparently resource-wasteful full-load assumption for nonlinear interference evaluation. The reach computation using the GN model for optical networking was explored in [9.165]. The LOGON strategy was analyzed in terms of blocking probability versus carried traffic in a theoretical setting [9.166] and recently for various network topologies [9.167], while in [9.168] the expected gain in the network throughput due to transceiver adaptation was studied in EONs using the full-load LOGON strategy.

Alternative, equivalent formulations of the GN model that make the single and cross-channel contributions explicit for networking applications appeared in [9.39].

The enhanced GN (EGN) model, which takes into account the effect of the modulation format on nonlinear interference, can alternatively be used in place of the GN model [9.169] for applications where route establishment can take place on time scales of several

minutes, due to the development of fast computing techniques [9.170].

Recently, many papers have appeared that use either the GN or the EGN model within RMSA algorithms and try to remove the full-load assumption in order to make a better use of network resources.

One line of such developments [9.171–176] explores the use of the GN analytical OSNR within a mixed nonlinear programming framework in order to obtain the absolute optimal RMSA in a static traffic scenario (one where a traffic matrix is offered to a green-field network, and light paths are set up one by one to satisfy as many connections as possible) from complete knowledge of each network fiber's active light paths.

Since the problem is provably NP-hard [9.177, 178], such techniques can work in reasonable time only for impractically small networks. Heuristics have, thus, to be found in order to make them work in practical-sized networks. In this context, linearized GN formulas have been proposed in order to effectively use the GN model within a mixed integer linear programming framework [9.178, 179].

Another line of development explores instead a statistical approach to the RMSA problem, i.e., a model-based approach for light path selection, which is extremely fast to compute but has a bounded probability of being incorrect, and thus may sometimes require path recomputation. For instance, in [9.180], a QoT-based routing method was proposed, where a light path is set up based solely on wavelength load measurements along its selected physical path, and the probability that the newly set-up light path is unfeasible is bounded below a desired threshold.

Another instance of the statistical RMSA approach is one that makes use of machine learning techniques for route selection. Here, the GN/EGN model can be used to synthesize positive and negative examples of feasible light paths, and such examples are used to train the weights of a parametric model, for instance a neural network [9.181] or a random forest [9.169].

In summary, the use of the GN/EGN model for network planning and optimization is gaining momentum and is likely to become the method of choice for RMSA in future EoNs.

9.11 Nonlinearity Mitigation

This section discusses the main approaches for nonlinearity mitigation based on DSP. The interested reader might also refer to [9.182] for an extensive review on this subject.

We point out that very recently artificial neural networks (ANNs) have also been advocated as a possible DSP approach for the mitigation of nonlinear effects. We refrain from dealing with it here, but the interested reader can see, for instance, a recent prominent result [9.183].

We also point out that nonlinearity mitigation can be carried out by means of all-optical techniques as well. One example is, for instance, optical phase conjugation [9.184]. All-optical mitigation techniques are a vast and interesting investigation field, but they are outside of the scope of this chapter.

9.11.1 Digital Backpropagation

One of the most promising and studied strategies to combat fiber nonlinearity is digital backpropagation (DBP). DBP is a channel inversion technique that aims at removing fiber propagation effects by digitally emulating the propagation of the received signal through a fictitious fiber link—equal to the actual fiber link but reversed in space and with opposite-sign parameters $-\alpha_P$, $-\beta_2$, and $-\gamma$ for each span of fiber [9.185–187]—as schematically depicted in Fig. 9.19.

A simple analysis reveals that DBP can, in principle, exactly invert the propagation equation (9.1), hence removing all deterministic propagation effects due to the interplay between dispersion and nonlinearity. DBP can be implemented at the transmitter, at the receiver, or both. Several numerical studies and experimental demonstrations of DBP are available, reporting different gains in terms of SNR and reach, depending on the scenario considered [9.57, 188–190]. There is, anyway, a general consensus that gains up to 1 dB might be realistically achieved, and that DBP is a practical candidate for extending the reach of next-generation transponders.

In practice, DBP operates on a digitized version of the signal and is usually implemented by the SSFM algorithm (Sect. 9.2) for its good characteristics in terms of performance and complexity. The sequence of received samples is divided into several overlapping blocks of length N, with N_m overlapping samples. Each block is propagated through the whole link according to the algorithm in Fig. 9.3, with a total of N_s steps. For a dual-polarization signal, the number of real additions and multiplications required by an SSFM-based implementation of DBP per each processed sample is reported in Table 9.2 [9.191]. The parameter N_c accounts for alternative implementations of DBP (see

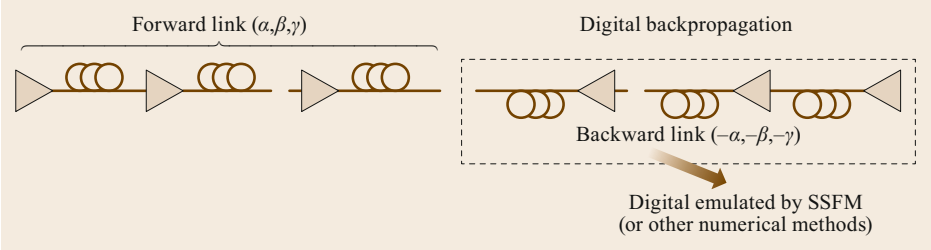

Fig. 9.19 The DBP strategy

below) and must be set to zero for a standard SSFM implementation; N_m is of the order of channel memory induced by GVD (Sect. 9.2), and N is optimized to minimize the overall computational complexity. For comparison, Table 9.2 shows the same figures also for GVD compensation based on a frequency-domain feedforward equalizer.

Each DBP step typically requires about 10–20% more operations than GVD compensation, such that the overall complexity of conventional DBP (based on standard SSFM and employing one step per span) easily exceeds a factor ×10 the complexity of GVD compensation in terrestrial links [9.190].

Attaining better improvements with lower complexity is one of the big challenges to bring DBP from the lab to the field. A first solution is filtered DBP [9.117, 192, 193], in which the nonlinear step uses a low-pass filtered version of the signal power. The nonlinear step (9.5) is, thus, replaced by

$$A_{k,i} = A'_{k,i} \mathrm{e}^{-\alpha_\mathrm{p} h/2} \times \mathrm{e}^{-\mathrm{j}\gamma h_\mathrm{eff}[c_0|A'_{k,i}|^2 + \sum_{\ell=1}^{N_\mathrm{c}} c_i(|A'_{k-\ell,i}|^2 + |A'_{k+\ell,i}|^2)]}, \quad i = 1, \ldots, N, \tag{9.106}$$

where $c_0, \ldots, c_{N_\mathrm{c}}$ are $N_\mathrm{c}+1$ real coefficients of a tapped-delay-line low-pass filter. For $N_\mathrm{c} = 0$, the algorithm reduces to the standard SSFM. The idea is to overcome the inability of the standard SSFM to account for the continuously varying phase mismatch induced by GVD along each nonlinear propagation step—a problem that is particularly significant at large frequencies. Filtered DBP attempts to mitigate such a problem by low-pass filtering signal power during the nonlinear step in a way to limit the intensity fluctuations induced by the artificial phase matching condition of GVD [9.192]. Few taps are generally required in the additional filtering operation, such that the additional complexity per step (shown in Table 9.2) is usually more than compensated for by the step elongation, with about one order of magnitude reduction of the overall complexity. A similar strategy is the one based on the enhanced SSFM algorithm, in which the nonlinear step is still replaced by (9.106), with the difference that the expression is derived from a perturbation analysis based on the FRLP model (Sect. 9.7), and the $N_\mathrm{c}+1$ coefficients are optimized by a minimum mean square error criterion [9.194]. A single-step DBP achieving the same performance as a standard DBP with a 16 times higher complexity has been experimentally demonstrated [9.191].

Alternative DBP design methods showed that finely positioning the nonlinear step in a symmetric-SSFM implementation of DBP can enhance the algorithm performance [9.195]. *Gonçalves* et al. [9.196] showed that DBP can be aided by a memory polynomial model, a technique used in wireless communications to relax the requirements of the Volterra equation. In dispersion-managed links, the strong correlation of the nonlinear interference from span to span can be efficiently exploited to build a folded DBP, where many spans are folded into a single span [9.197].

Low-complexity intrachannel nonlinearity mitigation techniques based on the perturbation analysis in [9.22] have also been proposed. In the special case of QPSK symbols, *Tao* et al. [9.198] showed how to exploit the constant modulus property of the constellation to build a multiplier-free intrachannel Volterra-based equalizer by substituting multiplications with summations. *Tao* et al. [9.199] proposed reducing the number of multiplications in the perturbation evaluation by quantization of the kernel function. By using 50% pre-

Table 9.2 Number of real operations required by GVD compensation and SSFM-based DBP (per step)—$N_\mathrm{c} = 0$ for standard SSFM and $N_\mathrm{c} > 0$ for filtered or enhanced SSFM with N_c coefficients

	GVD compensation	DBP (per step)
Additions	$\frac{N}{N-N_\mathrm{m}}(8\log_2 N + 8)$	$\frac{N}{N-N_\mathrm{m}}(8\log_2 N + 21 + N_\mathrm{c})$
Multiplications	$\frac{N}{N-N_\mathrm{m}}(8\log_2 N + 4)$	$\frac{N}{N-N_\mathrm{m}}(8\log_2 N + 11 + 2N_\mathrm{c})$

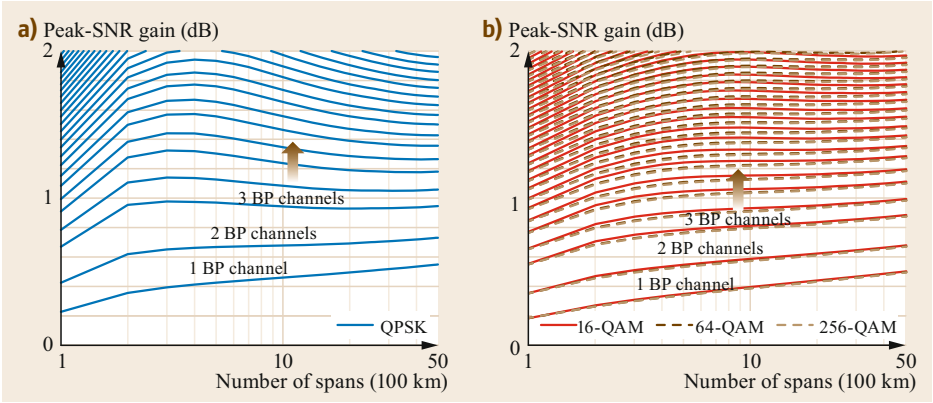

Fig. 9.20a,b Peak-SNR gains achievable by single and multichannel DBP over a fully-loaded (115 channels) dispersion-unmanaged WDM system over SMF, with a channel symbol rate of 32 GBaud. The system parameters are set as in [9.78]

compensation, the number of quantized coefficients has been shown to be reduced down to few units, still keeping significant gains [9.200]. *Gao* et al. [9.201] showed that with 50% precompensation, the symmetry of the dispersion map with respect to the midpoint of transmission link can be used to reduce the number of multiplications in a perturbation-based nonlinear precompensation. The reason is that, this way the kernel coefficients are i) real valued, thus halving the number of complex multiplications and ii) evaluated over half link length. A reduction factor of 6.8 has been experimentally demonstrated. Although the kernel description of the perturbation is a global input/output description of the link, it has been shown that implementing the perturbative nonlinear equalization by a multistage compensation cascade may relax complexity at a given accuracy [9.202]. Indeed, when dividing the link into N stages, the equalization procedure is repeated N times, once per stage. Nevertheless, since the total number of nonlinear interactions per stage decreases *quadratically* with N due to the shorter memory of each stage, the overall complexity is reduced. A comprehensive analysis of the symmetries in Volterra-based nonlinear equalization that help practical implementation was investigated in [9.203]. An analytical expression for the computation of the coefficients of perturbative nonlinear precompensation for Nyquist pulses was derived and experimentally verified in [9.204]. The gains achievable by DBP or perturbative nonlinear compensation were investigated and compared in a C+L band ultra-longhaul transmission experiment in [9.205].

Besides computational issues, and despite the theoretical possibility of an exact channel inversion, both fundamental and practical limitations prevent DBP from completely removing nonlinear impairments. A first limitation arises in WDM systems, which are impaired by both intra and interchannel nonlinearity. In typical systems, each channel is separately detected and processed, such that only a *single-channel DBP* can be actually implemented, effectively compensating only for intrachannel nonlinearity. In principle, it is possible to implement a *multichannel DBP* by jointly detecting and processing two or more WDM channels [9.117, 189]. As the number of backpropagated channel increases, a higher portion of interchannel nonlinearity can be effectively mitigated. However, the required computational resources grow more than linearly with the number of backpropagated channels.

The peak-SNR gains that can be theoretically achieved by ideal single and multichannel DBP over the typical dispersion-unmanaged WDM systems are shown in Fig. 9.20 as a function of the number of spans [9.78], for systems operating at 32 GBaud.

The various solid curves correspond to the number of channels that are jointly backpropagated. The potential gain of single and three-channel DBP is limited to about 0.5 and 1 dB, respectively. Beyond three-channel DBP, each additional backpropagated channel provides an incremental gain of no more than ≈ 0.1 dB, possibly not enough to justify the corresponding increase of the computational resources required. Slightly higher gains are achievable when considering systems with interchannel phase noise and polarization rotation compensation [9.78]. Moreover, in optically routed networks, signals at different wavelengths may follow different paths in the network, such that an effective multichannel DBP is no longer possible.

The possibility to obtain a perfect channel inversion may be limited also by the presence of PMD [9.137]. In principle, an exact knowledge of the PMD evolution both in time and along the fiber link would still allow for a perfect channel inversion without any performance degradation. In practice, such a knowledge is unavail-

able both at the transmitter and receiver, and DBP is usually performed by ignoring the presence of PMD (which is separately compensated for by an adaptive linear equalizer after DBP). In typical WDM systems, the impact of PMD is negligible for single-channel DBP, but becomes relevant when increasing the number of backpropagated channels, practically limiting the SNR gains achievable [9.189]. Some possible countermeasures, based on the insertion of PMD sections among the DBP steps, were investigated in [9.206–208], considering different strategies to configure the PMD sections.

Eventually, the nonlinear compensation achievable by DBP is fundamentally limited by signal–noise interaction, for which a channel inversion strategy turns out to be ineffective. This is easily understood by noting that the ASE noise injected by each in-line amplifier interacts with the propagating signal along a different portion of the optical link, such that DBP reduces the signal–noise interaction due to the first amplifiers, but enhances that due to the last amplifiers. The impact of signal–noise interaction on DBP is generally negligible compared to that of interchannel nonlinearity and of PMD. It is, therefore, of little practical relevance in real systems. However, it becomes essential when investigating the ultimate limitations of optical fiber systems—for instance, when considering single-channel scenarios or, equivalently, in the case of an ideal multichannel DBP covering the whole WDM spectrum. This kind of analysis is complicated by the unavailability of an exact model of the optical fiber channel accounting for signal–noise interaction, though some approximated models, based on perturbation theory, are, indeed, available, e.g., [9.43, 95, 114–116, 121, 209], which would be required to optimize the detection strategy, as discussed more in detail in Sect. 9.12. In fact, DBP is not sufficient to implement an optimum detector, and alternative strategies have been proposed to replace or complement DBP [9.210–212]. One possible approach is that of extending the DBP concept to include the uncertainty due to amplifier ASE noise when backpropagating the received signal. This procedure, known as stochastic DBP (SDBP), consists in backpropagating distributions rather than signals, eventually obtaining an estimate of the posterior distribution of the transmitted symbols given the received signal, which is required to implement an optimum detector [9.211]. The specific SDBP algorithm proposed in [9.211] is based on a particle representation of the distributions. It is too complex for a practical implementation but offers a benchmark for simpler implementations.

Most DBP demonstrations assume that the required system parameters (e.g., launch powers and fiber parameters for each span of a fiber) are known at the receiver. Often, this is not the case. Moreover, some parameters may change over time due, for instance, to network reconfigurations. It is, therefore, essential to devise adaptive strategies for the configuration and dynamic control of DBP parameters [9.213, 214]. While there are no particularly stringent requirements in terms of convergence and adaptation speed for standard DBP algorithms, this issue becomes critical when considering PMD-aware DBP algorithms.

9.11.2 Symbol-Rate Optimization

One of the features of nonlinear fiber propagation is that the amount of generated NLI power depends on the symbol rate of the WDM channels. Specifically, it was shown simulatively [9.215, 216] and then experimentally [9.217] that, by distributing the same total data throughput across the same optical bandwidth, over a *larger* number of WDM channels at a *smaller* symbol rate, the NLI power impairing reception would *decrease*. Initial theoretical studies concurred [9.132, 218]. These findings were then investigated by means of the EGN model [9.219]. Further investigation was carried out in [9.78], using both time-domain and the pulse-collision models, which also clarified the role and impact of NLPN in this phenomenon. Interestingly, SRO was predicted by the EGN model results to actually slightly increase its effectiveness when the overall system WDM bandwidth is widened [9.219], contrary, for instance, to DBP. Due to all these findings, the idea of reducing the symbol rate per carrier in order to improve system performance has been considered as a potential NLI mitigation technique, under the acronym SRO (symbol-rate optimization).

SRO theory predicts that the optimum symbol rate is, in uniform links of N_s spans, each of length L_s [9.219]

$$R_{\mathrm{opt}} = \sqrt{\frac{2}{\pi |\beta_2| L_s N_s}} \,. \tag{9.107}$$

Values typically range between 1 and 10 GBaud. These rates are quite low as compared to industry standards. In addition, the industrial trend, for techno-economic reasons, has historically been that of constantly ramping up symbol rates, with a transition between 32 to 64 GBaud currently taking place. This circumstance clearly clashes with the SRO prescription of operating at low symbol rates.

One way to make an increase in *total* symbol rate per transponder compatible with a decrease of symbol rate *per carrier* is to resort to *subcarrier multiplex-*

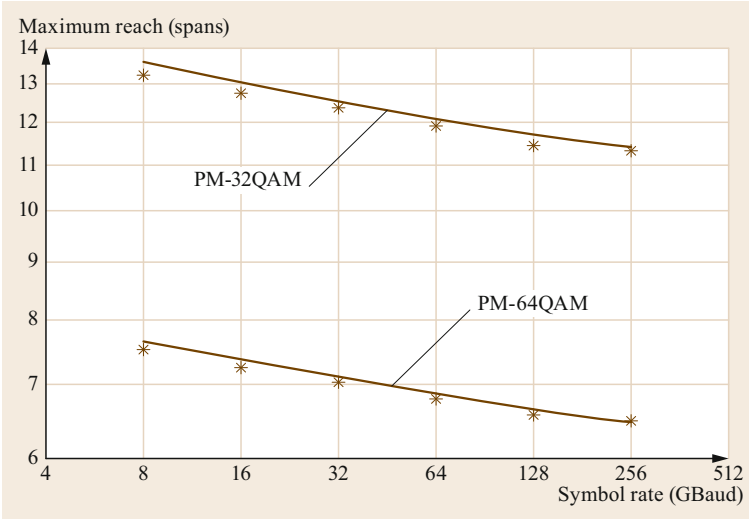

Fig. 9.21 Maximum reach versus per-channel symbol rate. *Solid lines*: calculations using the EGN model. *Markers*: simulations. Span length 100 km, SMF, EDFA noise figure 6 dB, roll-off 0.2. Target performance: GMI 8.7 and 10.44 bits/symb, for PM-32QAM and PM-64QAM, respectively. The total optical bandwidth is 1.83 THz for all rates. For symbol rates from 8 to 256 GBaud, the number of channels ranges from 192 to 6. Carrier spacing: $\Delta f = 76.2(R_s/64)$, where R_s is the symbol rate in GHz

ing. Essentially, high symbol-rate channels are created as a collection of DAC-generated electrical subcarriers, which operate at the symbol rate that is optimum from the viewpoint of NLI mitigation. For instance, a 64 GBaud-channel could consist of 16 4 GBaud subcarriers.

No closed-form formula currently exists for the prediction of the potential MR gain. Estimating it requires the numerical evaluation of the EGN model. Incidentally, SRO is one of those contexts where the GN model is inadequate, as suggested by the strong violation of criterion (1), which prescribes a high symbol rate for GN model accuracy (Sect. 9.4.7). Direct EGN (or time-domain model) calculations or Monte-Carlo simulations are required.

Figure 9.21 provides a pictorial appreciation of the predicted MR gain for two high-cardinality systems, either PM-64QAM or PM-32QAM. The relevant system data is reported in the figure caption. Both the solid line (EGN model) and the markers (simulations) concur in predicting a 16–18% MR increase between the figure extremes, i.e., from 256 GBaud down to 8 GBaud. The latter is close to the theoretical optimum, which according to (9.107) is about 5 GBaud for PM-32QAM and about 6.5 GBaud for PM-64QAM. Note that in order to clearly show an optimum, Fig. 9.21 would have to be pushed down to about 2 GBaud. This was not possible because the CPU time of the simulations, as well as the their memory occupation, is inversely proportional to the symbol rate. For the almost 2 THz total optical bandwidth considered in Fig. 9.21, 8 GBaud was the practical limit. It was done instead in [9.219], Figs. 9.1 and 9.4, because the total bandwidth was 500 GHz. There, the optimum is clearly visible.

The MR percentage gain due to SRO is actually larger for longer links and for smaller constellations [9.78, 219], with PM-QPSK being the format benefiting the most, with potential MR gains on the order of 25–30% across the same symbol rate range as in Fig. 9.21. Also, there are important aspects as to the role played by NLPN in the context of SRO. For more details on this [9.78].

In addition, when GSCs are used, the gain due to SRO essentially vanishes, as predicted by the GN model (which is equivalent to the EGN model for GCSs). Part or all of the gain could be gained back for GSCs if NLPN mitigation was possible at low symbol rates. This is currently unclear and the subject of ongoing research [9.78].

Despite all the limitations, SRO could be a possible way to partially mitigate NLI, at least for QAM-based systems, with relatively low complexity. In [9.219], it was shown by EGN-model calculations that for full C-band ultra-long-haul systems, at 32 GBaud, its MR gain could be comparable to DBP.

It should, however, be mentioned that negative findings regarding SRO have also been published. In particular, in [9.220] very limited gain from SRO was found, which also tended to vanish as the number of WDM channels was increased, in contrast with SRO theory. Overall, a conclusive specific experiment proving the effectiveness of SRO over a fully populated C-band system is not yet available. Therefore, SRO should still be considered a research topic needing confirmation. We should also mention that presently there are commercial systems that use multisubcarrier transmission. Whether its use grants actual performance gain in these commercial systems, and why, is currently undisclosed information.

9.11.3 The Nonlinear Fourier Transform

The nonlinear Fourier transform (NFT)—also known in the mathematical community as the inverse scattering transform—is a mathematical tool to solve a certain class of nonlinear partial differential equations—the so-called *integrable* equations. The NFT was introduced in [9.221] for the Kortweg–de Vries equation and later applied to many other equations, including the NLSE [9.222] and the Manakov equation [9.223]. A general treatise on the NFT can be found in [9.224], while a more specific review of the NFT for the NLSE and its application to optical fiber communications can be found in [9.225, 226].

The NFT can be regarded as the generalization of the ordinary Fourier transform to nonlinear systems [9.224]. The basic idea is that of representing the propagating waveform through a proper set of spectral data—the scattering data or *nonlinear spectrum*—whose evolution along the fiber link is simple and linear. As with linear systems and the ordinary Fourier transform, the initial value problem is, therefore, solved by performing three main steps:

1. Computation of the input nonlinear spectrum by a direct NFT. For the NLSE, this operation consists in solving the Zakharov–Shabat spectral problem [9.222]. In general, the Zakharov–Shabat operator has both a discrete and a continuous spectrum. The former consists of a set of eigenvalues in the complex plane and the related norming constants and is associated with *soliton* components. The latter is defined over the real line and is an analogue to the ordinary Fourier transform, to which it converges in the low-power limit.
2. Propagation of the nonlinear spectrum. For the NLSE, this is equivalent to the propagation of the linear spectrum in a linear dispersive fiber.
3. Reconstruction of the output waveform from its nonlinear spectrum by an inverse NFT (INFT). For the NLSE, this is classically done by solving the Gelfand–Levitan–Marchenko integral equation [9.222, 224].

Many integrable equations, including the NLSE, have *soliton* solutions, which play an important role in NFT theory. Solitons maintain their shapes (or return periodically to them) during propagation due to a cancellation of nonlinear and dispersive effects. This property makes them attractive for communications. Indeed, soliton-based communications were extensively explored during the 1980s and 1990s ([9.227] and references therein). However, they never made their way to commercial systems because of their low spectral efficiency (about 0.2 (bits/s)/Hz) and the detrimental impact of the Gordon–Haus effect and intersoliton interaction.

Soliton communication is just the simplest way in which NFT-related concepts can be used to design nonlinearity-tolerant communication systems. A more general approach, originally named *eigenvalue communication* [9.228], is that of avoiding nonlinear interference by encoding information on the spectral data of the Zakharov–Shabat operator. After going almost unnoticed for a couple of decades, this approach was recently resurrected—with different names and flavors, such as *eigenvalue communication* [9.229], *nonlinear frequency-division multiplexing (NFDM)* [9.225], and *nonlinear inverse synthesis* [9.230]—due to the impressive progress in DSP technology, which makes conceivable, if not yet feasible, a realtime implementation of the NFT.

All the NFT-based approaches proposed so far can be generally represented by one of the four schemes depicted in Fig. 9.22 (the first three are also discussed in [9.226]). In the standard NFDM scheme of Fig. 9.22a, information is encoded and decoded in the nonlinear frequency domain, using INFT and NFT to convert the nonlinear spectrum into a time-domain waveform and the other way around, respectively [9.225, 228, 230–232]. On the other hand, in the scheme of Fig. 9.22b, information is encoded and decoded in the time domain, as in conventional systems, while NFT and INFT are used to implement DBP [9.233]. Figure 9.22c represents a hybrid approach in which information is encoded in the time domain and decoded in the nonlinear frequency domain [9.229, 234]. Finally, Fig. 9.22d shows the complementary hybrid approach in which information is encoded in the nonlinear frequency domain and decoded in the time domain [9.235, 236]. While the first two approaches achieve a diagonalization of the channel, such that symbol-by-symbol detection can be employed, the last two do not, in fact, they require some kind of sequence detection. Quite interestingly, time-domain detection of NFDM signals (the fourth approach) seems to achieve a superior performance compared to the conventional NFDM scheme (the first approach), though with some additional complexity, probably due to a better matching between the detection metrics employed and the actual channel statistics [9.236].

NFDM schemes can be further classified according to which part of the nonlinear spectrum is used to encode information: the discrete part [9.225, 228, 229, 235], the continuous part [9.225, 230, 232, 236], or both [9.237]. Furthermore, NFT theory can also be applied to the Manakov equation, such that the proposed

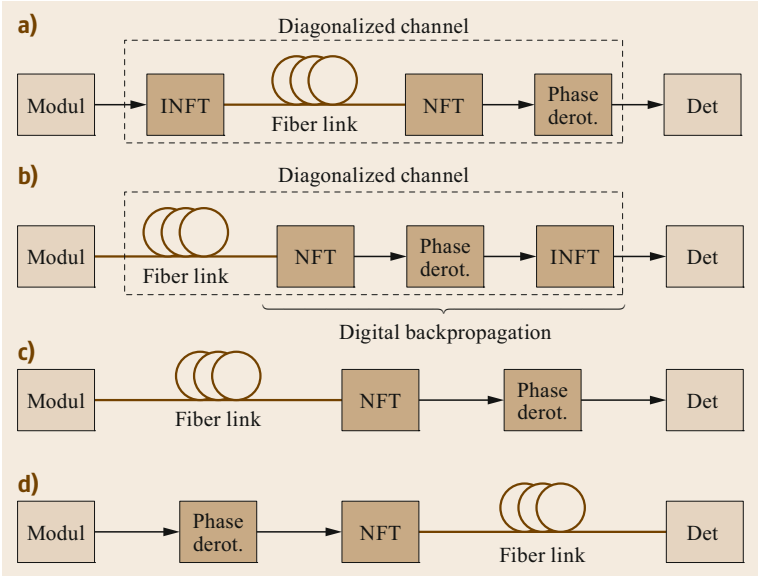

Fig. 9.22a–d Different ways to use NFT in optical communications. **(a)** Modulation and detection in the nonlinear frequency domain; **(b)** modulation and detection in the time domain, with NFT-based DBP; **(c)** modulation in the time domain and detection in the nonlinear frequency domain; **(d)** modulation in the nonlinear frequency domain and detection in the time domain

schemes can be extended to consider polarization-multiplexed signals [9.238, 239].

As for the ordinary Fourier transform, the NFT and the INFT can be computed analytically only in a few simple cases. In general, one has to resort to numerical methods. An overview of the numerical methods available can be found in [9.225, 226]. While the complexity of the most classical methods usually scales at least quadratically with the number of processed samples, super fast algorithms with log-linear complexity (such as the FFT) have been also developed [9.240]. Research of low-complexity methods with general validity is still ongoing and will play an important role in determining the feasibility of NFT-based techniques.

The NFT theory and the techniques mentioned in this section are based on *vanishing boundary conditions*, i.e., they assume that the optical signal decays sufficiently fast as $t \to \pm\infty$. In a real transmission system, this condition can be emulated by operating in burst mode and inserting a sufficiently long guard time between bursts [9.230]. The NFT theory has also been developed under different boundary conditions. A typical case, which has been extensively studied in the literature, is that of *periodic boundary conditions*. This approach may offer some advantages compared to the case of vanishing boundary conditions [9.226], but its application to optical communications has been much less explored [9.241].

Research on NFT-based techniques is still at an early stage, and there is no general consensus about their potentials, perspectives, and suitability for optical communications. Research mostly follows a trial-and-error approach, and the lack of a unified theory makes it hard to understand which strategy (among those depicted in Fig. 9.22) is the most promising, which part of the spectrum should be modulated, how information should be encoded on it, and what kind of boundary conditions should be considered. Several experimental demonstrations of the schemes in Fig. 9.22 can be found. Yet, so far, there is no clear evidence of performance improvement compared to conventional systems. In fact, some critical issues that seriously hamper the use of NFT operations at high power [9.242] and the achievement of high spectral efficiencies [9.232] have been highlighted. Performance needs to be significantly improved and complexity reduced before NFT-based techniques can make their way to real systems. Moreover, some propagation effects, which are not included in the NLSE (9.1) but can be easily described and coped with in the time domain (e.g., attenuation, higher-order dispersion, PMD), break the integrability of the system and are extremely hard to model in the nonlinear frequency domain. Their impact on NFDM systems needs to be better investigated, as it might be potentially more detrimental than the impact of nonlinear effects on conventional systems. Yet, the promise of a tool able to harness fiber nonlinearity keeps research alive.

9.11.4 Other Nonlinear Compensation Techniques

While DBP is certainly one of the most studied nonlinear compensation techniques, other techniques have been also proposed in the literature in recent years, ranging from the quite practical and simple approach of SRO to the more visionary techniques based on the

NFT, both of which are reviewed in this section. Nonlinearity compensation based on the inverse Volterra series transfer function [9.203] has been also studied. Given the equivalence between the RP method and the Volterra series approach, discussed in Sect. 9.3, this technique can be included in the broader category of perturbation-based channel inversion techniques for alternative DBP implementations.

According to the time-domain perturbative model and the FRLP model, which were introduced in Sects. 9.5 and 9.7, respectively, interchannel nonlinearity causes the emergence of phase noise, polarization rotations, and ISI. These effects can be partly mitigated by some classical algorithms typically employed to counteract them, when generated by causes other than fiber nonlinearity. These algorithms can, hence, in all respects be considered as nonlinearity mitigation strategies. Some examples are reported in [9.82, 83, 85, 243].

Another class of nonlinearity mitigation techniques aims at reducing the amount of NLI generated by a proper combination of coding and modulation. Possible examples are the design of nearly constant-envelope modulation formats [9.244], the ad-hoc probabilistic shaping of QAM constellations over one [9.245] or several time slots [9.246], and the use of twin waves [9.247] or conjugate data repetition [9.248] to partly cancel NLI.

9.12 Capacity of the Nonlinear Channel

One of the key results of *Claude Shannon's* pioneering work was the demonstration that a reliable communication over a noisy channel is possible, provided that the information rate is less than a characteristic quantity determined by the statistical properties of the channel, which he named *channel capacity* [9.249].

9.12.1 Capacity and Spectral Efficiency

Other than laying the foundations of what is now called *information theory* and establishing such a general result, Shannon also derived a specific closed-form expression for the capacity of an AWGN channel. As we shall see, this expression is also widely employed in the context of optical fibers, though its validity and interpretation need some care. Shannon's work has been since extended and generalized both to account for a broader class of channels and to obtain closed-form capacity expressions for other specific channels ([9.250] and references therein). In this context, the optical-fiber channel is a major challenge due to its peculiar nonlinear behavior. In fact, as we shall see in this section, research to determine channel capacity is still ongoing, and the problem, so far, remains essentially open [9.251].

We start by considering the generic digital communication system schematically depicted in Fig. 9.23. Firstly, the channel encoder takes a stream of information bits from the source and adds some redundancy to it (e.g., parity check bits) to be used for error correcting purposes. Then, the encoded bits are mapped onto a sequence of information symbols belonging to the input modulation alphabet $\mathcal{X}$. Since the physical channel is usually a *waveform channel* (e.g., an optical fiber link), a DAC converts the sequence of symbols into a waveform (e.g., by linearly modulating a sequence of pulses of given shape) that propagates through the channel. The opposite operations are then performed at the receiver; the output waveform (which is possibly distorted and corrupted by noise) is converted to a sequence of symbols belonging to the output alphabet $\mathcal{Y}$ (e.g., by filtering and sampling the waveform). The detector converts the output symbols into a sequence of bits, which are finally decoded (correcting possible errors) and sent to the destination. The combination of DAC, waveform channel, and ADC constitutes the *discrete-time channel*, which is usually the subject of the information theoretical analysis. In practical cases, the input and output alphabets $\mathcal{X}$ and $\mathcal{Y}$ are determined by the quantization levels available in the DAC and ADC and are, hence, finite. Often, when no constraints about the DAC and ADC characteristics are given, the whole field of complex numbers is considered for both alphabets. The discrete-time channel is characterized by a family of conditional distributions $p(\boldsymbol{y}_N|\boldsymbol{x}_N)$, for $N = 1, 2, \ldots$, where $\boldsymbol{x}_N = (x_1, x_2, \ldots, x_N)$, with $x_i \in \mathcal{X}$, and $\boldsymbol{y}_N = (y_1, y_2, \ldots, y_N)$, with $y_i \in \mathcal{Y}$, are length-N realizations of the input and output processes $X = X_1, X_2, \ldots$, and $Y = Y_1, Y_2, \ldots$, respectively.

A typical problem in information theory is that of determining channel capacity—operationally defined as the maximum bit rate at which information can be reliably (i.e., at an arbitrarily low error probability) transmitted through the channel with the best possible combination of coding and modulation—without actually trying such (infinitely many) possible combinations. Given the statistics of the input process, i.e., the input distributions $p(\boldsymbol{x}_N)$ for $N = 1, 2, \ldots$, the maximum bit rate at which information can be reliably transmitted through the channel is given by the infor-

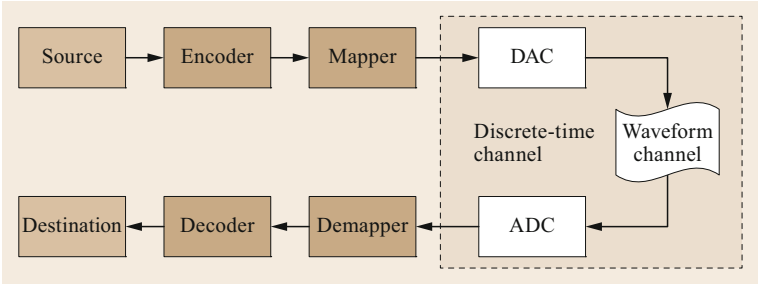

Fig. 9.23 A digital communication system

mation rate [9.252]

$$I(X;Y) = \lim_{N\to\infty} \frac{1}{N} I(\boldsymbol{X}_N;\boldsymbol{Y}_N)\,, \tag{9.108}$$

where

$$I(\boldsymbol{X}_N;\boldsymbol{Y}_N) = E\left\{\log_2 \frac{p(\boldsymbol{Y}_N|\boldsymbol{X}_N)}{p(\boldsymbol{Y}_N)}\right\} \tag{9.109}$$

is the mutual information between $\boldsymbol{X}_N$ and $\boldsymbol{Y}_N$, $E\{\cdot\}$ is the expectation operator. The information rate (9.108) depends both on the input statistics—which are determined by the channel user by selecting a combination of code and modulation—and on the channel itself. Eventually, the capacity of the channel is obtained by selecting the input statistics for which the information rate is maximized

$$C = \lim_{N\to\infty} \frac{1}{N} \sup_{\boldsymbol{X}_N} I(\boldsymbol{X}_N;\boldsymbol{Y}_N)\,, \tag{9.110}$$

where the supremum $\sup_{\boldsymbol{X}_N}$ is taken with respect to all input distributions $p(\boldsymbol{x}_N)$ satisfying a specific constraint (usually on the average power) [9.252]. The capacity is, hence, a specific property of the channel, which determines a fundamental limit for transferring information.

Both quantities in (9.108) and (9.110) refer to the discrete-time channel and are measured in bit/symbol (or bit/channel use). The corresponding information rate and capacity of the waveform channel are expressed in bit/s and are obtained by multiplying (9.108) and (9.110) times the baud rate R at which symbols are mapped to and demapped from the input and output waveforms. A further normalization by the *occupied bandwidth* (whenever a suitable definition of it is available) yields the *spectral efficiency* (SE) in (bit/s)/Hz.

In general, only the capacity of some specific channels can be evaluated analytically, the AWGN channel perhaps being the most notable example [9.249]. A discrete-time AWGN channel is characterized by the input–output relation $y_k = x_k + n_k$, where the noise samples n_k are realizations of i.i.d. variables with a zero-mean proper complex Gaussian distribution [9.253]—often referred to as circularly symmetric complex Gaussian (CSCG)—with variance P_n. The analysis in this case is greatly simplified by the absence of memory, which allows us to compute (9.109) by considering only a single pair of input and output symbols ($N = 1$). Given a constraint on the average signal power P_s, the capacity of the AWGN channel is given by the well-known expression $C = \log_2(1 + P_\mathrm{s}/P_\mathrm{n})$ and is achievable by i.i.d. CSCG input symbols [9.249]. As the capacity achieving input distribution and the corresponding output distribution are zero-mean, this capacity can also be expressed in terms of the input variance $\sigma_x^2 = P_\mathrm{s}$, output variance $\sigma_y^2 = P_\mathrm{s} + P_\mathrm{n}$, and covariance $\sigma_{xy} = P_\mathrm{s}$ as

$$C = \log_2\left(1 + \frac{P_\mathrm{s}}{P_\mathrm{n}}\right) = \log_2\left(\frac{\sigma_x^2\sigma_y^2}{\sigma_x^2\sigma_y^2 - |\sigma_{xy}|^2}\right). \tag{9.111}$$

In this case, it is apparent that, since the noise power P_n is fixed and independent of the signal, the channel capacity grows unbounded with signal power P_s. This means that the channel capacity is limited only if the available resources (power) are limited (e.g., due to economic or technological constraints).

When turning our attention to the optical fiber channel, the picture is more complicated. At low signal power, the nonlinear term of the NLSE (9.1) is practically negligible, and the channel essentially behaves like an AWGN channel with a capacity that grows logarithmically with launch power according to (9.111). (Linear propagation impairments, such as chromatic dispersion and polarization mode dispersion, are characterized by a slowly varying (or constant) unitary transfer matrix. Hence, in the linear regime, their presence has no impact on channel capacity as they can be fully compensated by a linear equalizer.) However, at higher signal power, the nonlinear term of the NLSE is no longer negligible and must be accounted for in the evaluation of channel capacity. This is an extremely difficult task. First of all, an exact and mathemati-

cally tractable expression for $p(\boldsymbol{y}_N|\boldsymbol{x}_N)$ is unavailable, making the analytical evaluation of (9.108) unfeasible. Moreover, its numerical estimation, which must be performed in a $4N$-dimensional space, is practically limited to very small values of N. On the other hand, the convergence of (9.108) and (9.110) to their actual limit can be expected when N is of the order of the channel memory, which can be many hundreds of symbols in typical dispersion-unmanaged systems. For the same reasons, the optimization of $p(\boldsymbol{x}_N)$ in (9.110) cannot be performed analytically either, and, when resorting to numerical approaches, it is limited to small values of N. A further issue arises when considering the discretization of the waveform channel. In fact, due to nonlinearity, the propagating signal is subject to spectral broadening and signal–noise interaction during propagation. Therefore, the structure and bandwidth of an optimum demodulator (providing a sufficient statistic) is also unknown. Moreover, since the signal bandwidth changes during propagation, there is no general consensus on how the spectral efficiency should be defined [9.254].

Typical optical systems employ WDM, in which many transmitter/receiver pairs share the same fiber to transmit and receive signals at different wavelengths. This multi-user scenario requires some extra care when being modeled and analyzed. A typical and reasonable assumption is that each user has access only to its allotted portion of the WDM spectrum, and that all the signals are independently generated and detected. In this situation, the capacity analysis is performed from a single-user perspective, i.e., by focusing on a single WDM channel (user), typically referred to as the COI, and considering all the other channels as a source of possible interference. Moreover, a specific behavioral model for the interfering channels, i.e., a rule that relates the input distribution on the interfering channels to the COI input distribution, should be specified [9.255]. The most common (and fair) assumption is that all the users transmit with same input distribution and power. Different choices are possible, which correspond to different network scenarios and lead to completely different results in terms of capacity [9.255]. Eventually, in the WDM scenario, spectral efficiency is usually defined by considering that the bandwidth occupied by each channel equals the channel spacing.

All the difficulties highlighted in this section make the exact evaluation of the capacity of the optical fiber channel extremely difficult. In cases like this, a typical approach is that of resorting to the computation of upper and lower bounds on the capacity, trying to identify a possibly narrow range of values in which the actual (unknown) capacity lies. This will be discussed in the next sections.

9.12.2 Achievable Information Rate with Mismatched Decoding

When the actual channel law is unknown, such as in the case of the optical fiber channel, it is useful to consider the more general case, depicted in Fig. 9.24, of a discrete-time channel with a detector that makes maximum-a-posteriori-probability (MAP) decisions based on a mismatched channel law $q(\boldsymbol{y}_N|\boldsymbol{x}_N) \neq p(\boldsymbol{y}_N|\boldsymbol{x}_N)$. Following [9.147], we define the *achievable information rate* (AIR) with the mismatched decoding metric $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$ as

$$I_q(X;Y) \triangleq \lim_{N\to\infty} \frac{1}{N} E\left[\log \frac{q(\boldsymbol{y}_N|\boldsymbol{x}_N)}{\int p(\boldsymbol{x}_N) q(\boldsymbol{y}_N|\boldsymbol{x}_N) d\boldsymbol{x}_N}\right]. \tag{9.112}$$

(In [9.147], this quantity is actually referred to as the *auxiliary-channel lower bound* to the information rate.) With respect to the average mutual information rate (9.108), (9.112) is obtained by replacing the actual channel law $p(\boldsymbol{y}_N|\boldsymbol{x}_N)$ with an arbitrary mismatched law $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$, while the expectation is still taken with respect to the actual true distribution $p(\boldsymbol{y}_N|\boldsymbol{x}_N)p(\boldsymbol{x}_N)$ induced by the input distribution and the actual channel law.

The AIR (9.112) has some interesting properties that hold for any true and auxiliary channel and make it suitable for practical use in optical communications: i) it is a lower bound to the information rate and, therefore, to the channel capacity $I_q(X;Y) \leq I(X;Y) \leq C$; ii) its maximization over any possible detection law (obtained for $q(\boldsymbol{y}_N|\boldsymbol{x}_N) = p(\boldsymbol{y}_N|\boldsymbol{x}_N)$) leads to the actual information rate; iii) its further maximization over the input distribution $p(\boldsymbol{x}_N)$ leads to channel capacity; iv) it is achievable over the true channel with source probability $p(\boldsymbol{x}_N)$ and a MAP detector matched to $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$; and v) it can be computed through numerical simulations, without an explicit knowledge of the true channel law $p(\boldsymbol{y}_N|\boldsymbol{x}_N)$, provided that $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$ can be computed.

In practice, the system is designed by selecting a modulation format that determines the input distribution $p(\boldsymbol{x}_N)$, and an approximated (auxiliary) channel model (e.g., one of the ones discussed in Sect. 9.3), which determines the mismatched channel law $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$ and, hence, the detection metrics. The

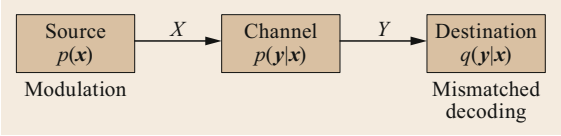

Fig. 9.24 Discrete-time channel with mismatched decoding

AIR (9.112) for this configuration is then computed through numerical simulations. Possibly, $p(\boldsymbol{x}_N)$ and/or $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$ can be numerically optimized by using the AIR as a performance metric to be maximized.

While an exact analytical evaluation of (9.112) is still unfeasible—as the joint distribution $p(\boldsymbol{x}_K, \boldsymbol{y}_K)$ of the true channel, with respect to which the expectation in (9.112) must be computed, is generally unknown—an accurate numerical estimate can be efficiently obtained by relying on the asymptotic equipartition property [9.146] and following the procedure described in [9.147]:

1. Draw a long input sequence $\boldsymbol{x}_N = (x_1, \ldots, x_N)$ of samples from the selected input distribution $p(\boldsymbol{x}_N)$.
2. Compute the corresponding output sequence $\boldsymbol{y}_N = (x_1, \ldots, x_N)$ by using the SSFM to simulate the true channel.
3. Compute the selected conditional distribution $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$.
4. Compute the corresponding output distribution $q(\boldsymbol{y}_N) = \int p(\boldsymbol{x}_N) q(\boldsymbol{y}_N|\boldsymbol{x}_N) \mathrm{d}\boldsymbol{x}_N$.
5. Estimate the AIR as

$$\hat{I}_q(X;Y) = \frac{1}{N} \log \frac{q(\boldsymbol{y}_N|\boldsymbol{x}_N)}{q(\boldsymbol{y}_N)} \,.$$

For finite-state source and auxiliary channel models, the actual computation of $q(\boldsymbol{y}_N|\boldsymbol{x}_N)$ and $q(\boldsymbol{y}_N)$ can be efficiently carried out by the sum-product algorithm on a suitably defined factor graph [9.147]. The procedure can be extended to the more general case of a continuous state space by resorting to particle methods [9.256].

9.12.3 The Nonlinear Shannon Limit (NSL) Lower Bound

As was already mentioned in the previous section, at low signal powers the optical fiber channel behaves like an AWGN channel; in fact, modern optical systems can achieve information rates close to channel capacity (9.111) when working in such a linear regime [9.257]. However, contrarily to the AWGN case, when the signal power increases, the ensuing nonlinearities impair the existing systems to the point that they cease to work. This naturally poses questions about the impact of nonlinearities on the capacity of a fiber-optic channel and the possible existence of an ultimate limit to channel capacity.

A variety of studies and facts hint at the possibility that a finite limit to the fiber-optic channel capacity does exist, so much that a name for it was coined—the *nonlinear Shannon limit* (NSL) [9.257]. To the best of our knowledge, a finite capacity limit for a fiber-optic channel was predicted for the first time in [9.28]. Similar results were later obtained by using different models and either analytical approximations or numerical methods [9.24, 75, 100, 258, 259]. Such a convergence of results has induced the belief that the actual channel capacity is very close to the NSL or, at least, follows the same trend. However, an analysis of the literature reveals that the NSL, as defined in [9.100, 257], but also as computed in many other publications [9.24, 75, 258], is just an instance of the AIR (9.112), computed with specific input distributions (usually i.i.d. symbols with CSCG or uniform-ring distribution) and mismatched channel laws (usually memoryless Gaussian). Therefore, it is only a lower bound to channel capacity, whose tightness is not known a priori.

A special case of (9.112)—referred to as the Gaussian AIR in the sequel—is obtained when considering i.i.d. CSCG input variables and a detector matched to an AWGN channel with the same input–output covariance matrix of the real channel

$$I_{\mathrm{G}}(X;Y) = \log_2 \left(\frac{\sigma_x^2 \sigma_y^2}{\sigma_x^2 \sigma_y^2 - |\sigma_{xy}|^2} \right) . \tag{9.113}$$

This result shows that the Gaussian AIR can be computed for *any* channel by simply estimating—either analytically, through an approximated channel model, or numerically, through accurate but time-consuming SSFM simulations—a covariance matrix. Remarkably, (9.113) equals the expression of the AWGN channel capacity (9.111). This means that the same expression can be used (and, in fact, it is commonly used) for any channel, but with different meanings. It gives the true channel capacity for AWGN channels, while it provides only a lower bound (achievable by a conventional detector optimized for the AWGN channel) for generic channels [9.260]. In fact, the information theoretical limits computed in [9.28, 75, 76, 100, 259] were all obtained by using (9.113), though computing the covariance matrix with different approaches. A good agreement between those results can generally be observed.

When considering the GN model, (9.113) reduces to the simple expression

$$I_{\mathrm{G}}(X;Y) = \log_2 \left(1 + \frac{\mathrm{P_s}}{P_{\mathrm{ASE}} + P_{\mathrm{NLI}}} \right) , \tag{9.114}$$

where P_{ASE} is the power of the accumulated ASE noise over the signal bandwidth W, and P_{NLI} is the nonlinear interference power obtained by integrating (9.34). Note that in this case, since the input process is Gaussian by assumption, the EGN model gives exactly the same result, as the correction term vanishes.

An alternative closed-form expression is obtained with the FRLP model in Sect. 9.7. In this case, (9.113) reduces to

$$I_{\mathrm{G}}(X;Y) = \log_2\left(1 + \frac{P_{\mathrm{s}}\mathrm{e}^{-\overline{\sigma_\theta^2}}}{P_{\mathrm{ASE}} + P_{\mathrm{s}}(1-\mathrm{e}^{-\overline{\sigma_\theta^2}})}\right), \tag{9.115}$$

where $\overline{\sigma_\theta^2}$ is the effective variance of the XPM term $\theta(f,t)$ over the signal bandwidth [9.96]. A very good agreement between (9.115) and the numerical computation of (9.113) based on SSFM simulations has been demonstrated [9.96]. A similar expression, with the same functional dependence on signal power P_{s}, can be obtained through Feynman's path integral approach [9.100]. Moreover, when $\overline{\sigma_\theta^2} \ll 1$—i.e., in most cases of practical interest— (9.115) reduces to (9.114), with $P_s\overline{\sigma_\theta^2}$ replacing P_{NLI}. In this case, the scaling of (9.114) and (9.115) with system parameters becomes the same and equals the one obtained in [9.75] with the RP method.

As an example, we compute the Gaussian AIR (9.115) for a single-polarization fully-loaded Nyquist-WDM system (81 channels) with 50 GHz-channel spacing, employing a standard transmission fiber with attenuation, dispersion, and nonlinearity coefficients $\alpha = 0.2\,\mathrm{dB/km}$, $D = 17\,\mathrm{ps/(nm\,km)}$, and $\gamma = 1.27\times10^{-3}\,\mathrm{W^{-1}m^{-1}}$, respectively. We consider both ideal distributed amplification (IDA), with spontaneous emission coefficient $\eta_s = 1$, and the more practical case of lumped amplification (LA) with $\eta_s = 1.6$ (a noise figure of about 5 dB) and different dispersion maps and span lengths. The system includes single-channel ideal DBP to remove intrachannel nonlinearity. The difference between the single and dual-polarization cases is usually small and will be investigated in the next section. Figure 9.25 shows the Gaussian AIR as a function of the signal launch power (per channel) P_{s}, for dispersion-unmanaged IDA links with different lengths. All the curves reach a maximum at the same optimum power ($\approx -10\,\mathrm{dBm}$ per channel). Doubling the distance, the AIR decreases of about 1 bit/symbol.

The more practical case of an LA link is considered in Fig. 9.26, which shows the maximum Gaussian AIR (at optimum launch power) for different link lengths. In particular, Fig. 9.26a considers the case of a dispersion-unmanaged link and shows the dependence of the maximum AIR on the amplifier spacing (span length). Longer spacing means higher attenuation; hence, more ASE noise, higher optimum power, higher nonlinear interference, and, eventually, lower maximum AIR. The limit of zero amplifier spacing corresponds to the case of an IDA link (though with a higher noise figure and, hence, a lower maximum AIR than Fig. 9.25). On the other hand, Fig. 9.26b considers the case of a dispersion-managed link with an amplifier spacing of 100 km and shows the dependence of the maximum AIR on the residual dispersion per span. Inline dispersion compensation turns out to be detrimental in terms of AIR, as it reduces the walk-off between channels causing a coherent accumulation of the nonlinear interference generated in different fiber spans. However, since nonlinear interaction mostly takes place at the beginning of each fiber span, a small residual dispersion per span (about 20–30%) is sufficient to avoid such a coherent accumulation and practically approach the dispersion-uncompensated case.

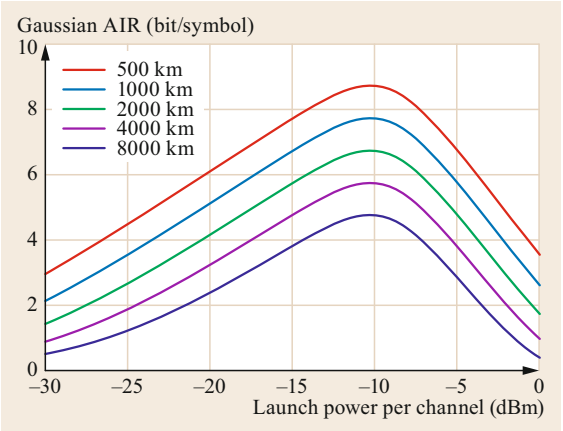

Fig. 9.25 Gaussian AIR for a single-polarization fully-loaded WDM system (81 channels) with 50 GHz channel spacing on a dispersion-unmanaged IDA link

9.12.4 Improved Lower Bounds

The Gaussian AIRs shown in Figs. 9.25 and 9.26 are the capacity lower bounds achievable by a detection strategy that does not account for residual channel memory (after DBP) and for the peculiar characteristics of nonlinear interference. The possible exploitation of the long time coherence of nonlinear interchannel interference (Sect. 9.7) to compute tighter capacity lower bounds was suggested in [9.76] and then demonstrated in [9.261], with further improvements obtained in [9.82, 262].

Figure 9.27 shows the AIR for a dispersion-unmanaged WDM system, considering the same configuration of Fig. 9.25, an IDA link of 1000 km, and different detection strategies. Both the single and dual-polarization cases are shown by solid and dashed lines, respectively. Since these curves are obtained by full SSFM simulations, only five WDM channels are

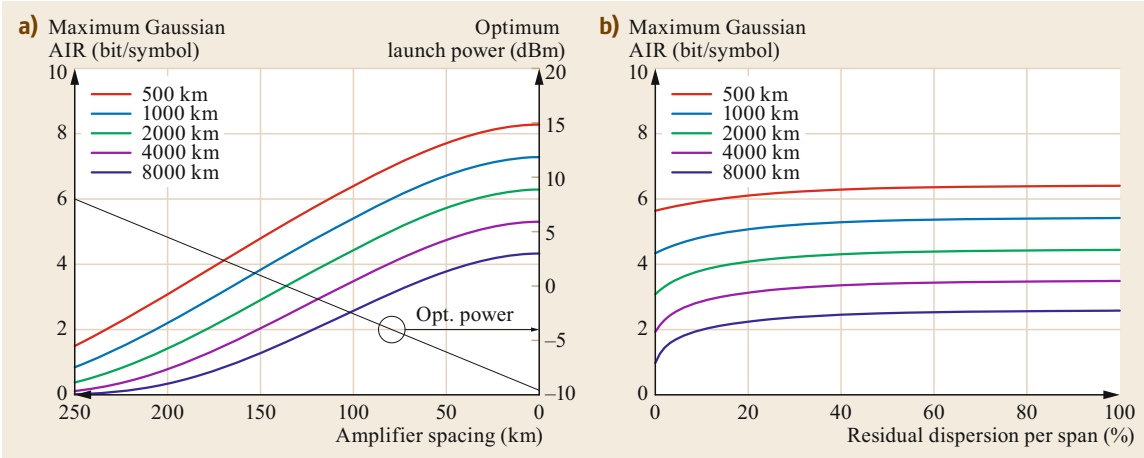

Fig. 9.26a,b Maximum Gaussian AIR for a single-polarization fully-loaded (81 channels) WDM system with 50 GHz channel spacing on an LA link as a function of: **(a)** amplifier spacing (without inline compensation); **(b)** inline residual dispersion (and a fixed amplifier spacing of 100 km)

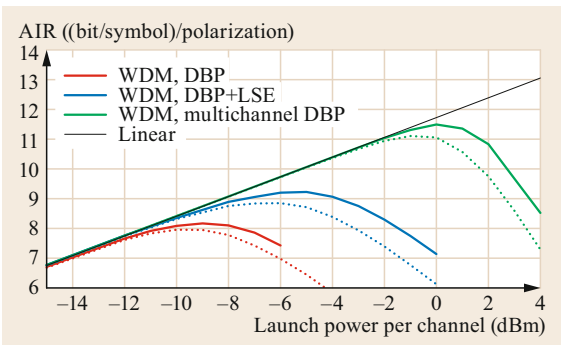

Fig. 9.27 AIR for a single or dual-polarization five-channel WDM system employing different detection strategies

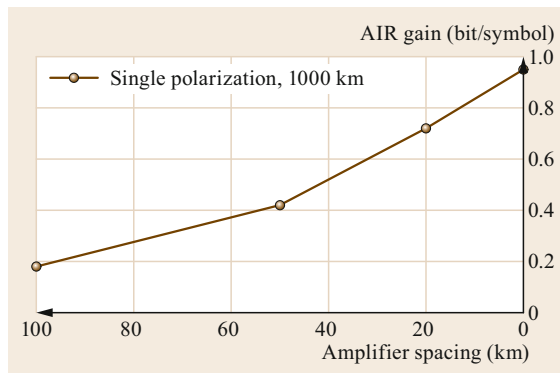

Fig. 9.28 AIR gain as a function of the amplifier spacing for a five channel single-polarization WDM system over a 1000 km link with lumped amplification

considered rather than a fully-loaded system. Before estimating the Gaussian AIR (9.113), different nonlinear mitigation strategies are considered: single-channel DBP as in Fig. 9.25 (the AIR is slightly higher because only five channels are considered), single-channel DBP followed by adaptive least-squares equalization (LSE), and multichannel DBP performed on the whole received WDM spectrum. It turns out that the maximum AIR can be improved by at least 1 bit/symbol by including LSE to mitigate interchannel nonlinearity (the gain increases with the number of WDM channels [9.82]).

As is shown in Sect. 9.7, the XPM term generated by nonlinear interference is highly coherent (both in time and frequency) for IDA links, but much less coherent for links with lumped amplification. Thus, lower AIR gains are expected over the latter. More generally, the coherence decreases as the portion of the link along which nonlinear interaction takes place decreases, such that the AIR gain achievable by LSE (or similar techniques) compared to the Gaussian AIR over links with lumped amplification decreases with amplifier spacing. Figure 9.28 shows the AIR gain (difference between the maximum AIRs obtained with and without LSE) as a function of the amplifier spacing for the same single-polarization system of Fig. 9.27 over a 1000 km link with lumped amplification (but unitary spontaneous emission factor). The limit of zero amplifier spacing corresponds to the case of an IDA link.

9.12.5 Beyond the Nonlinear Shannon Limit

So far, only some capacity *lower bounds* have been presented, all sharing the same typical dependence on optical power—they all reach a maximum at some op-

timum power and then decrease again. We might be tempted to conclude that even the true channel capacity follows the same trend and has a finite maximum. However, as we have already argued, there is no proof of the existence of such a *nonlinear Shannon limit*. In fact, the tightest available *upper bound* is the one proposed in [9.254], which states that the capacity of the optical-fiber channel is upper bounded by $\log_2(1 + \mathrm{SNR})$—the capacity of an AWGN channel with same total accumulated noise. This has important theoretical and practical implications. In fact, it essentially leaves the capacity problem open, as the distance between the available lower and upper bounds diverges at high power, and stimulates the research to build communication systems that operate in the highly nonlinear regime with increased spectral efficiency. Nevertheless, despite significant research efforts, only small improvements with respect to the Gaussian AIR (the conventional NSL) have been demonstrated so far, which does not leave much room for optimism. Yet, some theoretical results suggest that more significant improvements might be possible, and that channel capacity might even increase unbounded with signal power.

One such result is the nondecreasing capacity lower bound [9.263], which states that the capacity of a discrete-time channel cannot decrease with power. This entails that the typical behavior of the capacity lower bounds discussed before—their decrease after some optimum power—is not a characteristic of the true channel capacity and should be more properly ascribed to the use of nonoptimized input distributions. For instance, the capacity bounds obtained with a Gaussian input distribution (e.g., the Gaussian AIR) are very tight at low power but vanish at high power, where, instead, satellite distributions [9.263] or ripple distributions [9.264] can be used to obtain nondecreasing lower bounds. This is a clear indication that, in a strongly nonlinear regime, conventional modulation formats are highly suboptimal, and that significant gains might be expected from the optimization of the input distribution.

Other important results in this sense are the demonstrations of the infinite asymptotic capacity (for $P \to \infty$) of some simplified channels related to the optical-fiber channel. This is the case, for instance, of the zero-dispersion fiber channel [9.265], of the memoryless FWM model [9.255] and of the RP model [9.260]. In all those cases, the Gaussian AIR has a finite maximum, but the (per symbol) capacity grows unbounded with power. This is still very far from a practical scheme that can guarantee such an unlimited capacity over a realistic fiber channel. Moreover, none of the previous results account for spectral broadening induced by fiber nonlinearity, such that a finite spectral efficiency limit can be still expected [9.266].

The asymptotic capacity of the optical fiber channel in the presence of signal–noise interaction is eventually investigated in [9.267], which suggests an alternative approach to address the capacity problem in this case.

9.13 Conclusion

The field of the investigation of the generation, characterization, and assessment of the impact of nonlinear fiber effects has been extremely active over the last 10–15 years. Undoubtedly, remarkably useful results and practical tools have been obtained and put at the community's disposal. Their use has become quite pervasive, both in transmission and in optical networking sectors.

Investigations are still ongoing. What is probably at the forefront of current research is the devising of mitigation techniques to suppress the nonlinear disturbance affecting signals. To this end, the current (and future) results obtained in modeling provide an indispensable tool. The next few years will certainly see further progress in mitigation, also because the DSP power that can be used in transceivers is still ramping up exponentially, so that sophisticated techniques that seemed to be unrealistically complex not long ago, are gradually becoming viable. This might lead to further substantial increase in the performance of optical transmission systems and networks.

9.A Conversion Among SNR, *Q*-Factor, MI and GMI for the AWGN Channel

The BER is related to the *Q*-factor by the following definition

$$Q\text{-factor} \triangleq 20\log_{10}\left[\sqrt{2}\,\mathrm{erfc}^{-1}(2\mathrm{BER})\right] \quad (\mathrm{dB})\,,$$

with erfc^{-1} the inverse of the complementary error function. The main advantage of the *Q*-factor is that it is linearly, or almost linearly, related to SNR with slope 1 in a dB/dB scale for several modulation formats, thus helping rule of thumb design.

The relation between BER and SNR is modulation format dependent. For the AWGN channel with square *M*-QAM, and by neglecting more than one bit error per symbol error, we have

$$\mathrm{BER} \cong \frac{2}{\log_2 M}\left(1-\frac{1}{\sqrt{M}}\right) \times \mathrm{erfc}\left(\sqrt{\frac{3}{2(M-1)}\mathrm{SNR}}\right), \quad \text{square QAM}\,. \tag{9.116}$$

The formula can be used even for BPSK with $M = 4$ but by multiplying the SNR by 2, since QPSK, aka 4-QAM, has the same minimum symbol distance as BPSK at twice SNR.

In the relevant case of a signal modulated with symbol rate *R* GBaud at 1550 nm and traveling in a *N* span periodic link with EDFAs of gain G_{dB} and a noise figure

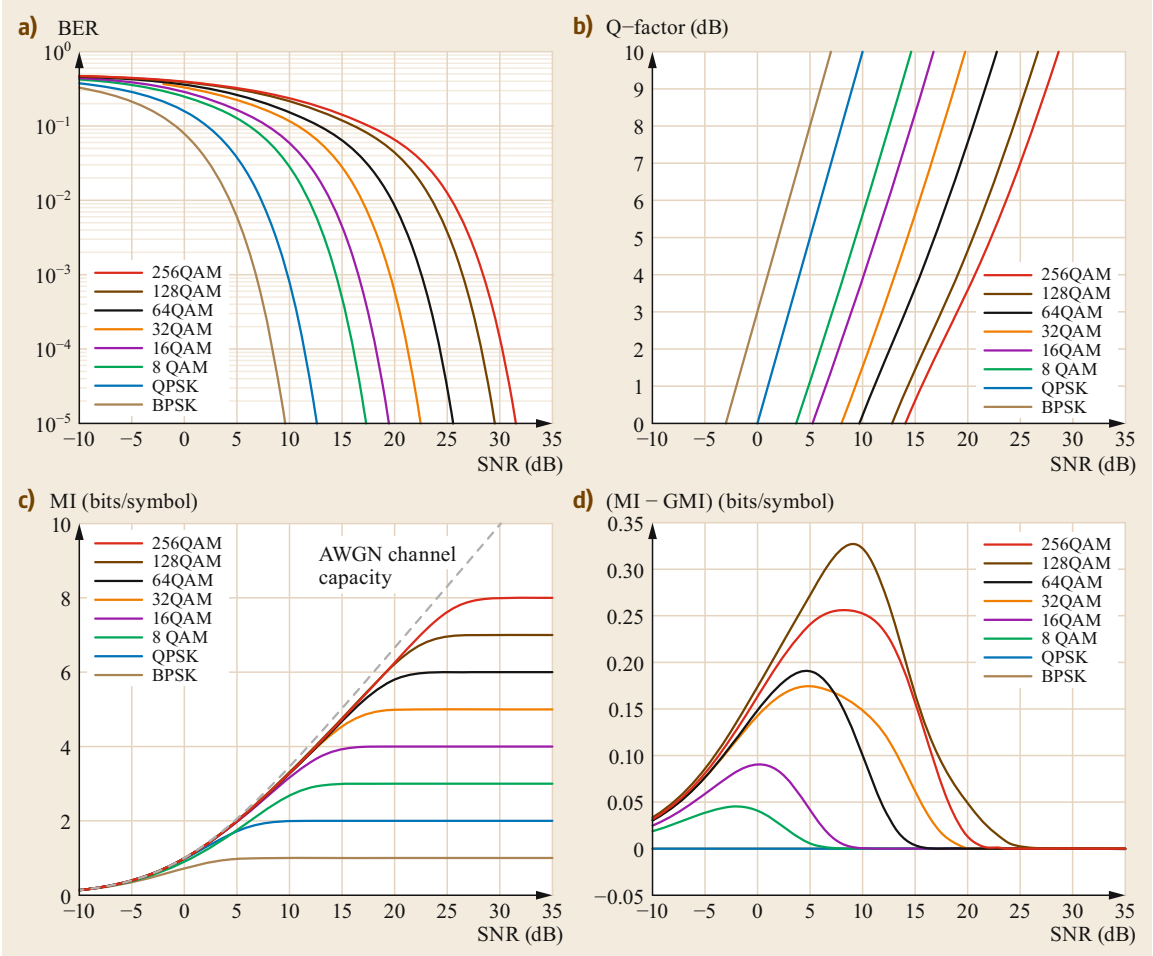

Fig. 9.29a–d Bit error rate (BER), *Q*-factor, mutual information (MI), and generalized mutual information (GMI) for the additive white Gaussian noise channel; 8 QAM is a rectangular QAM, 32 and 128 QAM are cross-QAM

F_{dB}, the SNR in dB is related to signal power P_{dBm} by

$$\mathrm{SNR}_{\mathrm{dB}} = P_{\mathrm{dBm}} + 58 - 10\log_{10} N - G_{\mathrm{dB}} - F_{\mathrm{dB}} - 10\log_{10}\frac{R_{\mathrm{GBaud}}}{12.5}\,.$$

If we neglect the last term accounting for R, we get the optical SNR (OSNR) that could be measured on an optical spectrum analyzer (OSA) over a bandwidth of 12.5 GHz (0.1 nm).

Figure 9.29 shows the relation between SNR, BER, MI, and GMI for the AWGN channel for the most popular modulation formats. We reported the difference between GMI and MI to better highlight the numerical values. The figure for single polarization is: for PDM without polarization crosstalk just multiply the MI and GMI values by 2.

The SNR mismatch between MI and GMI curves is a fraction of dB at practical code overheads. For instance, error-free transmission of single-polarization 64-QAM in AWGN is possible by using FEC with an overhead of 50% at SNR = 9 dB without BICM (i.e., at MI = 3 bits/symbol), or at SNR = 9.44 dB with BICM (i.e., at GMI = 3 bits/symbol). For smaller overhead the difference is smaller.

9.B Detailed List of Symbols, Notation, and Conventions

- z is the longitudinal spatial coordinate, along the link (km).
- α is the fiber *field* loss coefficient (km^{-1}), such that the signal *power* is attenuated as $\exp(-2\alpha z)$.
- α_{P} is the fiber power-loss coefficient (km^{-1}), with $\alpha_{\mathrm{P}} \triangleq 2\alpha$.
- β_2 is the dispersion coefficient ($\mathrm{ps}^2\,\mathrm{km}^{-1}$). The relationship between β_2 and the widely used dispersion parameter D in ps/(nm km) is: $D = -(2\pi c/\lambda^2)\beta_2$, with c the speed of light in km/s and λ the light wavelength in nm.
- γ is the fiber nonlinearity coefficient ($\mathrm{W}^{-1}\,\mathrm{km}^{-1}$).
- L_{s} is the span length (km).
- L_{eff} is the span effective length defined as: $[1-\exp(-2\alpha L_{\mathrm{s}})]/2\alpha$ (km).
- N_{s} is the total number of spans in a link, sometimes written as N_{span} when necessary for clarity.
- $G_{\mathrm{S}}(f)$ is the PSD of the overall WDM transmitted signal (W/Hz).
- $G_{\mathrm{NLI}}(f)$ is the PSD of NLI noise (W/Hz).
- N_{ch} is the total number of channels present in the WDM comb.
- P_n is the launch power of the n-th channel in the WDM comb (W). The power of a single channel is also sometimes written P_{ch} when necessary for clarity.
- R_n is the symbol rate of the n-th channel (TBaud). The symbol rate of a single channel is also written R, or R_{ch} when necessary for clarity.
- $T_n = R_n^{-1}$ is the symbol time of the n-th channel (ps).
- Δf is the channel spacing, used for systems where it is uniform (THz).
- $s_n(t)$ is the pulse used by the n-th channel, in the time domain. Its Fourier transform is $s_n(f)$. The pulse is assumed to be normalized so that the integral of its absolute value squared is T_n. (Note that according to such normalization a channel with an ideal rectangular spectrum and bandwidth R_n would have the flat-top value of its Fourier transform $s_n(f)$ equal to R_n^{-1}.) If any predistortion or dispersion precompensation is applied at the transmitter, this should be taken into account in $s_n(t)$ and $s_n(f)$.
- B_n is the full bandwidth of the n-th channel (THz). If the channel is Nyquist, then $B_n = R_n$.
- f_n is the center frequency of the n-th channel (THz).
- $a^k_{x,n}$, $a^k_{y,n}$ are random variables corresponding to the symbols sent on the n-th channel at the k-th signaling time, on either the polarization $\hat{x}$ or $\hat{y}$; note that $|a^k_{x,n}|^2$, $|a^k_{y,n}|^2$ must have dimensions of power (W). See also (9.63).
- $\mathbb{E}[.]$ is the expected value of a random variable.
- $F_{l,k,m}(\Omega_1, \Omega_2, \Omega_3)$ are kernels describing the NLI contribution resulting from FWN interaction between frequency tones Ω_1, Ω_2, and Ω_3. The SPM and XPM kernels are given by $S_{l,k,m} = F_{l,k,m}(0,0,0)$ and $X_{l,k,m}(\Omega) = F_{l,k,m}(0,\Omega,\Omega)$, respectively.
- $g_\Omega(z,t)$ represents the dispersed waveform of the pulse transmitted over a WDM channel spaced by Ω from the channel of interest, when reaching point z along the fiber; $\tilde{g}_j()$ represents the baseband spectral shape of the transmitted pulses from the j-th interfering WDM channel.
- $\boldsymbol{a}_n$ and $\boldsymbol{r}_n$ represent the transmitted and received polarization multiplexed data symbols of the channel of interest in the n-th time slot.
- $\boldsymbol{b}_{n,j}$ represents the two-element data vector transmitted in the n-th time-slot over the j-th interfering WDM channel.
- $\mathbf{H}_l^{(n)}$ are 2×2 matrices representing the l-th nonlinear ISI term in the n-th time slot.
- $h_{zs}(t)$ is the impulse response of a filter collecting all linear effects accumulated from coordinate z to coordinate s.

$R_{zs}(\tau)$ is the cross-correlation function between the electric field at coordinate z and coordinate s, i.e., $R_{zs}(\tau) = \mathbb{E}[A(z, t+\tau)A^*(s,t)]$.

$\kappa_{n;n}$ is n-th-order cumulant of data symbols a. They are also written as $\kappa_{2;2} = -\mu_2^2\Phi$ and $\kappa_{3;3} = -\mu_2^3\Psi$, with $\mu_2 = \mathbb{E}[|a|^2]$.

F is the noise figure (dB) of an EDFA.

P_{NLT} is the nonlinear threshold, i.e., the optimal launched power maximizing the SNR at the receiver.

η is the normalized nonlinear interference variance $(1/\mathrm{mW}^2)$, i.e., $\sigma^2_{\mathrm{NLI}} = \eta P^3$. For a single-span it is indicated by η_1.

ϵ is the coherence accumulation factor of nonlinear interference along the distance. It is $0 \leq \epsilon \leq 1$, where $\epsilon = 0$ and $\epsilon = 1$ indicate incoherent and fully-coherent accumulation, respectively.

N_0 is the system reach (spans) of an homogeneous optical link, i.e., the maximum distance for which the SNR is equal to a given threshold. The reach in km is $N_0 L_s$.

$\mathcal{L}$ is a linear operator accounting for dispersive effects, i.e., $\mathcal{L} = \mathrm{j}(\beta_2/2)(\partial^2/\partial t^2)$.

$\mathcal{N}$ is a nonlinear operator accounting for the nonlinear Kerr effect and fiber attenuation, i.e., $\mathcal{N} = -\alpha_{\mathrm{p}}/2 - \mathrm{j}\gamma|A|^2$. Fiber attenuation, although a linear effect, is included in the nonlinear operator to make the SSFM more efficient.

$h(X)$ is the differential entropy of the random variable X. It gives a measure of the average rate at which information is produced by X. The differential entropy is also called continuous entropy to emphasize focus on a continuous random variable X, contrary to the entropy that refers to a discrete random variable.

Alberto Bononi

Dipt. di Ingegneria e Architettura
Università degli Studi di Parma
Lesignano de' Bagni (Parma), Italy
alberto.bononi@unipr.it

Alberto Bononi received his PhD from Princeton University in 1994. He was an assistant professor at SUNY Buffalo before joining Parma University, Italy, in 1996, where he now serves as Full Professor in Telecommunications. His main research is in optical networks and optical transmission performance modeling.

Ronen Dar

Optical transmission systems
Nokia Bell Labs
Holmdel, NJ, USA
ronendar@yahoo.com

Ronen Dar received his PhD from Tel-Aviv University in 2015. During 2015–2017 he was a Member of Technical Staff in the optical transmission systems group at Nokia Bell Labs. He is coauthor of several patents in the fields of communication and coding and the recipient of several academic awards, including the Israeli Academy of Sciences and Humanities Adam's Fellowship.

Marco Secondini

Institute of Communication, Information and Perception Technologies
Sant'Anna School of Advanced Studies
Pisa, Italy
marco.secondini@sssup.it

Marco Secondini received his PhD from Scuola Superiore Sant'Anna, Pisa, Italy, in 2006. He visited the Photonics Group of the University of Maryland Baltimore County in 2005. He is currently an assistant professor at Scuola Superiore Sant'Anna and collaborates with the Photonic National Laboratory of the CNIT. His research is focused on the theoretical aspects of optical fiber communications.

Paolo Serena

Dipt. di Ingegneria e Architettura
Università degli Studi di Parma
Parma, Italy
paolo.serena@unipr.it

Paolo Serena received his PhD from the University of Parma, Italy, in 2003. He has been Assistant Professor at the same university since 2005. His main research interest is in optical communications, including fiber-optic transmission modeling in the nonlinear regime, numerical methods for efficient simulations, and performance estimation methods.

Pierluigi Poggiolini

Dept. of Electronics and Telecommunications (DET)
Politecnico di Torino
Torino, Italy
pierluigi.poggiolini@polito.it

Pierluigi Poggiolini recevied his MS (1988) and his PhD (1993) from Politecnico di Torino. He did his postdoc at Stanford University (1994–1995). He is currently Full Professor at Politecnico di Torino and is co-recipient of two best paper awards (IEEE/OSA Journal of Lightwave Technology, 2013 and 2014). His current interest lies in modeling of nonlinear effects in WDM coherent optical systems and application of neural networks to optical communications.

10. Space-Division Multiplexing

Roland Ryf, Cristian Antonelli

Fiber-based optical communication networks are reaching a point where the capacity required on a single link can significantly exceed the capacity of a single-mode fiber, and at the same time conventional network architectures can no longer be scaled cost-effectively. Space-division multiplexing (SDM) addresses the capacity bottleneck imposed by the use of single-mode fibers within a completely new approach that relies on new fiber types, optical amplifiers, and optical switches capable of supporting multiple spatial channels.

The aim of this chapter is, on one hand, to provide an overview of the components that are necessary for the implementation of SDM transmission and, on the other hand, to review the modeling of the main propagation effects that occur in multimode and multicore fibers. The chapter also includes a description of the techniques that are used in SDM transmission experiments and an update on transmission records reported from around the globe. The chapter ends with the description of potential architectures supporting SDM networks.

Optical communications over fiber networks are the backbone of our current communication infrastructure, and the essential network components and subsystems have been described in detail in Part A of this Springer Handbook. Fiber-optic networks have scaled in capacity over the years by first adding multiple wavelength channels, and most recently by increasing the spectral efficiency of the transmitted signals through advanced modulation techniques enabled by the introduction of digital coherent transceivers [10.1]. This allowed to use pulse shaping in combination with multilevel complex formats to optimize the use of the optical spectrum, as well as transmitting independent signals on two orthogonal polarizations of the electric field propagating in a single-mode fiber (SMF) (See Chaps. 4–7 for a detailed description). In this way, a single SMF is able to provide around 50 Tb/s for distances up to 10 000 km. This high capacity, which

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_10

was once considered much higher than required for telecommunications, is now becoming the bottleneck of the cloud-centric information-technology communication networks. It is therefore of paramount importance to identify and develop new technologies to increase the capacity of fiber-optic communication systems by 2–3 orders of magnitude, while simultaneously reducing the cost per bit of the transmitted data. As current state-of-the-art fiber-optic systems operate close to the theoretical capacity limit [10.1], this can only be achieved by increasing the number of parallel spatial channels, which is the aim of research in space-division multiplexing (SDM) [10.2–4].

The simplest approach to overcome the capacity limit of SMFs is using traditional single-mode systems operated in parallel. However, this approach results in costly and inflexible optical networks.

Significant cost reductions can be expected by better integrating components at various levels, in particular by sharing components whenever possible or placing multiple devices in a single planar waveguide circuit or in a common free-space subsystem.

Integration offers great opportunities for cost reduction, most remarkably for transponders, which represent a significant expense in a transmission system and require large numbers of wavelength and spatial channels (presently an independent line card is used for each wavelength channel).

Optical amplifiers supporting multiple spatial channels also offer a great potential for integration: starting from simple parallel erbium-doped amplifiers sharing some components and control boards, to advanced pump-sharing schemes like for example cladding pumped amplifiers, where a common pump is guided in the fiber cladding and the signals to be amplified are guided in the fiber cores.

Optical switches, which are the basic building blocks of optical networks, can also be modified to support systems with multiple spatial channels. In particular, the concept of *joint switching* means a beam-steering-based switching element (for example microelectro-mechanical system (MEMS) mirror arrays, or liquid crystal on silicon (LCOS) pixel arrays) can be used to switch multiple spatial channels simultaneously.

At the physical transmission level, consisting of the optical fiber, it is also possible to utilize waveguide structures that support multiple spatial modes, either by using single cores that support multiple modes, or by adding multiple cores in the common cladding of an optical fiber. While the single-mode fiber transmission channel is very well known in terms of both the linear (chromatic dispersion, polarization-mode dispersion, and Rayleigh scattering) and nonlinear (Kerr effect, stimulated Raman scattering, and stimulated Brillouin scattering) effects, the characterization of the same propagation effects can become fairly complex if multiple modes are involved, as all possible intermodal interactions have to be accounted for. Modeling propagation effects in fibers supporting multiple modes is an imperative step towards the assessment of the transmission capacity in SDM systems.

10.1 Basic Concepts in Space-Division Multiplexed Optical Networks

Adding spatial channels to traditional wavelength-division multiplexed (WDM) networks can significantly affect the overall network complexity, as both the wavelength and space dimensions can be used for the routing of optical signals. Current network architectures are also often constrained by reliability requirements: for example, networks are designed such that a single failure at any component level can always be overcome by either a protection scheme (where a second independent physical path is available) or a restoration scheme (where a second independent path is configured when needed). Using multiple independent spatial paths provides more flexibility to overcome failure by appropriately designing and operating the network.

Finally, at a physical point-to-point link level, fibers supporting multiple light paths, like multimode and multicore fibers, can be utilized to reduce the component count by integrating functionalities in the spatial domain.

Routing in optical networks, network reliability, and point-to-point link engineering are not independent of each other, and the three domains have to be optimized jointly, which makes SDM networking a formidable challenge with no obvious winning network architecture, but rather with multiple possible solutions that depend on the specific network requirements.

In this chapter, we focus on SDM point-to-point links (Sect. 10.2) and routing in SDM networks (Sect. 10.8), as these two topics are key for understanding SDM networks.

10.2 SDM Point-to-Point Links

An SDM point-to-point link is schematically described in Fig. 10.1. It includes the following main components: A bank of transmitters $\mathrm{Tx}_{n,m}$, a multiplexing device that encodes N spatial channels and M wavelength channels into the physical spatial and wavelength channels, an SDM fiber possibly followed by K sections, each consisting of an optical amplifier and an SDM fiber span. At the end of the transmission fiber, a demultiplexing device splits all transmitted channels by spatial and wavelength channels, and the individual channels are received by a bank of single-mode receivers $\mathrm{Rx}_{n,m}$. The subscripts $n \leq N$ and $m \leq M$ in Fig. 10.1 are the indices of the spatial and wavelength channels, respectively.

Note that spatial and wavelength channels are not equivalent: Wavelength channels are formed by arbitrarily allocating portions of the continuous optical spectrum, whereas spatial channels are in a one-to-one correspondence with a discrete set of modes or cores of the transmission fiber. This has important implications for optical switching as we will see in Sect. 10.8. Additionally, there is also a fundamental difference between spatial and wavelength channels concerning crosstalk: Optical fibers do not introduce linear crosstalk between different wavelength channels (nonlinear effects can potentially do so, but we will neglect nonlinear effects in this stage), whereas linear crosstalk can be present between spatial channels, particularly if the spatial channels are arranged very closely, like in multicore fibers, where light can couple between neighboring cores, or in multimode fibers, where the modes spatially overlap and coupling can be produced by fiber imperfections. In practice, the presence of crosstalk between spatial channels, is not detrimental for optical transmission. In fact, the crosstalk between spatial channels can be undone using digital signal processing (DSP) techniques, which are similar to multiple-input-multiple-output (MIMO) algorithms used in wireless networks. A major advantage of optical fibers, as compared to the wireless channel, is that they have very low loss, and often also very low difference in loss between modes, which results in an almost unitary MIMO channel, which according to information theory, provides N times the capacity of a single channel, where N is the number of spatial channels. MIMO transmission is particularly effective if the received signals are detected using polarization-diverse coherent receivers (PD-Rxs), which are able to measure amplitude and phase for both polarizations of the received spatial channels. In fact, in the case where all modes guided by the fiber under test are detected using PD-Rxs, the optical field impinging upon the receiver is fully known and propagation-induced impairments (most effectively unitary linear effects) can be compensated for in the digital domain. The MIMO DSP that is necessary to undo linear impairments, is a generalization of the 2×2 MIMO implemented in commercially available digital coherent transceivers (Chap. 6), where $2N\times2N$ MIMO is required for N coupled spatial modes, and additionally a larger number of equalizer memory (taps) is needed owing to the fact that, as discussed in the next section, the group velocity difference between modes in multimode optical fibers is several orders of magnitude larger than the group velocity difference between the two polarizations of a single-mode fiber. The design of SDM fibers is therefore often optimized to make the magnitude of the group velocities of all the fiber modes as close as possible. Note that in the case of multimode fiber, this optimization is very similar to that performed on commercial OM3 and OM4 multimode fibers used for short-reach interconnects, where the difference in group velocities between modes can limit transmission reach and bandwidth [10.5–7].

Coherent MIMO transmission over SDM fiber can maximize the transmission capacity of the fiber close to the theoretical limit imposed by information theory under any crosstalk condition. The crosstalk in the n-th mode $X_\mathrm{t}(n)$ is defined as

$$X_\mathrm{t}(n) = \frac{\sum_{m\neq n} P_{m,n}}{P_{n,n}}\,, \tag{10.1}$$

where $P_{m,n}$ is the power transfer matrix between an excited mode m and a mode n received after transmission

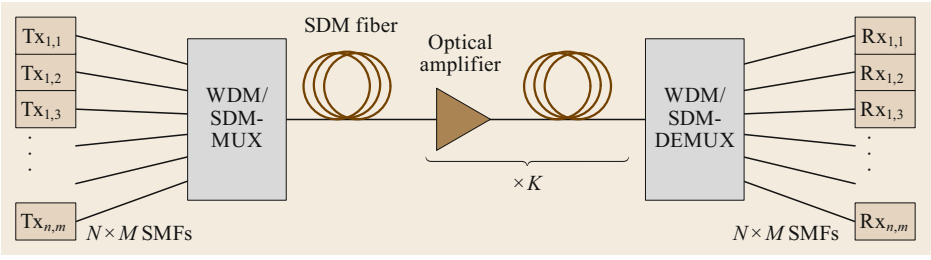

Fig. 10.1 Point-to-point combined WDM/SDM transmission

Table 10.1 Maximum acceptable crosstalk level for an additive system penalty obtained at a BER of 10^{-3} for quadrature phase-shift keying (QPSK) modulation and various quadrature-amplitude modulation (QAM) formats (after [10.8])

Acceptable system penalty	Max crosstalk (dB)			
	QPSK	16 QAM	64 QAM	256 QAM
1 dB	−17	−23	−29	−35
3 dB	−12	−18.5	−25	−31

through the fiber. The added complexity of the MIMO DSP, even if within the realm of modern ASIC technology, is often undesirable, and alternatively SDM fibers can be designed so that the crosstalk between spatial channels is reduced to levels where electronic crosstalk mitigation is no longer required. In Table 10.1 we report the maximum acceptable crosstalk level for an added system penalty (degradation of the quality factor Q of the transmitted signal) of 1 and 3 dB, respectively, at a bit-error ratio (BER) of 10^{-3} [10.8], which using state-of-the-art hard-decision forward error correction (FEC) is sufficient to obtain error-free performance (post-FEC BER $< 10^{-12}$).

This is of particular interest in the case of a system based on the use of multicore fibers where distances over 10 000 km have been achieved without MIMO processing. We will refer to this technique as transmission in the *low-crosstalk regime*. Note that the low-crosstalk regime is challenging not only for the fiber, but also for all the in-line optical components, connectors and splices, which also have to meet the low-crosstalk requirement. This is sometimes a limiting factor for the level of integration that can be achieved.

Alternatively, it is also possible to combine MIMO-based transmission with the low-crosstalk regime as not all modes will show the same amount of coupling between each other and the total number of spatial channels can then be separated into groups, where strong coupling is present within the groups and little crosstalk is observed between the groups. This technique is used in multimode fibers for distances smaller than 100 km and also in multicore fibers with few-mode cores (few-mode multicore fibers (FM-MFCs)), where MIMO is performed across the core modes of each core but not across the core modes of different cores, and distances up to 1000 km have been demonstrated [10.9, 10].

In the following sections, we discuss in more detail the components of a point-to-point SDM link.

10.2.1 SDM Fibers

The single-mode fiber has been the work horse of high-capacity long-distance communications for over three decades. It is also the most common and lowest-cost glass fiber (Chap. 2), mostly because of its favorable optical properties, like low loss and large bandwidth (tens of THz). A common way to increase the capacity of optical links is therefore the use of single-mode fiber ribbons. Fiber ribbons can be spliced with commercial ribbon splicer and containerized, therefore offering advantages in high fiber-count cables, and cables with over 3000 fibers are commercially available. Recently, it has been proposed to increase the capacity of the fiber-optic channel using the following fiber types:

- Multicore fibers: fibers with multiple cores
- Multimode fibers: fibers with cores supporting multiple modes.

Both fiber types are well known and have been proposed for various applications, like sensing, endoscopy, and short-reach interconnects, but a significant effort was recently devoted to optimizing the fiber design to support long-distance transmission.

Multicore Fibers

Since low-crosstalk multicore fibers (MCFs) have been successfully engineered, various techniques to further reduce the crosstalk between cores have been investigated. These include, for example, the use of trenches and holes around the cores and the use of heterogeneous cores, where neighboring cores are designed with different propagation constants. Additionally, bidirectional transmission can be used, where neighboring cores carry signals propagating in opposite directions. Nevertheless, the maximum number of cores in multicore fibers is limited by the cladding diameter. Increasing the cladding diameter substantially above the standard diameter of 125 µm results in more fragile fibers with reduced reliability, and practical cladding diameters for long-distance communication are limited to around 250 µm maximum cladding diameter. Additionally, larger core density can be achieved in multicore fibers by reducing the effective area of the cores, which however reduces the transmission performance of the fiber. Multicore fibers with more than 30 cores [10.11] have been demonstrated for a distance up to 1645 km ultrahigh-capacity transmission, and longer distances can be achieved by reducing the core count to 12 cores, where distances up to 8800 km have been demonstrated [10.12]. Multicore fibers can be spliced using splicers designed to support polarization-maintaining fibers, but the nonstandard cladding diameters require customized fiber holders. Also, the core alignment is typically less accurate than in the case of single-mode fiber splices, particularly for cores located far from the fiber center, which are susceptible to fiber rotation er-

rors, resulting in slightly larger splicing losses (up to 1 dB). Multicore fibers can be connectorized and prototype connectors have been demonstrated [10.13].

Alternative multicore fibers can be operated in the so-called *coupled-core* regime, where the distance between cores is made small, such that the cores become coupled. The coupled-core multicore fiber (CC-MCF) will therefore behave more like a microstructured fiber supporting multiple modes. It is important to point out that coupled-core fibers show an optimum core spacing, where the properties of the modes are such that the fiber perturbations cause strong random coupling between the modes, while the modal group-velocity difference is still moderately small. This effect is described in detail in Sect. 10.3.3.

Multimode Fibers

Multimode fibers (MMFs) consist of fibers with a single core that is either larger in diameter or has a larger refractive index compared to an SMF, such that the fiber can support more than one mode. The modes can then be potentially used as independent transmission channels, and fibers with 100 or more modes can be easily produced. Various refractive index designs of the core have been proposed to support SDM, like step-index and multistep index profiles, graded-index profiles, and ring-core fibers.

Two design strategies have been pursued for multimode fibers. The first strategy is to minimize the group delay difference between the supported fiber modes. For few modes this is possible by using multistep index fibers, like for example a depressed-cladding design in the case of three spatial modes [10.14]. For larger numbers of modes, cores with a graded-index profile provide an optimum solution, and fibers with up to 45 modes at 1550 nm wavelength have been demonstrated using 50 μm core diameters [10.5–7]. The fibers are very similar in design and manufacturing to commercially available graded-index fiber optimized for 850 nm wavelength and referred to as OM3 and OM4 fibers in commercial products, which are amply used for short-reach interconnects, for example in datacenters. Graded-index multimode fibers have a typical residual group delay difference of around 100 ps/km [10.15, 16], which for long-distance communication that can reach up to 10 000 km would result in up to 1 μs of maximum delay between modes. Fortunately, the crosstalk between modes strongly reduces the effect as explained in Sect. 10.5.1, such that impulse response widths in the order of tens of nanoseconds are experimentally observed. Using low group delay multimode fibers, transmission distances up to 4500 km have been demonstrated using 3 spatial modes [10.17], whereas experiments with up to 45 spatial modes [10.18, 19] have been reported for shorter fiber lengths. The second design strategy aims to reduce the coupling between modes and use the modes as independent transmission channels. The main goal in this case is to increase the difference in phase velocity between modes by optimizing the index profile. The phase velocity of a mode describes the speed at which the optical phase front travels in the fiber (a formal definition is given in Sect. 10.3). This approach can yield a significant crosstalk reduction, particularly between nearly degenerate modes, however fiber manufacturing imperfections, geometrical deformations like bending and twisting, and Rayleigh scattering limit the achievable crosstalk reduction, with the smallest reported crosstalk levels being of the order of −30 to −40 dB/km, and the longest transmission distance demonstrated being about 50 km. Low-crosstalk fibers are of interest for short-distance applications (< 100 km).

We note that alternative fiber designs aiming to avoid degeneracy between modes have been proposed, for example by using elliptical cores [10.20–22], or high-contrast ring-core fiber designs [10.23], which allows accessing and using all fiber modes without any MIMO digital signal processing.

10.2.2 Mode Multiplexers and Fiber Couplers

Mode multiplexers (MMUXs) are devices that couple multiple single-mode fibers into the modes of a multimode fiber. There are two types of MMUXs: The so-called *mode-selective device* directly couples a given single-mode fiber with a specific fiber mode, whereas the *nonmode-selective device*, associates different single-mode fiber with different orthogonal linear combinations of modes. For coherent MIMO transmission a nonmode-selective MMUX can be utilized with no disadvantage, whereas in some specific cases, like for example transmission with low-crosstalk between mode groups, or for modal delay compensation, mode-selective MMUXs with high modal selectivity are required.

Since fiber modes are orthogonal to each other (the definition of mode orthogonality is provided in Sect. 10.3), it is theoretically possible to separate modes in a lossless way, similarly to the way in which a polarizing beam splitter can separate two polarization components, or a diffraction grating can separate different wavelengths. Numerous techniques have been proposed and demonstrated for realizing mode multiplexers [10.25–33]. In what follows, we describe two of the most promising techniques.

The Photonic Lantern

Photonic lanterns (PLs) provide an adiabatic transition between N single-mode fibers and a step-index

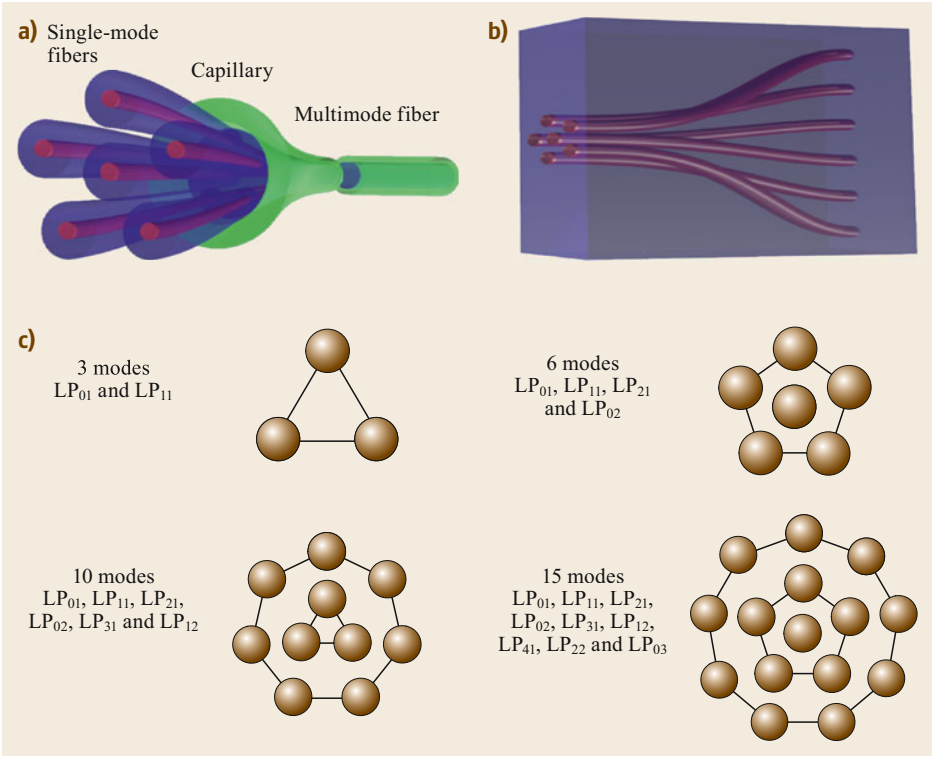

Fig. 10.2 (a) Principle of the fiber-based photonic lantern. (b) Photonic lantern implemented using laser-inscribed waveguides. (c) Core arrangement matching linearly polarized (LP) modes of multimode fibers with 3, 6, 10, and 15 spatial modes [10.24]

multimode fiber [10.24, 31, 32, 34–36]. This device is manufactured by using a glass processor starting from N single-mode fibers inserted in a low refractive index capillary. The composite structure is then continuously reduced in size (tapered) in the glass processor so that the cores of the single-mode fibers vanish and the claddings form the new core, whereas the low-refractive-index capillary forms the new cladding (Fig. 10.2a).

The end section of the PL can then be directly spliced to a multimode fiber with a matching core geometry. In order to map the correct modes between the single-mode and the multimode end, the SMFs have to be arranged into specific spatial patterns (Fig. 10.2c). Arranging the fibers according to these patterns is easily achieved for MMUXs up to six spatial modes, where the single-mode fibers self-arrange in the capillary. Photonic lanterns supporting a larger number of modes are fabricated more easily by using a drilled low-refractive-index preform instead of the capillary, where the fiber is held in the correct location by the drilled holes. This way MMUXs up to 15 spatial modes have been demonstrated [10.37]. Mode-selective PLs can be achieved by starting from nonidentical single-mode fibers, either by slightly changing the core diameter or the refractive index difference between the core and cladding of the single-mode fibers [10.31, 32, 38]. In this way, for example, the single-mode fibers with the lowest effective refractive index can be matched with the fiber mode that also has the lowest effective refractive index and a mapping between modes and the input SMF can be achieved. Photonic lanterns are of interest because devices with low insertion loss and low mode-dependent loss (MDL) can be achieved. For example, an MMUX supporting three spatial modes can have an insertion loss of less than 0.5 dB and less than 3 dB MDL (in short MDL is defined as the power ratio in dB between the least and most attenuated linear combinations of modes—see Sect. 10.5.2 for a more extended description). The corresponding values for six and ten modes are slightly larger, but PL technology is still the best performing in terms of loss.

Photonic lanterns can also be realized by using femto-second laser-inscribed three-dimensional waveguides (Fig. 10.2b), where waveguides are written into a glass substrate and brought close to each other arranged as shown in Fig. 10.2c, so that the waveguides almost merge [10.39]. In particular, there is an alternative design for the laser-inscribed PL, referred to as taper velocity couplers [10.40], where the inscribed waveguides are tapered within the coupling section. MMUXs fabricated this way are commercially available, and offer the advantage of being compatible with planar waveguide technology, as the input waveguide can be arranged in any desired geometry.

The Multiplane Light Conversion Mode Multiplexer

Multiplane light conversion has been proposed as a universal mode-converting device capable of transforming any input mode set into any output mode set [10.33]. This functionality is achieved by having the light traversing multiple phase-only transmission masks, each followed by a free-space transmission section. The number of required masks depends on the desired transformation, but fortuitously, one of the transformations of biggest interest in mode-division multiplexing, which is the transformation from spatially separated spots into Laguerre–Gaussian beams (which are in close approximation to the modes of a graded-index multimode fiber, as will be seen in the following sections), can be achieved with less than ten phase masks. Also, in practice, multiplane devices are implemented using a reflective geometry, where light is reflected multiple times between two planes: one plane consists of a substrate containing multiple phase masks, and the second is a high-reflectivity mirror. A schematic arrangement for a mode-multiplexer is shown in Fig. 10.3.

Using this technology, MMUXs with large mode selectivity have been realized with up to 45 spatial modes [10.41, 42], and proof-of-principle devices with up to 210 spatial modes using only 7 phase masks have been demonstrated [10.43]. Multiplane-based MMUXs offer great flexibility but up-to-date products and prototypes could not yet match the low-loss level of photonic lanterns. However, since theoretically they are lossless elements, lower loss devices can be expected by using a coating with higher reflectivity and improved mask fabrication and designs.

10.2.3 SDM Amplifiers

Optical amplifiers that support multiple spatial paths can be designed in several ways. A simple collocation of multiple erbium-doped fibers in a single module can already provide significant cost savings by sharing components and control electronics. Additionally, it is possible to share pump lasers and use arrays of integrated optics components like taps and detectors for power level monitoring. A higher level of integration is possible when using multimode or multicore erbium-doped fibers. It is then possible to extend the functionality of free-space optics-based components like for example optical isolators or gain-equalizing filters to support multiple modes or cores without the need for mode multiplexers or fan-in/fan-out devices in the case of multimode- and multicore fibers, respectively.

Multimode erbium-doped fibers, typically require a precisely controlled doping profile and/or specific modal excitation of the pump laser in order to achieve a similar gain for each mode of interest [10.44–47]. The situation is more advantageous in multicore doped fibers, where pump lasers are coupled into the individual doped core of the multicore fiber. The gain and noise figure of the core-pumped multicore amplifiers is expected to be comparable to traditional single-mode erbium-doped amplifiers, but the pump couplers will require at least one set of fan-in devices to couple the pump laser.

A particularly promising alternative approach to building optical amplifiers with multiple spatial channels is based on cladding pumping. In cladding pumping, a multimode high-power pump laser at 980 nm wavelength is coupled to the cladding of the amplifying fiber, which results in a homogeneous illumination of the entire fiber cross-section. The cores, which are erbium-doped, absorb the pump light and amplify the guided signals (Fig. 10.4).

The multimode pump can be coupled to the cladding by using the so-called *side-pumping* configuration, which consists of bringing a tapered multimode fiber carrying the pump light into contact with the external cladding of the amplifying fiber. Coupling efficiency of $> 80\%$ can be achieved without using traditional dichroic combiners.

Cladding pumping can be applied to both multicore and multimode fibers. In multicore fibers, all cores are illuminated by the pump light, which can produce homogeneous gain. This is advantageous compared to core pumping, where for each core the pump light has

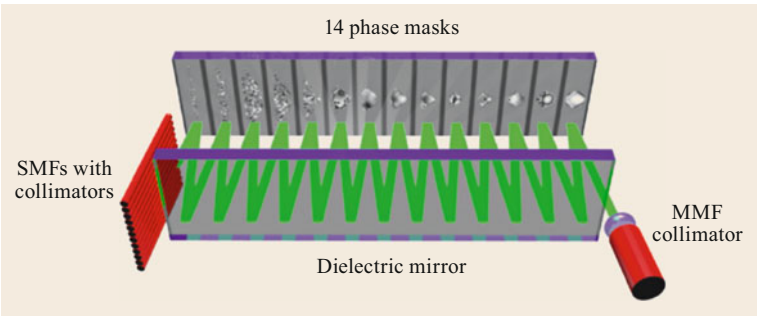

Fig. 10.3 Multiplane light converter configured as a mode multiplexer: Each single mode fiber (SMF) on the left-hand side will couple to a particular mode of the multimode fiber (MMF) on the right-hand side [10.41]

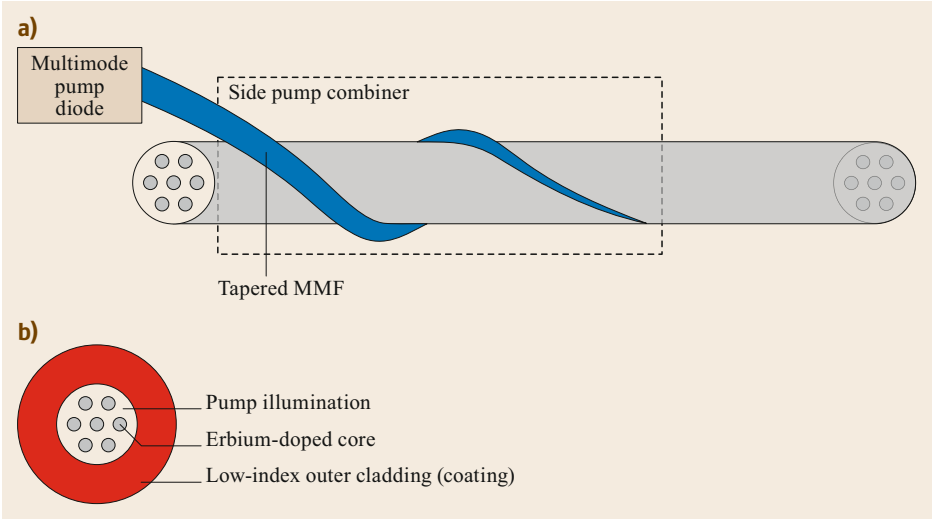

Fig. 10.4a,b Cladding pump amplifier scheme: **(a)** Side-pumping arrangement where a multimode pump is coupled into the cladding of a multicore fiber to homogeneously illuminate the cladding; **(b)** cross-section of multicore fiber showing the different fiber regions and the low-index coating used to confine the pump light

to be independently combined and coupled [10.48]. In order to minimize the gain variation between cores in cladding-pumped amplifiers, the core properties have to be precisely matched. Alternatively, variable gain attenuators (VOAs) acting on each core separately can be used in combination with a dynamic gain equalizing filter (DGEF), for example using an LCOS-based device [10.49]. Furthermore, cladding-pumped amplifiers, are typically operated in a nonsaturated output power regime, and therefore can naturally provide constant gain independently of the input power, which is desirable in optical networks to reduce the effect of transients caused by partial network failures. A drawback of operating the amplifier in a nonsaturated regime is however a reduced power efficiency of the cladding pump amplifier, which can in principle be overcome by means of pump-recycling schemes [10.50] able to reuse the pump light that is not absorbed by the cores at the end of the amplifying fiber (which otherwise is just dumped into free-space and absorbed).

Cladding pumping is advantageous also for multimode amplifiers: A homogeneous gain for all modes can be achieved by using a cladding pumping and in combination with a simple doping profile with constant erbium concentration across the whole core region [10.51, 52].

10.2.4 SDM Transceivers

Transceivers for SDM differentiate themselves from state-of-the-art single-mode digital coherent transceivers in two ways.

The first main difference is that additional DSP capabilities are required to support multiple modes, and a longer memory is necessary to accommodate larger group-delay differences in the MIMO DSP. Also, in order to simultaneously process multiple MIMO channels, a higher integration density of high-speed analog-digital converters (ADCs) is required. Note that the complexity of a conventional SMF digital coherent transceiver is dominated by the chromatic dispersion compensation (approximately 30%) and forward-error correction sections (approximately 25%), whereas the 2×2 MIMO section implies relatively little complexity (approximately 10%). Therefore, if the added complexity of the MIMO DSP grows hypothetically by one order of magnitude, the overall DSP complexity only increased by a factor of 2 per mode (see [10.53] for a detailed analysis).

The second main difference is that transceivers in a conventional WDM system require a tunable laser for each transceiver in order to cover the full wavelength channel map. Once the spatial dimension is added, it is in principle possible to share a single tunable laser among multiple spatial channels [10.54]. This is of particular interest in MIMO-based channels, where all spatial channels are treated as a single end-to-end MIMO transmission channel [10.55].

Additionally, the large count of basic components required in an SDM transceiver, like high-speed ADCs and digital-to-analog converters (DACs), modulators and optical coherent receivers, offers a great cost-saving potential through the integration of large pools of transceivers.

10.3 Fiber Modes

The modes of an optical fiber are the solutions of Maxwell's equations for electro-magnetic waves traveling along the propagation axis z of a dielectric waveguide characterized by some transversal refractive index profile. These solutions are invariant in the z-direction up to a phase term $\exp(\mathrm{j}\beta_n z)$, where n is the mode number and β_n is corresponding propagation constant. A single-mode electromagnetic field generated by a monochromatic source at the angular frequency ω_0 can be expressed as

$$\begin{aligned}\boldsymbol{E}_n(x,y,z,t) &= \mathrm{Re}\left[\boldsymbol{F}_n(x,y,\omega_0)\mathrm{e}^{\mathrm{j}(\beta_n z-\omega_0 t)}\right],\\ \boldsymbol{H}_n(x,y,z,t) &= \mathrm{Re}\left[\boldsymbol{G}_n(x,y,\omega_0)\mathrm{e}^{\mathrm{j}(\beta_n z-\omega_0 t)}\right],\end{aligned} \tag{10.2}$$

where $\boldsymbol{E}_n$ and $\boldsymbol{H}_n$ are real-valued three-dimensional vectors that represent the electric and magnetic field, respectively. The complex-valued vectors $\boldsymbol{F}_n$ and $\boldsymbol{G}_n$ are the corresponding lateral modal field distributions, and they are solutions of the Helmholtz equation in the form [10.56, 57]

$$\Delta_\mathrm{T}\boldsymbol{F}_n + \frac{\omega_0^2}{c^2}n^2(x,y)\boldsymbol{F}_n = \beta_n^2\boldsymbol{F}_n\,, \tag{10.3}$$

$$\Delta_\mathrm{T}\boldsymbol{G}_n + \frac{\omega_0^2}{c^2}n^2(x,y)\boldsymbol{G}_n = \beta_n^2\boldsymbol{G}_n\,, \tag{10.4}$$

where $n(x,y)$ is the transversal refractive index profile, c is the speed of light in a vacuum, and $\Delta_\mathrm{T} = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the transversal Laplace operator. Note that the first of the two equations is only exact if $\nabla\cdot\boldsymbol{E} = 0$, whereas in general $\nabla\cdot\boldsymbol{E} = -2\nabla\left[\log(n)\right]\cdot\boldsymbol{E}$, as follows from $\nabla\cdot\boldsymbol{D} = 0$ ($\boldsymbol{D}$ is the electric displacement vector). The condition $\nabla\cdot\boldsymbol{E} = 0$ is fulfilled exactly for step-wise constant refractive index profiles, and only approximately for slowly varying refractive index profiles.

In most cases that are of practical relevance, the fiber modes have to be calculated with numerical methods, and they fulfill the orthogonality condition [10.56]

$$\iint \mathrm{d}x\mathrm{d}y\left(\boldsymbol{F}_n\times\boldsymbol{G}_m^*\right)\cdot\hat{\boldsymbol{z}} = 2\mathcal{N}_n^2\delta_{n,m}\,, \tag{10.5}$$

where $\hat{\boldsymbol{z}}$ is a unit vector pointing in the propagation direction, $\delta_{n,m}$ is the Kronecker delta, and $\mathcal{N}_n$ is a normalization factor that is discussed later in the chapter. The orthogonality condition is used to decompose any electric and magnetic field at the fiber input characterized by the lateral profiles $\boldsymbol{\mathcal{F}}_\mathrm{fs}(x,y)$ and $\boldsymbol{\mathcal{G}}_\mathrm{fs}(x,y)$, respectively, as a linear combination of the fiber modes by using the following relations

$$\begin{aligned}\boldsymbol{\mathcal{F}}_\mathrm{fb}(x,y) &= \sum_{n=1}^{N} a_n\boldsymbol{F}_n(x,y)\,,\\ \boldsymbol{\mathcal{G}}_\mathrm{fb}(x,y) &= \sum_{n=1}^{N} a_n\boldsymbol{G}_n(x,y)\,,\\ a_n &= \iint \mathrm{d}x\mathrm{d}y\frac{\boldsymbol{\mathcal{F}}_\mathrm{fs}\times\boldsymbol{G}_n^*}{2\mathcal{N}_n^2}\cdot\hat{\boldsymbol{z}}\\ &= \iint \mathrm{d}x\mathrm{d}y\frac{\boldsymbol{F}_n^*\times\boldsymbol{\mathcal{G}}_\mathrm{fs}}{2\mathcal{N}_n^2}\cdot\hat{\boldsymbol{z}}\,,\end{aligned} \tag{10.6}$$

where the subscripts fs and fb refer to the input field in free space and to the guided field in the fiber, respectively.

Different modes have different propagation constants, unless they are degenerate. It is customary to represent each propagation constant as a Taylor expansion around the central frequency ω_0

$$\begin{aligned}\beta_n = \beta_{n,0} &+ \beta_{n,1}(\omega-\omega_0) + \frac{1}{2}\beta_{n,2}(\omega-\omega_0)^2\\ &+ \frac{1}{6}\beta_{n,3}(\omega-\omega_0)^3 + \ldots\end{aligned} \tag{10.7}$$

The different terms have the following physical interpretation. The first term is related to the phase velocity $v_{\mathrm{ph},n}$,

$$v_{\mathrm{ph},n} = \frac{\omega_0}{\beta_{n,0}}\,, \tag{10.8}$$

which describes the speed of the phase front of the propagating field. When two modes travel at the same phase velocity, energy can be exchanged and the coupled light is kept in phase over a long propagation distance. For pairs of modes with different phase velocities it is possible to define a beat length,

$$L_{n.m} = \frac{2\pi}{|\beta_{n,0}-\beta_{m,0}|}\,, \tag{10.9}$$

so that the accumulated phase difference between the two modes is $\Delta\phi = 2\pi z/L_{n,m}$, and the two modes are periodically in phase with the period being equal to the beat length. The second term of (10.7) yields the group velocity

$$v_{\mathrm{gr},n} = \frac{1}{\beta_{n,1}}\,, \tag{10.10}$$

which describes the speed of a light pulse traveling in mode n. The arrival time difference for two pulses trav-

eling in modes n and m, respectively, of a fiber of length ℓ is known as the differential group delay (DGD)

$$\mathrm{DGD}_{n,m} = \ell|\beta_{n,1} - \beta_{m,1}| \,. \tag{10.11}$$

The third term of (10.7) is related to the chromatic dispersion coefficient $\mathrm{CD}_n = (2\pi c/\lambda_0^2)\beta_{n,2}$, $\lambda_0 = 2\pi c/\omega_0$. Chromatic dispersion is responsible for the intramodal frequency dependence of the group velocity, which causes temporal pulse broadening even in the case when only a single mode is transmitted.

10.3.1 Modes of a Step-Index Fiber

The simplest optical fibers are based on a step-index profile, where the refractive index in polar coordinates is given by

$$n(r) = \begin{cases} n_c, & \text{if } 0 < r \le a \,, \\ n_0, & \text{if } r > a \,, \end{cases} \tag{10.12}$$

where a is the fiber core radius, and $r = \sqrt{x^2 + y^2}$. For step-index fibers the solution of (10.3) and (10.4) is known to be given by the Bessel function $J_n(r)$ in the core region, and by the modified Bessel function of the second kind $K_n(r)$ in the cladding region. Even if the solutions are known within each refractive index region, numerical methods have to be used to solve the boundary condition problem between core and cladding. The solutions for the first four mode groups of a step-index fiber are shown in Fig. 10.5.

The fundamental mode HE_{11} is degenerate in polarization, meaning that two modes with orthogonal polarizations, but with the same lateral profile and propagation constants are supported by the fiber. The next modes TM_{01} and TE_{01} are nondegenerate, and their polarization is position-dependent. The following HE_{21} mode is two-fold degenerate and can be represented as a linear combination of polarizations, by using circularly polarized light resulting in a ring-looking intensity profile (similar to TM_{01} and TE_{01}), but with a phase term of the form $\exp(\pm \mathrm{j}\varphi)$, where φ is the angle in polar coordinates. We note that fiber modes are often referred to as optical angular momentum (OAM) modes [10.23]. However, not all fiber modes can be represented as OAM modes, in particular TM_{0n} and TE_{0n} are not compatible with OAM modes [10.58], and also the concept of OAM modes breaks down when the effective index contrast is such as to break the degeneracy of the HE_{nm} modes [10.59, 60].

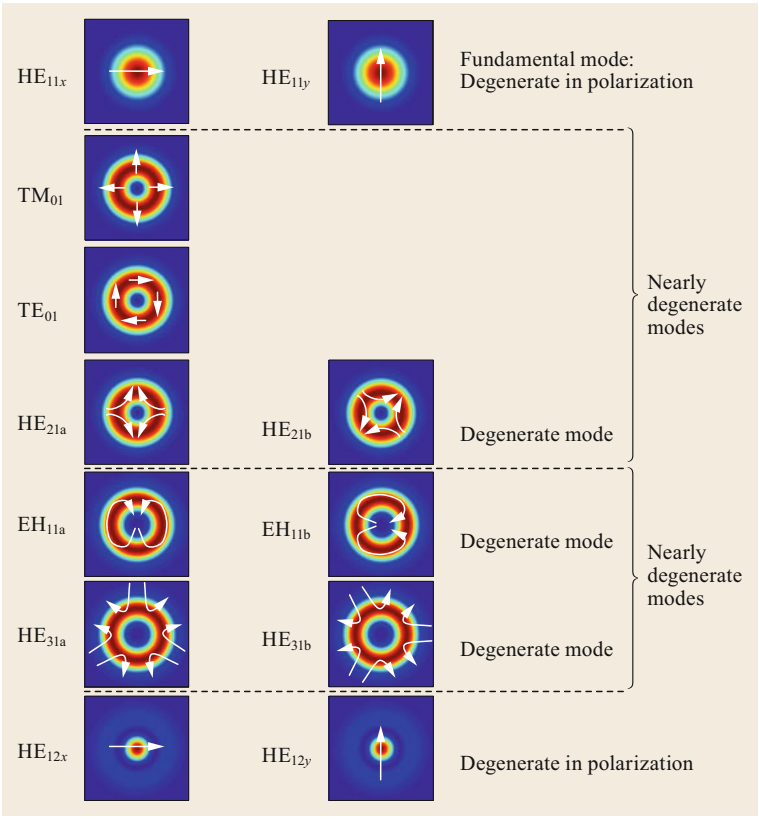

Fig. 10.5 First four mode groups of a step-index multimode fiber

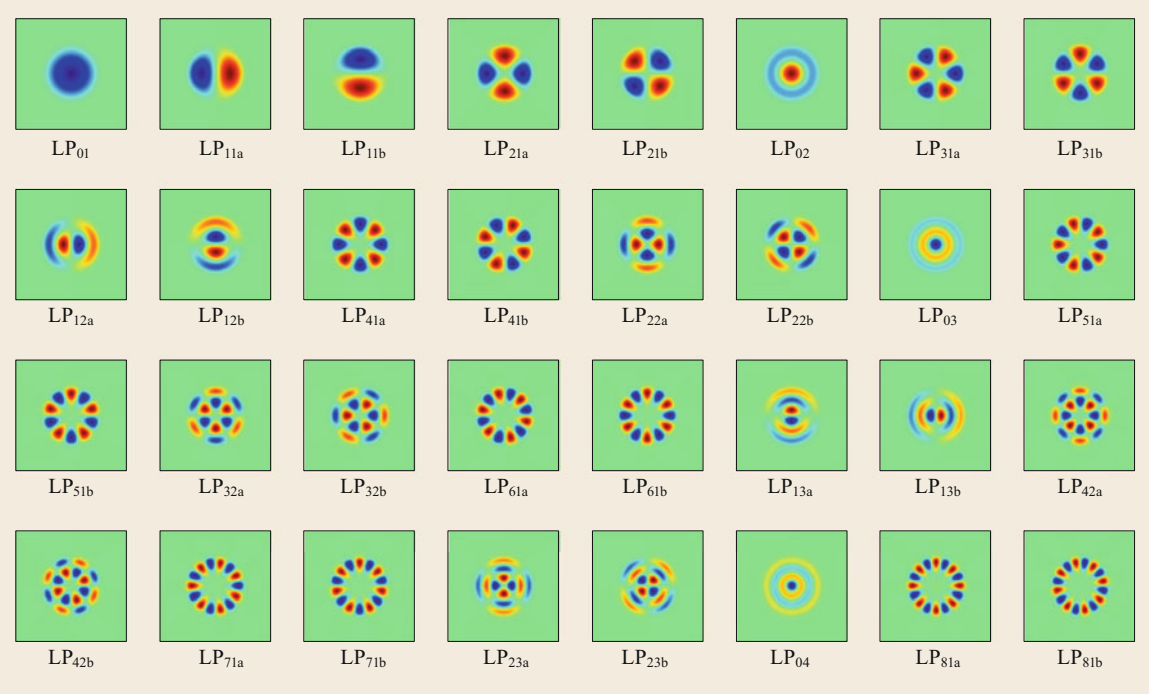

Fig. 10.6 First 32 modes of a step-index multimode fiber

Table 10.2 Cut-off frequencies of the modes of a step-index fiber

Mode	LP_{11}	LP_{21}	LP_{02}	LP_{31}	LP_{12}	LP_{41}	LP_{03}	LP_{32}	LP_{42}
V	2.4	3.8	3.9	5.1	5.5	6.4	7.1	8.4	9.8

In the relevant regime of weak guidance [10.61], where the index contrast is smaller or much smaller than 1%, the modes of a step-index fiber can be grouped in nearly degenerate mode groups (TM_{01}, TE_{01}, and the two-fold degenerate HE_{21} mode form a group). Modes belonging to the same group couple almost immediately due to fiber imperfections, and therefore do not propagate as individual modes in real fibers. Moreover, in the regime of weak guidance all modes are approximately linearly polarized (LP) [10.61]. Each LP mode is identified by two integers n and m and is denoted as LP_{nm}, where n characterizes the azimuthal dependence $\exp(\pm \mathrm{j}n\varphi)$ and sets the number of 2π phase changes for a rotation around the fiber axis, whereas m characterizes the radial dependence of the mode amplitude and sets the number of zero-crossings increased by one in the radial direction. Note that LP modes can equivalently be expressed either in terms of the functions $\exp(\pm \mathrm{j}n\varphi)$, or in terms of the functions $\cos(n\varphi)$ and $\sin(n\varphi)$. Figure 10.6 shows the first 32 modes of a weakly guiding step-index fiber in the $\cos(n\varphi)/\sin(n\varphi)$ representation. The main advantage of this representation is that the mode lateral profile functions are real-valued and can be plotted using a simple color map. In the figure red and blue indicate positive and amplitude values, respectively.

Modes with $n \neq 0$ are four-fold degenerate, as they are degenerate with respect to polarization and with respect to their azimuthal characteristics. Modes with $n = 0$ are two-fold degenerate, as they are only degenerate with respect to polarization. The number of LP modes that are guided by a step-index fiber depends on the normalized frequency V, which is defined as

$$V = \frac{2\pi a}{\lambda_0}\sqrt{n_\mathrm{c}^2 - n_0^2}\,. \tag{10.13}$$

Fibers with the same V number guide the same number of modes and the mode profiles are characterized by the same dependence on the normalized radial coordinate r/a. Step-index fibers are single-mode if $V < 2.4$. The cut-off frequencies of high-order modes are enumerated in Table 10.2.

According to (10.13), the number of modes of a step-index fiber can be increased either by increasing the core radius or by increasing the difference in refractive index $n_\mathrm{c} - n_0$.

10.3.2 Modes of a Graded-Index Fiber

Graded-index fibers have a nearly parabolic refractive index profile that is truncated at the core/cladding boundary. In order to reduce coupling between the last guided mode-group and the cladding modes, an additional low refractive index trench around the nearly parabolic core is added [10.5, 6]. The modes of a graded-index fiber with an ideally parabolic profile are Laguerre–Gaussian modes, where the radial term of the modal profile is a combination of a Gaussian function and a Laguerre polynomial, whereas the azimuthal term is still of the form $\exp(jn\varphi)$. As shown in Fig. 10.7, the modes of a graded-index fiber are divided into groups: all the modes of a given group are degenerate and each added group shows one additional

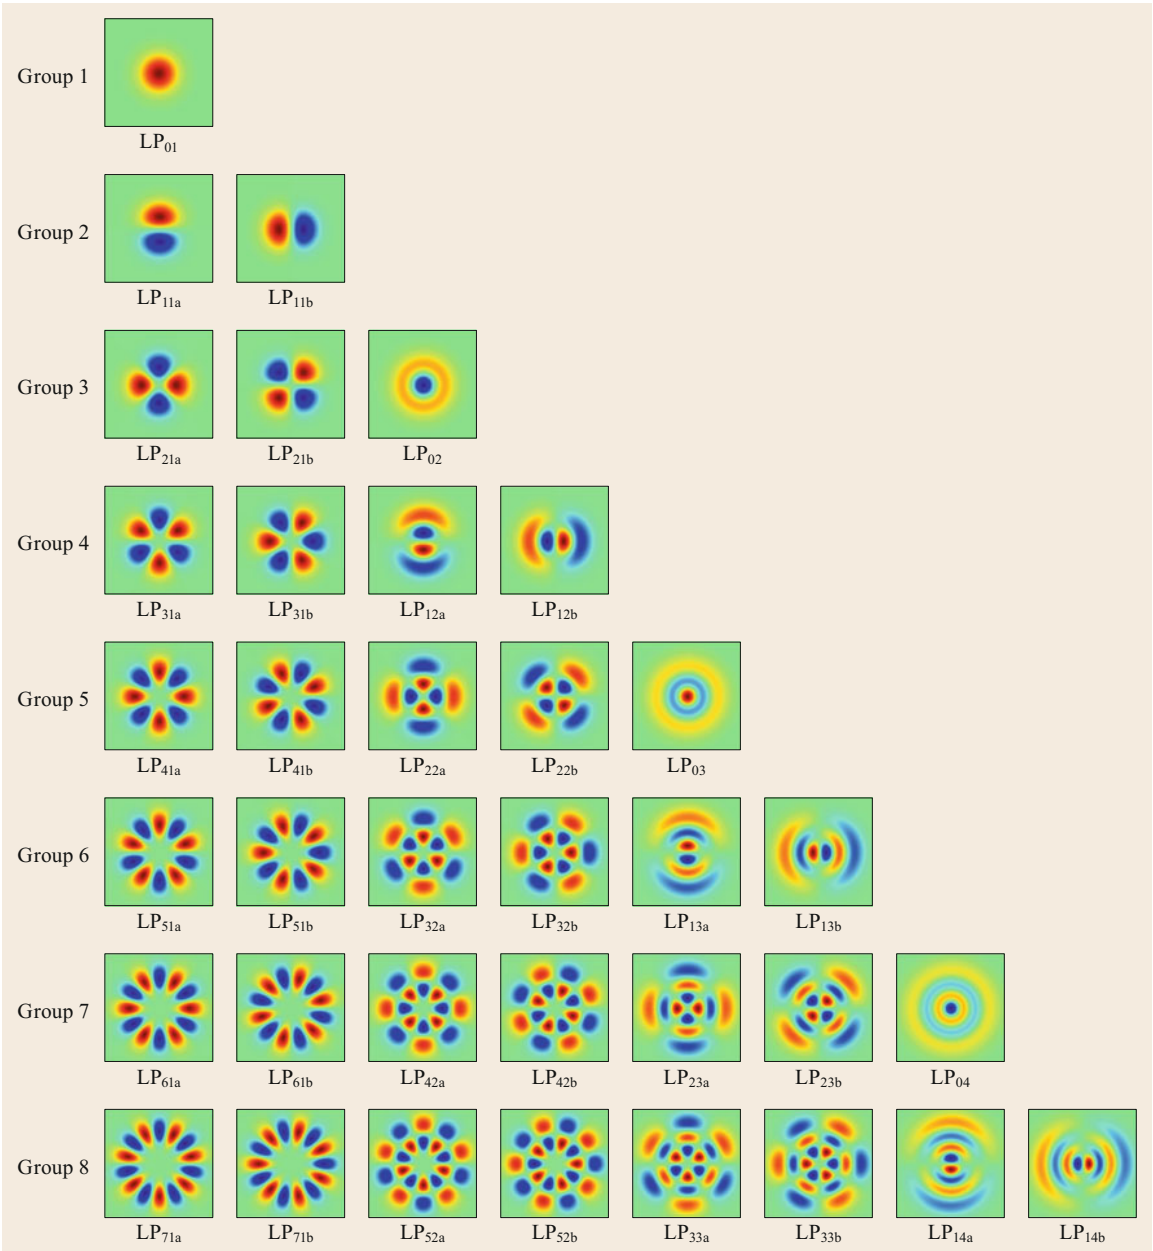

Fig. 10.7 The first 36 modes of a graded-index multimode fiber

degenerate mode. Although the modes of a graded-index fiber look similar to those of a step-index fiber, they have a different sequential order when sorted by the magnitude of their propagation constants. Also, the radial field extension, that in step-index fibers is mostly confined within the core for all modes, in graded-index fibers is proportional to the mode order, so that higher order modes have a significantly larger modal diameter. The propagation constants of the mode groups of an ideal graded-index fiber are equally spaced, and all modes have nearly the same group velocity, which makes the graded-index fiber the multimode fiber with the smallest theoretical DGD between pulses propagating in different modes. In practice, the DGD of a graded-index fiber is determined by the accuracy of the refractive index profile and by the dispersion properties of the core and cladding materials. Additionally, the modes of a graded-index fiber have the property of being invariant under spatial Fourier transformation. The spatial Fourier transform configuration can be achieved, for example, by placing the end face of the fiber in the back focal plain of a lens, so that the Fourier transform appears in the front focal plane of the same lens. For a graded-index fiber, this configuration reproduces a scaled version of the modes, which is not generally the case for other sets of guided modes like for example the modes of a step-index fiber.

10.3.3 Modes of Multicore Fibers: The Concept of Supermodes

Multicore fibers consist of multiple cores that are placed close to each other in a common cladding. The modes of a multicore fiber can be calculated by analyzing the modes of the ensemble of cores. The resulting modal field distributions spread across all cores and are referred to as supermodes. An example of supermodes for a three-core fiber is shown in Fig. 10.8.

When the coupling between cores is weak, the modes of a multicore fiber can be calculated using coupled-mode theory [10.62], where the supermodes are approximated by linear combinations of the modes of the individual cores (core modes), and the coupling coefficients depend on the overlap between the core modes [10.62, 63]. This approximation is useful to qualitatively study the systematic coupling between the cores. Note that both modal representations, supermodes and core modes, can be used to understand the coupling behavior of multicore fibers, however the supermodes representation has the advantage that it provides exact solutions for any core configuration including the case of strong core-mode overlap.

In practice, the modal properties of the multicore fibers depend strongly on the distance between the cores, and three distinct regimes can be identified:

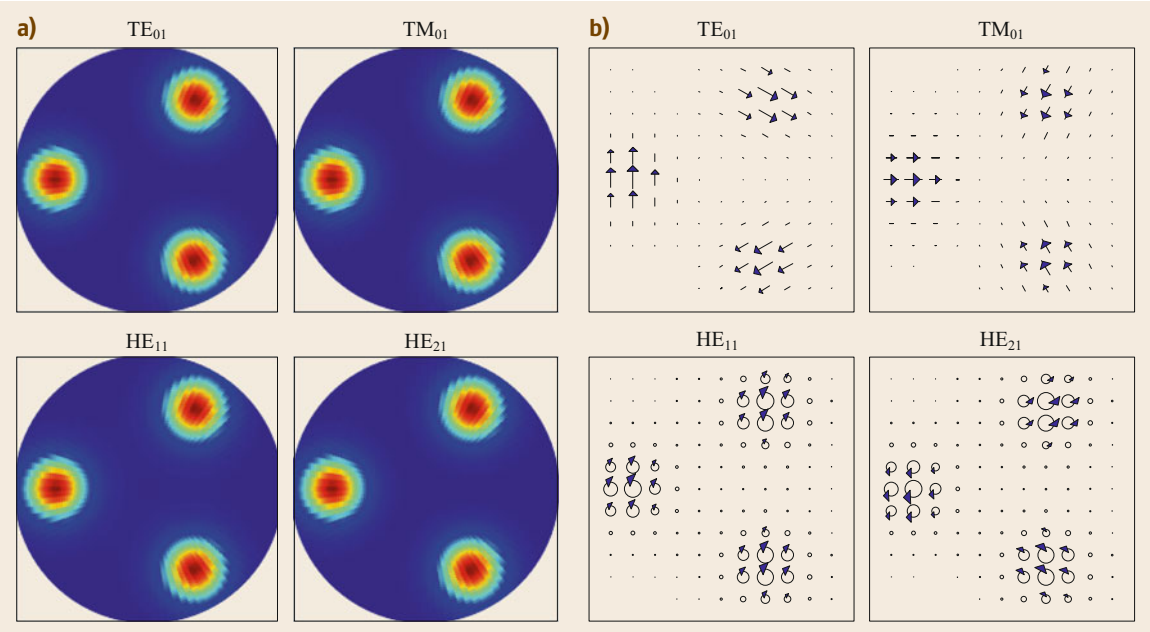

Fig. 10.8a,b Modes of a three-core multicore fiber supporting six vector modes. **(a)** The intensity profile, **(b)** direction of the electrical field indicated by *arrows*. *Arrows* arranged in circle indicates circular polarization and the position of the *arrow* relative to the circle indicates the overall relative phase

The first is the *weak coupling regime*, where the refractive index variations between the cores of the fiber structure produce an equivalent propagation-constant difference between the cores, that is bigger than the difference between the propagation constants of the supermodes. In this case, the cores behave as independent waveguides, showing a random-like coupling between neighbor cores, and the coupling between the cores is then described by the coupled power theory [10.64, 65]. The weak coupling regime is typically observed in multicore fibers where the core spacing is significantly larger than the core-mode field diameter.

The second regime is the *supermode regime*, where the difference in propagation constant between the supermodes is much bigger than the propagation constant variations introduced by the refractive index variations between the cores or external fiber perturbations like twists and bends. In this case, the supermodes are stable and can propagate unperturbed, and the fiber behaves similarly to a conventional multimode fiber, which shows a weak random-like coupling between the supermodes. The supermode regime is typically observed in multicore fibers where the core spacing is comparable or smaller than the core-mode field diameter.

The third regime can be observed when the difference in the propagation constant between the supermodes is comparable to the propagation constant variation induced by refractive index variation and the external fiber perturbations. In this case, the supermodes couple strongly and mix continuously. We refer to this regime as the *strong coupling regime*, and to the fibers operated in this regime as coupled-core multicore fibers. These fibers offer the advantage of showing very narrow impulse responses for all coupled cores, typically one order of magnitude (or more) narrower than impulse responses achievable in graded-index multimode fibers with an equivalent number of modes (Sect. 10.5.1). The strong coupling regime is typically observed in multicore fibers where the core spacing is comparable or slightly larger than the core-mode field diameter.

10.4 Representation of Modes in Fibers

We start by considering the case of a single-mode fiber, which for simplicity we assume to be a step-index fiber, where the fundamental mode is HE_{11}. We express the three-dimensional real-valued electric field vector $\boldsymbol{E}(x, y, z, t)$ introduced in the previous section as

$$\boldsymbol{E}(x,y,z,t) = \mathrm{Re}\left\{\left[\frac{\boldsymbol{F}_{\mathrm{HE}_{11x}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{HE}_{11}}(\omega_0)}E_x(z,t) + \frac{\boldsymbol{F}_{\mathrm{HE}_{11y}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{HE}_{11}}(\omega_0)}E_y(z,t)\right]\mathrm{e}^{-\mathrm{j}\omega_0 t}\right\}, \tag{10.14}$$

where $\boldsymbol{F}_{\mathrm{HE}_{11}x}$ and $\boldsymbol{F}_{\mathrm{HE}_{11}y}$ are the lateral profile functions of the fundamental mode aligned with the x- and y-directions, respectively. Note that the specific choice of the x- and y- directions is immaterial to this discussion, as any other pair of orthogonal directions would be equally suitable. The terms E_x and E_y are the corresponding complex envelopes of the field and the normalization coefficient $\mathcal{N}_{\mathrm{HE}_{11}}$ is introduced to ensure that the power in Watts that is carried by the x-oriented (y-oriented) mode is $|E_x|^2$ ($|E_y|^2$). We note that the mode lateral profile functions are evaluated at ω_0 owing to the fact that in all cases of practical relevance the bandwidth of the individual complex envelopes is sufficiently small to ignore the dependence of $\boldsymbol{F}_n$ on frequency. The form of (10.14) shows that the complex envelopes E_x and E_y are not exactly the x and y polarization components of the electric field, as follows from the fact that the HE_{11} lateral profile function possesses a nonzero component in the z-direction. The situation simplifies in the relevant case of weakly guiding fibers [10.61], where the fundamental mode LP_{01} is linearly polarized and its longitudinal component is negligible. In this case, E_x and E_y characterize fully and independently the x and y polarization components of the electric field (which is indeed a two-dimensional vector in the x–y plane) and the field vector can be expressed as

$$\begin{aligned}\boldsymbol{E}(x,y,z,t) &= \mathrm{Re}\left\{\left[\frac{\boldsymbol{F}_{\mathrm{LP}_{01x}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{LP}_{01}}(\omega_0)}E_x(z,t) + \frac{\boldsymbol{F}_{\mathrm{LP}_{01y}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{LP}_{01}}(\omega_0)}E_y(z,t)\right]\mathrm{e}^{-\mathrm{j}\omega_0 t}\right\}, \\ &= \frac{F_{\mathrm{LP}_{01}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{LP}_{01}}(\omega_0)}\mathrm{Re}\left\{[E_x(z,t)\hat{\boldsymbol{x}} + E_y(z,t)\hat{\boldsymbol{z}}]\mathrm{e}^{-\mathrm{j}\omega_0 t}\right\},\end{aligned} \tag{10.15}$$

where the second equality relies on the fact that the lateral profile of the fundamental mode is real-valued, and $\boldsymbol{F}_{\mathrm{LP}_{01x}} = F_{\mathrm{LP}_{01}}\hat{\boldsymbol{x}}$, $\boldsymbol{F}_{\mathrm{LP}_{01y}} = F_{\mathrm{LP}_{01}}\hat{\boldsymbol{y}}$, where $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{y}}$ are unit vectors pointing in the x- and y-directions, respectively. It is convenient to introduce the bi-dimensional vector $\boldsymbol{E}(z,t)$ defined as

$$\boldsymbol{E}(z,t) = \begin{pmatrix} E_x(z,t) \\ E_y(z,t) \end{pmatrix}. \tag{10.16}$$

This vector is related to the Jones vector introduced in Sect. 10.4.1. It provides a full characterization of the optical field not only in the weakly guiding approximation, where its components are in a one-to-one correspondence with the x and y polarization components of the field, but also in the most general case where the longitudinal component is non-negligible. Note that the same vector notation is used, yet with no risk of confusion, to denote both the three-dimensional vectors $\boldsymbol{E}(x,y,z,t)$ and $\boldsymbol{F}(x,y,\omega_0)$, and the two-dimensional vector $\boldsymbol{E}(z,t)$. The extension of this representation to the case of higher order modes is straightforward, but requires some clarifications. Let us consider the group of the nearly degenerate modes $\mathrm{HE}_{21\mathrm{a}}$ and $\mathrm{HE}_{21\mathrm{b}}$, and the transverse modes TE_{01} and TM_{01}, whose excitation yields the field

$$\begin{aligned}\boldsymbol{E}(x,y,z,t) = \mathrm{Re}\Bigg\{\Bigg[&\frac{\boldsymbol{F}_{\mathrm{HE}_{21\mathrm{a}}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{HE}_{21}}(\omega_0)}E_{\mathrm{HE}_{21\mathrm{a}}}(z,t)\\ &+\frac{\boldsymbol{F}_{\mathrm{HE}_{21\mathrm{b}}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{HE}_{21}}(\omega_0)}E_{\mathrm{HE}_{21\mathrm{b}}}(z,t)\\ &+\frac{\boldsymbol{F}_{\mathrm{TE}_{01}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{TE}_{01}}(\omega_0)}E_{\mathrm{TE}_{01}}(z,t)\\ &+\frac{\boldsymbol{F}_{\mathrm{TM}_{01}}(x,y,\omega_0)}{\mathcal{N}_{\mathrm{TM}_{01}}(\omega_0)}E_{\mathrm{TM}_{01}}(z,t)\Bigg]\mathrm{e}^{-\mathrm{j}\omega_0 t}\Bigg\}.\end{aligned} \tag{10.17}$$

In the weakly guiding approximation, the lateral profile functions of the HE, TE, and TM modes can be used to express those of the LP_{11} group as follows

$$\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{ax}}}}{\mathcal{N}_{\mathrm{LP}_{11}}} = \frac{1}{\sqrt{2}}\left(\frac{\boldsymbol{F}_{\mathrm{HE}_{21\mathrm{a}}}}{\mathcal{N}_{\mathrm{HE}_{21}}} + \frac{\boldsymbol{F}_{\mathrm{TM}_{01}}}{\mathcal{N}_{\mathrm{TM}_{01}}}\right), \tag{10.18}$$

$$\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{ay}}}}{\mathcal{N}_{\mathrm{LP}_{11}}} = \frac{1}{\sqrt{2}}\left(\frac{\boldsymbol{F}_{\mathrm{HE}_{21\mathrm{b}}}}{\mathcal{N}_{\mathrm{HE}_{21}}} - \frac{\boldsymbol{F}_{\mathrm{TE}_{01}}}{\mathcal{N}_{\mathrm{TE}_{01}}}\right), \tag{10.19}$$

$$\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{bx}}}}{\mathcal{N}_{\mathrm{LP}_{11}}} = \frac{1}{\sqrt{2}}\left(\frac{\boldsymbol{F}_{\mathrm{HE}_{21\mathrm{b}}}}{\mathcal{N}_{\mathrm{HE}_{21}}} + \frac{\boldsymbol{F}_{\mathrm{TE}_{01}}}{\mathcal{N}_{\mathrm{TE}_{01}}}\right), \tag{10.20}$$

$$\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{by}}}}{\mathcal{N}_{\mathrm{LP}_{11}}} = \frac{1}{\sqrt{2}}\left(\frac{\boldsymbol{F}_{\mathrm{HE}_{21\mathrm{a}}}}{\mathcal{N}_{\mathrm{HE}_{21}}} - \frac{\boldsymbol{F}_{\mathrm{TM}_{01}}}{\mathcal{N}_{\mathrm{TM}_{01}}}\right), \tag{10.21}$$

(where we dropped the dependence on x, y, and ω_0 for ease of notation) with the result

$$\begin{aligned}\boldsymbol{E}(x,y,z,t) = \mathrm{Re}\Bigg\{\Bigg[&\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{ax}}}}{\mathcal{N}_{\mathrm{LP}_{11}}}E_{\mathrm{LP}_{11\mathrm{ax}}}(z,t)\\ &+\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{ay}}}}{\mathcal{N}_{\mathrm{LP}_{11}}}E_{\mathrm{LP}_{11\mathrm{ay}}}(z,t)\\ &+\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{bx}}}}{\mathcal{N}_{\mathrm{LP}_{11}}}E_{\mathrm{LP}_{11\mathrm{bx}}}(z,t)\\ &+\frac{\boldsymbol{F}_{\mathrm{LP}_{11\mathrm{ay}}}}{\mathcal{N}_{\mathrm{LP}_{11}}}E_{\mathrm{LP}_{11\mathrm{by}}}(z,t)\Bigg]\mathrm{e}^{-\mathrm{j}\omega_0 t}\Bigg\}\end{aligned}$$

$$\begin{aligned}= \mathrm{Re}\Bigg(\Bigg\{&\frac{F_{\mathrm{LP}_{11\mathrm{a}}}}{\mathcal{N}_{\mathrm{LP}_{11}}}[E_{\mathrm{LP}_{11\mathrm{ax}}}(z,t)\hat{\boldsymbol{x}}\\ &+ E_{\mathrm{LP}_{11\mathrm{ay}}}(z,t)\hat{\boldsymbol{y}}]\\ &+ \frac{F_{\mathrm{LP}_{11\mathrm{b}}}}{\mathcal{N}_{\mathrm{LP}_{11}}}[E_{\mathrm{LP}_{11\mathrm{bx}}}(z,t)\hat{\boldsymbol{x}}\\ &+ E_{\mathrm{LP}_{11\mathrm{by}}}(z,t)\hat{\boldsymbol{y}}]\Bigg\}\mathrm{e}^{-\mathrm{j}\omega_0 t}\Bigg),\end{aligned} \tag{10.22}$$

where the complex envelopes of the linearly polarized modes are obtained from those of the true fiber modes through

$$\begin{bmatrix}E_{\mathrm{LP}_{11\mathrm{ax}}}(z,t)\\ E_{\mathrm{LP}_{11\mathrm{ay}}}(z,t)\\ E_{\mathrm{LP}_{11\mathrm{bx}}}(z,t)\\ E_{\mathrm{LP}_{11\mathrm{by}}}(z,t)\end{bmatrix} = \frac{1}{\sqrt{2}}\begin{bmatrix}1&0&1&0\\ 0&1&0&-1\\ 0&1&0&1\\ 1&0&-1&0\end{bmatrix} \times \begin{bmatrix}E_{\mathrm{HE}_{21\mathrm{a}}}(z,t)\\ E_{\mathrm{HE}_{21\mathrm{b}}}(z,t)\\ E_{\mathrm{TM}_{01}}(z,t)\\ E_{\mathrm{TE}_{01}}(z,t)\end{bmatrix} \tag{10.23}$$

as follows from using (10.18)–(10.21) into (10.22). The second equality in (10.22) shows that each of the complex envelopes in the LP representation provides a complete characterization of a space and polarization mode. All together, the four complex envelopes give a complete description of the field, and they are related to the generalized Jones representation presented in Sect. 10.4.3.

We can now move to the most general case of $2N$ modes, where the factor of two accounts either for the degeneracy of a spatial mode (as is the case for HE_{11} or HE_{21}), or for the fact that in all cases of practical relevance a fiber cannot guide only one out of two quasi-degenerate modes (as is the case for TE_{01} and TM_{01}). In the weakly guiding approximation, the factor of two accounts simply for polarization degeneracy. By suitably sorting the guided modes, we can express the electric field as

$$\boldsymbol{E}(x,y,z,t) = \mathrm{Re}\left[\sum_{n=1}^{2N}\frac{\boldsymbol{F}_n(x,y,\omega_0)}{\mathcal{N}_n(\omega_0)}E_n(z,t)\mathrm{e}^{-\mathrm{j}\omega_0 t}\right], \tag{10.24}$$

where the term $E_n(z,t)$ is the complex envelope of the field in the n-th mode and the vector $\boldsymbol{F}_n(x,y,\omega_0)$ is the corresponding mode lateral profile. As specified already in the examples illustrated above, the normalization coefficients $\mathcal{N}_n(\omega_0)$ are introduced to ensure that the power in Watts that is carried by the n-th mode

is given by $|E_n(z,t)|^2$ [10.66]. Note that a different normalization could be assumed (for instance, in [10.67] the power in Watts is given by $|E_n(z,t)|^2/(2Z_0)$, where $Z_0 = \sqrt{\mu_0/\epsilon_0}$ is the impedance of vacuum). Their expression follows from the mode orthogonality condition (10.5), which we recall here for convenience,

$$\int \mathrm{d}x\mathrm{d}y \left(\boldsymbol{F}_n \times \boldsymbol{G}_m^*\right) \cdot \hat{\boldsymbol{z}} = 2\mathcal{N}_n^2 \delta_{n,m} \,. \tag{10.25}$$

The orthogonality condition implies the following equation, which is often found in the literature [10.66–68],

$$\int \mathrm{d}x\mathrm{d}y \left(\boldsymbol{F}_n \times \boldsymbol{G}_m^* + \boldsymbol{F}_m^* \times \boldsymbol{G}_n\right) \cdot \hat{\boldsymbol{z}} = 4\mathcal{N}_n^2 \delta_{n,m} \,, \tag{10.26}$$

and in the weakly guiding approximation simplifies to

$$\frac{n_{\mathrm{eff}}}{2Z_0} \mathrm{Re}\left(\int \mathrm{d}x\mathrm{d}y\, \boldsymbol{F}_n \cdot \boldsymbol{F}_m^*\right) = \delta_{n,m}\mathcal{N}_n^2 \,, \tag{10.27}$$

where n_{eff} is the effective refractive index of the fundamental mode. With the field expression introduced in (10.24), in the ideal case of a perfectly circular fiber, in the absence of loss, mode coupling and nonlinear propagation effects, the complex envelopes evolve according to the simple evolution equation in the frequency domain

$$\frac{\partial \tilde{E}_n(z,\omega)}{\partial z} = \mathrm{j}\beta_n(\omega)\tilde{E}_n(z,\omega) \,, \tag{10.28}$$

where by the tilde we denote a (frequency) Fourier transform according to the definition

$$\tilde{E}_n(z,\omega) = \int E_n(z,t)\exp(\mathrm{j}\omega t)\mathrm{d}t \,. \tag{10.29}$$

An important feature of (10.24) is that the effect of perturbations is captured through the dependence of the complex envelopes on the longitudinal coordinate, while the modes used in the expansion are those of the unperturbed fiber. An alternative approach, that is not further discussed in this chapter, relies on using perturbed local modes [10.69].

It is worth pointing out that the true fiber modes form a complete orthogonal basis for representing locally the lateral profile of the field propagating in the fiber, and therefore any other orthogonal basis obtained from a unitary transformation of the true fiber modes lateral profile functions works as well [10.70]. However, since the resulting lateral profile functions are not in general fiber modes, the evolution of the corresponding complex envelopes is described by coupled equations even in the ideal case of an unperturbed fiber. Equations (10.18)–(10.21) and (10.23) can be interpreted as an example of this change of basis. Indeed, it is well known that LP modes are only true modes within the weakly guiding approximation, whereas in reality they couple during propagation, not only in fibers with high-index-contrast, but also in weakly guiding fibers where the accumulated effects of the small modal birefringence cannot be ignored [10.71].

In the remainder of this section we review the Jones and Stokes formalisms [10.72–74], which are widely used for the study of polarization-related phenomena in single-mode fibers, and discuss their generalization to the multimode case.

10.4.1 Jones and Stokes Formalism for Single-Mode Fibers

Jones calculus was originally proposed to describe polarized light by means of two-dimensional vectors [10.72]. Indeed, as discussed in the previous section, the vector $\boldsymbol{E}(z,t)$ defined in (10.16) provides a complete description of the electric field propagating in a single-mode fiber, and the physical interpretation of its two components is slightly different whether the fiber is weakly guiding or not. The corresponding Jones vector is defined as the Fourier transform of $\boldsymbol{E}(z,t)$ normalized to have unit modulus, namely

$$|e(z,\omega)\rangle = \frac{\tilde{\boldsymbol{E}}(z,\omega)}{|\tilde{\boldsymbol{E}}(z,\omega)|} = \begin{pmatrix} e_x(z,\omega) \\ e_y(z,\omega) \end{pmatrix} , \tag{10.30}$$

where we use the bra–ket notation to denote a Jones vector $|e\rangle$. By the bra $\langle e(z,\omega)|$ we denote the Hermitian adjoint of the field Jones vector (i.e., the complex conjugate row vector), so that the unit-modulus condition can be expressed as $\langle e|e\rangle = |e_x|^2 + |e_y|^2 = 1$, and the scalar product between two Jones vectors is given by $\langle u|e\rangle = u_x^* e_x + u_x^* e_y$.

We now move to introducing the Stokes representation of the electric field. This is an alternative description based on the use of real-valued three-dimensional vectors and it is isomorphic to the Jones representation [10.71]. If we denote by $\boldsymbol{e}$ the Stokes vector corresponding to the Jones vector $|e\rangle$, its three components are defined as

$$\begin{aligned} e_1 &= |e_x|^2 - |e_y|^2 \,, \\ e_2 &= 2\mathrm{Re}\left(e_x^* e_y\right) \,, \\ e_3 &= 2\mathrm{Im}\left(e_x^* e_y\right) \,. \end{aligned} \tag{10.31}$$

The length of the Stokes vector can be evaluated to be $|\boldsymbol{e}| = \sqrt{e_1^2 + e_2^2 + e_3^2} = \langle e|e\rangle = 1$, where the second equality follows from the normalization of $|e\rangle$ (in some cases the Jones vector is not normalized to have unit modulus, with the result that the length of the Stokes vector equals the optical power). The ensemble of all possible polarization states spans the surface of a sphere of unit radius in Stokes space, which is famously known as the Poincaré sphere. An alternative expression of the Stokes vector, which turns out to be highly convenient for the generalization of the Stokes formalism to the multimode fiber case is the one based on the use of Pauli spin matrices, which we recall here for convenience

$$\sigma_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 0 & -\mathrm{j} \\ \mathrm{j} & 0 \end{pmatrix}. \tag{10.32}$$

Note that the original definition of the Pauli matrices in quantum mechanics differs from the above by a circular permutation of the matrix subscripts. With the use of the Pauli matrices, (10.31) can be re-expressed as

$$e_n = \langle e|\sigma_n|e\rangle\,, \quad n \in \{1, 2, 3\}\,, \tag{10.33}$$

and by formally collecting the Pauli matrices into a column vector which we denote by $\boldsymbol{\sigma}$, the Stokes vector can be expressed in the following compact form

$$\boldsymbol{e} = \langle e|\boldsymbol{\sigma}|e\rangle\,. \tag{10.34}$$

Another relevant relation between the Jones and Stokes representations has to do with the projection operator. This is a 2×2 matrix returning the projection on a given Jones vector $|e\rangle$ of the Jones vector to which is applied,

$$|e\rangle\langle e| = \frac{1}{2}\,(\mathbf{I} + \boldsymbol{e}\cdot\boldsymbol{\sigma})\,. \tag{10.35}$$

Here, by $\mathbf{I}$ we denote the 2×2 identity matrix (in what follows we will use the same symbol to denote the $M\times M$ identity matrix as well, where M is an arbitrary integer), and where the scalar product between a Stokes vector and the Pauli matrix vector stands for the linear combination $\boldsymbol{e}\cdot\boldsymbol{\sigma} = e_1\sigma_1 + e_2\sigma_2 + e_3\sigma_3$. The equivalence between (10.33) and (10.35) follows from the equality

$$\langle e|\sigma_n|e\rangle = \mathrm{tr}\,(\sigma_n|e\rangle\langle e|)\,, \tag{10.36}$$

and from the trace-orthogonality of the Pauli matrices, that is

$$\mathrm{tr}\,(\sigma_n\sigma_m) = 2\delta_{n,m}\,, \tag{10.37}$$

where $\delta_{n,m}$ is the Kronecker delta. A useful consequence of (10.35) is

$$|\langle u|v\rangle|^2 = \frac{1}{2}\,(1 + \boldsymbol{u}\cdot\boldsymbol{v})\,, \tag{10.38}$$

which shows that orthogonal states of polarization, for which $\langle u|v\rangle = 0$, are antiparallel in Stokes space, namely $\boldsymbol{u}\cdot\boldsymbol{v} = -1$.

10.4.2 Polarization Coupling and Unitary Propagation in Single-Mode Fibers

Manufacturing imperfections and mechanical stress that are always present in real fibers are responsible for the fact that orthogonal polarization modes couple during propagation in single-mode fibers. In the absence of polarization-dependent loss (PDL), polarization-mode coupling can be conveniently described in Jones space by means of a unitary matrix $\mathbf{U}$ defined through the following input-output relation,

$$|\tilde{e}(z,\omega)\rangle = \mathrm{e}^{-\frac{\alpha}{2}z}\mathbf{U}(z,\omega)|\tilde{e}(0,\omega)\rangle\,, \tag{10.39}$$

where the term $\exp(-\alpha z/2)$ describes polarization-averaged loss. This term is immaterial to the present analysis and will be dropped in what follows. The unitary property $\mathbf{U}(z,\omega)\mathbf{U}^\dagger(z,\omega) = \mathbf{I}$ implies the following form for the evolution equation of $\mathbf{U}(z,\omega)$,

$$\frac{\mathrm{d}\mathbf{U}(z,\omega)}{\mathrm{d}z} = \mathrm{j}\mathbf{B}(z,\omega)\mathbf{U}(z,\omega)\,, \tag{10.40}$$

where $\mathbf{B}(z,\omega)$ is a Hermitian matrix. Indeed, by differentiating both sides of the equality $\mathbf{U}\mathbf{U}^\dagger = \mathbf{I}$, one obtains $(\mathrm{d}\mathbf{U}/\mathrm{d}z)\mathbf{U}^\dagger = -[(\mathrm{d}\mathbf{U}/\mathrm{d}z)\mathbf{U}^\dagger]^\dagger$, which implies that $(\mathrm{d}\mathbf{U}/\mathrm{d}z)\mathbf{U}^\dagger$ is anti-Hermitian, and hence can be expressed as $\mathrm{j}\mathbf{B}$, where $\mathbf{B}$ is Hermitian. Since the Pauli matrices form a basis for traceless Hermitian matrices, the above can be conveniently re-expressed as

$$\frac{\mathrm{d}\mathbf{U}(z,\omega)}{\mathrm{d}z} = \mathrm{j}\left[\beta_0(z,\omega)\mathbf{I} + \frac{1}{2}\boldsymbol{\beta}(z,\omega)\cdot\boldsymbol{\sigma}\right]\mathbf{U}(z,\omega)\,, \tag{10.41}$$

where by β_0 we denote the propagation constant of the fundamental mode, whose third-order Taylor expansion defined in (10.7) yields the terms describing polarization-averaged phase delay, group delay, and chromatic dispersion. The traceless matrix $\boldsymbol{\beta}(z,\omega)\cdot\boldsymbol{\sigma}$ accounts for the local (z-dependent) polarization-mode coupling that occurs during propagation (including its frequency dependence), where $\boldsymbol{\beta}$ is a three-dimensional real-valued vector, which we refer to as the *birefringence vector* [10.73, 75] (this definition relaxes the use

of the term birefringence vector, which normally is restricted to the frequency derivative of $\boldsymbol{\beta}$). The simple relation between $\boldsymbol{\beta}$ and $\mathbf{B}$ is $\beta_n = \mathrm{tr}(\sigma_n \mathbf{B})$.

A closed-form solution for (10.41) in the general case does not exist, however the evolution of $\mathbf{U}$ over a short fiber section of length Δz is given by the following expression

$$\mathbf{U}(z+\Delta z,\omega) \simeq \exp\left[\mathrm{j}\beta_0(z,\omega)\Delta z\right] \times \exp\left[\frac{\mathrm{j}}{2}\boldsymbol{\beta}(z,\omega)\cdot\boldsymbol{\sigma}\,\Delta z\right]\mathbf{U}(z,\omega)\,, \tag{10.42}$$

which is customarily employed in numerical simulations, where a fiber is modeled as a concatenation of multiple short sections (waveplates). If the birefringence vector is z-independent, namely $\boldsymbol{\beta}(z,\omega) = \boldsymbol{\beta}(\omega)$, the above expression can be readily modified to evaluate the fiber transfer matrix $\mathbf{U}$, with the result

$$\mathbf{U}(z,\omega) = \exp\left[\mathrm{j}\int_0^z \beta_0(\zeta,\omega)\mathrm{d}\zeta\right] \times \exp\left[\frac{\mathrm{j}}{2}\boldsymbol{\beta}(\omega)\cdot\boldsymbol{\sigma}\,z\right], \tag{10.43}$$

which ensures the initial condition $\mathbf{U}(0,\omega) = \mathbf{I}$. This case is of no practical relevance (in reality the fiber birefringence is rapidly varying along the propagation axis), however the form of (10.43) is interesting since also in the most general case $\mathbf{U}$ can be expressed in the same form,

$$\mathbf{U}(z,\omega) = \exp\left[\mathrm{j}\phi_0(z,\omega)\right]\exp\left[\frac{\mathrm{j}}{2}\boldsymbol{r}(z,\omega)\cdot\boldsymbol{\sigma}\right], \tag{10.44}$$

where ϕ_0 accounts for the accumulated phase and $\boldsymbol{r}$ for the accumulated effect of the fiber birefringence from the input to the generic position z. Indeed, a unitary matrix can in general be expressed as $\mathbf{U} = \exp(\mathrm{j}\mathbf{H}/2)$, where $\mathbf{U}$ is a traceless Hermitian matrix that in turn can be expanded in terms of the Pauli matrices as $\mathbf{H} = \boldsymbol{r}\cdot\boldsymbol{\sigma}$. A useful alternative expression for $\mathbf{U}$ follows from the eigenvector analysis of the matrix exponential appearing in (10.44), which yields

$$\mathbf{U} = \mathrm{e}^{\mathrm{j}\phi_0}\left(\mathrm{e}^{-\mathrm{j}r/2}|r\rangle\langle r| + \mathrm{e}^{\mathrm{j}r/2}|r_\perp\rangle\langle r_\perp|\right), \tag{10.45}$$

where $r = |\boldsymbol{r}|$, and by $|r\rangle$ and $|r_\perp\rangle$, we denote the two orthogonal Jones vectors corresponding to the (unit-length) Stokes vectors $\pm\boldsymbol{r}/r$. Equation (10.45) shows that $|r\rangle$ and $|r_\perp\rangle$ are the two eigenstates of $\mathbf{U}$ and their eigenvalues are equal to $\exp(-\mathrm{j}r/2)$ and $\exp(\mathrm{j}r/2)$, respectively. Equation (10.45) is consistent with a general property of unitary matrices of any dimension of having orthogonal eigenvectors with unit-modulus eigenvalues. A detailed derivation of (10.45) can be found in [10.73]. The derivation relies essentially on two properties of the Pauli matrices, $\sigma_n^2 = \mathbf{I}$ and $\sigma_n\sigma_m = -\sigma_m\sigma_n$, which yield $(\boldsymbol{r}\cdot\boldsymbol{\sigma})^{2k} = |\boldsymbol{r}|^{2k}\mathbf{I}$. Use of the latter equality in the power expansion of the matrix exponential yields $\exp(\mathrm{j}\boldsymbol{r}\cdot\boldsymbol{\sigma}/2) = \cos(|\boldsymbol{r}|)\mathbf{I} + \mathrm{j}\sin(|\boldsymbol{r}|)(\boldsymbol{r}\cdot\boldsymbol{\sigma})/|\boldsymbol{r}|$. Equation (10.45) is finally obtained by considering (10.35) and the subsequent discussion.

The evolution of the field polarization state can be conveniently described also in Stokes space, where the overall effect of unitary fiber propagation is rotation of the field Stokes vector, as follows from the invariance of the Stokes vector length (this invariance is not trivially the consequence of the normalization involved in the definition of the Jones vectors but rather the result of power conservation during unitary propagation). If we denote by $\mathbf{R}$ the 3×3 rotation matrix isomorphic to the unitary Jones matrix $\mathbf{U}$, the input-output relation $\boldsymbol{e}_{\mathrm{out}} = \mathbf{R}\boldsymbol{e}_{\mathrm{in}} = \langle e_{\mathrm{in}}|\mathbf{U}^\dagger\boldsymbol{\sigma}\mathbf{U}|e_{\mathrm{in}}\rangle$ yields the following simple relation [10.73]

$$\mathbf{R}\boldsymbol{\sigma} = \mathbf{U}^\dagger\boldsymbol{\sigma}\mathbf{U}\,, \tag{10.46}$$

which connects $\mathbf{U}$ and $\mathbf{R}$. The matrix $\mathbf{R}$ is also referred to as the Müller matrix. The known evolution equation for the field Stokes vector is obtained by differentiating the expression $\boldsymbol{e} = \mathrm{tr}\,(\boldsymbol{\sigma}|e\rangle\langle e|)$, which yields

$$\frac{\partial\boldsymbol{e}}{\partial z} = \mathrm{tr}\left[\boldsymbol{\sigma}\,\mathrm{j}\frac{(\boldsymbol{\beta}\cdot\boldsymbol{\sigma})(\boldsymbol{e}\cdot\boldsymbol{\sigma}) - (\boldsymbol{e}\cdot\boldsymbol{\sigma})(\boldsymbol{\beta}\cdot\boldsymbol{\sigma})}{2}\right] = \boldsymbol{\beta}\times\boldsymbol{e}\,, \tag{10.47}$$

where the first equality follows from using (10.41) and the second requires using some of the Pauli matrices algebra. Equation (10.47) provides an intuitive interpretation of the local birefringence vector $\boldsymbol{\beta}$. Indeed, it shows $\boldsymbol{\beta}$ to be the local rotation axis that characterizes the trajectory drawn by the tip of the field Stokes vector on the Poincaré sphere, as the field propagates along the fiber, as illustrated in Fig. 10.9. In the case of uniform birefringence the trajectory simplifies to a circle and the motion on this circle is described by the matrix $\mathbf{R}(z) = \exp(z\boldsymbol{\beta}\times)$, where by $\boldsymbol{\beta}\times$ we denote the matrix operator that, if applied to the vector $\boldsymbol{s}$, performs the vector product $\boldsymbol{\beta}\times\boldsymbol{s}$, namely

$$\boldsymbol{\beta}\times = \begin{pmatrix} 0 & -\beta_3 & \beta_2 \\ \beta_3 & 0 & -\beta_1 \\ -\beta_2 & \beta_1 & 0 \end{pmatrix}. \tag{10.48}$$

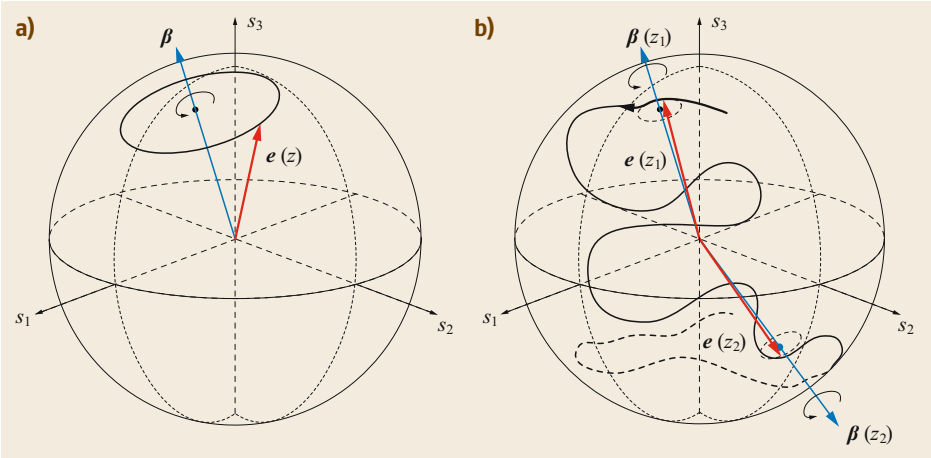

Fig. 10.9a,b Trajectory of the field Stokes vector on the Poincaré sphere. **(a)** If the birefringence vector $\boldsymbol{\beta}$ is constant along the fiber, the Stokes vector rotates around $\boldsymbol{\beta}$, namely the trajectory is a circle, the rotation axis is $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}/|\boldsymbol{\beta}|$, and the angular velocity is $|\boldsymbol{\beta}|$. **(b)** In the general case of varying birefringence, the Stokes vector trajectory can be approximated by means of infinitesimal rotations around the local birefringence vector $\boldsymbol{\beta}(z)$

The expression of $\mathbf{R}(z)$ shows that the rotation angle is $|\boldsymbol{\beta}|z$ and the rotation axis is $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}/|\boldsymbol{\beta}|$, thereby implying that the two orthogonal states whose Stokes vectors are parallel and antiparallel to $\boldsymbol{\beta}$ are propagation eigenstates. This argument is useful to clarify the isomorphic relation existing between the general unitary Jones matrix $\mathbf{U} = \exp(\mathrm{j}\phi_0)\exp(\mathrm{j}\boldsymbol{r}\cdot\boldsymbol{\sigma}/2)$ and the Müller matrix $\mathbf{R} = \exp(\boldsymbol{r}\times)$ (note that the phase shift ϕ_0 is immaterial in the Stokes representation, consistent with the definition of the Stokes vector itself).

10.4.3 Generalized Jones and Stokes Formalism

The example of the four-mode field discussed in Sect. 10.4 suggests that the complex envelopes $E_n(z,t)$ provide a complete description of the field, although their physical interpretation is slightly different whether the fiber is weakly guiding or not. The generalized Jones vector $|e(z,\omega)\rangle$, often referred to as the field *hyperpolarization* vector, is hence constructed by stacking the Fourier transform of the individual complex envelopes on top of each other, and by normalizing the resulting $2N$-dimensional column vector to have unit modulus, formally identically to the definition used in (10.30) for the single-mode case [10.76–78],

$$\boldsymbol{E}(z,t) = \begin{pmatrix} E_1(z,t) \\ E_2(z,t) \\ \vdots \\ E_{2N} \end{pmatrix}, \quad |e(z,\omega)\rangle = \frac{\tilde{\boldsymbol{E}}(z,\omega)}{|\tilde{\boldsymbol{E}}(z,\omega)|}\,. \tag{10.49}$$

The symbol $\boldsymbol{E}$, which was previously used to denote a two-dimensional column vector, here denotes a $2N$-dimensional column vector.

The generalization of the Stokes representation is less straightforward and entails a generalization of the Pauli matrix formalism. A convenient starting point is (10.35), which shows that the Stokes representation of a single-mode field is related to the expansion of the projection operator $|e\rangle\langle e|$ in terms of the Pauli matrices. Since $|e\rangle\langle e|$ is a $2N\times 2N$ Hermitian matrix for $N > 1$ as well as for $N = 1$, (10.35) can be generalized into

$$|e\rangle\langle e| = \frac{1}{2N}\left(\mathbf{I} + \boldsymbol{s}\cdot\boldsymbol{\Lambda}\right), \tag{10.50}$$

where $\boldsymbol{s}$ is the generalized Stokes vector and $\boldsymbol{\Lambda}$ is a vector collecting the generalized Pauli matrices Λ_n, which must be traceless Hermitian matrices fulfilling the following trace-orthogonality condition,

$$\mathrm{tr}\{\Lambda_m\Lambda_n\} = 2N\delta_{n,m}\,. \tag{10.51}$$

Matrices of this type form a basis for all $2N\times 2N$ traceless Hermitian matrices (a recursive algorithm to construct the matrices Λ_n for any number of modes is illustrated in the appendix of [10.78]). These have $D = 4N^2 - 1$ degrees of freedom, as follows from the fact that the elements on the main diagonal are real-valued and the off-diagonal elements are complex-conjugate in pairs. The subtraction of one accounts for the zero-trace constraint. These considerations imply that the generalized Stokes vectors are D-dimensional and real-valued, where D is hence the dimensionality of the generalized

Stokes space. Note, however, that the region spanned by the Stokes vectors is only $(4N-2)$-dimensional, like the hyperpolarization space (the $2N$ complex-valued entries of $|e\rangle$ minus the unit-magnitude constraint and the common phase of the hyperpolarization vector).

Equations (10.50) and (10.51) imply the following generalized properties

$$e_n = \langle e|\Lambda_n|e\rangle, \quad n \in \{1,\ldots,D\}\,, \tag{10.52}$$

$$\boldsymbol{e} = \langle e|\boldsymbol{\Lambda}|e\rangle\,, \tag{10.53}$$

$$|\langle u|v\rangle|^2 = \frac{1}{2N}\left(1+\boldsymbol{u}\cdot\boldsymbol{v}\right)\,. \tag{10.54}$$

Note that the length of the generalized Stokes vectors is given by $|\boldsymbol{e}| = \sqrt{2N-1}$, as follows from (10.54) for $u = v$. Another important consequence of the same equation is that Stokes vectors corresponding to orthogonal Jones vectors (for which $\langle u|v\rangle = 0$) are characterized by the relation $\boldsymbol{u}\cdot\boldsymbol{v} = -1$, which in the multidimensional case does not imply that $\boldsymbol{u}$ and $\boldsymbol{v}$ are antiparallel. In fact, since their magnitude is not 1, one can define the angle α formed by two Stokes vectors corresponding to orthogonal Jones vectors through the equality $\boldsymbol{u}\cdot\boldsymbol{v} = (2N-1)\cos(\alpha) = -1$. We note that this result does not change by normalizing the generalized Stokes vectors to have unit length, as is done in [10.79].

10.5 Mode Coupling and Unitary Propagation in SDM Fibers

In the absence of MDL, mode coupling in a fiber that supports $2N$ modes is described by a unitary $2N\times 2N$ matrix $\mathbf{U}(z,\omega)$, whose evolution obeys the equation,

$$\frac{\mathrm{d}\mathbf{U}(z,\omega)}{\mathrm{d}z} = \mathrm{j}\mathbf{B}(z,\omega)\mathbf{U}(z,\omega)\,, \tag{10.55}$$

which is identical to (10.40), provided that the symbol $\mathbf{B}$ denotes a $2N\times 2N$ Hermitian matrix. The individual terms of $\mathbf{B}$ account for the coupling between pairs of modes, whereas blocks of $\mathbf{B}$ describe the coupling within and between groups of degenerate modes. An illustration is presented in Fig. 10.10.

The matrix $\mathbf{B}$ can be expanded in terms of the generalized Pauli matrices, thereby rendering (10.50) into

$$\frac{\mathrm{d}\mathbf{U}(z,\omega)}{\mathrm{d}z} = \mathrm{j}\left[\beta_0(z,\omega)\mathbf{I} + \frac{1}{2N}\boldsymbol{\beta}(z,\omega)\cdot\boldsymbol{\Lambda}\right]\mathbf{U}(z,\omega)\,, \tag{10.56}$$

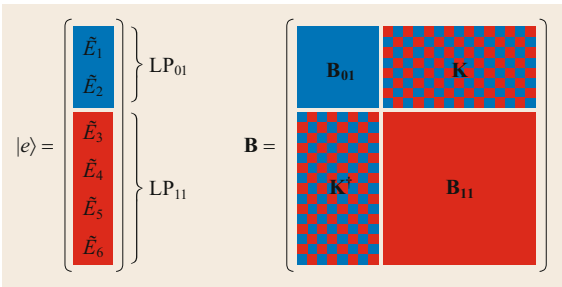

Fig. 10.10 The matrix $\mathbf{B}$ describing linear coupling in a fiber that supports propagation of LP_{01} and LP_{11} mode groups. The 2×2 block $\mathbf{B}_{01}$ accounts for polarization coupling within the fundamental mode, while the 4×4 block $\mathbf{B}_{11}$ accounts for mode coupling within the LP_{11} group. The 2×4 block $\mathbf{K}$ and its Hermitian adjoint $\mathbf{K}^\dagger$ describe intergroup mode coupling

where $\beta_0(z,\omega)$ has the meaning of the mode-averaged propagation constant, whereas the D-dimensional vector $\boldsymbol{\beta}(z,\omega)$ accounts for the mismatch between the various propagation constants, as well as for the local mode coupling [10.80, 81]. An alternative form of (10.55), which is often encountered in the literature, is obtained by accounting separately for the propagation constants of the individual modes,

$$\frac{\mathrm{d}\mathbf{U}(z,\omega)}{\mathrm{d}z} = \mathrm{j}\left[\mathbf{B}_0 + \frac{1}{2N}\boldsymbol{b}(z,\omega)\cdot\boldsymbol{\Lambda}\right]\mathbf{U}(z,\omega)\,, \tag{10.57}$$

where $\mathbf{B}_0$ denotes a diagonal matrix whose nonzero elements are the propagation constants of the individual modes, and where the vector $\boldsymbol{b}(z,\omega)$ only accounts for the mode coupling caused by the fiber perturbations. Clearly, this description is only appropriate in the case where the spatial modes used as a basis for the field lateral profile are also true fiber modes. In this case, in the absence of coupling ($\boldsymbol{b} = 0$) (10.57) yields $\mathbf{U} = \exp(\mathrm{j}\,\mathbf{B}_0 z)$. If the spatial modes assumed for the field lateral profile expansion are not true fiber modes (as is rigorously the case in the LP representation), then $\mathbf{B}_0$ is nondiagonal [10.71, 80, 82] and it accounts for the deterministic and periodic coupling that occurs between the spatial modes of the basis.

Similarly to the single-mode case, there is no closed-form solution for (10.57), except when the generalized birefringence vector is independent of z. In this situation (10.42)–(10.44) apply also to the case of multiple modes, provided that the quantity $\boldsymbol{\sigma}/2$ be replaced with $\boldsymbol{\Lambda}/2N$. A major difference between the single-mode and the multimode case stems from the fact that while the matrix $\boldsymbol{r}\cdot\boldsymbol{\sigma}$ admits two orthogonal eigenvectors, the matrix $\boldsymbol{r}\cdot\boldsymbol{\Lambda}$ admits $2N$ orthogonal eigenvectors,

and hence the matrix $\mathbf{U}$ can be expanded as

$$\mathbf{U} = \mathrm{e}^{\mathrm{j}\phi_0} \sum_{n=1}^{2N} \mathrm{e}^{\mathrm{j}\phi_n} |p_n\rangle\langle p_n| \tag{10.58}$$

where $|p_n\rangle$ and ϕ_n are the n-th eigenstate of $\boldsymbol{r}\cdot\boldsymbol{\Lambda}$ and the corresponding eigenvalue, respectively, and where $\sum_n \phi_n = 0$.

The Stokes-space representation of unitary evolution in the case of multiple-mode propagation is formally identical to the one discussed for single-mode fibers, and the main differences have to do with the increased dimensionality of the generalized Stokes space. Indeed, a unitary $4N\times 4N$ Jones matrix $\mathbf{U}$ corresponds to a norm-preserving transformation $\mathbf{R}$ in the $D\times D$ Stokes space, which can be still interpreted as a rotation, yet on a hypersphere, thereby failing to provide an intuitive description of the Stokes vector evolution. The relation connecting $\mathbf{U}$ and $\mathbf{R}$ is obtained from (10.46), by replacing the Pauli matrices with their generalized version, while the evolution equation for the generalized Stokes vector becomes

$$\begin{aligned}\frac{\partial \boldsymbol{e}}{\partial z} &= \mathrm{tr}\left[\boldsymbol{\Lambda}\,\mathrm{j}\frac{(\boldsymbol{\beta}\cdot\boldsymbol{\Lambda})(\boldsymbol{e}\cdot\boldsymbol{\Lambda}) - (\boldsymbol{e}\cdot\boldsymbol{\Lambda})(\boldsymbol{\beta}\cdot\boldsymbol{\Lambda})}{2N}\right] \\ &= \boldsymbol{\beta}\times\boldsymbol{e}\,,\end{aligned} \tag{10.59}$$

where the first equality follows from (10.56) and the second relies on the generalization of the vector product to the multidimensional case [10.78]. The k-th component of the generalized vector product between vectors $\boldsymbol{A}$ and $\boldsymbol{B}$ is defined as

$$(\boldsymbol{A}\times\boldsymbol{B})_k = \sum_{i,j} f_{i,j,k} A_i B_j\,, \tag{10.60}$$

where by $f_{i,j,k}$ we denote the structure constants

$$f_{i,j,k} = \frac{\mathrm{j}}{(2N)^2}\mathrm{tr}\left[\Lambda_k(\Lambda_i\Lambda_j - \Lambda_j\Lambda_i)\right]. \tag{10.61}$$

Equation (10.59) is formally identical to the dynamic equation (10.47) obtained for single-mode propagation, and in principle it can be used for numerical simulations, just like in the single-mode case. Also, similarly to the case of a single-mode fiber, the Jones matrix $\mathbf{U} = \exp(\mathrm{j}\boldsymbol{r}\cdot\boldsymbol{\Lambda}/2N)$ is isomorphic to $\mathbf{R} = \exp(\boldsymbol{r}\times)$, where by $\boldsymbol{r}\times$ we denote the $D\times D$ matrix operator that returns the vector product $\boldsymbol{r}\times\boldsymbol{s}$, when applied to the vector $\boldsymbol{s}$. The expression of $\boldsymbol{r}\times$ follows from (10.60). It is interesting to note that the propagation matrix $\mathbf{R}$ cannot pull a legitimate Stokes vector out of the manifold of the legitimate Stokes vectors, and it can be shown that only Stokes vectors corresponding to the eigenstates of $\boldsymbol{r}\cdot\boldsymbol{\Lambda}$ are eigenstates of $\mathbf{R}$.

10.5.1 Modal Dispersion

The term modal dispersion is used to address two distinct phenomena. One is the modal dependence of the field group velocity, and the other is the frequency dependence of the random coupling process.

In the case of single-mode fibers, where the two polarizations of the fundamental mode are perfectly degenerate, modal dispersion is referred to as polarization-mode dispersion (PMD) and is a manifestation of the frequency dependence of the fiber random birefringence. In the case of multimode fiber structures, modal dispersion arises primarily from the group velocity mismatch existing between the fiber modes, but its properties are profoundly influenced by the regime of coupling that characterizes the multimode propagation. In all cases modal dispersion introduces a delayed channel response which needs to be equalized at the receiver end by means of MIMO techniques, thereby obviously increasing the complexity of the MIMO-DSP receiver. In what follows, we review the formalism developed for the study of PMD in single-mode fibers and discuss its generalization to the case of SDM fibers.

Polarization-Mode Dispersion in Single-Mode Fibers

The unitary condition $\mathbf{U}(z,\omega)\mathbf{U}^\dagger(z,\omega) = \mathbf{I}$ implies that the equation describing the frequency dependence of $\mathbf{U}$ is of the same form as (10.41) (which describes its z-dependence), namely

$$\frac{\partial \mathbf{U}(z,\omega)}{\partial\omega} = \mathrm{j}\left[\tau_0(z,\omega)\mathbf{I} + \frac{1}{2}\boldsymbol{\tau}(z,\omega)\cdot\boldsymbol{\sigma}\right]\mathbf{U}(z,\omega)\,. \tag{10.62}$$

The meaning of τ_0 and $\boldsymbol{\tau}$ is easily understood when they do not depend on frequency and hence (10.62) has the following simple solution

$$\mathbf{U}(z,\omega) = \exp(\mathrm{j}\tau_0\omega)\exp\left(\frac{\mathrm{j}}{2}\boldsymbol{\tau}\cdot\boldsymbol{\sigma}\,\omega\right)\mathbf{U}(z,0) \tag{10.63}$$

$$= \mathrm{e}^{\mathrm{j}\tau_0\omega}(\mathrm{e}^{\mathrm{j}\tau\omega/2}|\tau\rangle\langle\tau| + \mathrm{e}^{-\mathrm{j}\tau\omega/2}|\tau_\perp\rangle \times\langle\tau_\perp|)\mathbf{U}(z,0)\,, \tag{10.64}$$

where the second equality follows from the discussion related to (10.45). Here by $|\tau\rangle$ and $|\tau_\perp\rangle$, we denote the Jones vectors that correspond to the Stokes vectors $\pm\hat{\tau} = \pm\boldsymbol{\tau}/\tau$, with $\tau = |\boldsymbol{\tau}|$. This form indicates that a polarized input signal characterized by a state vector $|p\rangle$ such that $\mathbf{U}(z,0)|p\rangle = |\tau\rangle$ or by an orthogonal state $|p_\perp\rangle$ such that $\mathbf{U}(z,0)|p_\perp\rangle = |\tau_\perp\rangle$ is simply delayed by $\tau_0 + \tau/2$ or $\tau_0 - \tau/2$, respectively, at propagation dis-

tance z, namely

$$f(t)|p\rangle \rightarrow f\left(t-\tau_0-\frac{\tau}{2}\right)|\tau\rangle\,, \tag{10.65}$$

$$f(t)|p_\perp\rangle \rightarrow f\left(t-\tau_0+\frac{\tau}{2}\right)|\tau_\perp\rangle. \tag{10.66}$$

The polarization states $|p\rangle$ and $|p_\perp\rangle$ are known as *principal states of polarization* (PSP) and the relative delay τ that they accumulate during propagation is known as the *differential group delay* (DGD) (it is customary to refer to $|\tau\rangle$ and $|\tau_\perp\rangle$ as the slow and the fast PSPs, respectively, consistent with the fact that $|\tau\rangle$ is delayed with respect to $|\tau_\perp\rangle$). The vector $\boldsymbol{\tau}$, which as discussed provides a complete characterization of the PSPs, is famously known as the PMD vector.

The effect of PMD on arbitrarily polarized input states can be more conveniently described by introducing the distinction between *input* and *output* PSPs (this distinction is often erroneously ignored in the literature, however it becomes unnecessary if one assumes that no coupling occurs at $\omega = 0$ ($\mathbf{U}(z,0) = \mathbf{I}$), or equivalently if the Jones vectors are expressed in a rotating reference frame where this is the case). Indeed, $|p\rangle$ and $|p_\perp\rangle$ should be more correctly referred to as the *input* PSPs, whereas $|\tau\rangle$ and $|\tau_\perp\rangle$ should be referred to as the *output* PSPs. Using the simple relation existing between them, (10.64) can be re-expressed in the following form

$$\mathbf{U}(z,\omega) = \mathrm{e}^{\mathrm{j}\tau_0\omega}\left(\mathrm{e}^{\mathrm{j}\tau\omega/2}|\tau\rangle\langle p| + \mathrm{e}^{-\mathrm{j}\tau\omega/2}|\tau_\perp\rangle\langle p_\perp|\right), \tag{10.67}$$

which can be used to see that an input signal characterized by the state vector $|u\rangle$, during propagation splits into two replicas that are separated in time by the DGD,

$$f(t)|u\rangle \rightarrow \langle p|u\rangle f\left(t-\tau_0-\frac{\tau}{2}\right)|\tau\rangle + \langle p_\perp|u\rangle f\left(t-\tau_0+\frac{\tau}{2}\right)|\tau\rangle\,. \tag{10.68}$$

The two replicas are polarized along the output PSPs, whereas their amplitudes are equal to the projections of the input signal state vector onto the input PSPs. Equation (10.68) reduces to (10.65) or (10.66) if $|u\rangle = |p\rangle$ or $|u\rangle = |p_\perp\rangle$, respectively.

We recall that (10.67) and (10.68) were derived under the assumption that the PMD vector does not depend on frequency. The resulting description of PMD is hence an approximation usually referred to as a *first-order PMD picture*. Assessing the accuracy of this approximation requires studying the statistical properties of the PMD vector, which are briefly reviewed in what follows.

The PMD vector evolution equation is obtained in two steps. We first equate the two expressions for $\partial^2\mathbf{U}/\partial z\partial\omega$ obtained from (10.41) and (10.62), with the result

$$\frac{\partial\tau_0}{\partial z} = \frac{\partial\beta_0}{\partial\omega}\,, \tag{10.69}$$

$$\frac{\partial\boldsymbol{\tau}}{\partial z}\cdot\boldsymbol{\sigma} = \frac{\partial\boldsymbol{\beta}}{\partial\omega}\cdot\boldsymbol{\sigma} + \mathrm{j}\frac{(\boldsymbol{\beta}\cdot\boldsymbol{\sigma})(\boldsymbol{\tau}\cdot\boldsymbol{\sigma}) - (\boldsymbol{\tau}\cdot\boldsymbol{\sigma})(\boldsymbol{\beta}\cdot\boldsymbol{\sigma})}{2}\,. \tag{10.70}$$

The first equation describes the accumulation of the polarization-averaged delay. The second can be further simplified by tracing out the Pauli matrices, with the same procedure illustrated in (10.47). The result is the famous PMD dynamic equation

$$\frac{\partial\boldsymbol{\tau}}{\partial z} = \frac{\partial\boldsymbol{\beta}}{\partial\omega} + \boldsymbol{\beta}\times\boldsymbol{\tau}\,. \tag{10.71}$$

The dependence of the birefringence vector on propagation distance renders the evolution of the PMD vector nontrivial. Most importantly, since $\boldsymbol{\beta}$ is random in nature (it describes random mode coupling), the PMD vector $\boldsymbol{\tau}$ is also random. The statistical properties of the birefringence vector of single-mode fibers have been accurately characterized in the past decade, and a well-established result is that its typical correlation length ranges from a few meters to a few hundreds of meters [10.75], implying that thousands of independent contributions accumulate over typical fiber lengths in metro and long-haul systems. This simple argument, in conjunction with the central-limit theorem, legitimates the description of the PMD vector evolution in terms of a three-dimensional Brownian motion [10.83]. That is, the three components of the PMD vector are independent and identically distributed Gaussian variables, and its length—the DGD—is characterized by a Maxwellian probability density function (plotted in Fig. 10.11a). The mean PMD vector length (or, equivalently, the mean DGD) is proportional to the square-root of the propagation distance

$$\langle\tau(z)\rangle = \kappa_{\mathrm{PMD}}\sqrt{z}\,, \tag{10.72}$$

where by angled brackets we denote ensemble averaging, and where the proportionality coefficient κ_{PMD} is the familiar PMD coefficient (note that the mean value of the DGD is frequency-independent, as it follows from the stationarity of the PMD process with respect to frequency). The PMD coefficient is customarily specified in units of $\mathrm{ps}/\sqrt{\mathrm{km}}$ and typical values range from $0.01\,\mathrm{ps}/\sqrt{\mathrm{km}}$ in modern low-PMD fibers to $0.5\,\mathrm{ps}/\sqrt{\mathrm{km}}$ in installed vintage systems [10.84]. We stress that the square-root growth of the mean DGD results from the random nature of the birefringence vector $\boldsymbol{\beta}$, while the details of the birefringence statistics

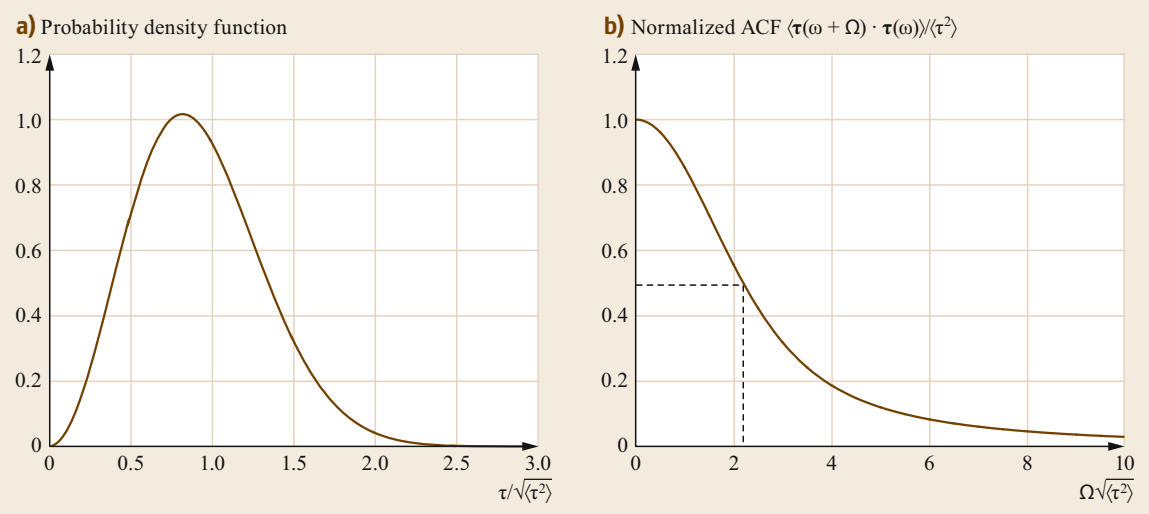

Fig. 10.11 **(a)** The probability density function of the DGD normalized to its root-mean-square value. **(b)** Normalized autocorrelation function of the PMD vector

are not relevant, as long as the fiber length exceeds by some orders of magnitude the birefringence correlation length. Just to mention one relevant example, it is worth pointing out that all the work carried out by Galtarossa's group [10.75, 82, 84, 85] relies on the assumption that circular birefringence is absent everywhere along the fiber, thereby implying that the third component of $\boldsymbol{\beta}$ vanishes. In this case, the second term at the right-hand side of (10.71) is the one responsible for lifting the PMD vector out of the equatorial plane in Stokes space, thereby making the assumption of vanishing circular birefringence immaterial, with the result that all of the described properties of the PMD vector are not affected by this detail of the model. Equation (10.72) can be expressed in the following equivalent form,

$$\langle \tau^2(z) \rangle = \kappa^2 z \,, \tag{10.73}$$

where $\kappa = \kappa_{\mathrm{PMD}} \sqrt{3\pi/8}$.

The random nature of PMD manifests itself also through the frequency dependence of the PMD vector, which is key to assessing the accuracy of the first-order approximation. This dependence is conveniently characterized by means of the two-frequency correlation function of the PMD vector [10.86–88], whose expression is

$$\langle \boldsymbol{\tau}(z,\omega) \cdot \boldsymbol{\tau}(z,\omega+\Omega) \rangle = 3 \frac{1 - \mathrm{e}^{-\frac{\Omega^2 \langle \tau^2(z) \rangle}{3}}}{\Omega^2} \tag{10.74}$$

The derivation of (10.74) is straightforward if one uses the tools of stochastic calculus [10.88]. The same result can also be obtained by approximating the fiber with a finite number N of constant-birefringence plates and then by taking the limit $N \to \infty$, which is the approach used in the work where (10.74) was first presented [10.86]. Note that the derivation of the autocorrelation function is performed by assuming a first-order expansion of the birefringence vector $\boldsymbol{\beta}(z, \omega + \Omega) \simeq \boldsymbol{\beta}(z,\omega) + \Omega(\partial\boldsymbol{\beta}/\partial\omega)(z,\omega)$. A similar assumption underpins the derivation of the generalized PMD vector autocorrelation function (ACF) in the multimode case. Inspecting the plot of (10.74) in Fig. 10.11 shows that the PMD vector ACF reduces to one half of its peak value at the angular frequency difference $\Omega_{3\mathrm{dB}} \simeq 2.18/\sqrt{\langle \tau^2 \rangle}$, which suggests that for smaller differences two PMD vectors are highly correlated with each other and hence the frequency dependence of the PMD vector is negligible. The corresponding frequency difference $B = \Omega_{3\mathrm{dB}}/2\pi \simeq 0.347/\sqrt{\langle \tau^2 \rangle}$ is often used as a definition of the PMD bandwidth, with the idea that the first-order PMD approximation only applies to the transmission of signals whose bandwidth does not exceed the PMD bandwidth. It is worth pointing out that in the case of single-mode fiber systems, this is almost always the case, for single-channel bandwidths of the order of a few tens of GHz. As an example consider a 1000 km link: for a legacy fiber with a PMD coefficient $\kappa_{\mathrm{PMD}} = 0.1\,\mathrm{ps}/\sqrt{\mathrm{km}}$, the PMD bandwidth is $B \simeq 100\,\mathrm{GHz}$, and it increases to $B \simeq 1\,\mathrm{THz}$ in the case of a low-PMD fiber with $\kappa_{\mathrm{PMD}} = 0.01\,\mathrm{ps}/\sqrt{\mathrm{km}}$. The situation is substantially different in the case of multimode fibers, as is discussed in the next section.

To conclude this section, we remind the reader that PMD is a unitary effect and hence, unlike PDL [10.89],

does not imply a fundamental system information capacity loss. For this reason, its effect can in principle be fully compensated for in the digital domain at the receiver of a polarization-multiplexed coherent system. The complexity of the necessary DSP scales with the magnitude of the system PMD (the differential delay that needs to be accommodated in time-domain equalization algorithms [10.90]), or equivalently with the PMD bandwidth (the resolution required in frequency-domain equalization algorithms [10.91]).

Generalization of the PMD Formalism

The derivation of (10.62) relies solely on the unitary nature of the Jones matrix $\mathbf{U}(z,\omega)$. Its extension to the case of multimode fiber structures is thereby straightforward, and the resulting equation can be expressed as

$$\frac{\partial \mathbf{U}(z,\omega)}{\partial \omega} = \mathrm{j}\left[\tau_0(z,\omega)\mathbf{I} + \frac{1}{2N}\boldsymbol{\tau}(z,\omega)\cdot\boldsymbol{\Lambda}\right]\mathbf{U}(z,\omega)\,, \tag{10.75}$$

where τ_0 is now the mode-averaged group delay, and $\boldsymbol{\tau}$ is a D-dimensional real-valued vector that generalizes the PMD vector and that is referred to as the *mode dispersion* (MD) vector [10.78]. Its evolution equation is also derived with the same procedure described in the single-mode case and the result is identical to (10.71), provided that the symbol $\times$ is used to denote the generalized vector product. A major difference with respect to the single-mode case is due to the phase and group velocity mismatch existing between the various fiber modes. As pointed out in the discussion of (10.56) and (10.57), this mismatch is captured by the generalized birefringence vector, which can be conveniently expressed as the sum of two contributions,

$$\boldsymbol{\beta}(z,\omega) = \boldsymbol{\beta}_\mathrm{d}(\omega) + \boldsymbol{\beta}_\mathrm{r}(z,\omega)\,, \tag{10.76}$$

where the term $\boldsymbol{\beta}_\mathrm{d}$ is the deterministic content of $\boldsymbol{\beta}$ accounting for the propagation constants mismatch (which is constant along the fiber, unless some specific special fiber design is considered), while the term $\boldsymbol{\beta}_\mathrm{r}$ models random coupling between modes. Moreover, if the spatial modes used for representing the field lateral profile are not true fiber modes, $\boldsymbol{\beta}_\mathrm{d}$ must also account for the deterministic coupling between them. With the formalism of (10.57), $\boldsymbol{\beta}_\mathrm{d}$ can be extracted using $\beta_{\mathrm{d},n} = \mathrm{tr}(\Lambda_n \mathbf{B}_0)/2N$, where $n = 1\ldots D$. As an example, Fig. 10.12 illustrates the case of a coupled-core three-core fiber where the spatial-modes basis consists of the fundamental modes of the individual cores (they are not true fiber modes—the true fiber modes are supermodes, as discussed in Sect. 10.3.3). In this case, one can compute [10.80] $\boldsymbol{\beta}_\mathrm{d} = 2b\sqrt{N}(\hat{e}_{10}+\hat{e}_{16}+\hat{e}_{18}+\hat{e}_{24}+\hat{e}_{26}+\hat{e}_{32})$, where $\hat{\boldsymbol{e}}_j, j = 1\ldots 35$ is a unit vector in the j-th direction of the generalized Stokes space.

Using (10.76), the MD vector evolution equation reads as

$$\frac{\partial \boldsymbol{\tau}}{\partial z} = \frac{\mathrm{d}\boldsymbol{\beta}_\mathrm{d}}{\mathrm{d}\omega} + \frac{\partial \boldsymbol{\beta}_\mathrm{r}}{\partial \omega} + (\boldsymbol{\beta}_\mathrm{d} + \boldsymbol{\beta}_\mathrm{r})\times\boldsymbol{\tau}\,. \tag{10.77}$$

The term $\partial\boldsymbol{\beta}_\mathrm{r}/\partial\omega$, which accounts for the frequency dependence of the perturbations, contributes to the evolution of the MD vector to a negligible extent as compared to the $\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega$, which accounts for the deterministic walk-off between nondegenerate modes, and hence can be ignored. The simplified evolution equation,

$$\frac{\partial \boldsymbol{\tau}}{\partial z} = \frac{\mathrm{d}\boldsymbol{\beta}_\mathrm{d}}{\mathrm{d}\omega} + (\boldsymbol{\beta}_\mathrm{d} + \boldsymbol{\beta}_\mathrm{r})\times\boldsymbol{\tau}\,, \tag{10.78}$$

shows that the local contribution to the MD vector $\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega$ is constant along the fiber, while the overall z-dependent birefringence vector $\boldsymbol{\beta}_\mathrm{d}(\omega) + \boldsymbol{\beta}_\mathrm{r}(z,\omega)$ rotates the MD vector as it accumulates along the fiber. This dynamics suggests that in the multimode case the statistics of the MD vector depend on the effectiveness with which the MD vector is randomized by the random birefringence, with different results in the two relevant regimes of weak and strong mode coupling.

Like in the single-mode fiber case, an intuitive interpretation of the MD vector can be gained from the first-order picture. In fact, the PSP expansion of the channel transfer matrix $\mathbf{U}$ in (10.67) is generalized to the multimode case in the following form,

$$\mathbf{U}(z,\omega) = \mathrm{e}^{\mathrm{j}t_0\omega}\sum_{n=1}^{2N}\mathrm{e}^{\mathrm{j}t_n\omega}|\tau_n\rangle\langle p_n|\,, \tag{10.79}$$

$$\boldsymbol{E} = \begin{bmatrix} E_{1x} \\ E_{1y} \\ E_{2x} \\ E_{1y} \\ E_{3x} \\ E_{3y} \end{bmatrix} \qquad \mathbf{B}_0 = \begin{bmatrix} 0 & 0 & b & 0 & b & 0 \\ 0 & 0 & 0 & b & 0 & b \\ b & 0 & 0 & 0 & b & 0 \\ 0 & b & 0 & 0 & 0 & b \\ b & 0 & b & 0 & 0 & 0 \\ 0 & b & 0 & b & 0 & 0 \end{bmatrix}$$

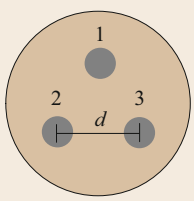

Fig. 10.12 State vector $\boldsymbol{E}$ in a three-core fiber, where the field is represented in the basis of the fundamental modes of the individual fiber cores, and the matrix $\mathbf{B}_0$ describing the deterministic coupling between them

where the output principal states (PSs) $|\tau_n\rangle$ are the $2N$ orthogonal eigenstates of the matrix $\boldsymbol{\tau}\cdot\boldsymbol{\Lambda}$ (they are related to the input PSPs $|p_n\rangle$ through $|\tau_n\rangle = \mathbf{U}(z,0)|p_n\rangle$), and the corresponding delays are referred to the mode-averaged group delay t_0, so that $\sum_n t_n = 0$. Thus, an input signal characterized by the state vector $|u\rangle$, as a result of propagation splits into $2N$ replicas, each delayed by $t_0 + t_n$,

$$f(t)|u\rangle \rightarrow \sum_{n=1}^{2N} \langle p_n|u\rangle f(t - t_0 - t_n)|\tau_n\rangle \,. \tag{10.80}$$

The analytical extraction of the mode delays, which are the eigenvalues of the matrix $(\boldsymbol{\tau}\cdot\boldsymbol{\Lambda})/2N$, in the multimode case is not as straightforward as in the single-mode case (where $t_1 = \tau/2$ and $t_2 = -\tau/2$), however the mode delays are related to the MD vector through the following simple relation

$$\tau^2 = 2N\sum_{n=1}^{2N} t_n^2 \,. \tag{10.81}$$

Within the first-order picture, the most relevant quantity is the largest differential group delay (LDGD), also referred to as the *delay spread* [10.92]), which is defined as the difference between the largest and the smallest of the $2N$ delays. The LDGD is the time interval that needs to be accommodated at the MIMO-DSP receiver, and it obviously affects the complexity of the MIMO-DSP receiver [10.93]. In this framework the statistics of the LDGD is of primary importance, as LDGD fluctuations might cause system outages if not properly accounted for in the receiver design. These considerations underpinned early studies of MD in SDM fibers, which were focused primarily on characterizing the probability density function of the LDGD [10.77, 78]. More recently, however, it became clear that the first-order picture can accurately describe MD in fibers with negligible mode coupling, whereas it is fundamentally inconsistent in the most relevant case of SDM fibers with strong mode coupling [10.80, 81, 94]. These two cases are discussed in what follows.

Modal Dispersion in the Regime of Weak Mode Coupling

Weak coupling between modes results from a large mismatch between the modes' propagation constants. In this regime modal dispersion manifests itself primarily in the form of modal walk-off, where distinct groups of quasi-degenerate modes accumulate a differential delay that increases proportionally to the propagation distance. Using the Stokes-space formalism, this result emerges from (10.78), which by setting $\boldsymbol{\beta}_\mathrm{r} = 0$, yields $\boldsymbol{\tau} = (\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega)z$ (this simple result follows from the fact that $\boldsymbol{\beta}_\mathrm{d}$ and $\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega$ are parallel vectors, as discussed in [10.80]). In this case, the first-order approximation is legitimate for signals within whose bandwidth the term $\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega$ does not vary significantly. In particular, in the familiar case of two uncoupled groups of degenerate modes, this expression of the MD vector can be shown to produce two distinct delays, whose absolute difference is equal to the differential group delay $L|v_{g1}^{-1} - v_{g,2}^{-1}|$, where $v_{g,1}$ and $v_{g,2}$ denote the group velocities of the two mode groups. Modal dispersion within the two groups of modes adds to the much larger intergroup dispersion, implying an almost negligible effect on the MIMO-DSP complexity, which depends primarily on the intergroup differential delay. This regime includes transmission in LP_{01} and LP_{11} mode groups of weakly guiding fibers, under the simplifying assumption of perfect degeneracy of the LP_{11} modes.

Obviously, the regime of weak mode coupling evolves into a regime of intermediate coupling, and eventually of strong coupling, as propagation distance increases. The analysis of this transition and its consequences for the fiber modal dispersion are rather complex and go beyond the purpose of this review. Recent studies on this subject can be found in [10.80, 94–97].

Modal Dispersion in the Regime of Strong Mode Coupling

Modes with similar propagation constants get strongly coupled over relatively short propagation distances, as a result of the fiber's perturbations. In this situation, the effect of the random birefringence vector $\boldsymbol{\beta}_\mathrm{r}$ is dominant and the most relevant properties of the MD vector can be derived by neglecting the deterministic birefringence vector $\boldsymbol{\beta}_\mathrm{d}$ in (10.78). The simplified equation,

$$\frac{\partial\boldsymbol{\tau}}{\partial z} = \frac{\mathrm{d}\boldsymbol{\beta}_\mathrm{d}}{\mathrm{d}\omega} + \boldsymbol{\beta}_\mathrm{r}\times\boldsymbol{\tau} \,, \tag{10.82}$$

differs from the PMD vector evolution equation in the forcing term, which is deterministic. Note that because of the many uncorrelated rotations of the accumulating MD vector driven by the random birefringence vector, the orientation of $\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega$ is immaterial, and the same argument used in the single-mode case can hence be used here to conclude that the MD vector evolves as a Gaussian vector too (indeed, direct measurements of the generalized birefringence vector statistics are not available yet, however the observed mode-coupling dynamics indicate that the modal content of the transmitted field in the regime of strong mode coupling is randomized over a few meters, suggesting that the correlation length of the generalized birefringence vector

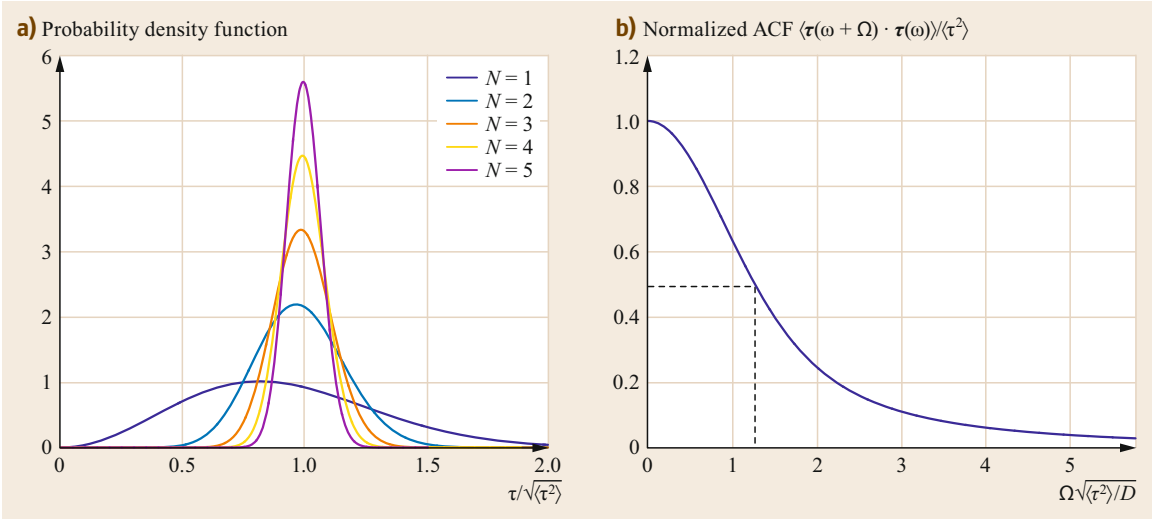

Fig. 10.13 **(a)** The probability density function of the MD vector modulus normalized to its root-mean-square value for various numbers of spatial modes. **(b)** Normalized autocorrelation function of the MD vector (the single-mode case corresponds to $D = 3$)

is of the same order or smaller than in single-mode fibers). Its modulus follows the chi distribution with D degrees of freedom (its square modulus follows the chi-squared distribution), and its mean-square value grows linearly with propagation distance, namely $\langle \tau^2 \rangle = \kappa^2 z$ (however, the dependence of the MD coefficient κ on the fiber design and perturbation statistics is rather complex [10.80]). We remind the reader that a random variable Y is chi-square-distributed with D degrees of freedom if it results from the sum of the squares of D identically distributed and zero-mean independent Gaussian variables X_n: $Y = \sum_{n=1}^{D} X_n^2$. The probability density function of τ is plotted for several values of N in Fig. 10.13a.

A major difference between the single-mode and the multimode case is in the fact that while the PMD vector length scales with the strength of the perturbations, the length of the MD vector scales with the modulus of the deterministic birefringence vector derivative $|\mathrm{d}\boldsymbol{\beta}_\mathrm{d}/\mathrm{d}\omega|$, which can be greater by orders of magnitude, depending on the deterministic walk-off between the fiber modes. An important consequence of this difference is that the MD bandwidth can be correspondingly smaller than the PMD bandwidth. Indeed, the MD vector autocorrelation function has the following form,

$$\langle \boldsymbol{\tau}(z, \omega + \Omega) \cdot \boldsymbol{\tau}(z, \omega) \rangle = \frac{D}{\Omega^2} \left[1 - \mathrm{e}^{-\frac{\Omega^2 \langle \tau^2(z) \rangle}{D}} \right], \tag{10.83}$$

and the MD bandwidth is $B_\mathrm{MD} \simeq 0.2\sqrt{D/\langle \tau^2 \rangle}$, as obtained by inspection of Fig. 10.13b (this expression can also be obtained by multiplying the PMD bandwidth by $\sqrt{D/3}$). It should be noted at this point that, while measurements of the PMD vector and its statistics are routinely performed in traditional single-mode systems, the experimental characterization of the MD vector in SDM systems is more involved [10.99] and therefore the system modal dispersion is typically characterized by exploiting the concept of the *intensity impulse response* (IIR). This is defined as the mode-averaged output power that is measured by exciting a single mode at the fiber input with a spectrally flat signal of bandwidth B. In formulae, we define the matrix $\mathbf{H}(t)$ whose (j, k) element $H_{j,k}(t)$ is the signal received in the j-th mode when the k-th mode was excited,

$$\mathbf{H}(t) = \int_{-B/2}^{B/2} \mathbf{U}(L, \omega) \mathrm{e}^{-\mathrm{j}\omega t} \frac{\mathrm{d}\omega}{2\pi}, \tag{10.84}$$

so that the IIR can be expressed as

$$I(t) = \frac{1}{2N} \sum_{j=1}^{2N} \sum_{k=1}^{2N} |H_{j,k}(t)|^2 . \tag{10.85}$$

Here the inner sum is the total output power that is measured when the j-th mode was excited, while the outer sum performs the mode averaging. If the probing signal bandwidth is sufficiently larger than the MD bandwidth (by one or more orders of magnitude), it can be shown [10.81] that the IIR is deterministic and practically independent of B. Most importantly, its temporal profile is Gaussian and the mean-square duration is very

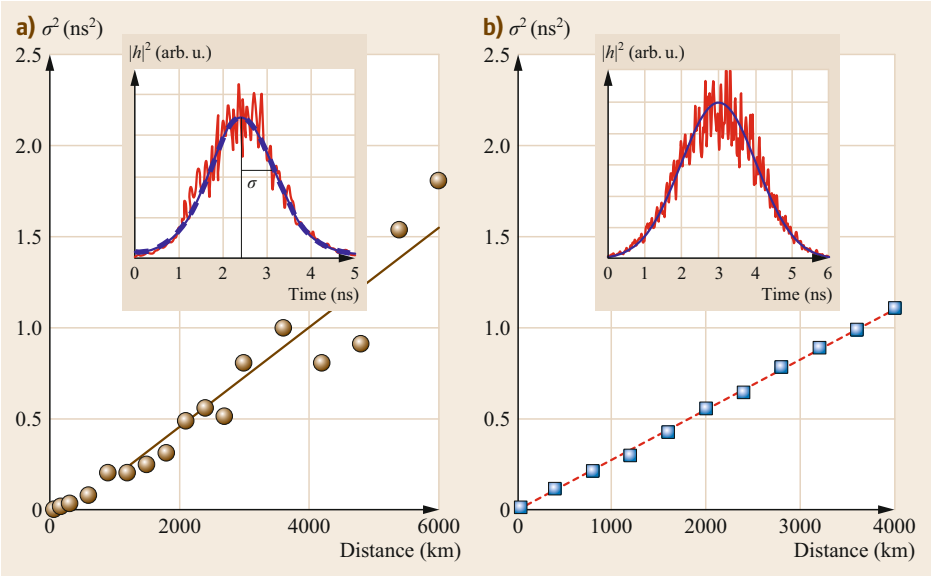

Fig. 10.14a,b The mean-square width of the intensity impulse response versus propagation distance for the coupled-core three-core fiber of [10.98]. The *inset* shows the intensity impulse response for the right-most data point. **(a)** and **(b)** present experimental [10.98] and simulation [10.81] results, respectively. The *dashed curve* in **(b)** is a plot of (10.86) (the relation between the MD coefficient κ and the fiber characteristics is discussed in [10.80])

simply related to the mean-square length of the MD vector (or, equivalently, to the MD bandwidth), namely

$$I(t) = I_0 \exp\left(-\frac{t^2}{2T^2}\right), \tag{10.86}$$

$$T^2 = \frac{\langle \tau^2 \rangle}{4N^2} = \frac{\kappa^2 z}{4N^2}, \tag{10.87}$$

where I_0 is a normalization coefficient immaterial to the present discussion. The Gaussian shape of the IIR has been observed in various experiments [10.53, 98, 100] and can be reproduced in simulations. Figure 10.14 presents a comparison between the measured and simulated IIR for the coupled-core three-core fiber used in [10.98]. The measured IIR mean-square duration of about 0.25 ns^2 at a propagation distance of 1000 km corresponds to an MD bandwidth of approximately 400 MHz, a value much smaller than typical WDM channel bandwidths used today in commercial systems. We remind the reader that, in contrast, typical PMD bandwidth values for the same link length are of the order of several hundreds of GHz (as seen in Sect. 10.5.1 *Polarization-Mode Dispersion in Single-Mode Fibers*).

The above argument shows the inadequacy of the first-order approximation to characterize the MD of SDM fibers for medium-to-long-reach transmission, where modes undergo strong coupling, and at the same time clarifies that a correct approach to designing the MIMO-DSP receiver must rely on the knowledge of the IIR duration. Strategies to reduce the receiver complexity include pursuing the reduction of the fiber MD through fiber design optimization. This approach means studying the dependence of the MD coefficient κ on the fiber characteristics (core number/geometry and/or refractive index profile), as well as on the statistics of the fiber perturbations. This is a rather challenging task and only a limited number of preliminary investigations are available in the literature [10.80, 85, 94].

10.5.2 Stokes-Space Analysis of Mode-Dependent Loss and its Impact on Information Capacity

Mode-dependent loss is a nonunitary propagation effect and as such it is responsible for impairing the capacity of SDM systems [10.55, 101–104]. The Stokes-space formalism has proven to be a convenient tool for the modeling of MDL and its impact on system performance. If we denote by S the average transmit power per mode and by $\mathbf{Q}$ the coherency matrix of the propagated amplification noise, the channel spectral efficiency in the absence of channel state information can be expressed as

$$C = \log_2\left[\det\left(\mathbf{I} + S\mathbf{Q}^{-1/2}\mathbf{U}\mathbf{U}^{\dagger}\mathbf{Q}^{-1/2}\right)\right]. \tag{10.88}$$

The matrix $\mathbf{U}\mathbf{U}^{\dagger}$ (which, in the absence of MDL, would equal the identity matrix) is Hermitian and can be expressed in terms of the generalized Pauli matrices,

$$\mathbf{U}\mathbf{U}^{\dagger} = \gamma_0 \left(\mathbf{I} + \boldsymbol{\Gamma} \cdot \boldsymbol{\Lambda}\right), \tag{10.89}$$

where γ_0 is the mode-averaged gain and the Stokes vector $\boldsymbol{\Gamma}$ is the MDL vector that generalizes the familiar PDL vector used in the single-mode fiber case. In the regime of strong mode coupling and large signal-to-noise ratio (SNR), the average spectral efficiency reduction per mode induced by MDL has been shown to be [10.103, 104]

$$\frac{C_0 - \langle C \rangle}{2N} = \frac{\langle \Gamma^2 \rangle}{3\ln(2)}, \tag{10.90}$$

where C_0 is the spectral efficiency of a perfect link, where the received SNR equals the ratio between the mode-averaged signal and the noise powers. The accuracy of (10.90) is excellent for SNR values larger than 10 dB [10.104]. A simple method for measuring $\langle \Gamma^2 \rangle$ is presented in [10.103].

A quantity which is often used as a figure of merit in the analysis of MDL is the power ratio between the least and the most attenuated hyperpolarization states, which is given by

$$\rho_{\mathrm{dB}} = 10 \log_{10}\left(\frac{1+\lambda_{\max}}{1+\lambda_{\min}}\right), \tag{10.91}$$

where $\lambda_{\max}$ and $\lambda_{\min}$ denote the largest and smallest eigenvalues of $\boldsymbol{\Gamma} \cdot \boldsymbol{\Lambda}$ (note that the corresponding loss/gain values that are measured in experiments are $\gamma_0(1+\lambda_{\max})$ and $\gamma_0(1+\lambda_{\min})$, respectively). Interestingly, in the regime of small-to-moderate MDL the mean-square length of the MDL vector is related to this quantity by the following simple relation,

$$\langle \rho_{\mathrm{dB}}^2 \rangle = \frac{10^2}{\ln^2(10)} f(N) \langle \Gamma^2 \rangle \tag{10.92}$$

with

$$f(N) = 4\frac{(N-1)^2 + 24.7(N-1) + 16.14}{0.2532(N-1)^2 + 7.401(N-1) + 16.14}. \tag{10.93}$$

This connects the average MDL-induced spectral efficiency reduction per mode caused by MDL (10.90) with the mean-square MDL expressed in logarithmic units,

$$\frac{C_0 - \langle C \rangle}{2N} = \frac{\ln^2(10)}{300\ln(2) f(N)} \langle \rho_{\mathrm{dB}}^2 \rangle. \tag{10.94}$$

This expression does not depend on the specific way in which the in-line amplifiers are operated, as discussed in [10.104].

10.6 SDM Transmission Experiments

Numerous transmission experiments have been performed over multimode fibers with the numbers of spatial modes ranging from 3 to 45 [10.14, 18, 19, 105–109]. Also, multicore fibers have been studied experimentally in detail for many possible core arrangements up to 36 cores and spatial multiplicity (number of cores × number of modes) larger than 100.

Space-division multiplexed transmission experiments are very equipment-intensive: A typical SDM transmission experiment for six spatial channels is shown in Fig. 10.15.

The transmitter consists of a traditional WDM signal, where odd and even wavelength channels are modulated separately by two double-nested Mach–Zehnder (DN-MZM) modulators driven with four independent signals carrying the underlaying transmission pattern, like for example QPSK, 16-QAM, or 64-QAM, generated by high-speed digital-to-analog converters (DACs), where pseudo-random patterns are chosen such that the cross-correlation peaks between patterns are significantly smaller than the autocorrelation peaks. This is required to properly identify the timing of the received channels, and to evaluate their performance using digital signal processing [10.121]. Additional copies of the signal are generated and decorrelated using fiber delays such that each mode and polarization carries a locally independent signal. The decorrelated signals are then injected into a six-fold recirculating loop arrangement, which is used to emulate long-distance experiments (often in SDM experiments only limited lengths of prototype fibers are available).

The loop arrangement is similar to a traditional SMF loop, except that it consists of six loops which have to be adjusted to a path-length difference of typically within 1 cm, corresponding to a time delay of 50 ps. The loop contains amplifiers to overcome the fiber loss and the loss of the additional loop components, loop switches (that are used to open and close the loop during the loading and recirculation time, respectively), combiners and splitters (to inject and extract the light from the loop), and finally programmable gain equalizing filters (denoted as blockers in Fig. 10.15), to maintain a flat spectrum after each recirculation.

The signals extracted from the loops are captured by an array of polarization-diverse coherent receivers (PD-CRXs), which extract the amplitude and phase of all modes and polarizations, so that the optical field after transmission is fully known. Note that it is necessary to measure all modes and polarization for the same time windows, therefore a digital storage oscilloscope (DSO) with 24 real-time channels is required for a transmission with 6 spatial modes (alternatively, time-multiplexed receiver schemes, where subsets of modes are delayed by single-mode fibers, have been proposed to reduce the number of ports that are necessary in the DSO [10.109, 122]).

The resulting signals are stored in the DSO, and subsequently processed by applying MIMO-DSP techniques, similar to the methods presented in Chap. 6.

Some representative results of MIMO-based transmission in multimode and coupled-core fibers are summarized in Table 10.3. By the terms *capacity* and *spectral efficiency* in the table, and more in general

in this review of experimental results, we refer to the largest achieved transmission rate, and to the same quantity divided by the total transmission bandwidth, respectively.

The longest transmission distances and highest spectral-efficiency-distance products were demonstrated in CC-MCFs, clearly confirming the advantages of the strong coupling regime. The maximum experimental capacity demonstrated in MIMO-SDM transmission clearly surpasses the largest reported values for single-mode fibers. In particular, the largest spectral efficiency demonstrated is as high as 202 (bit/s)Hz which is well above the nonlinear Shannon limit for single-mode fibers [10.1, 136] which is 26.5 (bit/s)Hz for a fiber length of 27 km, indicating that mode-multiplexed transmission over a few-mode fiber (FMF), that is, a fiber that supports 10 or fewer modes, has the technical potential to be considered as a replacement for single-mode fibers.

Transmission results for some representative multicore fiber transmission experiments are summarized in Table 10.4.

Multicore fibers, especially in combination with few-mode cores, can achieve spatial multiplicities larger than 100, providing an impressive transmission capacity in excess of 10 Pb/s, however only for distances shorter than 100 km. Longer distances up to 8800 km can be achieved using single-mode cores at a notable capacity of 520 Tb, which is of interest in particular for submarine transmission, where multiple parallel paths can achieve superior performance under a constraint of limited power [10.131].

10.7 Nonlinear Effects in SDM Fibers

In the previous sections we only considered linear effects in multimode fiber propagation. However, the transmission capacity of multimode systems, just like in the single-mode counterpart [10.1], is ultimately limited by nonlinear effects. The theory of nonlinearities in multimode fibers is challenging as all possible interactions between all involved modes have to be considered. Nonlinear multimode propagation is described by the coupled nonlinear Schrödinger equations [10.66, 67, 137]. If, for ease of discussion, we neglect loss and mode-dependent chromatic dispersion, the equations can be expressed as follows

$$\frac{\partial \boldsymbol{E}}{\partial z} = \mathrm{j}\mathbf{B}_0\boldsymbol{E} - \mathbf{B}_1\frac{\partial \boldsymbol{E}}{\partial t} - \mathrm{j}\frac{\beta_2}{2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \mathrm{j}\gamma\sum_{h,k,m,n=1}^{2N} C_{nhkm}E_h^* E_k E_m \hat{\boldsymbol{u}}_n \,, \tag{10.95}$$

where $\mathbf{B}_0 = \mathbf{B}(z,\omega_0)$ and $\mathbf{B}_1 = \partial\mathbf{B}(z,\omega_0)/\partial\omega$ account for random mode coupling and intermodal walk-off, respectively, β_2 is the mode-averaged chromatic disper-

sion coefficient, γ is the nonlinearity coefficient defined for single-mode fibers [10.138], and where by $\hat{\boldsymbol{u}}_n$ we denote a $2N$-dimensional column vector whose n-th component is equal to one and the others to zero. The nonlinearity coefficients C_{nhkm} involve overlap integrals between the modes, lateral profile functions and their expressions can be found in [10.66] and references therein. As can be seen in (10.95), the Kerr nonlinearity produces a total of $(2N)^4$ coefficients ($(2N)^3$ coefficients per mode) that have to be considered in the study of nonlinear effects. This can be a challenging task, especially when the modal properties vary strongly between modes, and in general only detailed numerical simulations will provide representative results [10.137]. In contrast, when all modal properties are similar, like in the case of strongly coupled fibers, theoretical results have indicated a significant advantage for strongly coupled SDM fibers over equivalent single-mode fibers [10.66, 139]. In the following two sections we briefly describe nonlinear experimental work performed in few-mode fibers and coupled-core multicore fibers.

10.7.1 Impact of Nonlinearities in the Strong-Coupling Regime

Coupled-core fibers are interesting for the study of nonlinear effects because all fiber modes have similar modal properties in terms of effective area and propagation coefficients, and hence the electric field propagates in the regime of strong mode coupling described earlier in this chapter. One important consequence of this situation is that the nonlinear term that appears in the propagation equation (10.95) can be drastically simplified by taking into account the fact that the length-scale on which random mode coupling is effective is by orders of magnitude smaller than typical nonlinear length-scales. The simplified propagation equation, which is known as the multicomponent Manakov equation [10.140], is in the form

$$\frac{\partial \boldsymbol{E}}{\partial z} = -\beta_1 \frac{\partial \boldsymbol{E}}{\partial t} - \mathrm{j}\frac{\beta_2}{2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \mathrm{j}\gamma\kappa|\boldsymbol{E}|^2\boldsymbol{E}\,, \tag{10.96}$$

where β_1 is the inverse group velocity common to all modes, and where the nonlinearity appears through the total optical power only, consistent with the fact that the electric field is isotropically distributed in the $2N$-dimensional hyperpolarization space. As can be seen, the $(2N)^4$ nonlinearity coefficients C_{nhkm} are replaced by a single coefficient κ, which is given by [10.140]

$$\kappa = \sum_{h,n} \frac{C_{nhhn} + C_{nhnh}}{2N(2N+1)}. \tag{10.97}$$

Equations (10.96) and (10.97) describe nonlinear propagation in the most general case of $2N$ strongly coupled modes. In the specific case of coupled-core fibers, which is considered in this section, (10.97) can be further simplified, with the result [10.66]

$$\kappa\gamma = \frac{1}{3}\frac{8}{2N+1}\gamma_0\,, \tag{10.98}$$

where γ_0 is the nonlinearity coefficient of a single-mode fiber with the same radius and refractive-index profile of the individual cores (for $N = 1$, (10.98) yields $\gamma\kappa = \frac{8}{9}\gamma_0$, the nonlinearity coefficient of the famous Manakov equation describing nonlinear propagation in single-mode fibers with random polarization coupling [10.141, 142]).

The scaling of κ with the number of modes is key to understanding the improved tolerance of coupled-core multicore fibers to nonlinear distortions. This can be easily seen by expressing the nonlinear term as $\gamma\kappa|\boldsymbol{E}|^2 \sim 4\gamma_0/3\sum_n |E_n|^2/2N$, which shows that the various modes can be considered as sources of nonlinear noise whose power is proportional to $1/(2N)^2$. Since they carry independent signals, the total nonlinear noise power results from the sum of the individual contributions and hence it scales like $\sim 2N\times 1/(2N)^2 = 1/2N$, thereby reducing with the number of strongly coupled modes supported by the fiber [10.66, 139]. A formal characterization of the nonlinear interference noise can be found in [10.143]. Note that while (10.98) is an analytical result derived specifically for coupled-core multicore fibers, the scaling $\gamma\kappa \sim 1/N$ is a more general characteristic of fibers operating in the regime of strong mode mixing. The simple argument underpinning this statement is that random mode coupling distributes the power transmitted in each mode equally between all modes, with the result that on average the nonlinearity must be proportional to the mode-averaged power, which is equal to $|\boldsymbol{E}|^2/2N$.

The superior tolerance of coupled-core multicore fibers to nonlinear distortions, as analytically predicted in [10.66, 139] and seen in early simulation work [10.144], has recently been confirmed in transmission experiments performed with a four-core fiber [10.117]. The results of an experimental comparison between a single-mode fiber [10.145] and a four-core coupled-core fiber [10.146] with nominally identical cores and the same span length are shown in Fig. 10.16.

The pure-silica core design realizes an ultralow loss and larger effective area high-performance fiber typically utilized in submarine links (see also Chap. 2 for more detail). Figure 10.16a shows the quality factor Q as a function of the launch power per wavelength

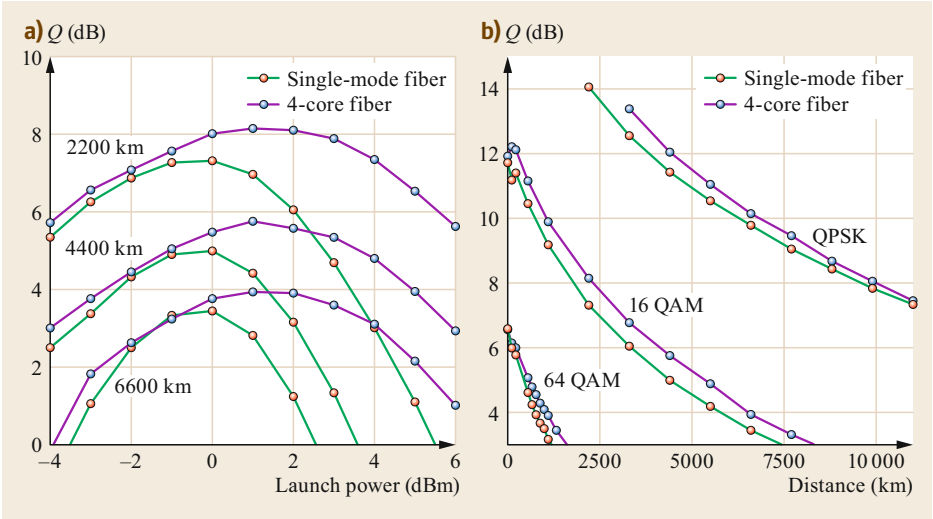

Fig. 10.16a,b Transmission performance comparison between a single-mode fiber and a 4-core coupled-core fiber with identical length and core design for a WDM signal with 15 channels at a baudrate of 30 GBd and a channel spacing of 33.33 GHz. **(a)** Quality factor Q as a function of the launch power for distances of 2200, 4400, and 6600 km, for a 16 QAM signal. **(b)** Q factor as a function of distance for QPSK, 16 QAM, and 64 QAM modulated signals

channel in a recirculating-loop system with 110-km-long spans. As can be clearly seen, the optimum launch power for the coupled-core fiber is about 2 dB larger, indicating a better tolerance to nonlinearities, which results in Q factors that are about 0.8 dB larger. Figure 10.16b compares the launch-power-optimized Q factors as functions of the propagation distance in the same recirculating-loop experiment, and for different modulation formats. The results clearly show that for all tested formats and distances up to 10 000 km the coupled-core fiber outperforms the equivalent single-mode fiber.

10.7.2 Impact of Nonlinearities in Few-Mode Fibers

Nonlinear effects in few-mode fibers are different than in single-mode fibers, as the modal properties allow for phase-matching conditions that are forbidden in single-mode fibers (see also Chap. 9 for a description of Kerr nonlinearities in single-mode fibers). For example, four-wave mixing is strongly suppressed in nonzero-dispersion single-mode fibers, because of the impact of chromatic dispersion on the phase-matching condition. In few-mode fibers, however, modal dispersion can compensate for chromatic dispersion, and therefore strong four-wave mixing can be observed. The effect can be better understood considering cross-phase modulation, where the intensity fluctuations of a signal traveling in one mode can imprint a phase on a second signal traveling in another mode. If both signals travel at the same group velocity, the interaction length for this effect becomes long, and a strong effect can be observed. As the group velocity depends on wavelength and mode, in low DGD few-mode fibers (like optimized GI fibers) it is possible to find conditions where two different modes at two different wavelengths have a matched group delay. This effect was experimentally observed in a fiber with three spatial modes [10.147] and a length of 5 km, confirming that the effect does not degrade significantly even in the presence of perturbations along the fiber. Similar experiments were also reported for fully nondegenerate four-wave mixing [10.148, 149], also confirming that four-wave mixing effects in few-mode fibers are non-negligible and can provide significant penalties for mode-multiplexed MIMO-based transmission.

As for the modeling of nonlinear propagation in few-mode fibers, we note that a similar simplification of the coupled NLSEs as in the case of coupled-core multicore fibers is obtained by taking into account the fact that modes belonging to the same group of quasi-degenerate modes mix strongly during propagation. The result is a set of coupled multicomponent Manakov equations, which in the case of two mode groups denoted a and b can be expressed in the following form,

$$\frac{\partial \boldsymbol{E}_\mathrm{a}}{\partial z} = -\beta_{1,\mathrm{a}}\frac{\partial \boldsymbol{E}_\mathrm{a}}{\partial t} - \mathrm{j}\frac{\beta_{2,\mathrm{a}}}{2}\frac{\partial^2 \boldsymbol{E}_\mathrm{a}}{\partial t^2} + \mathrm{j}\gamma\left(\kappa_\mathrm{a}|\boldsymbol{E}_\mathrm{a}|^2 + \kappa_\mathrm{ab}|\boldsymbol{E}_\mathrm{b}|^2\right)\boldsymbol{E}_\mathrm{a}\,, \tag{10.99}$$

$$\frac{\partial \boldsymbol{E}_\mathrm{b}}{\partial z} = -\beta_{1,\mathrm{b}}\frac{\partial \boldsymbol{E}_\mathrm{b}}{\partial t} - \mathrm{j}\frac{\beta_{2,\mathrm{b}}}{2}\frac{\partial^2 \boldsymbol{E}_\mathrm{b}}{\partial t^2} + \mathrm{j}\gamma\left(\kappa_\mathrm{ab}|\boldsymbol{E}_\mathrm{a}|^2 + \kappa_\mathrm{b}|\boldsymbol{E}_\mathrm{b}|^2\right)\boldsymbol{E}_\mathrm{b}\,, \tag{10.100}$$

where $\boldsymbol{E}_a$ and $\boldsymbol{E}_b$ are state vectors of dimensions $2N_a$ and $2N_b$, respectively, which describe the electric field in the two mode groups. The coupled Manakov equations, derived in [10.150] for arbitrary values of N_a and N_b, and in [10.137] for $N_a = N_b = 1$, can be used for the analytical study of intergroup nonlinear effects [10.143] under the assumption of negligible linear coupling between mode groups. However, if the propagating groups couple to a non-negligible extent, (10.99) and (10.100) must be supplemented with additional terms that account for linear intermodal crosstalk, which reduces their analytical tractability significantly [10.66, 95, 151–153].

10.8 Routing in SDM Networks

The signals transmitted over an SDM link, are typically associated with a spatial channel s_n and a wavelength channel λ_m, where the indices n and m identify the respective spatial and wavelength channel. Note that spatial channels are defined either as modes of an optical waveguide, as physically separated light-paths using multiple waveguides, or as a combination of the two.

In conventional wavelength-multiplexed networks, wavelength is used to optically route signals when traversing a network node. For each wavelength of an ingress fiber it is possible to select an egress fiber, as long as the wavelength channel of the egress fiber has not been assigned to another incoming signal at the same wavelength. This limitation is referred to as wavelength blocking and makes the initial network configuration and the subsequent channel provisioning (adding new channel routes in a live network) mathematically more complex, increases the blocking probability, and therefore reduces the capacity of the network [10.154].

For spatial channels similar limitations may occur, for example, when spatial channels are implemented by using distinct spatial modes. In contrast, if the spatial modes are carried by spatially separated waveguides, or separated by a spatial mode multiplexer, the individual spatial channels are all equivalent and can be switched between each other with no restriction.

In the general case, optical networks can be built based on nodes that are capable of switching any wavelength from any spatial channel coming from any direction, to any wavelength and to any spatial channel going to any direction (here we define directions as geographically separate routes and spatial channels as parallel-running channels, either in a single fiber like a multicore fiber, or multiple single-mode fibers hosted in a single conduit or cable). The complexity of such a node in terms of physical implementation and dynamic operation (traffic provisioning) is undesirably larger and is not cost-effective. It is therefore necessary to limit the complexity by forming logical units of switching, to reduce the logical channel number to around 100 channels for each direction. This can be achieved in various ways [10.155], and in the next sections the three most promising approaches to the bundling of wavelength/spatial channels are reviewed.

10.8.1 Parallel Single-Mode Systems

The first approach consists of duplicating conventional single-mode WDM systems and operating them in parallel. This approach in not cost-effective, but represents the baseline to be considered for alternative approaches. The most relevant limitation of this approach is that it is not possible to share resources between the duplicated systems, which may be responsible for significant blocking probability and under-utilization of resources.

10.8.2 Spatial Superchannels

In this approach the spatial channels are bundled together in a fixed number N, and components are used that can perform the equivalent single-mode operation on all N channels at the same time. The term *spatial superchannel* was coined [10.156] in reference to spectral superchannels where multiple subsequent wavelength channels are bundled to form a single spectrally wider transmission channel. Spatial superchannels look similar to a traditional single-mode system in terms of operation, except that the capacity is increased by a factor of N. This concept is particularly attractive because wavelength-selective switches supporting spatial superchannels, can be implemented using the joint switching architecture, where a single switching element can be reused to switch N channels in parallel, therefore effectively increasing the switch capacity of the switching element. This principle is shown in Fig. 10.17, where a tilt mirror is used to switch light between one input and two output superchannels, by tilting the mirrors such that the light is reflected from the input to the desired output.

In Fig. 10.17a a groupwise switching arrangement is shown which requires an N-times larger tilt angle compared to a traditional single-mode switch, whereas Fig. 10.17b shows the advantageous interleaved switching arrangement, where the superchannels can be switched by using tilt angles that are comparable

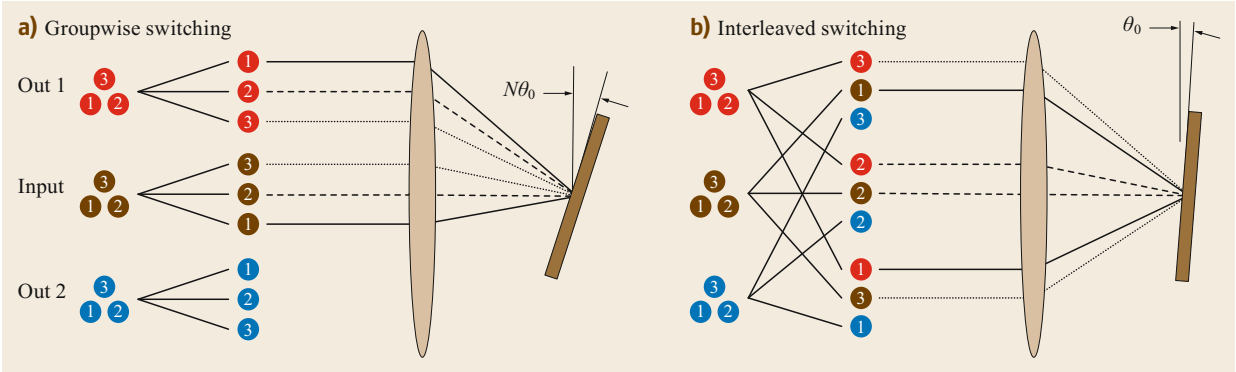

Fig. 10.17a,b Switching multiple spatial channels with a single switching element: Groupwise switching versus interleaved switching geometry

to the single-mode switch. Note that the overall switch size of a spatial superchannel switch is larger than the single-mode counterpart, as it needs to accommodate the larger required optical aperture and a more complex lens design. However, the switch element, which is often the main factor limiting the number of channels that can be switched, can stay the same size. Figure 10.17 shows the principle of a simple switch, but the same idea can also be used to build wavelength-selective switches, where light is separated in wavelength in the out-of-plane direction and the single mirror is replaced with a mirror array [10.155].

Optical networks based on the concept of spatial superchannels can be implemented with multicore fibers, where the number N of parallel channels coincides with the number of cores. The spatial superchannel architecture is of interest also for multimode fibers, where it is required to transmit all fiber modes in a common link, so that MIMO processing can be used to compensate for propagation-induced mode coupling.

Additionally, a spatial superchannel can also be used to logically bundle multiple single-mode fibers and therefore constitutes a very promising architecture for all possible SDM fiber types.

The main drawback of the spatial superchannel architecture is that there is no simple way to increase the number of parallel spatial channels N composing the superchannel once the network is deployed and operated.

10.8.3 Space-Routed Networks

An alternative way to build SDM optical networks is to completely drop the wavelength dimension for the switching domain and utilize pure spatial switching based on traditional switches that are wavelength transparent. This solution offers several advantages: All channels are equivalent and therefore no wavelength blocking is observed, which can dramatically simplify the network reconfiguration. Also, space switches are much easier to build and typically have lower loss compared to wavelength-selective switches. Furthermore, the local add/drop ports of the nodes become significantly simpler, as they are equivalent to ports carrying traffic from fibers coming from different directions.

The disadvantage of this solution is that it requires fibers with completely uncoupled spatial channels, and therefore it is not compatible with MIMO-based multimode transmission. The solution is therefore particularly attractive for single-mode and uncoupled multicore fibers. Space-routed networks also require transceivers capable of generating signals that occupy the whole transmission band. Potentially, such full-band transceivers are expected to be more economical as they offer a larger potential for integration. However, the network can suffer from granularity issues if the desired link capacity is small compared to the capacity of the full-band receiver.

10.9 Conclusion

Space-division multiplexing addresses the technologies needed to scale the link and network capacities of current optical communication systems. The main proposed solutions include new fiber types, optical amplifiers, and optical switches.

As an alternative to standard single-mode fibers, multimode fibers and multicore fibers offer effective ways to increase the spatial multiplicity of optical fibers, at the expense of more complex linear and nonlinear transmission effects that we reviewed in detail in the chapter. The

linear transmission effects in a system supporting N spatial modes can be mitigated by using $2N \times 2N$ MIMO digital signal processing, which is a generalization of the 2×2 MIMO processing used in conventional single-mode digital coherent transmission. Nonlinear impairments are typically moderately increased compared to the single-mode case, when the spatial modes are weakly coupled, whereas a reduction of nonlinear effects can be observed in the regime of strong mode mixing, like for example in the case of coupled-core multicore fibers.

Cladding- and core-pumped optical multicore and multimode amplifiers offer a sizeable potential for cost reduction by significantly reducing the number of required optical elements per amplified spatial channel.

Optical switches supporting multiple modes or spatial channels can be effectively implemented by using *joint-switching* architectures, which dramatically increase the switching capacity of the switching element by acting on all spatial channels at the same time.

Space-division multiplexing also enables multiple new network architectures. Even though no single one-size-fits-all SDM architecture is currently transpiring, technologies that are currently being investigated, have the potential to offer a significant advantage in terms of costs over parallelizing conventional single-mode fiber-based systems. The optimum solution will depend on the targeted application and in particular on the required link capacity and network granularity.

Cristian Antonelli received his PhD in 2006 from the University of L'Aquila, where he joined the Department of Physical and Chemical Sciences in 2014. Previously he was with AT&T Labs, NJ, the Research Laboratory of Electronics at MIT, and CNISM, the Italian inter-university consortium for the physics of matter. His work focuses on the modeling and characterization of fiber-optic communication systems.

Part B Core Networks

Core Netw

Part B Core Networks

Ed. by Biswanath Mukherjee

Optical networks form the high-capacity backbone of our global Internet. They provide the worldwide information superhighways that are essential to our economies and personal lives. Optical networks transport signals encoded onto light over fiber-optic cables made from glass fibers. These signals are transmitted across a telecommunications network consisting of various optical switching and processing nodes that are connected together in appropriate network architectures. Optical networks can transmit signals at extremely high bandwidths (in the Tbps regime). Since the 1980s, these networks have been a key enabling technology for cloud networks and the Internet, which are currently used to perform the vast majority of all human-to-human and machine-to-machine information data transmission.

Optical networks are used for a huge range of applications. For example, they are employed to link continents using submerged optical cables, and to connect different countries and the major cities of each country with one another using terrestrial cables. They are also applied in metropolitan area and access networks to link to end users and individual homes (i.e., fiber-to-the-home or FTTH networks), and optical networking has recently been used in datacenters.

This part (B) of the Handbook focuses on optical core networks, which provide long-distance, wide-area network coverage. Note that Part A (Optical Subsystems for Transmission and Switching) dealt with the enabling technologies upon which optical networks are built, while Part C (Datacenter and Supercomputer Networks) focuses on the application of optical networking in datacenters and supercomputers and Part D (Access Networks) covers optical access networks that connect to the core network and provide coverage to individual homes and businesses.

The material in Part B is organized as described below.

Core (backbone) network architectures as deployed by telecommunication carriers are studied in Chapter 11. While the focus is on core networks, the chapter also provides invaluable information on how the core network interworks with various types of access networks, such as FTTH networks, hybrid fiber-coaxial networks used by cable network operators, and radio access networks used by cellular network operators. This chapter also outlines the resilience strategies used by telecom carriers in their networks to ensure that network connectivity is rapidly recovered if there is a network outage. This chapter is a must-read, as it provides a clear perspective on practical core network architectures for beginners as well as those experienced in this field.

In a core network, when a node needs to communicate with another node, an efficient (and typically inexpensive) route needs to be selected from among many possible routes that may be available and then established. Also, the huge capacity of an optical fiber is carved up into smaller bandwidth chunks (typically wavelengths) to address the optoelectronic bandwidth mismatch, so an electronic transmitter can transit into a wavelength. This gives rise to the routing and wavelength assignment (RWA) problem and the light path concept for connecting two end points through a wavelength across the optical core network. Recently, to address the extensive and diverse bandwidth capabilities of transmitters and the requirements of applications/services, it is has become possible to assign bandwidth spectra of various sizes, leading to the routing and spectrum assignment (RSA) problem. Such networks are also called elastic optical networks. These topics are covered in Chapter 12.

As optical networks have matured, their design and operational standards have also evolved. These issues are covered in Chapter 13.

Chapter 14 addresses a companion topic: traffic grooming, where a connection that is set up between any two end nodes can not only carry a single service between the end points but also 'groom' (i.e., appropriately multiplex, switch at intermediate nodes, and demultiplex) multiple lower-capacity services onto higher-capacity light paths.

Chapter 15 investigates automation of the control and management of optical networks for fast optical service provisioning, as well as automated recovery from failures. It covers network discovery, dynamic service provisioning, and seamless fault recovery for optical control planes ranging from fully distributed to more recent software-defined network (SDN) frameworks.

Chapter 16 consists of two parts: (1) cross-layer design, focusing on the interactions between the physical/optical and network layers; (2) design aspects relating to the interactions between the network and application layers. Given that optical signals degrade in quality as they travel through the fiber, it is important to understand physical-layer impairments (PLIs) so that the signal can be detected at the destination. PLI-aware RWA is therefore a key issue. Also, the optical network should ultimately serve the needs of the application, so application-aware optical networking is very important too.

Virtualization is a major topic in networking, as the vast resources of a physical network can be carved up into smaller 'slices,' where each slice can, for example, be operated as an independent virtual network, pro-

vide a different service, or be dedicated to a different operation/operator. Aspects of optical network virtualization such as methods of isolating network slices from each other and the roles of SDNs and network function virtualization (NFV) technologies are discussed in Chapter 17.

Metropolitan area networks (MANs) span cities, regions, districts, and municipalities, and they connect core optical networks to access networks as well as providing broadband networking to enterprises. Chapter 18 describes MAN architectures as well as relevant technologies such as SONET/SDH, OTN, WDM, IP/MPLS, and carrier ethernet from a MAN perspective.

Energy efficiency is very important for the sustainability of our planet. Chapter 19 reviews various aspects relating to optical network energy efficiency, including the energy used by various hardware components, energy-efficient software control strategies for cross-layer design and operation, and network survivability strategies.

Strategies such as RWA, RSA, and traffic grooming mentioned above are based on optical circuit switching (OCS), which is very practical and widely deployed, particularly since OCS can also accommodate the opto-electronic bandwidth mismatch. However, client traffic can be highly dynamic and bursty, so the past few decades have seen significant interest in all-optical switching of a client's optical packets or group of packets (called a burst), giving rise to optical packet switching (OPS) and optical burst switching (OBS), respectively. While the jury is still out on the practicality of these methods today, they are included in Chapter 20 of this Handbook, as unforeseen developments may eventually make these methods more practical.

11. Carrier Network Architectures and Resiliency

Robert D. Doverspike

In this chapter we investigate carrier network architectures, and how and where resilience is provided by commercial telecommunications carriers in today's optical networks. Much of the content is generally unpublished and we provide the reader a unique insight into this topic through our privilege of working for decades on the inside of different telecommunications carriers. To provide a fuller understanding of this complex topic, we first describe the typical partitioning of terrestrial networks into their metro-access, metro-core, and intermetro segments and then describe the multilayered structure within each of these segments (Sect. 11.2). Within these constructs, we describe where and how network resiliency is provided against a modeled set of potential outages and other network impacting events (Sect. 11.3). To better understand how the resiliency techniques deployed in various layers and segments are engineered, we discuss how end-to-end services are pieced together across these segments to provide their needed network quality of service and availability. Finally, to even better understand why today's network resiliency techniques have been deployed, we take the reader through a historical evolution of how and why key resiliency technologies and methodologies were developed and deployed, including why some phased out (Sect. 11.4).

There are many published articles about optical networks, their architectures, and potential restoration and resiliency techniques. However, there is a great disparity between the published world and the reality of installed, commercial networks. One of the reasons for this disparity is that the exact structure and operation of networks in a large telecommunication carrier (or *carrier*) are generally unpublished. In general, network planners, architects, provisioners, operations, and maintenance personnel do not disclose details about their business. Furthermore, internal organizations are careful about maintaining the proprietary nature of how they run their networks. However, to understand restoration methods and operations that are vital to network resiliency, one must understand both the network architecture and how it operates. Fortunately, we have had

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_11

the privilege of working in or with some of these organizations over many decades and, as a result, the reader will enjoy a realistic development of this topic. In terms of scope, we will concentrate on terrestrial carrier-based optical (and their related) networks.

We note that there is a parallel topic of resiliency within datacenters. Networks inside large datacenters (*intradatacenter* networks) transport orders of magnitude more traffic than the networks that connect those datacenters (*interdatacenter* networks), often via privately owned and operated networks; therefore, they have a substantially different set of architectures, technologies, economics, and quality of service objectives. As such, the topic of intradatacenter networks is a major topic unto itself and is beyond the scope of our chapter. However, there are many private enterprise interdatacenter networks. These networks are usually leased overlays or cutouts from larger commercial networks and, as such, have some of the same resiliency aspects as commercial networks. We will discuss these private networks briefly in Sect. 11.3.6, *Large Enterprise Private Networks*.

Following the script of many historical movies, we will give a present-day view (snapshot) of architectures and their resulting network resiliency and then step backwards in time to discuss how these particular architectures came to be:

- Sect. 11.1 broadly discusses today's network architectures
- Sect. 11.2 examines where and how resiliency is provided in today's network architectures
- Sect. 11.3 presents why networks evolved to their present architectural state, plus looks forward to how they might evolve going forward
- Sect. 11.4 provides a summary and future directions.

As a final introductory comment, we note that there is a plethora of network restoration and resiliency papers in the published literature. It is not our objective to attempt to cover all these different ideas and proposals because there is a large gap between an idea for network restoration or resiliency applied to an abstracted, mathematical network model versus a usable and cost-effective implementation of that idea in a commercial network. For, implementing a restoration method in commercial networks that is reliable, dependable, and cost-effective is technically difficult and fraught with potential hazards. Implementing even the simplest restoration method can take many years of fine-tuning and adaptation and even after years of attempts, some of these ideas never get over the "bar" of operational reliability and performance. We will illustrate some of these real-life experiences as we go along.

11.1 Today's Network Architectures

We begin by describing how most carrier networks are architected today. Most publications study optical network availability and resiliency within a narrow context, often dominated by the abstraction within a contiguous, simplified network model. However, to provide a broader understanding of how resiliency in optical networks is related to overall service, it is important to give a more comprehensive view.

11.1.1 Network Segments and Layer

Figure 11.1 illustrates how we conceptually segment a large national terrestrial network. As mentioned in the introduction, this chapter will focus on *terrestrial* networks and therefore we will suppress the term going forward. We organize the networks of large telecommunications carriers into different segments. A national *intermetro segment* interconnects many metropolitan (metro) areas. Each of these metro areas is further decomposed into a *metro-core segment* and a *metro-access segment*. The intermetro segment directly interfaces to the metro-core segments. In the metro-core segments and intermetro segments, large carriers place most of their equipment in buildings called *central offices* (*COs*). Alternatively, smaller carriers (or sometimes large carriers in less dense areas) may instead use a large *hut* or lease portions of a larger carrier's CO (i.e., they are *colocated*). Today most central offices in developed countries are interconnected by optical fiber. The metro-access segment of the network refers to the portion of the network between a customer location and its first (serving) central office. Note that the term *customer* could include another carrier who purchases wholesale services from an incumbent carrier. While this chapter is focused on optical networks, end-to-end services must often be transported over mixed media in the metro-access segment and therefore we will also consider other media, such as coax and wireless.

The networks in each of these segments are further organized into network layers that consist of nodes (switching or cross-connect equipment) and links (logical adjacencies between the equipment), which we can visually depict as network graphs vertically stacked on top of one another. Links (capacity) of a higher layer network are provided as *connections* in lower layer networks (also called traffic, demand, or circuits, de-

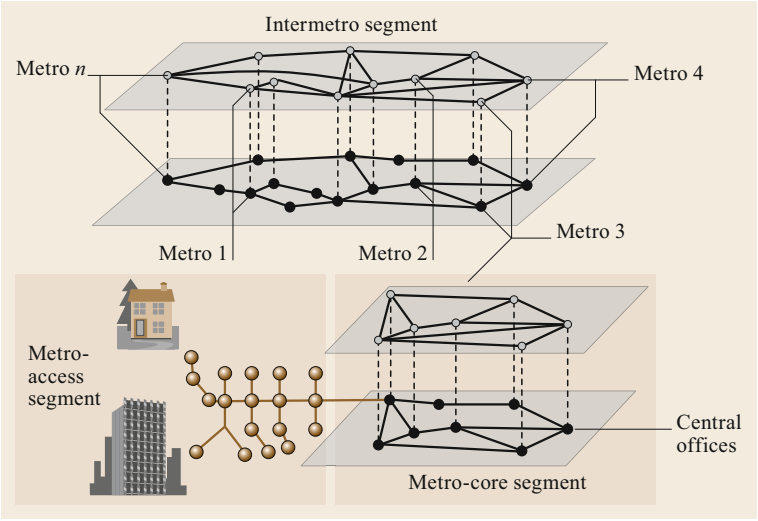

Fig. 11.1 Terrestrial network layers and segmentation

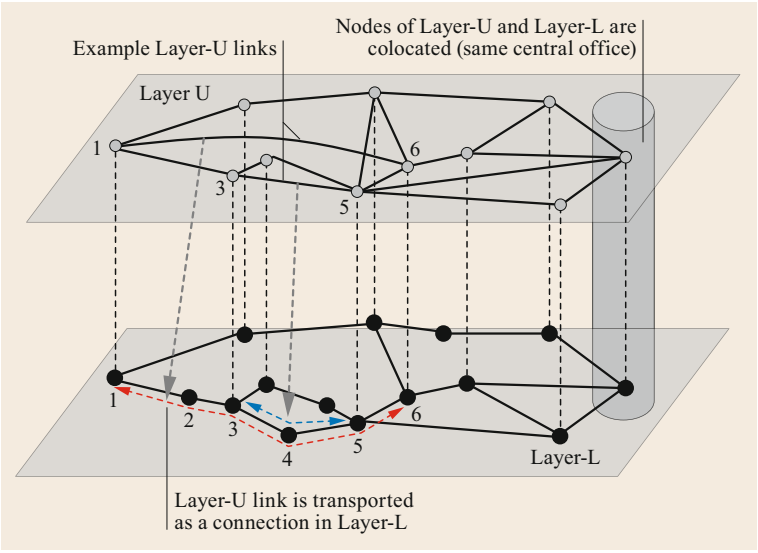

Fig. 11.2 Example of multilayered network graphs

pending on the layer). See [11.1] and [11.2] for more details about the networking and business context of this segmentation.

Before we detail how each of these segments is architected, we provide some background on a simple graph model of multilayer networking and its effect on the topic of network resiliency. This graphical network-layering model is shown in Fig. 11.2, which depicts two layers. This figure and description is adapted from [11.2]. The abstract units of this graph model are nodes, edges (aka links), and connections (aka demands). Nodes represent the cross-connect or switching equipment of a network technology layer. Here, Layer-U (*upper layer*) connects such equipment to their counterpart nodes in Layer-L (*lower layer*) by interlayer links, depicted as lightly dashed vertical lines. While this model has no specific geographical correlation, we note that the switching or cross-connect equipment represented in Layer-U usually are colocated in the same buildings/locations (e.g., COs) as their lower layer counterparts in Layer-L. In such representations, the interlayer links are called *intraoffice* links. The links of Layer-U are transported as connections in lower Layer-L. For example, Fig. 11.2 highlights a link (edge) between nodes 1 and 6 of layer U. This link is transported via a connection between nodes 1 and 6 of Layer-L. The path of this connection is shown through nodes (1, 2, 3, 4, 5, 6) at Layer-L. Another example is given by the link between nodes 3 and 5 of Layer-U. This routes over nodes (3,4,5) in Layer-L. From

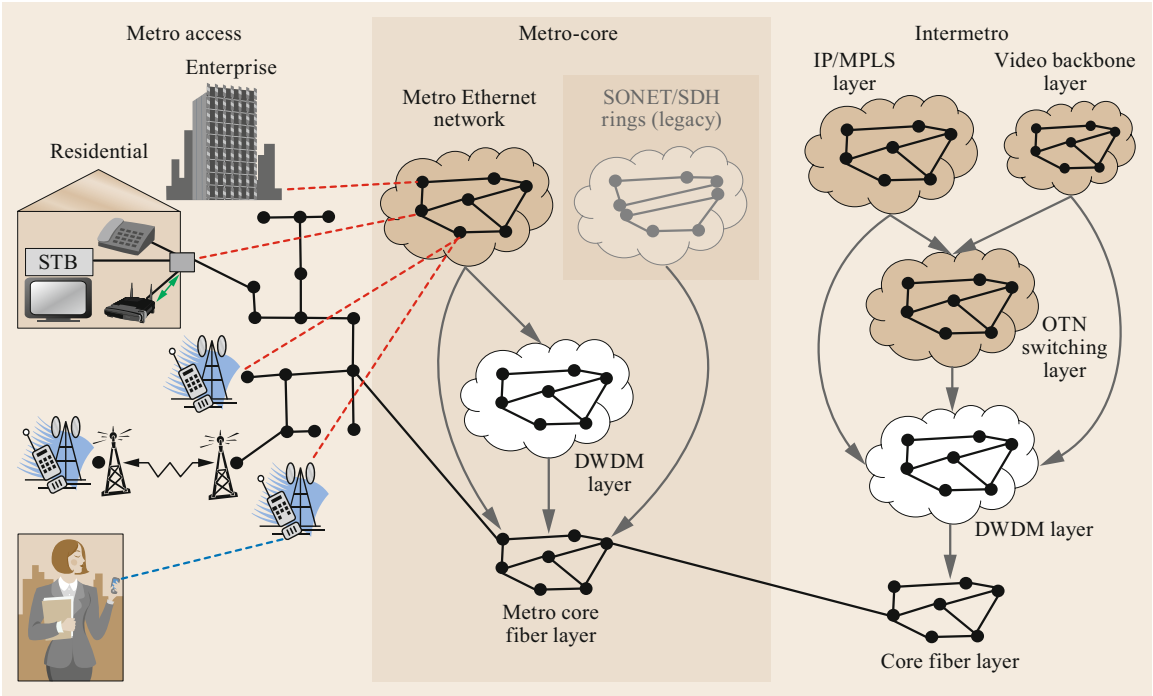

Fig. 11.3 Network layers and segmentation: more details

the perspective of network resiliency, we identify some interesting characteristics in Fig. 11.2 that are also common to real networks:

1. There are more nodes in Layer-L than Layer-U.
2. When viewed as separate abstract graphs, the degree of logical connectivity in Layer-L is less than Layer-U. For example, there are at most three edge-diverse paths between nodes 1 and 6 in Layer-U. However, there are only at most two edge-diverse paths between that same pair of nodes in Layer-L.
3. When we project the links of Layer-U onto their paths in Layer-L, we see some overlap. For example, the paths of the two logical links highlighted in Layer U overlap on links (3,4) and (4,5) in Layer-L. This example highlights the concept of a *shared risk link group* (*SRLG*). For example, if link 3–4 of Layer-L fails, then both links 1–6 and 3–5 of Layer-U fail. More generally, failures of links of lower layer networks often cause multiple link-failures in higher layer networks. If one applies these concepts to the segments and multilayer networks that we will describe, it will help to demonstrate the complexity of providing network resiliency.

Figure 11.3 gives a more detailed (but still simplified) view of the context of network layers and segmentation for large carriers. This figure is derived from [11.3]. As one observes, each segment can be a complex combination of layers and technologies. Furthermore, as we will see, network resiliency is achieved differently segment-by-segment and layer-by-layer. That is why it is important to garner an understanding of this abstraction before launching into descriptions of resiliency methodologies. We will describe the various aspects of Fig. 11.3 in the next few sections.

11.1.2 The Metro–Access Segment

Figure 11.4 expands the metro-access portion of Fig. 11.3, wherein it shows five different example architectures. These are still simplified diagrams and many more complex variations and hybrids of these architectures can be found in practice. Most carriers further segment a metro-access segment network into a *local access* segment and a *feeder* or *distribution* segment. In most large carriers, fiber is used in the distribution segment but as mentioned previously, the type of media is mixed in the local access segment. Furthermore, we try to avoid some of the common terminology found in many published articles of *Fiber to the X*, where X is curb, street, home, premises etc., because we feel this unnecessarily stereotypes the architectures.

Residential Broadband Service – PON

The access architecture shown in Fig. 11.4a shows a residential broadband service for a *single dwelling unit* (*SDU*) connected by a *passive optical network*

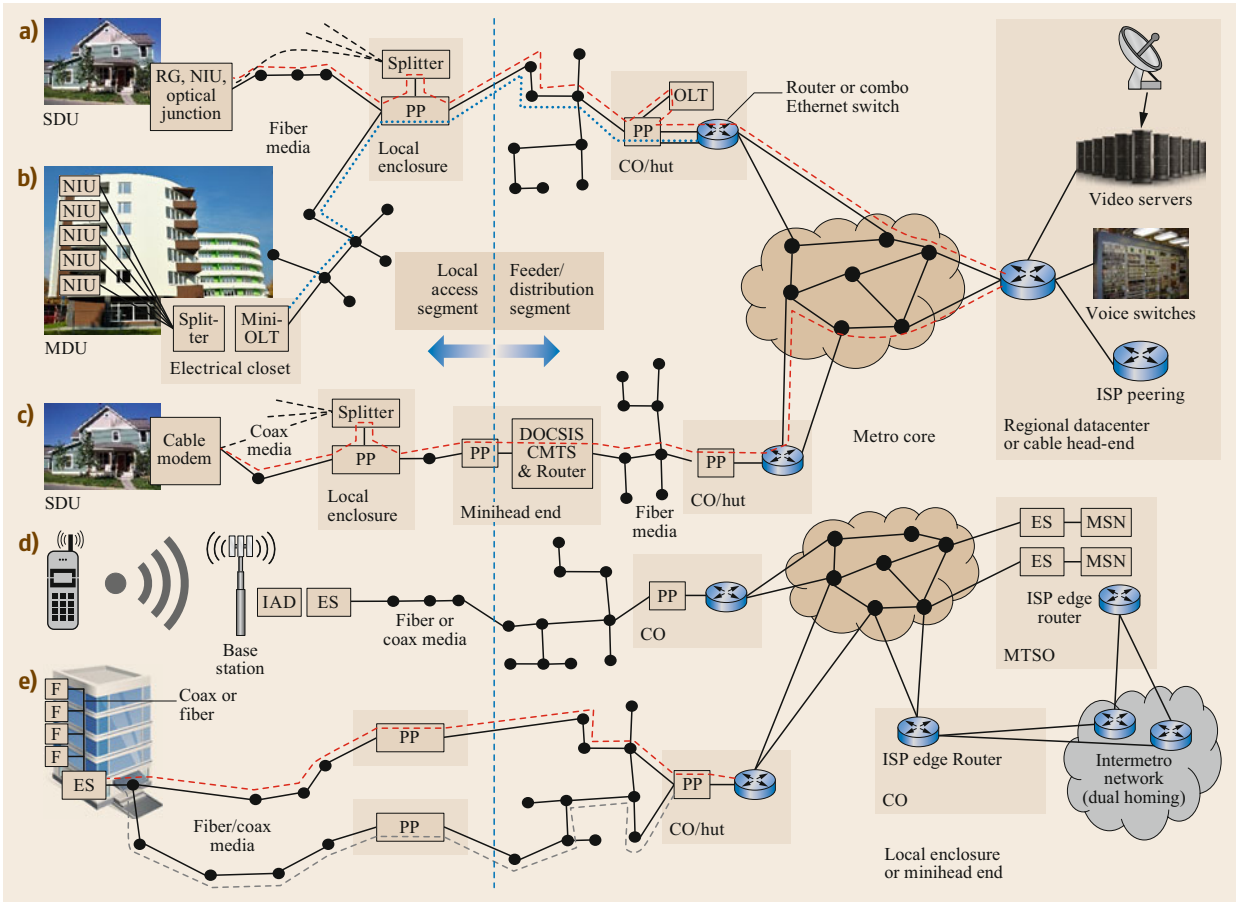

Fig. 11.4a–e The metro-access segment and connections to other segments (CO: Central office; MDU: Multiple dwelling unit; SDU: Single dwelling unit; RG: Residential gateway; OLT: (PON) optical line terminal; NIU: (PON) network interface unit; PP: Patch panel; ES: Ethernet switch; ISP: Internet service provider; MSN: Multiservice node; IAD: Intelligent access device; MTSO: Mobile telephone switching office). **(a)** Residential broadband service for an SDU via PON access network technology, **(b)** residential broadband service for an MDU via PON access network technology, **(c)** residential broadband service via hybrid coax/fiber access network technology, **(d)** residential broadband service via cellular wireless network technology, **(e)** enterprise Ethernet access service via fiber and/or coax access network technology

(*PON*) architecture, such as *GPON* [11.4]. There are different instantiations of the customer premises equipment for a PON architecture. A typical configuration on the customer premises is one or more set-top boxes connected to (functionally) a *residential gateway* and *network interface unit* (*NIU*). The NIU communicates directly with an *optical line terminal* (*OLT*). The inside wiring (sometimes called *inside plant* – *ISP* – however this term conflicts with other uses of the acronym *ISP*, so we avoid it) can be provided by a combination of coax cable, Ethernet cable, or Wi-Fi. This combination differs by individual residence and carrier policy. However, the connection from the outside of the house all the way to the OLT is provided over optical fiber. The outside fiber often interconnects with the inside wiring via a fiber junction box that is installed on the outside of the house. Often, this box in turn connects via coax or Ethernet cable to a small, combo *black box* that serves as a hub to the set-top boxes.

An outside-hardened form of thin fiber leaves the house and is routed (either aerially or buried) to a local cross-connect enclosure, often called a *local connection point* (*LCP*), where the GPON splitter is located. Some carriers have retrofitted their copper plant to support PON architectures, in which case this local enclosure is often colocated in a *digital subscriber line access multiplexer* (*DSLAM*)-type enclosure. Generally, for this architecture the local access portion of the plant is provided by a large fiber access cable, from which individual drops to houses from the access cable

are implemented by small cross-connect boxes, aerially mounted or buried. The local enclosure feeds multiple local access cables and forms the boundary of the local access and distribution segments of the metro-access network.

Note that our figures show, in honored carrier tradition, that every significant point of cross-connection in the network will use some form of a *patch panel* (*PP*). A patch panel is equipment that enables concentration of all physical interfaces of equipment and cable in a location (i.e., either fiber, copper, or coax connectors) to be centrally connected onto ports of the patch panel. Then, interconnection among equipment interfaces or interlocational transport cable can be accomplished by cross-connecting the ports of the patch panel, as needed for provisioning purposes. We note that most access patch panel ports are manually cross-connected. This is an important fact in studying network restoration since automation for rerouting connections in the network cannot be achieved at such choke points. By preconnecting transport fibers and ports of equipment into the patch panel when they are installed, the patch panel enables rapid reconfiguration of equipment and transport fibers without impacting the physical interfaces on the equipment or transport cables themselves. Furthermore, for provisioning and maintenance purposes, inventorying of equipment cable interconnection can be deduced by storing a *map* of the interconnection of the ports of the patch panels and work orders to add new or reconfigure equipment interconnection can be specified in terms of port IDs on the patch panels.

The GPON splitter offers usually a 16 : 1 or 32 : 1 *wavelength-division multiplexing* (*WDM*) splitting capability. Let us refer to the direction of transmission towards the customer as *downstream* and the reverse as *upstream*. The fiber on the upstream side of the splitter is then routed through the distribution portion of the network, sometimes even cross-connected through other local enclosures along the way, to the central office or hut where the fiber terminates on the OLT. One can think of today's typical OLT equipment as a PON device on the downstream side and an Ethernet switch on the upstream side. Thus, the middle of the OLT forms the conceptual boundary between the distribution network and metro-core network. Generally, the upstream side of the OLT equipment connects to a router or combo router/Ethernet switch that hangs off the metro-core network.

Notice in Fig. 11.4a or 11.4b that this upstream switch is *dual-connected* to other switches in the metro network. Therefore, this is, generally, the first encounter of network restoration capability in this metro-access segment. We discuss network availability later in an end-to-end context. Note that we display with a red dashed line the path of transmission between the customer premises and the *regional datacenter* (*RDC*), noting that this functional name varies per local carrier, such as *video hub office (VHO)*, etc. This is because a residential broadband service is almost always bundled with some form of entertainment or video content service; therefore, the purpose of the metro-access network in this example is to connect the customer to the servers and switches in the RDC, where the customer is provided with his/her various optional contracted services, such as broadcast video, video-on-demand, voice services, and Internet service. The customer can receive video content in the downstream direction (often via some form of multicast) or two-way phone service from circuit switches or two-way Internet service from the peering *Internet service provider(s)* (*ISPs*). Note that in many carriers this ISP is owned by the same holding company (corporation) as the access carrier.

Although optical fiber in the local access network is not highly deployed in general, when optical fiber is used exclusively to transport residential customer data and content, the architectures shown in Fig. 11.4a,b are typically the most pervasive form of access. At this stage we could go into a lengthy discussion of how the various PON fiber architectures have penetrated different parts of the world, but this would be beyond our present scope. We instead generalize that because of its high installation and maintenance cost, architecture Fig. 11.4a (single family unit) has had little penetration. In fact, as of the writing of this chapter many US carriers have trimmed back their planned investment in this architecture (for example [11.5]). In contrast, architecture Fig. 11.4b, the *multiple dwelling unit* (*MDU*) or, more colloquially, *apartment building*, has fared better because of its significantly lower cost per subscriber and ability to grow the subscriber base more rapidly. Furthermore, if an apartment building is prewired and has a standardized configuration, then addition of new subscribers can be very rapid and efficient. However, overall adoption of architecture Fig. 11.4b has not fared comparatively well in the USA compared to other countries, such as Korea and Japan [11.6], where a higher proportion of people live in apartment buildings and there are more nationalized approaches to promote the MDU PON fiber architecture.

Residential Hybrid COAX/FIBER Access

Hybrid coax/fiber access networks are the far more prevalent type for residential broadband services in the USA. This is mostly due to many decades of the amortized cost of cable coax installation and evolution. We illustrate this in the architecture shown in Fig. 11.4c via an oversimplified picture, where a cable modem is connected via inside wiring and then *drop cable*

to various sizes of coaxial cable in a local enclosure. Generally, the outgoing coax cable is of a different resistance/impedance and connects to the distribution network at a minihead-end. Note that there are many different types of coaxial architectures which we do not attempt to show here. However, today most adhere to the DOCSIS standards for transmitting content and encapsulating data packets [11.7]. Like the PON architectures, for residential broadband service, the purpose of the access and distribution networks is to connect the customer with the Regional Datacenter or to the *cable head-end* in the case of cable companies (also called *multiple system operators* (*MSOs*). (For brevity in Fig. 11.4, we show the head-end and RDC architectures sharing the same schematic but, in reality, they would be distinct locations across different types of carriers). Note in the figure that the minihead-end is placed at the boundary of the access/distribution network and that switching equipment connects via fiber to the metro-core network. At some near point the customer packets and signals encounter optical fiber and stay on a fiber network for the majority of their trip to their destination. We provide these detailed pictures of segments and their interconnections because the point where fiber begins and its type of architecture in that network segment will be a critical factor of why, where, and how network resiliency is provided. This is discussed in Sect. 11.2.4.

Wireless Access

The most widespread residence access architecture today is shown in Fig. 11.4d, which shows a cellular wireless network. The devices that connect over this network range over a wide range of devices, including phones, tablet computers, PCs, etc. There are also devices that offer broadband service by providing a modem in the customer premises with Wi-Fi or Ethernet connections to other devices. The modem then connects to a broadband carrier over the cellular network. This type of device is often called a *wireless hotspot* and today most data phones and tablets can mimic such a device, although the pricing for bandwidth on such devices varies depending on whether such a wireless broadband service is provided by the carrier.

The wireless modem/device then connects to the cellular network via a base station, with various vintages of cellular technology depending on location and wireless carrier. The base station is usually mounted on a cell tower antenna system, often shared with a plethora of base stations of different vintages and carriers. Typically, the base station consists of an antenna system mounted at the top of the tower and then cabled to an *intelligent access device* (*IAD*) located at the bottom of the tower. The IAD connects to an Ethernet switch, usually provided by a *metro Ethernet network* (*MEN*) carrier as some form of *network terminating equipment* (*NTE*). Figure 11.4c shows optical fiber or coax cable connected to the Ethernet switch. The Metro Ethernet carrier then provides a pair of unidirectional Ethernet private lines (often dubbed with various other Ethernet-related names, such as VLAN, VPN, E-line, etc.) between the base station NTE Ethernet switch and a paired NTE in the *mobile telephone switching office* (*MTSO*). Such an Ethernet private line from a base station to its MTSO location is typically called *cell-site backhaul* or *wireless backhaul*. These Ethernet services are provided as Enterprise Services by almost all incumbent local carriers and are usually provided/leased with various *quality of service* (*QoS*) and *class of service* (*CoS*) features, such as packet loss guarantees and data rate ranges, e.g., typically between 50-Mb/s and 1-Gb/s *committed information rate* (*CIR*). The feasible QoS features depend strongly on network resiliency and network availability. The IAD communicates with a *multiservice node* (*MSN*) device in the MTSO where it separates the voice and data services. Generally (in 4G, LTE architecture) it then forwards the data streams to a datacenter called the *evolved packet core* (*EPC*), where further service processing and routing occurs. Note that there are other methods and technologies to transport the Ethernet private line that we did not show, mostly line-of-sight (point-to-point) wireless microwave technologies. However, most of these wireless technologies are short distance and terminate on a central office or other distribution location where fiber is provided. For example, if the wireless carrier also has wireline serving central offices in that metro area, then they may transport the Ethernet private line from the cell site, which is not in the footprint of the wireless carrier, to a location that is in the footprint of the wireless carrier.

The wireless industry is also deploying variations to the wireless architecture described above, wherein the base station and antenna functionality described above is partitioned ever further. In this case (often designated within the evolving 5G technology) the base station equipment is centrally located rather than at each antenna location. In that case, the cell site locations become antenna-only locations and then their analog signals are backhauled (often called *fronthaul*) to the central base station via local access fiber. In such an architecture it is argued that the centralized base station can better load balance interference and channels among its many cell sites and thus significantly improve throughput over multiple cell sites compared to the (4G/LTE) architecture described above. However, we note that this requires a significant reconfiguration of the local access and cellular network plus richer deploy-

ment of fiber because of the very high speed required for fronthaul (usually 10 Gb/s or higher per antenna site). Various options of this idea include installation of more small cell sites that are centrally managed. This approach, while studied and promoted intensely requires significant capital investment by carriers. Thus, its potential deployment and extent is still under debate.

An interesting observation of architecture Fig. 11.4d is that the Ethernet backhaul can also be provided by architectures Fig. 11.4a,c, but in a business services (Enterprise) context. That is, some fiber and coax carriers offer enterprise versions of their residential broadband IP services using similar technology as shown in Architectures Fig. 11.4a,c. However, most large incumbent carriers who provide a fiber PON residential broadband service do not mix their enterprise Ethernet services (illustrated in Fig. 11.4e) with the transport of their residential PON services on the same fiber facilities downstream of the switch in the Metro CO/hut.

Another very important observation of architecture Fig. 11.4d is the network restoration ability in the local access segment of the network. For, while cellular technology is usually viewed as a poor second cousin to the previous architecture in terms of performance and bandwidth, it ironically has some advantages in terms of network resiliency. This will be discussed in Sect. 11.2.4.

Enterprise Access

Finally, architecture Fig. 11.4e shows a simplified picture of the enterprise Ethernet service. Such a service is most often of the *virtual private-line service* (*VPLS*) type, which connects Ethernet customers to their locations (or to different enterprise locations) in the same metro or in far metros. One of the advantages of a VPLS-type service is that the MEN carrier can make an enterprise customer's wide-area network appear to function as a simple LAN. Furthermore, the MEN carrier often provides an enterprise portal (basically a Web site) where the enterprise customer can configure many features of his/her wider area Ethernet network, such as firewalls, VLANs, encryption capabilities, committed information rates (CIRs), Ethernet private lines, private IP addressing, etc. Providing enhanced Ethernet services is one of the most hotly contested enterprise services among MEN carriers today.

A final comment about architecture Fig. 11.4e is that MSOs (cable companies) are also MEN carriers for enterprise services, hence the designation of either fiber or coax in the local access portion of the network in Fig. 11.4e. In fact, the MSOs are keen to compete with other incumbent carriers using enhanced versions of their DOCSIS cable plant. In particular, for the small to medium business (SMB) enterprise locations, they often experience an edge in customer premise self-provisioning of DOCSIS modems because most business location managers historically have coax cable preinstalled up risers, across floors/telecom closets, and into customer locations.

11.1.3 The Metro-Core Segment

Because of the evolution of technologies, regulatory climate, and economic/business environment, today's metro-core networks come in all vintages, types, and architectures. To that end, we have shown a prototypical (and very simplified) version in the middle of Fig. 11.3. In particular, we only show the metro Ethernet network (MEN) (introduced in the previous section), the (legacy) SONET, *dense wavelength-division multiplexing* (*DWDM*) layer, and fiber layers. We note that while vintages of layers whose nodes consist of legacy technologies, such as circuit switches, *digital cross-connect systems* (*DCSs*) and *frame relay* switches still exist, virtually all major carriers have plans to cap and retire them. For example, some of these are illustrated in Fig. 11.5, which is adapted from the presentation in [11.8]. While the present focus of most metro carriers is to transport packets over the metro Ethernet network layer (or a similar packet network), larger carriers also lease legacy *time-division multiplexing* (*TDM*) private lines to other carriers and large enterprises. The low-rate private-line market (DS3 and below) uses many of these legacy networks, shown in Fig. 11.5 but omitted from Fig. 11.3, as described above. In the future, high-rate private-line circuits will be provided as either a switched Ethernet *permanent virtual circuit* (*PVC*)-type service over the MEN layer or as a private-line high-rate circuit over the DWDM layer (but where the circuit usually encapsulates an Ethernet PVC circuit) using various forms of muxponders or *optical transport network* (*OTN*) switching cards on the DWDM equipment. (A *muxponder* is a combination of TDM multiplexer and optical transponder). Since the technologies are basically the same as in the intermetro segment, more detail on these technologies will be described in Sect. 11.1.4.

However, in Fig. 11.3 we still show the legacy SONET/SDH ring layer. We do this for the following three reasons: (1) large quantities of SONET rings are still common in most USA networks and in fact, are carrying many circuit switches and private-line circuits. Perhaps to the despair of some metro carrier executives, significant purchasing of SONET equipment continues; (2) SDH rings are still very common in Europe. This is mainly because many European countries are roughly the size of some large USA metros and the resiliency qualities of SDH rings have certain advantages; and (3)

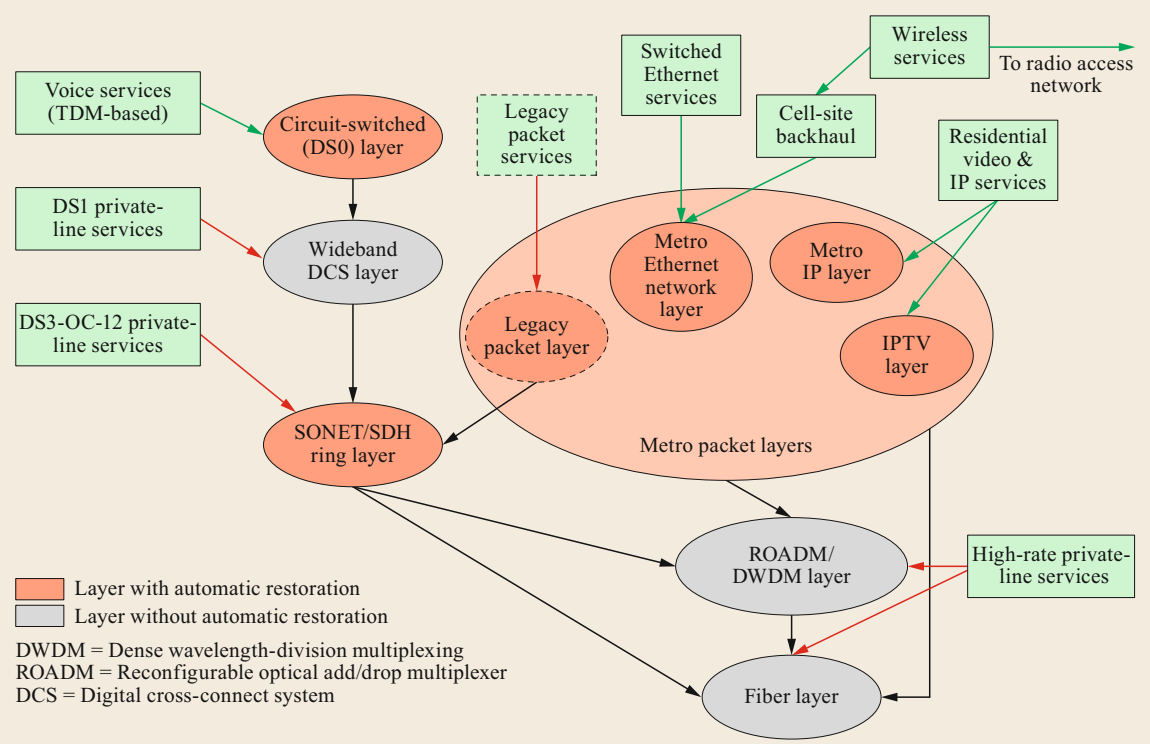

Fig. 11.5 Illustrating some legacy technology layers in the metro-core segment

as the optical layers of today's networks have evolved away from SONET/SDH, this has implied a significant strategy shift to where and how restoration capabilities exist. We will examine that shift in Sect. 11.3.

We make another important observation about legacy network layers. While most carriers make claims and issue press releases of advanced packet capability, old circuit switches are amazingly persistent in the incumbent carriers of the USA and Europe. In fact, one can state that the likelihood of a large proportion of one's voice call being carried over a circuit-switched network (64 Kb/s trunks) is high. Even calls made over cellular phones get routed at the MTSO onto circuit-switched networks. The reasons for this are mostly the legacy and prevalence of world-wide voice standards, signaling, local penetration, and rules for revenue-sharing among competing voice carriers.

Metro Ethernet Network (MEN) Layer

The metro Ethernet network (MEN) layer has become the workhorse of today's metro-core network. As noted above, while most voice calls and TDM private lines are carried over circuit-switched, DCS, and SONET networks, the vast growth of demand for bandwidth has arisen from residential broadband access and enterprise Ethernet services (such as Internet access, LAN services, Ethernet private line, VPLS, and cell-site backhaul). For example, the residential broadband services described in Sect. 11.1.2 all intersect the MEN from the metro-access segment and are carried as some form of enterprise Ethernet service, often by the same residential broadband services provider. The nodes in the MEN layer of Fig. 11.3 represent routers. This dichotomy in the use of IP routers and Ethernet switching comes from the fact that Ethernet interfaces have emerged as the economical interface of choice on virtually all switches. This was a significant driver for the evolution of the network and its resiliency methodology, as will be discussed in Sect. 11.3. In Fig. 11.4 as one goes downstream towards the edge of the metro-access network, one finds smaller Ethernet switches, i.e., with limited Layer-3 routing capabilities. Conversely, as one travels upstream towards the metro-core network, one encounters larger Ethernet switches with dual IP Layer-3 routing capability. In fact, most MEN networks are a hybrid, wherein they appear as Ethernet switches on the exterior (add/drop side of the switch), but behave as Layer-3 routers on the interior (network-side of the switch), mostly through various *Internet engineering task force* (*IETF*) VPLS approaches. The principal reason for this dichotomy is the carrier-grade resiliency and interoperability of Layer-3 switches. This feature

is also critical to our chapter goal and will be discussed later.

ROADM and Fiber Layers

While there are important differences among the technical characteristics of DWDM technologies between the metro-core and intermetro segments (e.g., amplifiers, coherency, need for regeneration, optical impairments, optical reach, etc.), from the standpoint of resiliency functionality, the DWDM and fiber layers of the metro-core segment are similar to that of the intermetro segment and as such will be discussed in more detail. However, there are differences in characteristics of outages and outage recovery between the segments and these also will be discussed later. Therefore, we conclude the section on the metro-core segment by noting that the links of the switches in the MEN today are mostly 10-Gb/s and 100-Gb/s Ethernet links. These links are routed as circuit demands over either direct fiber or the DWDM layer. The nodes of the DWDM layer are usually some version of *reconfigurable optical add-drop multiplexer* (*ROADM*).

As of this writing, the largest carriers are deploying (or planning to deploy) 400-Gb/s MEN links between the hub offices. Various flexi-grid DWDM spectrum approaches are being considered, if the client interfaces (in this case from the router links) can interoperate with the optical layer on the ROADMs [11.9]. Because of the diversity of traffic sizes at COs (or huts), it is still economical to route some packet links over direct fiber at the smaller demand nodes of the MEN layer. Thus, it is not uncommon for a MEN link to route over a mixture of direct fiber and ROADM links. This makes automatic and universal optical-layer restoration a challenge, as we will discuss in Sect. 11.3.3.

11.1.4 The Intermetro Segment

The intermetro-network segment is shown in the rightmost section of Fig. 11.3. However, note that Fig. 11.3 is a simplification that does not show the many legacy network layers that are still in existence today. For, similarly to the metro-core segment, there are various legacy layers, such as circuit-switched, DCS layer, SONET broadband switching, frame relay and other layers still in practice. Generally, these legacy layers mostly still carry TDM voice services and PVC or TDM/SONET/SDH private-line services. Figure 11.3 shows, most importantly, the *Internet protocol over multiprotocol label switching* (*IP/MPLS*) layer. It then shows the *video backbone layer* and the other (lower) network layers: OTN switching, DWDM, and fiber. We will describe the architectures of these layers. This will provide a basis for the resiliency discussion in the next major section. Before embarking we make the important comment that only a limited number of very large carriers in the world fully deploy all these network layers, let alone over a large national (or continental, such as Europe) footprint. Most ISPs deploy only a few (or none) of these other layers and, instead, lease various connections from other carriers who deploy lower layers. The reader should keep this in mind while we describe these layers. We will provide some more background on this limited aspect at the end of this section.

IP/MPLS Layer

As with the MEN of the metro-core segment, the IP/MPLS layer has become the modern workhorse for intermetro carriers. Thus, when Ethernet services need to connect across different metros, they can be transported over MPLS virtual links, often called MPLS *labeled switched paths* (*LSPs*) or *pseudowires*, for which their QoS and CoS features can be preserved. The use of MPLS as a protocol underlayer is critical, as it creates a Layer-3-free methodology that enables a mix of different types of traffic. This is an important feature to guarantee security, segregation, and the ability to provide different degrees of CoS/QoS to private enterprise traffic versus general Internet traffic. It also enables enterprise private LANs to use their own local, customized IP addresses that originate at their metro endpoint locations, yet not conflict with general Internet addressing in the intermetro network. Because IP routing and MPLS label switching are such integral parts of the resiliency of this layer, we will postpone more discussion about their functionality until Sect. 11.2.2.

Video Backbone Layer

Why do some carriers deploy a separate overlay network for video transport versus combining video traffic with other Internet and enterprise traffic in the IP/MPLS layer? The answer boils down to QoS and resiliency of the video service itself. Providers of residential broadband services (as shown in Fig. 11.4) must customize the design of their intermetro networks to achieve high network availability. This is because customer perceived quality of video service is very sensitive to outages, even short ones. And, most importantly, the intermetro network will distribute much of the same content to all customers (in multiple metros) and so disruptions in the intermetro network will impact many customers. It is generally considered in the industry that less than *five nines* (5 9s) availability will be viewed as poor performance by large quantities of video customers. Five nines availability means the service is up 0.99999 of the time, which implies no more than 5 min cumulative downtime per year. We delve into these issues more in later sections.

OTN Switching Layer and DWDM Layer

The OTN switching layer is shown below that of the IP/MPLS layer, meaning links of the IP/MPLS packet layer (router-to-router links) can be transported as connections (circuits) over the OTN layer. The OTN layer can also transport high-rate private-line traffic for those carriers who offer to lease circuits to other carriers and enterprise customers. However, many carriers prefer to route some or all their router links over the DWDM layer and hence in Fig. 11.4 we show an arrow from the IP/MPLS layer that routes directly onto the DWDM layer, thus skipping the OTN switching layer. As economics and technology have evolved, a common architecture (or *policy*) for intermetro carriers is to carry the smaller (less bandwidth) links or a particular *role* of router link on the OTN switching layer. Most design their intermetro IP/MPLS layer in a hierarchical method and consequently classify their routers and switches into various *roles*. For example, *edge* routers are homed onto *backbone* routers. The links between the edge and backbone routers are typical candidates to be carried by the OTN switching layer. We note that these internal role names differ widely across carriers, e.g., edge routers are sometimes called *access routers* (not to be confused with *metro-access segment*) and subcategories of backbone routers are called *aggregate* routers. See [11.2] for more detailed examples.

We provide some background on the OTN switch here, but more will be discussed in the section on network evolution. The OTN switch is an evolution of the *intelligent optical switch* (*IOS*). See [11.10] for a vendor announcement of an IOS product. The IOS is a SONET or SDH-based cross-connect system with automatic restoration capabilities. It was (and still is) widely used to carry TDM (pre-OTN) private-line traffic, where the basic switching unit is the SONET STS-1 or higher rate SDH STM-1 signal. As the OTN standards evolved, some of these same ideas and principals were used to develop the next-generation system. The OTN switch generally switches constituent channels of OTN signals at the ODU-1 rate (roughly 2.5 Gb/s) or, with standardized extensions, at the ODU-0 rate (1.25 Gb/s). The ODU-0 rate is especially adapted to transport and switch 1-Gb/s Ethernet private-line services, including those gigabit Ethernet links of a packet overlay network from the carrier itself.

We need to first make a technical distinction here between use of *OTN signals* and *OTN switching*. Virtually all DWDM equipment in the DWDM layer use the data protocols associated with the ITU OTN standards to channelize their high-speed digital signals. They also use the overhead data channels, alarm features, *forward error correction* (*FEC*), and other features associated with the OTN standard. Thus, one also can encapsulate, channelize, and transport a variety of different rate signals, such as 1-, 10-, 40-, or 100-Gb/s Ethernet, fiber channel, or even TDM signals over a very high rate wavelength (such as 100 Gb/s) by multiplexing these signals into appropriate ODU signals. If OTN switching is not deployed, the typical implementation of this capability in ROADMs is via muxponder cards on the ROADM. The muxponder ports form point-to-point, channelized signals that are demultiplexed at the far-end muxponder and vice versa in the opposite direction. Typically, to cross-connect a lower rate signal (say from ROADM-A to ROADM-B) the highest rate signal must be demultiplexed by a muxponder at A and then manually cross-connected from the add/drop port of muxponder A to the add/drop port of muxponder B via a fiber cross-connect device (e.g., fiber patch panel) and then remultiplexed by muxponder B. This demultiplexing function is common in a large intermetro optical network. For example, this function is needed if the carrier deploys ROADMs from different vendors and a circuit needs to cross different vendor ROADM network domains.

This is illustrated via an example in Fig. 11.6, adapted from [11.11], where a 10-Gb/s circuit is provisioned between ROADMs A–G. For example, this circuit might transport a higher layer link between two routers which generate the client signals at ROADMs A and G. The ROADMs in this example support 40-Gb/s channels/wavelengths. To provision our example 10-Gb/s circuit, we must first provision two 40-Gb/s *channelized* circuits. Furthermore, because of optical reach limitations in this example, the 40-Gb/s circuit must demultiplex at F and thus traverse two lightpaths in the second subnetwork. A *lightpath* is defined as a path of optically cross-connected DWDM channels, i.e., with no intermediate optical-electrical-optical (OEO) conversion. This need for signal regeneration requires interconnection between the ports of the two transponders at ROADM F. Once the two 40-Gb/s channelized circuits are brought into service, two 10-Gb/s circuits are provisioned (one is A–C and the other D–G). The end-to-end client signal is interconnected to the muxponders at A and G and the two subnetwork circuits are interconnected via the muxponder ports at C and D (assume ROADM C and D are in the same CO). Note that without OTN switching capability, this example uses a mixture of three different types of cross-connect technology: manual patch fibering (e.g., at node F), remote controlled optical cross-connect (e.g., at node B), and electrical time-division multiplexing (e.g., assigning the 10-Gb/s circuit to a channel of the channelized 40-Gb/s circuit at A).

In contrast, if the carrier deployed the OTN switching layer, then the high-speed links of the OTN layer

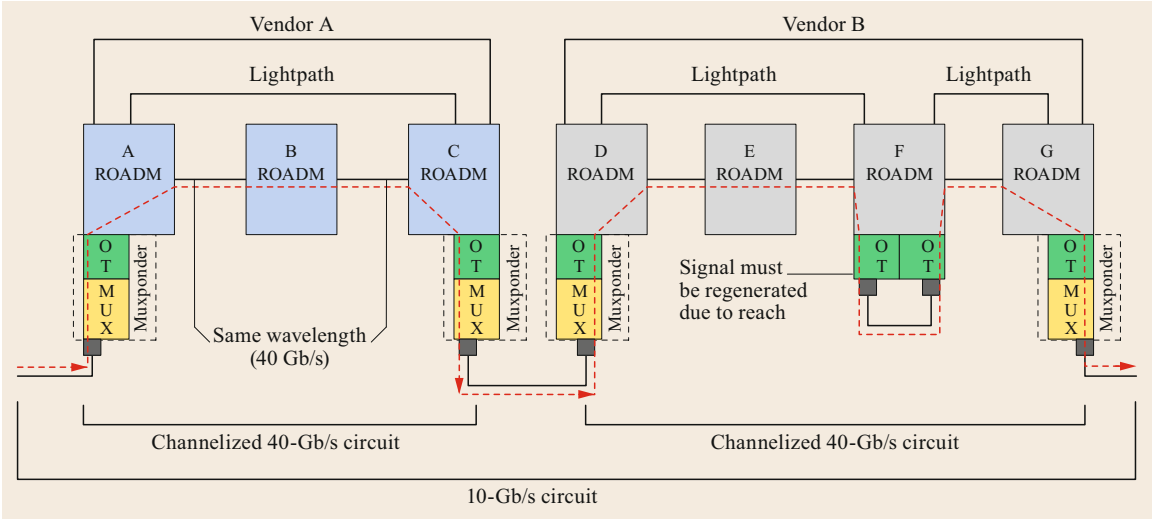

Fig. 11.6 Example path of 10-Gb/s connection (circuit) in the intermetro segment using ROADM muxponders (lightpath: path of optically (i.e., w/o electrical regeneration) cross-connected DWDM channels with same wavelength; OT: optical transponder; MUX: 10-Gb/s to 40-Gb/s multiplexer, 40-Gb/s circuit is *channelized* into 4×10-Gb/s channels; muxponder: integrated OT and MUX)

would be routed as high-speed connections (client signals) over the ROADM network. Figure 11.7 illustrates how this might look with an OTN switch at CO A, CO C/D, and CO G. In terms of the OTN network layer, this picture represents a topology of two ODU-3 (40 Gb/s) OTN links: one between OTN-A and OTN-C/D and another between OTN-C/D and OTN-G. The 10-Gb/s circuit in the example of Fig. 11.6 enters the OTN switch at A. In the direction of transmission left to right, it is encapsulated into the ODU-3 high-speed signal and then transports over the A–C lightpath. At ROADM-C, the ODU-3 signal add/drops into the OTN switch (via the OTs), and then the OTN switch automatically demultiplexes, cross-connects (via its switching fabric), and then remultiplexes the 10-Gb/s signal into the ODU-3 link between D and G (via two lightpaths).

The OTN switch has sophisticated automatic restoration features and so is very relevant to this chapter. We describe these in Sect. 11.2.2. One final observation for the intermetro segment is that in contrast to the metro-core segment, where links of the packet overlay networks (such as the MEN) often route over direct fiber, direct fiber routing is very uncommon today in the intermetro segment. Most large intermetro carriers deploy DWDM equipment in virtually all their COs. Thus, these carriers who provide the intermetro segment are well positioned to provide resiliency via some form of optical restoration method. However, we find (to the contrary) that this is not the case. This fact will be described and explained in the next few sections.

Leased Connectivity

As previously mentioned, only a few large ISPs will fully deploy all the lower network layers. In fact, very few (if any) ISPs own all the intercity fiber that they use and many lease all their fiber. Therefore, most ISPs lease some type of lower layer connectivity. The most common types of lower layer connection leasing are in order from top to bottom: Type-1) virtual private line (a virtual circuit); Type-2) lower layer private line, often called simply a *circuit*); and Type-3) *dark* fiber, often via a long-term lease called *indefeasible right of use* (*IRU*).

Although Type-1 and Type-2 look similar, they are quite different. For example, Type-1 is provided over the IP/MPLS layer of another carrier. Therefore, such a virtual circuit can indeed route through intermediate routers via MPLS label switching, which we describe in more detail later. In fact, a carrier with a more limited IP/MPLS-layer network might indeed lease Type-1 virtual circuits to connect its routers (or Ethernet switches) from the IP/MPLS layer of another (usually larger, more diverse) carrier. In contrast, the Type-2 circuit lease is generally not considered packet *virtual* and does not pass through any intermediate routers. That is, the circuit is totally provided via lower layer technologies, such as routed over a sequence of ROADMs, OTN switching layer, or direct fiber. While many intermetro carriers lease connectivity of Type-1 or Type-2, very few indeed extensively lease Type-3 dark fiber. An example of such a carrier in the USA is CenturyLink, who now expanded its leasing of intermetro-segment

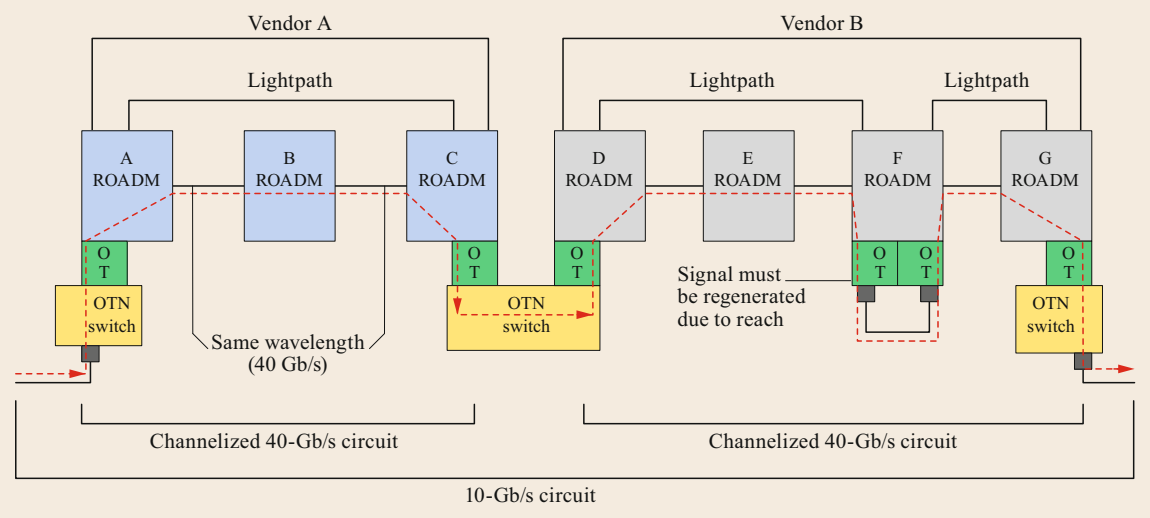

Fig. 11.7 Example path of 10-Gb/s connection (circuit) in the intermetro segment using OTN switch (lightpath: path of optically (i.e., w/o electrical regeneration) cross-connected DWDM channels with same wavelength; OT: optical transponder (of ROADM))

dark fiber through its acquisition of Level-3 Communications, Inc. [11.12]. Prior to the acquisition, many of the largest USA commercial ISPs, government entities, and *research and education networks* (*RENs*) leased intermetro-segment dark fiber from Level-3.

Why do most intermetro carriers who own fiber tend to not lease dark fiber (Type-3)? A generic (although not universal) answer is that they make substantially more revenue per unit of bandwidth by leasing the first two types of circuits, plus they believe that if they lease dark fiber that they might negatively impact or *cannibalize* their business of leasing connections of Type-1 and Type-2.

We list a few examples of types of carriers who deploy a subset of Fig. 11.3 (not exhaustive). For example, consider a carrier who:

- Does not deploy an OTN switching layer and instead relies on the muxponder capability of ROADMs and manual (or in a few rare cases automated) fiber patch panels as illustrated in Fig. 11.6.
- Deploys the OTN switch layer but uses it solely for grooming. That is, it uses the OTN switch to cross-connect circuits, such as shown in Fig. 11.7, but does not implement its advanced network restoration features.
- Does not offer residential broadband service and so does not deploy a video packet overlay layer.
- Offers residential broadband service but transports its video content over a shared IP/MPLS layer, i.e., does not deploy a separate video packet overlay layer.
- Offers residential broadband service and perhaps also intermetro private-line services but leases its intermetro video transport from another carrier. However, note that the leasing option can occur anywhere and everywhere – that is, every carrier might lease capacity or IP transport from another carrier in certain situations.

Enterprise Private Networks

Given our previous discussion of the various parts and combinations of layers that different carriers might deploy, an analogous discussion can apply to Enterprise private networks. These networks can be created by a company leasing various parts of layers in a similar fashion to a carrier who sells (leases) network capacity. However, ignoring those RENs and companies who lease a few scattered private-line circuits, the main application of such large private optical networks is to support interdatacenter communications. The difference in functionality is that some of the largest enterprise companies customize and narrow the functionality of their networks. For example, consider an Internet service enterprise (i.e., this could be a standalone company or a separate business unit of a large carrier) who deploys servers in datacenters that may offer search services, video/web content, cloud services, advertising, or social networking. Such an enterprise usually connects end-customers with their servers by employing a *content distribution network* (*CDN*) carrier. A CDN provider has multiple peering connections with many ISPs and metro-access-segment carriers that enable it to reach a large percentage of residential

customers. The traffic between datacenters of the Internet service enterprise is created by its own servers. This creates a unique advantage in that such an enterprise can mold and shape its traffic, CoS, and QoS in conjunction with the transport of its traffic among datacenters. Therefore, there are customized, forward-looking configurations and implementations that arise with such interdatacenter networks. But, as with the complex issue of resiliency in intradatacenter networks, we cannot cover all such private network configurations here. However, we will discuss a few specific examples in the last section on potential future extensions.

11.2 Network Resiliency in Today's Network

We now discuss where and how network resiliency is provided, but within the context of the architectural descriptions provided previously. As a precursor, we note that because of the disparate types of network segments, layers and architectures, plus the varied restoration techniques that we will describe, the reader will see that piecing together reliability standards is more art than science. But, first we give more clarification about network resiliency and how it is measured and evaluated.

11.2.1 Network Resiliency, Availability, QoS, CoS

By definition the engineered QoS of a service (often qualified by its specified CoS) must include an expectation of its network resiliency. Also, measuring network resiliency requires good traffic models, outage/failure detection methods, well-modeled restoration methods and both real-time and predictive outage-quantification methods. Thus, unfortunately, our characterization becomes somewhat theoretical or hypothetical and one might be surprised to find that most networks in practice are neither built nor maintained under such a strict analytical framework. There is no handbook of network practices that preaches *thou shall build your network thusly and thou shall be rewarded with desired network resiliency*.

Our experience indicates that in practice most networks are engineered *reactively* for resiliency: when network outages occur network administrators and operations personnel subsequently make network alterations, often resulting in rearchitecting or redesigning the network, its measurement processes and/or the operations practices. In other words, networks slowly evolve via experience, practice, and development of new technologies. The resulting network states balance the opposing forces of improving network detection and restoration techniques versus business economics and organizational realities. Therefore, we will proceed to analyze network resilience by first defining the types of outages that can occur and discussing what defenses have been provided in the networks previously presented. This might help the reader to recognize where network resiliency may fall short of desired levels, but where the business tradeoff is obvious. A high-level diagram of the sources of QoS impacts that can degrade expected network resiliency is shown in Fig. 11.8. At the highest level, we divide them into two major causes: (1) un-expected changes in traffic pattern and (2) network outages.

Potential Sources of QoS Degradations: Changes in Traffic Pattern

Unexpected changes in traffic can be caused by a large variety of causes and will vary with the type of traffic, the type of carrier, and depend on type of services, layer and network segment. For example, an intermetro ISP often provides (sells) packet transport or customer access to CDN providers. For example, CDNs are used to provide broadband video content to residential broadband customers of ISPs. CDN providers often have multiple points where they interface with such an ISP (called *peering points*). It is a practice of CDN suppliers to load-balance transport of their content across their peering points for different reasons, such as data storage backup, reconfiguring their own network, load balancing their servers across different datacenters, lowering network latency, rebalancing the load on their links at peering points, reacting to outages in their own network or servers, or balancing spikes in network traffic (just to name a few). While most of these changes to the traffic are instigated by the CDN, they appear to the ISP as randomly generated changes in traffic patterns. In other words, they are not human-instigated from the point of view of the ISP operations team. While these types of changes in traffic pattern and intensity are not easily modeled and predicted, in most cases they can be accommodated by adding additional network capacity and/or adding more dynamic routing capability at the appropriate layer (mostly packet layers). However, economic/business realities mentioned previously can generally constrain the methods of reaction by the ISP.

Thus, in most cases a large change in traffic pattern or intensity causes some loss of QoS and then remediation, both short and long term, occur. In packet layers, with newer *interior gateway protocol* (*IGP*) traffic

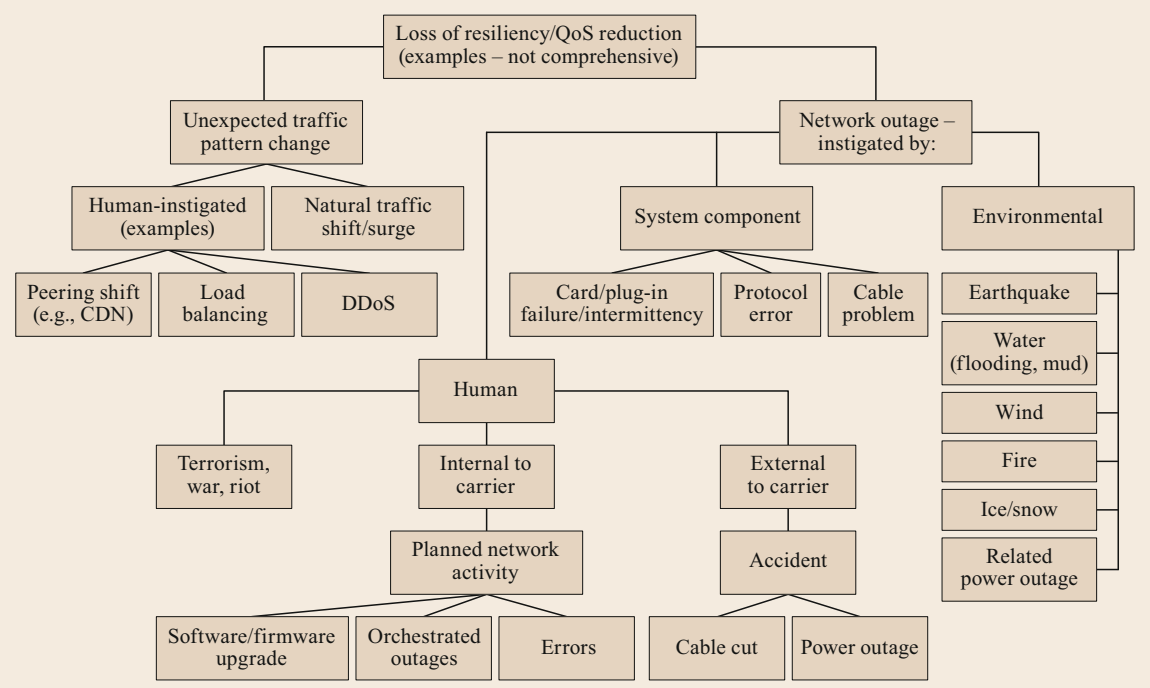

Fig. 11.8 Example graph of potential source of QoS degradations

routing methods, link congestion and capacity is considered in routing techniques, such as *resource reservation protocol – traffic engineering* (*RSVP-TE*) [11.13], *open shortest path first – traffic engineering* (*OSPF-TE*) [11.14], or *intermediate system to intermediate system – traffic engineering* (*IS-IS-TE*) [11.15]. With these methods, as traffic patterns change, so do the assigned virtual tunnels over which the traffic is routed. Furthermore, as newer *software-defined network* (*SDN*) capabilities emerge, intelligent network controllers or orchestrators can automatically react to changing traffic by creating more fundamental changes in underlying capacity at lower layers. We discuss examples in Sect. 11.3.6.

In virtually all carriers, the last resort for short-term traffic changes (or if no such auto-routing techniques are installed) is for the *network operation center* (*NOC*) to instigate changes in traffic routing, such as reweighting network links in packet routing methods or even shutting down various links or sources of IP traffic to prevent downstream congestion. This latter technique is often used to combat a particular human-instigated type of change in traffic pattern (but not caused by the carrier itself), namely, cyber-network attacks, such as *distributed denial of service* (*DDoS*). In such an attack, one does not want to accommodate the routing of more traffic but, instead, cut-off the source(s) without affecting legitimate traffic in the process.

Longer-term remediation generally includes performing a network planning/design process to anticipate the changes in the traffic matrix over the next planning period (usually 3–6 months) and then planning network capacity augmentation *jobs* (often called *capacity provisioning*) to add or reconfigure link capacity. The process of adding/reconfiguring network capacity often has a long lead time because of the need to install and configure equipment in COs/huts (where, because of limited installation crews, jobs for each CO/hut often must be combined and scheduled) and outside cable construction or rewiring jobs, often called *outside plant* jobs. There are some proposed techniques to speed up the capacity provisioning process, such as *as-needed* or *on-time* capacity provisioning, but these ideas usually require some degree of preinstallation of equipment, cards and prewiring (e.g., through a patch panel), including advanced technologies of equipment that integrate multiple layers in a given *box* [11.16]. However, despite this description, it is always a challenge in the network planning and design process to differentiate between the short-term changes in traffic pattern versus longer term (more permanent) changes.

Network Outages

Following along the right subtree of Fig. 11.8, another culprit that can reduce expected QoS below the ideal is network outages. Unfortunately, while most published

papers tend to define a somewhat simplified list of sources of outages (usually overabstracting to a *node or link failure*), the list of the real sources of such outages is large. The list can be divided into three basic types, as shown in Fig. 11.8: (1) human-instigated outages, (2) system-instigated outages, and (3) environmentally instigated outages.

Human-Instigated Outages

Human-instigated outages are very common and perhaps the most common, depending on network segment. Following down the subtree of human-instigated outages, we see three subtrees: (1) outages caused by terrorism, war, or civil unrest; (2) outages instigated by the carrier itself; and (3) outages caused by those external to the carrier (excluding outages of the first type).

Carrier-Instigated Outages and Outages due to Planned Network Activity

Internal, carrier-instigated outages cover a wide variety of causes. However, we just concentrate on one type, for which a lone subtree is labeled *planned network activity* in Fig. 11.8, which is related to planned maintenance, network configuration, and operations activity. In any carrier there is significant daily network activity. Every day network equipment somewhere is being tested, engineered, installed, and reconfigured and interlocation media (fiber, copper, or coax cables) somewhere is being installed, repaired, or modified. Usually the operations organization (or NOC) produces a daily log of planned network activity, sometimes called *planned cable intrusions* or analogous terminology. If possible, the NOC tries to prepare the network for these daily events by rerouting traffic around a link, network node, or equipment port on nodes that might be affected. Of course, this requires the ability to reroute traffic, which we will soon see is not universal. Because of inability to avoid an outage caused by such *planned network activity*, we get the further subtrees: (1) software, firmware upgrade, i.e., that are not fully *hitless* to QoS; (2) orchestrated outages, for example where the NOC schedules the activity at *off-hours* and hard-moves enterprise customer connections to alternate equipment; and (3) unanticipated errors.

Let us briefly discuss unanticipated errors caused by planned network activity. These include mis-cross-connecting circuits and equipment interconnections and inadvertently taking down a part of the network. These latter outages are particularly problematic since the service impacts can be large in the metro-core or intermetro-core segments. Furthermore, they are hard to detect, since a network element may not have failed and therefore the network detection notifications may be confusing or missing. Examples of this involve the fiber patch panel in COs/huts. Generally, installers prewire the ports of switches and DWDM equipment to the patch panel. Then, links (especially inter-router links) are installed by cross-connecting the correct ports on the patch panel. For example, in Fig. 11.6, if the ports of the muxponders at ROADMs C and D are mis-cross-connected, it will be difficult and lengthy to sort out what happened. Another impact of mis-cross-connection is that a link with live traffic may be inadvertently disconnected. For example, consider all the optical *directions* (i.e., *links* in the DWDM layer) associated with the ROADM-A in Fig. 11.6. These DWDM multiplexed links are enabled by connecting patch fibers from the ROADM MUX and DEMUX cards in each direction to the fiber patch panel and then connecting those patch-panel ports to patch-panel ports that connect the fibers from the cable vault of the CO. Figure 11.6 shows one direction/link between ROADM-A and ROADM-B, but many other directions (links) can emanate from ROADM-A to other locations (not shown). The ports associated with all the directions for ROADM-A will likely be in proximity to one another on the patch panel. Thus, if operations or provisioning personnel happen to inadvertently interfere with the patch cord to one of these working ports, an entire ROADM direction may experience an outage. For example, the entire link between ROADM-A and ROADM-B may go down. This could potentially affect many 100s of gigabits worth (or even terabits worth) of traffic in metro-core or intermetro networks.

Environmentally Instigated Outages

Looking now at the subtree labeled *environmental* outages, we note that while the large events generally have low probability, they have the worst impact. One reason is that while we illustrate the metro-access, metro-core, and intermetro segments in a separated fashion, the infrastructure media containing intermetro cables always overlap those of metro-core cables (e.g., conduit and aerial runs). Thus, such events also can affect large areas of metro-access networks in addition to the metro-core locations. There are many examples of large environmental outages, some of which are shown in the subtree of Fig. 11.8. We note that we formally categorize fire as an environmental outage, even though sometimes fires are human instigated.

Flooding is by far the most pervasive of these environmental events. Examples include hurricanes in the Southeast portion of the USA and monsoon rains in Brazil. Mud is a secondary effect of flooding from rain. Mud slides and floods are quite common in many parts of the world. Earthquakes are not as common as flooding, but the impacts can be much greater, wherein a huge number of simultaneous CO and metro-access

locations are taken out of service. One of the secondary (and the most common) service-affecting impacts of all these events is loss of power. Many COs have backup power generators, but as one travels downstream from the intermetro network, through the metro-core network and into the metro-access network, one finds gradually less sites provisioned with backup power. Generally, as one might anticipate, there are few (if any) cost-effective methods to maintain network resiliency against the larger of these events. Fortunately, such environmental events are less frequent than the other sources in the tree. We discuss more in the section on how resiliency is provided. We also refer the reader to a sequence of papers on this topic in IEEE Communications Magazine [11.17, 18].

System Component Outages

Finally, we discuss the subtree of outages labeled *system component*. The outages down this subtree represent failures of network components of the equipment represented by the nodes of each of the layers, such as shelf controllers, interface cards, plug-ins (e.g., optical small form-factor pluggable (SFP), 10 gigabit SFP (XFP)), *wavelength selective switch* (*WSS*), splitters, multiplexers, etc. These outages represent inherent failures of these components themselves, rather than outages not contained in this subtree that cause them to malfunction, e.g., cable cuts, power outages, etc. Equipment suppliers often express their estimation of the frequency of such outages per each major component, such as the *failures in time* (*FIT*) rate, which is defined to be the expected number of failures in one billion hours of operation (the reciprocal times one billion is the meantime hours between such failures). The meantime to repair such component failures is determined by the maintenance policy of each carrier and can also vary greatly across network segment and layer.

Most publications only examine this subtree plus the (human-caused subtree of) fiber cuts. They perhaps reason that all the other sources of outages ultimately result in outages of system components anyway, so why not lump all the outage-tree events together and estimate a convolution under this one system-component subtree. So, why do we show all these other sources of outage and QoS disruption in Fig. 11.8? The answer lies in the more formalized state space of potential outages and the associated probabilities associated with each state, abstractly represented by a distribution with a mean time between outages and outage repair time. That is, outages outside of the subtree labeled *system component* in the tree of Fig. 11.8 can cause multiple outages of the components identified within this subtree. For example, a particular potential flood, cable cut, or an earthquake are all outages that target a set of links and nodes in specific network segments and layers of Fig. 11.3. However, the probabilistic characteristics of the members of the system component outage event set (basically a type of *shared risk group*) are basically defined by the underlying outage, rather than these individual system components themselves. It would be impossible to properly model an outage event which affects a large set of links and nodes of the network layers if we did not know the basic cause of outage. While we admit that modeling all the potential events in Fig. 11.8 is intractable and, thus, some approximation is needed, having a knowledge of these relationships and how to model an outage state space properly can give insight into where and how to approximate the state space while bounding probabilistic estimation error.

Performance and Availability Assessment

Given our discussion above about modeling the (abstract) outage state space, a *rigorous* performance and availability assessment of the network that estimates its ability for a service to achieve its target QoS (as a function of each CoS) is complex: the network has to be designed, engineered, and operated so that this QoS is maintained under the bombardment of *potential* traffic changes and outages summarized in Fig. 11.8. Thus, in a theoretical sense, to engineer such a network one must have a traffic model, the probabilities of outages, including their distributions, expected interarrival and repair times, the corresponding restoration or rerouting mechanisms, and metrics that reflect the resulting QoS.

Because of the overwhelming complexity of the previous statements, designing a network to meet such a service QoS is more of an art than a science and, hence, this is the reason for our earlier comments about why most carriers do this in a *reactive* rather than a *proactive* way (despite what they may state publicly or publish from their Research organizations). Lacking all this intractable modeling sophistication, carrier experiences over many years or decades provide them with the opportunity to collect statistics on some of these types of outages (not including the *once in a century* outages). The first such event causes a major disruption, but then the carrier can be ready for the next one. This readiness includes a business decision about establishing a target network downtime for the next event. That is, given the frequency and extent of a potential outage in Fig. 11.8, plus its impact on expected QoS, is it worth the cost (if even possible) to make the network sufficiently resilient – or should the carrier tolerate the expected drop in QoS? A good example of this type of decision is given by USA Hurricanes Sandy and Harvey [11.19].

If we are to formalize an assessment of performance and availability, we need to briefly discuss the metrics

for expressing QoS. Network availability is much easier to evaluate for private-line services, such as leasing a 10-Gb/s Ethernet circuit service between two locations. If the circuit maintains its *bit error rate* (*BER*) below a threshold (a rigidly defined metric), then it is *available*. If it goes above for a prescribed amount of time, it is *unavailable*. Such a metric provides a simple 0 or 1 binary state. However, virtually all such private-line circuits are leased to form a link of an overlay packet network, so the 0/1 state can be deceptive. Typical metrics of packet networks are packet throughput, rate of packet loss (as a function of time) and packet round trip time or packet delay. However, there is benefit to using the simple 0/1 unavailability/availability model to unify concepts of QoS across all the different layers we have discussed. An example of such a simplification is quantifying network congestion via a utilization ratio threshold on a packet link. If utilization is below the threshold for a give proportion of time, then QoS targets of packet loss and delay can be assumed to be met. The simplification is that if the traffic congestion on any link is *above* the threshold, then that link is unavailable. Translating this to packet services, if the path of a packet service (of a given CoS) routes over a link that exceeds this threshold, then the service between the source and destination switches is defined as unavailable. In addition, if any of the lower layer links over which a packet link routes is unavailable, then the service is also defined as unavailable. If any of the components that comprise the lower layer link are unavailable, then that lower layer link and hence the packet link and hence the service is unavailable and so on. Of course, we then also must introduce rerouting/restoration methods in these network layers to offset the unavailability of that service. We will discuss these methods in the next section.

Given our informal discussion of the 0/1 availability model above, how then do we express whether an entire network along with its transported services meets the collections of target QoS? A network-wide availability metric can be expressed across the entire network by assessing the traffic matrix of services, their respective classes of service (CoS), and their intensity (volume) over each point-to-point. Two ways to express this are *average availability* and *worst-case availability*. For example, if any point-to-point service is unavailable, then the worst-case performance of the overall network is *unavailable*. As an example of the importance of CoS, suppose we wish to express the network availability objective for a *best effort* service as three nines and a premium service as five nines. In this context, worst-case availability is useful for broadband carriers to provide service to their metro head-ends (or RDCs or VHOs) from their national head-end. Every carrier would prefer to achieve the magical *five nines* of availability to reach every head-end because individual customer availability will further drop as data crosses the metro-core and metro-access network. After we present network resiliency methods, we further discuss these concepts of availability for residential broadband and enterprise services in Sect. 11.2.4.

Finally, simply determining the resulting (theoretical) network availability of a given (fixed) network is itself an intractable problem. If fact, this is an extremely complex network problem to describe, let alone solve, especially in multilayered networks. However, a simplified description can be found in [11.1, Sect. 2.2] and a more detailed multilayered example can be found in [11.20]. The significantly harder problem is how to cost-optimize the design/sizing/layering/routing of a network to achieve a target QoS. Perhaps now the reader may get a feel for why most network managers perform *reactive* architecture, design, and network management rather than proactive.

We next discuss the main resiliency capabilities of the architectures we described earlier. We again examine Fig. 11.3 and reveal the purpose of the colors in the figure. A network layer that is colored signifies where automatic restoration can be provided today. However, this is qualified by whether a carrier deploys that layer and enables its restoration features. We discuss this network segment by network segment, but in reverse order of our earlier descriptions.

11.2.2 Resiliency in the Intermetro-Core Segment

Figure 11.3 shows restoration capability in three layers in today's core intermetro segment: the OTN switching layer, the video backbone layer, and the IP/MPLS layer. However, as described previously only a few large ISPs will deploy all these layers in a comprehensive way. A key observation is that in all these cases no significant, automatic restoration capability occurs at the DWDM layer. This might seem surprising to some readers given the title of this book and chapter. For this reason, we provide the later section that discusses the evolution of resiliency and these architectures.

Restoration Methods in the IP/MPLS Layer

In general, the most common restoration capabilities in this layer are IGP reconvergence and *MPLS fast reroute* (*FRR*) [11.21]. We mentioned earlier some of the more capacity-sensitive IGP routing mechanisms, such as OSPF-TE, ISIS-TE, and RSVP-TE, within the context of responding to changes in traffic, rather than network outages specifically. However, these same IGP mechanisms can be used to respond to outages. In the

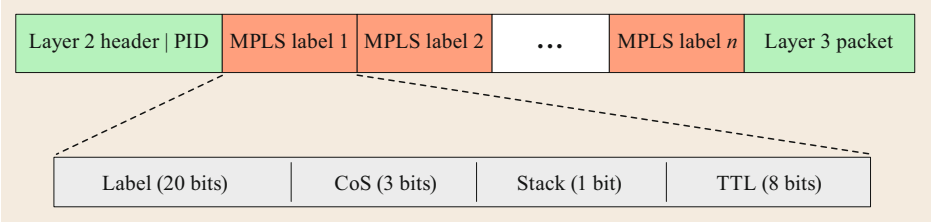

Fig. 11.9 Typical protocol data unit for MPLS (after [11.2])

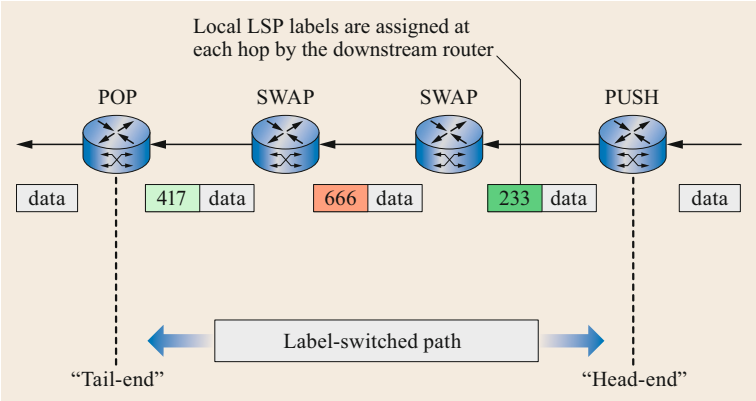

Fig. 11.10 Example of MPLS label-switched path (LSP) (after [11.2])

case of a network outage, wherein a packet link goes down or experiences reduced throughput, all these IGP protocols reflect this change via broadcast of *link state advertisements* (*LSAs*) and then recompute their paths between routers based on remaining paths and capacities. However, IGP reconvergence is slow compared to legacy SONET rings, which were originally engineered to restore within 50 to 100 ms, with the longer times for more complex outages, such as node failures (to be described later). This was one of the motivations to develop MPLS fast reroute. We also make a technical note that the most common way the IGP topology view sees a link capacity reduction (rather than the entire link going down) is with link bundling techniques. Each router vendor has its own method of bundling router-to-router links into a larger bandwidth bundle. The IGP protocols then only see the bundle and not each individual link. Also, the Ethernet protocols allow multiple links to be bundled into a larger bundle called a *link aggregation group* (*LAG*) and all switches allow an IP address to be associated with the LAG bundle instead of each individual link member. Each of these types of link bundles has its own rule about how packets are load balanced among its members and how individual failing links are handled and reported. We refer the reader to [11.2] and [11.22] for more detail about link bundling in packet networks.

Figure 11.9 shows the most common method of how MPLS encapsulates IP packets in an MPLS header (Figs. 11.9 and 11.10 are adapted from [11.2]). It consists of one or more MPLS labels, known as a label stack. The first 20 bits are the actual numerical label. There are three bits for inband signaling of class of service, followed by an end-of-stack bit and a time-to-live field, which serves the same function as an IP packet time-to-live field (i.e., to prevent infinite cycling of packets and to enable traceroute-type commands). Figure 11.10 shows how MPLS is used to define a type of virtual link in MPLS networks, called a *label-switched path* (*LSP*). To create an LSP, a path of links is precalculated by the routers, for example using a protocol such as RSVP, or via a centralized controller using more advanced SDN operations (discussed later). At the origin of that path (the *head*) a label is pushed onto the queue shown in Fig. 11.9. Note that in the world of packet routing, all connections are uni-directional. The label is generally chosen locally by the router and used to identify the outgoing port(s) of the desired link in the MPLS forwarding table (not shown). Intermediate routers along the path have their MPLS forwarding table similarly defined to switch the incoming packets with the given incoming label to the outgoing ports of the next link in the path, upon which a new local outgoing label is *swapped* with the incoming label on the MPLS stack of the packet. Finally, at the last router (the *tail*) of the LSP, the incoming label is removed (*popped*) off the queue and the packet *virtually* exits the LSP.

MPLS-based restoration methods are heavily used by intermetro- and metro-core-segment carriers to achieve network resiliency against many of the outages

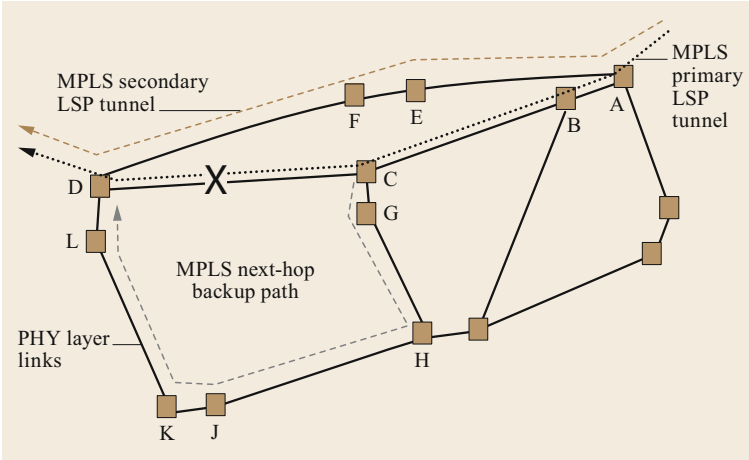

Fig. 11.11 MPLS fast reroute and IGP reconvergence (after [11.23])

identified in Fig. 11.8. Today, a hybrid combination of MPLS FRR and IGP reconvergence is commonly used to cover a wider variety of traffic changes and outages shown in Fig. 11.8. To illustrate, consider a primary LSP from router A to router D, as shown by the dotted path A–B–C–D in Fig. 11.11. This path is computed by a protocol, such as RSVP-TE under the *no–outage* network state, where there are no outstanding *link down* LSAs (that is, any previous ones have been cleared). Additionally, with the *next-hop* version of FRR, for each router link, a backup LSP has been precalculated and the forwarding tables of all the routers along the path of the LSP have been calculated and loaded with these label/port(s) switching rules. Note that this is a *link* in the IP/MPLS layer, not a link in the ROADM or fiber layer. Such a path is shown for the link C-to-D (C→D) in Fig. 11.11. If link C→D has an outage and a corresponding alarm is detected at the router at C or if router C has been notified by an exterior outage notification method, such as *bidirectional forwarding detection (BFD)* [11.24], then router C instigates the LSP FRR bypass mechanism that activates the push/swap/pop process discussed above. This process is instigated simply by pushing the predefined label of the bypass LSP onto the stack of any packet that is destined for link C→D. Since this is all done locally by router C, the bypass operation can execute very rapidly. If fact, most of the restoration time is outage *aging* and other IP timer mechanisms to prevent oscillation, false alarms, and other potentially nasty consequences.

The FRR next-hop link restoration mechanism can be fast, but it has downsides. A major downside is occurrence of a wider outage than just a single router link. In fact, an entire router could go down or be taken down for a maintenance event or other issue, i.e., the node labeled *software/firmware upgrade* in Fig. 11.8. Many of the outage events in Fig. 11.8 would produce multiple link outages in the IP/MPLS layer and clearly many of them are not statistical *rare events*. For example, if intermediate router C goes down in Fig. 11.11, then all the links coincident on it go down. The FRR link bypass method will not work and all packets trying to get from A to D will be lost. We note that there is also an MPLS FRR next-next-hop mechanism defined in the standards, wherein a path around router C can be predetermined. However, this is a potentially complex mechanism with its own additional downsides and we found through experience that it is generally not deployed.

A better method was found to cover the shortcomings of the MPLS FRR next-hop mechanism, namely by augmenting the FRR rerouting process with IGP reconvergence. The network resilience strategy behind this idea is as follows: A single link outage has a higher probability of occurrence than a multiple link outage. Therefore, a significant portion of probabilistic downtime (network unavailability) can be remediated with MPLS FRR next-hope link rerouting. For those lower probability (but higher impact) outages, such as downed routers and large-scale outage events, after a time-out period to complete network reconvergence, all the primary LSP paths are recomputed. By the virtual magic of packet/MPLS routing techniques, new paths can be implemented with virtually no packet loss by simply recalculating and reloading the MPLS forwarding tables and then pushing/swapping/popping labels of incoming packets. So, once the IGP reconvergence process has been completed and the MPLS forwarding tables reloaded, the entire network can converge to a new end-to-end routing scheme that compensates for the particular outage(s). In Fig. 11.11, the case of A→D traffic when the entire intermediate router C goes down is shown by the MPLS secondary LSP tunnel that now avoids router C. Of course, in this case traffic that originates or terminates at router C is lost, but this is

unavoidable for this high impact outage. Generally, the IGP reconvergence process takes from 1–60 s in large networks, so the packet loss would be in that range. This range is wide because each carrier sets its IP timers (for which there are many) to provide confidence in the process and avoid interference problems.

There is yet another downside of FRR next-hop link restoration, namely inefficient use of spare packet-link capacity. In fact, in large, highly connected networks, in many cases MPLS FRR will retrace its route through the same intermediate routers. To understand this in Fig. 11.11, consider traffic travelling from H→D along the path H–G–C–D. When link C–D fails, FRR will reroute it over path H–G–C–G–H–J–K–L–D. Furthermore, enough link capacity must exist on the links of the bypass path to accommodate the (now) extra packet traffic due to the bypass of link C→D. Clearly this bypass method is inefficient. Therefore, once the IGP reconvergence process is complete and capacity-sensitive routing methods are employed (as identified earlier), the revised end-to-end MPLS primary LSPs will be more capacity efficient. This can be combined with a CoS/QoS routing methodology so that the high-priority traffic will enjoy sufficient capacity on the bypass next-hop route, but the lower priority (e.g., *best effort*) traffic may find some congestion during the most severe outages. However, once IGP reconvergence is accomplished, the lower priority traffic will enjoy less congestion, as more efficient routes are established.

Clearly the above discussion leads us into one of the most important processes to economically provide QoS, namely network capacity design and planning. Abstractly stated, in this process one must engineer/optimize enough network capacity to maintain the objective QoS (as a function of CoS) under the plethora of traffic surges and network outages shown in Fig. 11.8, including how and when network restoration methods are applied at each potential layer. In fact, as previously noted, simply determining the resulting (theoretical) network availability of a given network capacity can be an intractable problem. This network design and routing problem in multilayered networks is too complex to be described here. However, a simplified description can be found in [11.1, Sect. 2.2].

Restoration Methods in the OTN Switching Layer

We briefly describe how mesh-network restoration is implemented in the OTN switch layer. Again, recall that not every carrier deploys the OTN switch and enables it for mesh-network restoration. A *Mesh-network* is one in which there are no architectural constraints about deploying rigidly structured topologies, such as hub-clusters, rings and chains. Let us first observe that since restoration techniques (such as we described previously) are universally deployed in the IP/MPLS layer today, there is essentially no ROADM-layer restoration process deployed. Thus, besides the legacy SONET/SDH rings, the OTN-layer restoration process is one of the few remaining (so-called) *optical-layer* restoration processes deployed. Figure 11.12 (adapted from [11.23]) gives a schematic of how the OTN switch can be deployed to handle network outages, i.e., respond to downed links of the OTN switch layer. Note the tight coupling between the network planning/design process and the restoration operation of the OTN switch

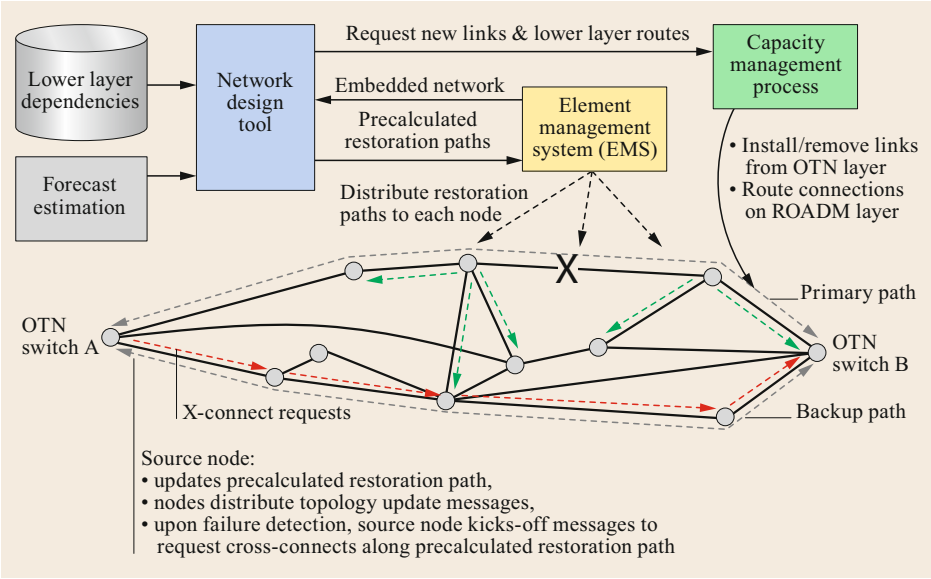

Fig. 11.12 OTN switching layer restoration process (after [11.23])

layer. This is highly motivated by our previous discussion on expected service QoS against potential network outages and how the network is designed and capacitated to meet that expectation. For the OTN layer, one can simplify by thinking of its connections as demands for private-line services which have a premium level CoS.

However, maintaining QoS gets very complex when the OTN switching layer also transports (as its demands) links of a higher packet layer (think back to the multilayer example of Fig. 11.2). The links of the packet layer that route over the same OTN link form an SRLG. Furthermore, the OTN link routes as a demand (circuit) over the DWDM layer and a DWDM link in turn routes over the links (spans) of the fiber layer. Thus, each of these links at lower layers forms an SRLG of packet-layer links. Describing such a complex network design process is beyond our scope. However, we will state that even the most complex network planning systems for this task (some even developed by the author) use narrowed assumptions about which parts and aspects of the outage tree given in Fig. 11.8 are modeled. Figure 11.12 shows such a network design tool. This tool models the parts of the QoS design process we have described previously to generate a future network design of the OTN Layer. We use the term *future* because there is usually a delay (lead time) in deploying links in this layer via a capacity management process, which in turn is usually part of a complicated capacity provisioning process that involves: equipment ordering, provisioning systems, network databases of record, issuance of work orders, management of installation, deploying testing crews, etc.

To provide network resiliency against link outages at the OTN switching layer when provisioning a network connection (circuit) over this layer, the network design tool calculates a primary path plus an end-to-end diverse backup path. That is, it calculates a secondary path whose links do not route over any of the lower layer links of the primary path. Stated alternatively, the SRLGs containing the links along the primary path are distinct from those of the backup path. If the carrier chooses to deploy a vendor *element management system* (*EMS*), the two paths are downloaded to the EMS, otherwise downloaded directly to the source OTN switch by the network design tool. The source node (OTN switch) of each provisioned connection (circuit) provisions the connection by sending cross-connect command messages in the OTN overhead data communications channels along the links of the primary route. This is a complex handshaking protocol whose description we omit here. The source node also stores the path of each of its provisioned connections along with its backup path. If a link outage occurs, link-down alarm information is flooded to all source nodes, as depicted by the blue dashed arrows in Fig. 11.12. Upon receipt of the link-down alarm at the source node (OTN-A), for those connections that route over the downed link, the source node begins a restoration process that reroutes those connections to their backup paths. The signaling to reprovision a connection is similar to the original path set-up, as shown by the red dashed arrows in Fig. 11.12, except a *bridge and roll* type of switch mechanism is often used to complete the connection with no disruption. For a descriptive example of a bridge-and-roll process see [11.25].

Since the backup path is diversely routed compared to the primary path, one of the simplifications of the network design process is that the probability of an outage of multiple, simultaneous lower layer links is low and, therefore, the probability that both the primary and backup path are simultaneously down is also low. Of course, glancing at the complexity of our network outage tree in Fig. 11.8, the probability of a multiple outage may be small, but not rare. For example, a common type of dual outage is when a link (or node) is down for planned network activity, such as capacity augmentation, rearrangements, software upgrade, etc. This process might take a long time and thus during this period a separate link outage might occur.

To accommodate this multiple link outage possibility, the OTN restoration methodology has a second phase rerouting step, where the source node dynamically computes new routes for those connections that remain down, i.e., cannot be restored after the initial rerouting process. There is typically a time-out between the first phase (using the precalculated backup path) and the second phase. The first-phase OTN switch rerouting process operates relatively quickly (but not universally as quickly as legacy SONET rings), usually in terms of at most a few seconds, depending on size of the network. The QoS motivation here is that this approach provides fast network restoration for a subset of network outages in the tree of Fig. 11.8 with highest probability of occurrence (or shortest mean time between outages), namely, single OTN card, ROADM link, or fiber span outages. For those outages beyond this subset, the restoration time will be longer or in some cases the connection will not be restored. However, even though circuits rerouted in the second phase take longer and the outage can affect larger groups of circuits, if the probabilities of the occurrence are sufficiently low, then the expected QoS objective can be achieved. As we mentioned earlier, since the metrics of such a complex tradeoff are hard to assess, this tradeoff is usually determined experientially by tracking statistics on circuit downtimes over time caused by actual network outages.

The timing and phasing of the OTN restoration process interaction can be fine-tuned by each carrier. Also, the carrier can choose to alternatively use the vendor-provided EMS or vendor-provided *network management system (NMS)* to provide the functionality of the network design tool. When a link is brought back into service (repaired) a *clear* alarm is distributed and the source OTN switch can move the connection back to its primary route, a process which is sometimes called *revertive*. However, to leave the rerouted connections on their secondary paths is generally not recommended else the network would be left in a un-designed state; if another outage occurs in such a state, the network might not meet its expected availability target. To address this problem and because the network changes over time from outages and changing traffic and network capacity, the OTN layer network also provides a *rebalancing* feature that reroutes already provisioned circuits to more efficient paths, enabled via a combination of network design tool, EMS, NMS.

11.2.3 Resiliency in the Metro–Core Segment

The metro core in Fig. 11.3 shows the metro Ethernet network (MEN), legacy SONET/SDH rings, DWDM and fiber layers. Although SONET/SDH is a legacy layer and most carriers are in the process of capping and/or retiring it, we provide a brief description to give perspective on its ability to restore as an optical-layer restoration method. However, we point out that this has been and will likely continue to be a prolonged retirement process in most legacy carriers. We will discuss both its evolution and de-evolution in the next section.

Figure 11.13 (from [11.1]) shows the two most popular architectures for the SONET/SDH ring. For simplicity, we describe the SONET version here, noting that the SDH version is very similar. See also [11.26]. The 2-fiber *unidirectional path-switched ring* (*UPSR*) (Fig. 11.13a) is configured over two unidirectional fiber rings, one transmitting in a counterclockwise direction over the nodes, the *add-drop multiplexers* (*ADMs*) of the ring (shown as the *outer ring* in Fig. 11.13), and the other transmitting in the clockwise direction (shown as the *inner ring* in Fig. 11.13). A SONET STS-*n* signal enters and leaves the ring via add/drop ports of the ADM at the two ends of the connection (let us call the nodes A-end and Z-end, respectively). For a ring in a nonfailed state, it transports the two uni-directional components of the SONET signal by A transmitting to Z and Z transmitting to A over the channels of the ring in the same counterclockwise direction on the outer ring. A STS-*n* connection transmits over *n* consecutive channels (or time slots), starting at a channel numbered $1 + kn$ (where k is an integer ≥ 0). It simultaneously sends duplicate signals from A to Z and Z to A in the clockwise direction on the inner ring (shown with blue dotted lines in Fig. 11.13). In a nonfailure state, a port selector switch at the receiver chooses the normal ser-

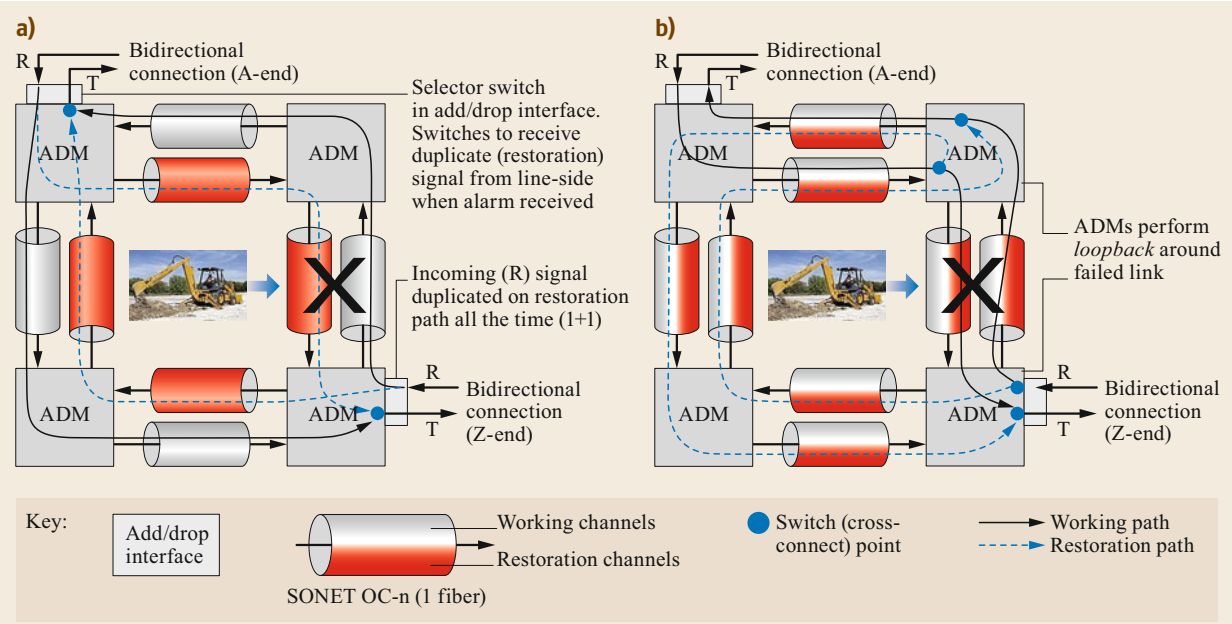

Fig. 11.13a,b SONET/SDH ring restoration (after [11.1]): **(a)** 2-fiber unidirectional path-switched ring (UPSR), **(b)** 2-fiber bidirectional line-switched ring (BLSR)

vice signal from one direction (counterclockwise). If this signal fails, i.e., one of the end ADMs receives an alarm, then the port selector switches to the alternate (duplicated) signal shown in blue. It reverts to the original signal after receipt of a clear signal or under other control messages.

In the 2-fiber *bidirectional line-switched ring* (*BLSR*) (Fig. 11.13b), the first half of the channels (time slots) of the high-speed optical signal of each link (i.e., ADM to ADM link) in each direction are used for transmission when the ring is in the nonfailed state. The second half of the channels is reserved for restoration shown as shaded in red. When a single link failure occurs, a loop back is executed at the add/drop port of the nodes surrounding the failed ring segment and the failed segment is patched with the restoration channels over the links in the opposite direction of the failed segment around the ring. In the case of node failures and multiple failures, complicated procedures using squelch tables and other mechanisms are standardized to prevent mis-cross-connection for connections whose ends are in the failed segment. Connections must be assigned to the same channel numbers on each link of the ring over which they route. A BLSR has the advantage over a USPR that the same channels (time slots) on different links can be assigned to different add/drop signals whose routes do not overlap links of the ring.

There was also defined a 4-fiber *BLSR* (not pictured), plus some other minor versions that were never deployed and we omit. In the 4-fiber version, one gets a full channel system on a pair of fibers plus a fully redundant system on another (backup) pair of fibers. This results in redundancy in the transponders in each direction. To picture the contrast, in the 2-fiber system of Fig. 11.13 there is a transponder in the (pictorially) left/west direction and then another transponder in the right/east direction. (However, note that when one looks at the physical equipment there is no sense of direction.) For example, the 2-fiber OC-192 system gets only 96 working (service) channels, whereas the 4-fiber system enjoys the full 196 working channels. Therefore, if one of the transponders fails (in one direction) on the 2-fiber system, then loop back must still occur for all channels. That is, it performs similarly as a fiber outage. In the 4-fiber version there is an extra set of (backup) transponders in each direction. Therefore, a transponder outage can be treated differently than a fiber outage. For example, in the case of a transponder outage, the system can execute a protection switch to the backup transponder and avoid a loop back around the other direction of the ring. This gives the entire ring higher availability since it can recover from dual failures where both a transponder outage and fiber cut occur. Other major advantages are that maintenance can be performed on the electronics on a single link without putting the ring into a loop back plus the restoration channels on the backup system can be used for other purposes. However, a huge disadvantage with the 4-fiber version is that it literally doubles the transponder costs compared to the 2-fiber version. As a result the 4-fiber BLSR was not widely deployed.

For those SONET subnetworks with more than four nodes (as shown in Fig. 11.13) and where the demand (signals) form a more a dense traffic matrix *mesh* (that is, the traffic/connections between most of the point-to-points is nonzero), the BLSR configuration typically uses optical capacity more efficiently than the UPSR. Since most connections (demands) in the feeder route of a metro-access network home on the same serving CO (such as in Fig. 11.4e), these demands do not form a dense traffic matrix network and thus the UPSR was mostly used to connect locations in the metro-access segment to the metro-core nodes, whereas the BLSRs were used to interconnect the COs of the metro core.

We note that most references generally label SONET/SDH rings, the legacy IOS switch, and the OTN switch with restoration enabled to be categorized as *optical layer restoration*. In reality this is a stretch of terminology since these restoration architectures make no fundamental changes to the optical components, e.g., transponders, lasers, amplifiers, wavelengths, arrayed waveguide grating (AWG) etc., but instead modify the payloads within the optical signals by modifying the signals after they convert to electrical digital signals at each node. While we described the OTN switch within the context of the intermetro segment, we note that some carriers also deploy a limited form of OTN switching, as well as its precursor legacy IOS switch, in the metro-core segment. However, it is much less used in the metro core compared to the intermetro core. Furthermore, if deployed in the metro core, then it tends to be used mostly for grooming with the restoration feature disabled. Therefore, we do not focus further on the OTN switching layer in this section.

That leaves the brunt of restoration capability to the MEN, which restores very similarly as described in Sect. 11.2.2 on the IP/MPLS layer. As noted earlier, the advantage of this architecture in most metro-core-segment carriers is that the MEN is a VPLS-type implementation, which is very amenable to enterprise customers to interface their Ethernet LAN environments.

11.2.4 Resiliency in the Metro-Access Segment

Let us examine the first three sample residential access architectures given in Fig. 11.4. Because of cost

and difficulty, in most of the world the metro-access-network portion has no restoration capability. That is, if an outage occurs along the path from the customer premises to the feeder network demarcation point, there is no installed methodology to reroute the connection. Many of the last mile infrastructure media in architectures Fig. 11.4a–c are aerial in vast parts of the United States.

Resiliency of Residential Wireline Access Architectures

This makes it even more susceptible to the potential outages on the environmental subtree of Fig. 11.8. Just one of these type events, such as a wind, ice, snow storm or a power outage coupled with the fact that it is unlikely such an outage will be repaired in less than 4 h (240 min), increases the yearly downtime almost halfway to three nines (500 min per year). This longer repair time is because in this part of the metro-access network a *truck roll* (maintenance personnel physically traveling to the site) is typically required to repair the outage and a large portion of this repair visit involves physically locating the source of the outage. In fact, a power outage from a downed or damaged utility line caused by wind, ice, or snow will usually far exceed four hours because the telecommunication cables usually ride on the lower part of poles and are often damaged. Repairs are complex and jobs have to be queued and are often dependent on power companies. Also, even if there is no damage to the network, power losses to the residences usually cause simultaneous outage of broadband service because the majority of residences do not have any form of power backup and residential broadband carriers almost universally do not provide battery backup for the residential gateways and set-top boxes for Internet services, although a few provide battery backup for wireline phone service. All these outages on the environmental and human/external-to-carrier part of the tree in Fig. 11.8 are in addition to the normal equipment outages that might occur to the PON and MSO equipment in the metro-access part of the network, such as failure of a PON plug-in on an OLT. However, many of these also require truck rolls to repair. Thus, this quick analysis shows that it is very unlikely that customers of these architectures will receive better than three nines of availability (and usually worse) over the long term.

We now illustrate why we left the metro-access segment to the end of the resiliency discussion. Consider a point-to-point packet flow, $P(A, Z)$, from a customer premises source in a metro-access network, A, to a destination in another (different) metro-access network, Z. For example, this could be a customer in metro access network A being served by a web site or server that is in metro-access network Z. Assume this flow is transported over the IP/MPLS layer of metro-core network $A1$ on the A-end and the IP/MPLS layer of metro-core network $Z1$ on the Z-end. Also assume it is transported between the IP/MPLS layers of metro $A1$ and metro $Z1$ via the IP/MPLS layer of intermetro-core network B. Because of aggregation of different IP flows, the multiplexed transport flow in network B could indeed contain hundreds, thousands, or even tens of thousands of individual point-to-point or multipoint connections of the same path. If we assume that the worst case availability of node-to-node (router-to-router) packet flows in networks $A1$, $Z1$, and B is at least five nines (that is, no more than five minutes of downtime per year for each of these segments) and then suppose that metro-access network A has at least three nines of availability (no more than 500 min of downtime per year), then, what can we conclude about the end-to-end availability of the flow $P(A, Z)$?

The answer is that when looking at availability of paths across multiple segments, one does no better than the weakest segment; because, assuming statistical independence, the end-to-end availability is the product of the three availabilities, which is less than the minimum of the three availabilities. Therefore, in this example the end-to-end availability of connection $P(A, Z)$ is no better than three nines and perhaps worse. Given our previous discussion about metro-access network availability for architectures Fig. 11.4a–c (that is, network availability for that segment is on the order of three nines or worse), why then provide such high availability in the metro-core and intermetro-core networks? Unfortunately, alluding back to our earlier comment about *more art than science*, we find that there is no simple, definitive answer.

However, one motivation is that carriers are more cautious about the potential magnitude of an outage, e.g., the number of customers affected times the length of outage. For, as one travels downstream, towards an end customer in Fig. 11.4, potential outages along the path generally affect fewer customers. Another motivation is that networks in the metro-core and intermetro segments provide transport to multiple types of customers. Thus, the residential customer in the access architecture shown in Fig. 11.4a may share the same metro-core or intermetro-core network as an enterprise customer in architecture Fig. 11.4e (Fig. 11.4e to be described in more detail later). Because of potential diverse fiber or coaxial routing in the metro-access network, the enterprise customer in Fig. 11.4e could enjoy much better network availability, hopefully approaching the *golden* standard of five nines. However, we admit that in practice such a stringent level of availability on an end-to-end basis is very hard to achieve. At

the minimum, to get close to this golden standard for the enterprise customer requires the very high availability of both the metro core and intermetro core that we described previously. Furthermore, a large carrier may lease transport across its metro-core and/or intermetro-core network to other access carriers, including its own enterprise business units, and so needs to provide universally high availability for those segment networks.

Resiliency of Enterprise Wireline Access Architectures

Let us now examine the architecture in Fig. 11.4e, which serves enterprise customers. We will discuss the architecture in Fig. 11.4d afterwards. The main difference between the architecture in Fig. 11.4e compared to residential architectures is that residential access in the USA and much of the developed world is dominated by coaxial cable. In contrast, this characteristic is less true in the world of enterprise services, where fiber is more prevalent, but not dominant because of the large quantity of small-to-medium businesses (SMBs), such as hotels, motels, small stores, etc. Our main observation is that the previous analysis of service availability for residential broadband Internet customers (architectures in Fig. 11.4a–c) is unacceptable for enterprise services, especially for larger enterprise services in large urban buildings.

Carriers handled this situation in the past with SONET/SDH path-switched rings, such as the stalwart UPSR. We discuss its downward evolution in the next section. The availability of the SONET architecture is much closer to the five nines availability that is typically characteristic of the intermetro-segment network. One reason is, whereas residential broadband service is often provided aerially, architecture Fig. 11.4e is often buried fiber or coax and it is quite common to provide an alternate, fiber-diverse path, shown by the light-colored dotted line. Thus, this dual-path access architecture is left vulnerable to switch or multiplexer outages at the building common space (usually in the basement or other designated closet area on the lower floors) and at the CO or hut location, but not to the myriad of other outages in Fig. 11.8, except for maintenance events, larger scope environmental outages, and other outages already discussed in the core metro and intermetro segments. Note that, technically speaking, carriers who lease Ethernet private lines for cell-site backhaul generally regard these services as enterprise services (not residential). However, we discuss cell-site backhaul in the discussion of the architecture in Fig. 11.4d instead of here in the context of architecture in Fig. 11.4e because the resulting service availability (network resilience) is engineered quite differently for end-to-end cellular services.

We mentioned path-switched SONET/SDN rings are in the (very long) process of being capped and retired so, then, what technology will be used to provide the dual-path switching in the metro-access network for enterprise-services? Many different architectures can be used. One example is that the carrier can define an Ethernet VPN and then define two packet layer-3 or layer-2 virtual links over which the VPN is routed. These links originate and terminate between the network terminating device at the enterprise common space (not shown in detail) and its network terminating device at the destination, e.g., in the first Metro CO or at another enterprise location on the far end. One virtual link routes over the primary path and the other link over the secondary path. Then, an end-to-end detection mechanism, such as BFD, can detect whether one of the links (paths) has failed. A simple mechanism, such as OSPF in the network terminating equipment, can be notified and perform network reconfiguration to use the secondary path, assuming it also remains up during the outage. In this case this simple overlay network consists of two nodes (i.e., Ethernet ports) and two links, so it operates very quickly.

Other Ethernet packet-like ring restoration methods have been developed, such as the ITU-T recommendation *Ethernet ring protection switching* (*ERPS*). For example, see [11.27] and [11.28]. Another example is IEEE 802.17 *resilient packet ring* (*RPR*) [11.29]. However, it is not clear which of these (if any) will see widespread adoption among access carriers across the world. In addition, their adoption will certainly not achieve the extent of SONET and SDH rings in the past.

Resiliency of Cellular Access Architectures

We now examine the architecture in Fig. 11.4d. The cellular network architecture and cell-site backhaul was discussed in Sect. 11.1.2. Although metro-access carriers may offer some form of restorable Ethernet PVCs under expensive enterprise service access options, few carriers provide fiber-diverse paths between a base station and its first metro CO. Also, in general the QoS of cellular service is worse than wireline service because of more susceptibility to weather events, traffic surges, limited spectrum, and interference from other cell sites. Wireless QoS is an extremely complex topic that involves more factors than wireline, such as power issues, distance from a cell site, line of site issues, geography, protocols, etc. Cell-site backhaul experiences similar outage impacts as described in the analysis of availability for architectures in Fig. 11.4a–c and then in addition the wireless portion of cellular service is affected by the wireless QoS impacts mentioned. Therefore, at first glance it appears that cellular service has

much worse network resiliency than the wireline residential broadband Internet architectures.

However, there are two differentiating and mitigating factors that may blunt some of this conclusion. First there are different QoS metrics between wireline and wireless. Because of the limited spectrum, substantial sharing (spectrum reuse), and different received power signatures of a cell service, the provided bandwidth (throughput in either direction) of the cell service does not enjoy the consistency of wireline throughput. Thus, it depends on how we define *availability* of cell service. Within a serving area, it is rare that one is totally disconnected from a cell site. Conversely, its QoS can be significantly reduced because of all the factors described above. Thus, like packet services in Sect. 11.2.1, if we define the availability QoS threshold sufficiently low (i.e., if QoS is below this threshold, then the service is unavailable), this architecture can almost be as resilient as wireline broadband service. Alternatively, if we define this threshold high, then resiliency is much lower because of reduced throughput. However, there is no universal definition of what such a QoS threshold for cellular service should be.

The second factor involves overlapping coverage by multiple base stations. Surprisingly, the second factor can indeed raise the resiliency of architecture Fig. 11.4d ABOVE that of architectures in Fig. 11.4a–c. For, the cell service will not enjoy availability to the SAME cell tower better than the architectures in Fig. 11.4a–c because cell-site backhaul experiences similar outage impacts. So, from this restricted viewpoint this classifies the service with a similar availability, around three nines, assuming that the threshold QoS defined above is less than that of its wireline counterpart. However, almost all cellular devices are within range of multiple cell towers. Since most cell towers (in the USA) are miles apart, they are likely to have different first gateway COs and thus diverse paths over the metro-access network, including possibly some part of the path routing over line-of-site microwave radio. Note that this first CO is not the MTSO, but rather the first point where the backhaul path intersects the metro-core network. This fact provides a very robust mechanism for resiliency. For, if an outage causes a cell site to become disconnected from the network, it is very likely that a cellular end device can and will switch to an alternate cell site, which is unaffected by the outage. Ironically, while this overlapping of cell sites is one of the most difficult problems in cellular engineering and management, namely *signal interference-to-noise ratio* (*SINR*), it also provides a robust methodology against network outages. If switching an end device to one of the surviving cell sites does not lower the throughput below the QoS threshold, then the network is resilient against the outage for those end devices. One can see an additional complexity of cellular QoS in that different end devices will experience different availability; uniform coverage definitions are difficult. Note that the addition of more small cell sites, as suggested by 5G, may further enhance the network availability, assuming the fiber paths to the neighboring small cells are diverse.

So can we, in general, claim that the network availability of a cell service as defined by the architecture in Fig. 11.4d is superior to the residential wireline broadband service architectures of Fig. 11.4a–c? On the basis of level of sophistication and implementation of cellular technology in today's cellular networks the answer is *no*. This is because engineering the QoS for cell service is significantly more complex, requires significantly more investment than that of wireline services, and has required decades of emerging wireless technologies, plus considerable network deployment and investment to get cellular services to today's level of widespread use and expectation of QoS. For example, if we set the threshold of QoS availability as that which enables uninterrupted, high-quality video service on data phones and personal devices, a rate typically in Mb/s, within a carrier serving area (assuming no service-affecting network outages, no bad-weather states, and ignoring video provider server difficulties), then we find that the level of availability differs widely across geography and different carriers for the reasons outlined previously. Another real-life example that can force the availability of cell service to be less than wireline, is the confusion of end devices to choose between Wi-Fi access points and cellular base stations. Many of today's end devices tend to latch onto Wi-Fi access points that have little or no throughput and/or get confused between choosing cellular or Wi-Fi communication links. This is because there is no reliable TCP-like layer that sits below TCP (or other streaming protocols) that can evaluate the availability/QoS between the links and seamlessly switch to the more reliable of the two. As an end device moves around, this problem occurs more frequently. This problem often causes downloads, such as steaming video content, to hang or drop. This is a good example of what we meant when we said that the resiliency of today's wireless networks even with the robustness to choose among surviving base stations is still short of wireline QoS. However, the capability to choose among different underlying wireless transport is still rapidly evolving and therefore, theoretically, as these difficulties are surmounted it will be possible for cell service availability to exceed that of the residential wireline broadband services described above (as we have defined availability in terms of a packet service QoS threshold). An example of protocol work to introduce such a layer is given by *multipath TCP*

(*MPTCP*) [11.30]. This protocol adds a layer below TCP that maintains multiple paths (lower layer links) and chooses among them. For example, it could maintain a background keep-alive connection over a cellular network virtual link as well as over a Wi-Fi connection.

One other outage issue for cellular service in this context merits discussion. The major environmental events listed in Fig. 11.8 can bring cell service availability below that of wireline broadband service. In particular, those events that cause power outages at the cell sites are most problematic, whereas this impact is usually less to the metro-access portions of wireline residential broadband Internet services (architectures Fig. 11.4a–c). For example, the PON architectures of Fig. 11.4a or Fig. 11.4b either see power outages at the apartment site (in which case all customers have lost service at that site anyway, regardless of architecture) or at the OLT site or minihead-end in a CO or hut. The latter generally have backup power. However, such is not the universal case for cell sites. As mentioned earlier, earthquakes and hurricanes have forced many carriers to think about equipping their cell sites with automatic back-up generators – and, of course, this capability in turn requires costly regular maintenance and certification of generators and safe fuel supplies [11.19]. Because the world has evolved so predominantly into wireless service some of the latest approaches to mitigate severe environmental disasters use rapidly deployable equipment and methodologies. Some of these are called a *movable and deployable resource unit* (*MDRU*). An example is given by the devastating 2011 Japan Tōhoku earthquake and resulting tsunami that disrupted communication facilities, as well as severely crippled nuclear power plants [11.31]. Other examples can be found in [11.17]. Even if these events only occur once per decade, if we factor in a multiday outage across an entire coverage area (that is, where a wireless end device is within range of multiple affected towers) into the yearly downtime calculation it raises the downtime significantly. For example, a five-day outage is 7200 min of downtime. Divided by 10 years, this is 720 min year^{-1}, which forces the availability to below three nines per year.

11.3 Evolution of Resiliency in Optical Networks

Looking at the present day view we provided previously, the inquisitive reader has already asked the question, *would we architect the same end-to-end architecture if we start from scratch with today's available technologies?* The answer is usually: *No*. This is because the architectures we presented arose from a slow evolution of competing and emerging forces, such as new services, new technologies, carrier corporate business models, emerging economics, and market realities. To prove this point, we can look at the types of network architectures that are quickly installed in emerging countries. They often look quite different to what we presented above [11.32].

11.3.1 Early Optical Transport Systems

We will now explore how and why the metro-core and intermetro-core networks evolved, but still focusing within our overall goal of network resiliency. This will explain what may seem at first glance an odd collection of architectures for network resiliency in Figs. 11.3 and 11.4. The earliest optical transport systems used nonstandard optical encryption schemes. The capacity of these early systems ranged roughly from 45 to 135 Mb/s. They were built to transport DS1 (T1), $n \times$ DS1, and DS3 signals in the USA. There were other intermediate rates defined, such as DS1C, DS2, but these rates/formats never played a large role. Plesiochronous rates, such as 2 Mb/s (E1) and 34 Mb/s (E3), were more common in Europe. These DS*n* or E*n* signals were architected mostly to carry voice trunks in early optical transport systems.

These early optical systems were generally point-to-point systems deployed in a two-way coupling, meaning that going in one direction all the constituent (client) signals were multiplexed into channels at the near-end terminal, then demultiplexed into drop ports at the far-end terminal and then vice-versa in the opposite direction. These early systems offered various forms of link protection/restoration, wherein a parallel pair of fibers could be connected to the equipment bay and high-speed switching would switch to the alternate fiber pair if an outage was detected. Switching was provided either in a 1:1 fashion (rerouting the channels of the high-speed system using only one set of high-speed cards) or 1+1 fashion (also called *path protection*), where the high-speed signal is split over a primary and backup/redundant path and the healthy signal is selected at the end terminal. This path selection could also be done on the ports of the receiving card of a channel independently of other channels carried by the optical transport system. There was also investigation into various 1:N restoration methods, where a single protection system covers multiple working systems. However,

1:N protection was not generally deployed for fiber or transponder outages and instead evolved mostly to protect shelf plug-ins and cards. That 1:N card protection strategy is still employed today.

11.3.2 SONET/SDH Optical Transport Systems

As optical transport systems became more prevalent, the deployment of many point-to-point systems, each with its own with line/fiber protection, became unwieldy and expensive. To overcome this problem, various add/drop features were added to intermediate terminals in these pre-SONET/SDH systems. However, these early optical transport systems were very limited in their add/drop capability and the variation in vendor product capabilities was wide.

To help understand this evolution of optical networks and their resiliency capabilities, it is helpful to study the evolution of the USA intermetro network, which was dominated in the early years of optical network development by the Bell System and AT&T. The AT&T Bell System was divested in 1984 following a USA federal court order called a *consent decree* into eight corporations: AT&T and the seven *regional Bell operating companies* (*RBOCs*). In addition, the RBOCs formed their central R&D arm called Bellcore in that same year. However, the intermetro (long distance) network remained with AT&T after divestiture and so we see a consistent evolution of the intermetro architecture through the 1980s and beyond. AT&T had settled on a pre-SONET 1.7-Gb/s optical system, called *FT series G*, for transporting DS3s through the late 1980s and middle 1990s [11.33]. The copper-based DS3 (or T3) signal was its target CO intraoffice cross-connect signal (i.e., client/constituent add/drop signal to the optical terminals). They used a Broadband DCS (tradename DACS-III) to cross-connect the DS3s in a CO, analogous in concept to that of the OTN switch in Fig. 11.7, although more technically primitive. This intermetro optical transport network of the era had some add/drop capability and employed forms of link/fiber protection for its high-priority private-line traffic. However, to reduce the cost of expensive 1:1 or 1+1 fiber system protection, they leveraged the cross-connect ability of the Broadband DCS to implement a centralized DS3 rerouting scheme called FASTAR [11.34]. Because FASTAR used a centralized controller to send cross-connect commands to the Broadband DCSs, this restoration scheme was relatively slow for large outages, i.e., slow compared to later SONET ring restoration speeds and IP-layer virtual rerouting. This was because at the time, their core network mostly transported voice trunk groups: DS0 trunks multiplexed into DS1s and then DS1s multiplexed into DS3s. The voice trunk network was very highly connected and so had its own form of dynamic (alternate) routing and therefore the speed of DS3 restoration was not as critical for this service. For more detail on AT&T's dynamic routing in circuit-switched (mostly voice service) networks see [11.35].

The reader may have already started to ask the question: *Why are the topics of FASTAR and pre-SONET fiber optic systems important to today?* The answer is that while AT&T had settled on (what it thought at the time was) its long-term transport and resiliency architecture, the evolution to today's networks started leapfrogging rapidly from that point in time. Also, the metro carriers did not go with the same architecture and were busy exploring alternative technologies, literally a technology generation ahead. As mentioned previously, the point-to-point pre-SONET/SDH fiber optic systems used in the metro-core network were becoming unwieldy. Note that during this period (1984 to the middle 1990s), voice trunks were still the predominant traffic/demand to be transported in the metro-core networks, excluding the MSO cable companies, who during that time mostly distributed rebroadcasts of over-the-air television channels. Bellcore was tasked to find a better solution to transport the odd collection of TDM signals (including Europe, Asia, and North America) and to standardize (even possibly synchronize) the signaling formats in the emerging optical transport systems. Thus, SONET was developed. The first accomplishment of SONET (later followed by the SDH standard in the European-based ITU-T), was to define the next generation of constituent digital rates and channels inside optical signals by defining the basic SONET synchronous transport signal (STS)-1 (SDH STM-1) internal rate. Bellcore decided to make a synchronous digital encapsulation, wherein as one increased the optical line-rate multiplexing capability, the bit rate would remain proportional. However, they also incorporated stuffing bits to accommodate the various asynchronous subrate signals. This standardization also enabled easy add/drop capability and the first flexible ADM. An important side-light of this standardization activity was the standardization of overhead bits and signaling bits. This enabled one to rapidly pass alarm information as *signatures* within the SONET overhead along the route of ADMs in a SONET system. Signature means a repeating bit or symbol code rather than an explicit protocol message. Once the add/drop standards were developed, the next step was standardization of a restoration/protection scheme and, in particular, one that was more efficient than the overlapping, point-to-point pre-SONET systems. By *efficient*, we mean both more automatic and controllable from a network management standpoint, as well as more capacity efficient.

At this point, a well-architected approach to optical-layer restoration could be adopted. The most deployed products were the SONET/SDH UPSR and BLSR, which we described in Sect. 11.2.3. However, we will find later that this new-found euphoria would soon run its course. Once the standard was developed and vendors developed products, the metro-core Telephony carriers in USA, Japan, Europe, etc., began to install SONET and SDH systems en masse. Because of the size and relative proximity of the countries in Europe, SDH rings could also be used for intermetro-core transport and restoration. In fact, as the Internet began to rapidly grow in the late 1990s, additional standards for encapsulating packet links (data transport) inside of TDM signals (e.g., DS1, DS3, E1, E3, STS-n and STM-n) enabled the carriers to reuse the same processes they had already developed for years that provisioned these TDM signals that transported circuit-switched trunks. For example, a DS3 signal that carried almost 45 Mb/s of data packets was called a DS3 *clear* signal. This enabled rapid growth of a retail and wholesale leasing market for data-carrying private lines (*circuits*). The term *wholesale* applied when a carrier leased such signals to another carrier and *retail* otherwise. In addition, these circuits could be sold as reliable (resilient) circuits, because the portion of a circuit in a metro-core network could be transported over SONET/SDH rings.

But what about network resiliency in the intermetro-core network during this rising period of SONET/SDH products? Use of the SDH rings for the intermetro-core segment in Europe, Japan, and other geographically smaller countries solved some of that question. But in the USA, as we described previously, the dominant intermetro-core network carrier (at that time) used pre-SONET optical transport systems and a slow DS3 rerouting scheme for most of its traffic. What occurred next was a tumultuous and short-lived love affair with SONET rings. AT&T attempted to cover its vast USA intermetro-core segment with a series of overlapping OC-192 BLSR 4-fiber rings. Note that to function as expected (from a QoS standpoint), the ADM-to-ADM links of a BLSR ring must be fiber-diverse of one another, else multiple link outages have a much higher likelihood of occurrence. Multiple link outages can cause a set of nodes of the ring to become disconnected from another set, in which case the ring has much less resiliency.

This was a daunting task to route and develop a series of massive rings across the country. It was quickly discovered by researchers that there were far better approaches for the USA intermetro core. One of the earliest articles on this can be found in [11.36]. These early studies showed that SONET rings were, from an economic standpoint, a bad choice to provide restoration at the optical layer in the intermetro-core segment. The optimization principal behind this discovery was that with a well-connected network (e.g., every major switch location has a topological degree ≥ 3), rings do not take advantage of maximal sharing of capacity over nonsimultaneous, potential fiber-span outages. Furthermore, one of the major shortfalls of SONET rings in intermetro networks (which is true also in metro-core networks) is that while they appear attractive when the entire network can be covered with a few large giant rings, when the network size and increasing demand dictates that multiple rings begin to overlap and overlay, the SONET/SDH network-wide architecture becomes unwieldy and expensive (plus a BLSR is limited to 16 ADMs). To understand this problem of multiple ring deployments, consider when a circuit needs to cross two rings. It needs to demultiplex and be connected through a fiber patch panel at the CO where the ADMs from the two rings are colocated, analogous to the cross-connect at locations C and D in Fig. 11.6. As the bandwidth requirements of these networks grew, plus the fact that commercial SONET/SDN rings never effectively exceeded the 10-Gb/s line rate, it became necessary to deploy many *intersecting* or *stacked* rings. *Stacked* rings mean that two or more independent rings are deployed whose ADMs are located in the same set of COs. However, there is nothing particularly special about two stacked rings. They are basically just a special case of two rings whose ADMs intersect at one or more COs. For, if a connection needs to be transported over the two rings, then it must add/drop at an ADM of each ring in the same CO and be cross-connected via a patch panel between the ports of the two ADMs. Extrapolating this problem over time, as the size of the Internet and private packet networks grew, deployment and management of SONET rings eventually became unwieldy, even in USA metro-core networks [11.1, Fig. 6]. Some metro networks grew to literally thousands of SONET rings, making the network virtually impossible to visualize. In fact, as of the writing of this chapter, many networks still have this situation. Furthermore, the management of the inter-ADM circuits via patch panels became a challenge unto itself.

We note that this intersecting ring problem could potentially have been ameliorated with deployment of a broadband DCS that internally integrates/connects the two ADMs. In fact, some vendors did provide potential solutions for these hybrid architectures by producing *ring cards* that could be installed on a broadband DCS. But this leads to the important question: if a DCS needs to be used to manage the massively overlapping ring problem, then why not use a better overall mesh restoration scheme, as potentially provided by the DCS? These issues plus the restoration optimization analysis work

of [11.36] led to the advancement and deployment of the intelligent optical switch (IOS) that we briefly described earlier. However, some breakthroughs in optical and digital multiplexing technology were needed to enable this evolution. To understand these breakthroughs, we digress a bit.

In telecommunications technology, the concept of multiplexing signals was invented to take advantage of economy of scale. For, using the same media (copper, radio-frequency-over-air, fiber, coax, etc.), one can transport more individual signals by multiplexing them via different technology schemes, such as analog carrier or digital time-slotting. However, there is a downside in that to provide the ability to add or drop individual signals which comprise the channels of the multiplexed signal, one must figure out an efficient way to *demultiplex* the signal. As we described previously, prior to SONET/SDH, one effectively had to demultiplex the entire signal and, as a result, this economic tradeoff created an extremely difficult network design optimization problem, called the *multiplex bundling problem*. For example, see [11.37], which was the first paper published in the newly formed Telecommunications Section of the Operations Research Journal. SONET time synchronous technology was developed to more efficiently multiplex and add/drop individual channels. However, SONET optical transport systems were only offered in very simple architectures, such as linear chains and rings. The IOS technology offered a breakthrough in that it found efficient ways to demultiplex the SONET high-speed signal into its constituent STS-1 channels at the incoming port on every IOS switch and then reassemble the through signals with any newly added or dropped signals on the outgoing ports of the switch. This required very high-speed digital processing so that delay and jitter would not accumulate and exceed a given tolerance. Thus, IOS technology overcame the historically difficult, combinatorial multiplex bundling problem, as well as enabled the deployment of more practical mesh-network deployments. In addition, another benefit was that it also enabled the development of rapid restoration methods based on more capacity-efficient mesh-network topologies. This answers the question we posed above.

The IOS is basically a progenitor of the OTN switch and thus the restoration method in the IOS is very similar to that of the OTN switch (described in Sect. 11.2.2), except the IOS uses SONET STS-1 (51.84 Mb/s) or SDH STM-1 (155.52 Mb/s) channelized building blocks versus ODU-0 (1.24 Gb/s) building blocks, as in the OTN switch (however, note that the internal switching architecture of the OTN switch may use even smaller data chunks than what we listed). One final remark in this section is relevant to our later discussion on the difficulty of implementing ideas for network resiliency in commercial carrier networks. The IOS paved a path for mesh-network restoration in optical networks. Yet, even though some of the first vendor models were demonstrated at the Optical Fiber Communications Conference (OFC) in 1999 by Lightera, and given the attractively simple-sounding idea of storing single fiber-diverse restoration paths for each provisioned connection, it took almost a decade of implementation and a staff of highly qualified analysts, optimization experts, and planners to deploy it to its full capability and maintain it (Lightera was later acquired by Ciena who renamed the switch *Core Director* [11.38]). In fact, as of this writing, it is still deployed and providing network resiliency in the intermetro-network segment [11.23].

11.3.3 The Decline of the Path-Switched Ring and the Emergence of IP-layer Restoration and Ethernet

Concurrent to the widespread deployment of SONET and SDH rings in the mid-1990s, packet networks were rapidly deployed. Carriers started by routing their router-to-router links over SONET/SDH transport systems or over packet private-line services, such as frame relay-based PVCs. As described in detail in Sect. 11.2.2 one of the fundamental capabilities of Layer-3 IP control protocols is their ability to recover and operate from massive network outages. This distributed survivability feature was one of the original goals of the government-sponsored ARPANET, the progenitor of today's private-based Internet. Thus, from their origins packet networks based on IP protocols inherently contained restoration capabilities. During this period an early technical competition sprung forth about which network layer would be the ultimate provider of network resiliency. We remark that a lower network layer, ATM, made a brief appearance during this evolution and despite its strong endorsement by many significant parties (including the US federal government, Bellcore, ITU, some carriers), it soon thereafter made an ignominious departure and thus we skip its discussion.

During this period, UPSR rings became the darling of resiliency to enterprise locations in metro-access networks, assuming diverse fiber paths for the ring could be provided, which is usually the case in dense urban environments. However, as one can see, we do not even show a UPSR ring in Fig. 11.4e. With the emergence of ultralow-cost gigabit Ethernet interfaces and switches, the SONET/SDH UPSR fell out of favor and is being replaced by the myriad of packet and Ethernet-based diverse routing technologies. We again highlight the discussion of Sect. 11.2.4: to approach five nines

availability for premium Enterprise services, it is critical to have a media-diverse routing capability in the *last mile* of the metro-access network. However, it is important to note that while the UPSR was the legacy gold standard for Enterprise access, we cannot yet say there is a *gold standard* replacement for the evolution to Ethernet-based restorable routing or even if a gold standard will emerge.

One additional observation about the emergence of Ethernet-based interfaces is that as already mentioned, a historical wholesale market developed for leasing DS1s (T1s) for trunks for voice service and then later the DS1 was enhanced and standardized to carry packet data traffic (the un-channelized *DS1 clear*). This enabled the T1 to become the workhorse of the private-line carrier industry. Jumping forward a few decades, one can now think of the gigabit Ethernet (*GigE*) signal as its modern day analog. For, almost all enterprise services today interface with carriers at $n \times$ gigabit Ethernet signal/rates, but usually contract for a smaller CIR than the maximum gigabit rate of the interface. Cell-site backhaul is an excellent example of this evolution. Cell sites used to interface with carriers via the $n \times$ DS1 interface. In today's networks, carriers mostly upgraded this interface to gigabit Ethernet, as shown in Fig. 11.4e, but police the traffic to the CIR appropriate for the traffic on each cell site. Thus, a wholesale market for leasing private-line GigE signals has arisen.

11.3.4 DARPA CORONET Study

Perhaps the most comprehensive study of the best combination of technologies to provide resiliency in an intermetro-core network was undertaken during the DARPA CORONET program [11.39]. The program began under the leadership of *Saleh* and *Simmons* and was motivated in part by their earlier history with intermetro carriers, optical start-up companies, and their original ideas about network design, as expressed in their paper [11.40]. Also see related work in the later book [11.41]. CORONET was a long-running DARPA program: a total of seven years and three phases, which by DARPA stringent contract renewal and review standards would have to be called quite successful. CORONET assembled teams of experts in network design and optimization from commercial carriers, academia, and the telecommunications optical and packet vendor community. We describe some of its findings here.

CORONET Goals

Some of the principal goals of CORONET were to explore the architecture, operation, and commercial feasibility of a packet-over-optical intermetro-segment network with the following features (requirements): (1) a dynamic optical layer, wherein circuits (either high-rate private line or links of the IP layer) can be rapidly provisioned under a highly distributed control plane, including *bandwidth-on-demand* (*BoD*); (2) high network availability, provided under a range of CoS for connection services at each network layer, where each class is targeted to survive a different severity of network outage; and (3) rapid connection/circuit provisioning. The severity of network outage was defined in terms of increasing combinations of fiber and/or total CO outage [11.42, 43]. We discuss later why they chose this particular outage model.

Because our primary interest in this chapter is network resiliency, we skip the provisioning and bandwidth-on-demand aspects of CORONET and instead briefly describe the types of solutions that CORONET recommended to handle its different range of modeled potential outages. Along with these recommended architectures, network capacity and performance studies, DARPA CORONET developed a nonproprietary, hypothetical (yet quite realistic) optical network topology of the USA network, shown in Fig. 11.14. Because of the participation in the project by analysts and network designers associated with large carriers, this hypothetical optical network has topological characteristics that are similar to those of the largest USA intermetro carri-

Fig. 11.14 DARPA CORONET hypothetical intermetro network

ers. These include key cities, fiber spans, DWDM links, node diversity, etc.

CORONET also derived a hypothetical global optical topology. We do not show this expanded global topology because it was derived mostly to test the global limits and constraints of the restoration algorithms, latency, and provisioning times, rather than to represent a realistic commercial, carrier-based network.

Summary of CORONET Results

CORONET defined many aggregate classes of demand/service. These included packet services and highest-rate private-line services, called *wavelength services*. Links between routers in the IP/MPLS layer that are provisioned to provide packet services were basically treated as a *slow* demand for high-rate private-line services, whereas other private-line services were classified as either *slow* or fast/dynamic (bandwidth-on-demand). The first Phase of CORONET did not model lower rate private-line services (below wavelength rate) and tacitly assumed these would be provided by the packet layer. However, it was found as the project progressed and through carrier feedback that providing private-line demand only via the IP/MPLS layer was not commercially practical and as a result an OTN-layer was added in later CORONET Phases. Thus, when this change is incorporated into later CORONET project progress, the good evolutionary news is that the intermetro-segment picture of Fig. 11.3 is fundamentally consistent with CORONET findings. [11.42], [11.43], and [11.44] provide many other important findings and details, such as the two-phase restoration in the IP/MPLS layers, which is similar to what we described in Sect. 11.2.2, how to design restoration in such networks to achieve class-of-service objectives, such as best-effort and premium services, how to mitigate router outages in a capacity-efficient manner compared to dual-homing, how to provide bandwidth-on-demand, and results on provisioning times.

We will not delve into these details, but instead briefly mention the results of the CORONET study of optical-layer restoration and higher layer restoration. CORONET proposed highest-rate private-line services defined by different survivable classes, namely, single (optical) link outage, simultaneous dual link outage, CO outage (restoration of through traffic only), simultaneous link and CO outage, and simultaneous triple outage. However, to be realistic, as one steps through the classes-of-service that must survive the more stringent outages, the magnitude of the corresponding traffic class decreases accordingly. For example, to expect large amounts of wavelength traffic to survive the worst-case type of outage, namely a simultaneous triple outage, is unrealistic because it would require a very highly connected network with significant spare capacity; therefore, this highly survivable traffic class was specified to be a small fraction of the total, e.g., no more than 5%. Furthermore, there were time limits placed upon how long it took to restore a circuit. CORONET project requirements required very rapid restoration times, e.g., approximately 50 ms or less for single link outages within the continental USA.

Before proceeding to further discuss studies/results on optical and IP/MPLS restoration methods in the early CORONET phases, we want to ground them within the commercial context of this chapter, namely that we are aware of no carrier who sells wavelength-rate private-line services as defined by the CORONET survivability classes; consequently, one should think of the CORONET demand/traffic classes and their network requirements as illustrative and the corresponding results as helpful to explain how and why network architectures evolved to their present state. Extending beyond commercial carriers, DARPA is a USA Department of Defense (DoD) entity and, as such, its affiliated federal agencies had interest in the results of the study of these conceptual outage traffic classes to help answer generic questions of USA network survivability and how such outage-stringent private-line services could potentially be offered within a commercially feasible approach. Furthermore, the USA federal government participates in and/or supports many RENs. Constructing such advanced services and corresponding network capabilities on a limited basis is more feasible than in large commercial networks. Also, Phase III of the CORONET project evolved to study such private-line capabilities using dynamic connection provisioning (bandwidth on demand), but within a commercial business context. We discuss more of this aspect when we discuss private networks starting in Sect. 11.3.6, *CORONET BoD*.

If we now refer to Fig. 11.3 (i.e., the colored network layers) and back to the discussion of resiliency in today's intermetro-segment networks in Sect. 11.2.2, we mentioned that there are no commercially deployed networks with optical layer restoration other than the OTN switching layer, legacy SONET/SDH, or legacy IOS layer. However, we also mentioned that these are not *purely optical* restoration methods, wherein optical lightpaths themselves are reconfigured. To explore why this situation transpired, it is useful to compare against a hypothetical, yet practical optical-layer restoration method. To this end, CORONET researchers decided to recommend and study a wavelength connection restoration strategy that had the most practical chance of

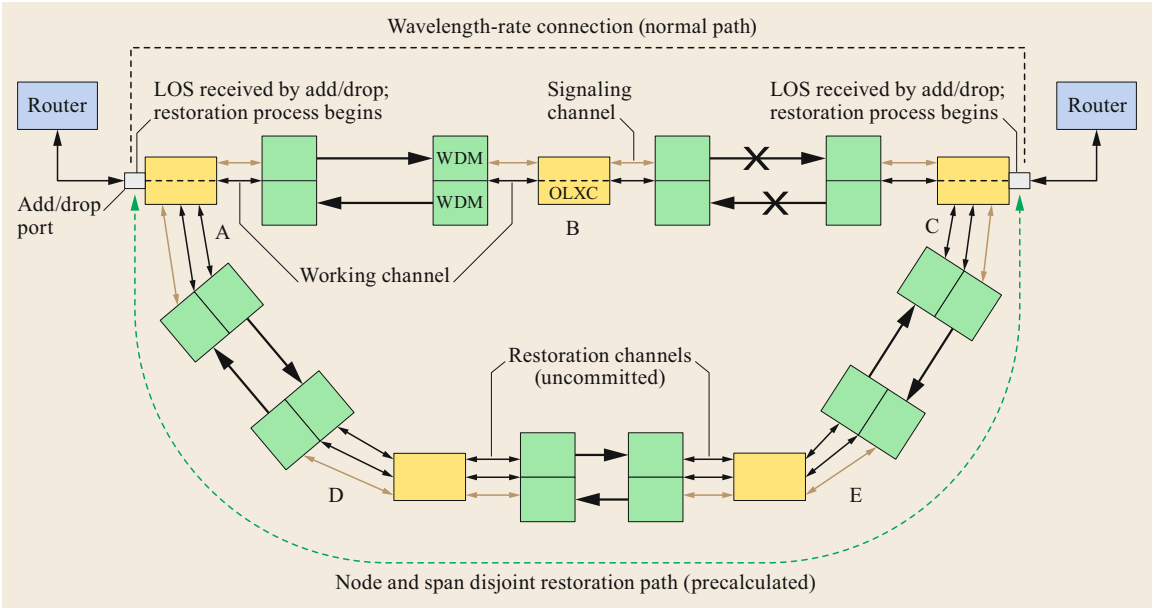

Fig. 11.15 Failure detected. ROLEX restoration: Outage detected at both ends (after [11.45])

implementation. They converged on a patented optical restoration method, colloquially called *rapid optical layer end-to-end X-connection* (*ROLEX*) [11.45, 46]. This restoration method has similar restoration characteristics to that of the OTN switching layer described previously, in that a secondary path that is fiber-diverse of the service path is precomputed and stored in the originating (and possibly terminating) node(s), namely, ROADM(s) or optical cross-connect(s), of each provisioned circuit.

This method is triggered by detecting a loss of signal or control-plane notification of an individual wavelength-rate connection (circuit) at the origin and/or terminating nodes of that connection. See Fig. 11.15, borrowed from [11.45]. In the two-ended version of ROLEX, a message protocol is initiated over the digital overhead channels of the circuit from both ends and along the precomputed restoration path. Note that such data overhead channels are clearly available in OTN standards. This protocol attempts to reserve the spare wavelengths (channels) in each node-to-node link along the restoration path, including algorithms for contention control as multiple circuits vie for unused wavelengths (channels) (Fig. 11.16). These messages meet somewhere in the middle of the path. Note that if the source side message travels faster, it could even meet at the opposite side of the first link (Fig. 11.17). The cumulative restoration time is minimized by wavelength (channel) cross-connection being enacted as the protocol progresses, instead of waiting until the process reaches the end node. However, if the signaling process is unsuccessful at any point along the path, the process is halted and a *back-off* process is initiated that sends disconnection messages along the path to clear selected channels.

Of course, at a minimum the network must be designed with sufficient spare wavelengths and transponders for the process to restore all high-rate private-line services against any single fiber link (span) outage. Fiber spans are shown in blue in the CORONET hypothetical network of Fig. 11.14. If this is so, then the probability of occurrence of circuit back-off is low. As in the OTN switching layer, when more complex outages occur, wherein both the primary and secondary paths fail or there is a high degree of contention for spare channels, then a second (and slower) dynamic path selection process is instigated to try and find alternate paths for those connections that could not be rerouted on the first attempt. We note that CORONET analysts did study methods to also precalculate and store multiple alternate paths to handle the more complex outages. However, given the inherent difficulties in implementing optical-layer restoration, we feel that these intense precalculation methods are not practical. Further note that CORONET Phase-1 requirements provided relaxed restoration time requirements for multiple simultaneous outages.

Much of the CORONET study investigated how to optimize the capacity of the network to provide the required network availability of the wavelength-

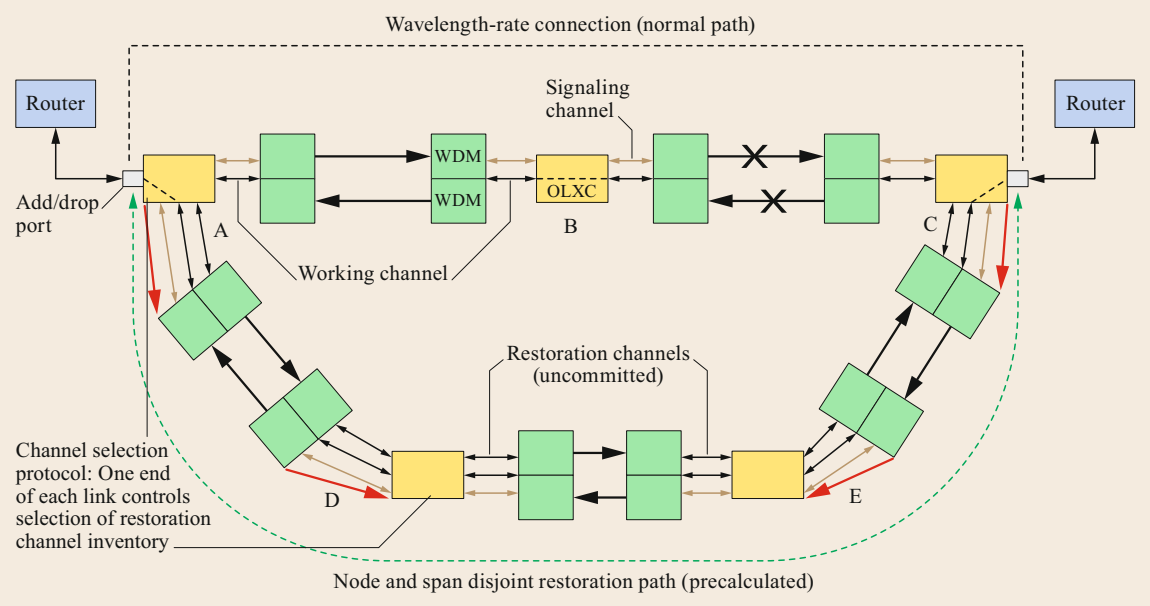

Fig. 11.16 Restoration process begins at both ends. ROLEX restoration: Signaling process instigated at both ends (after [11.45])

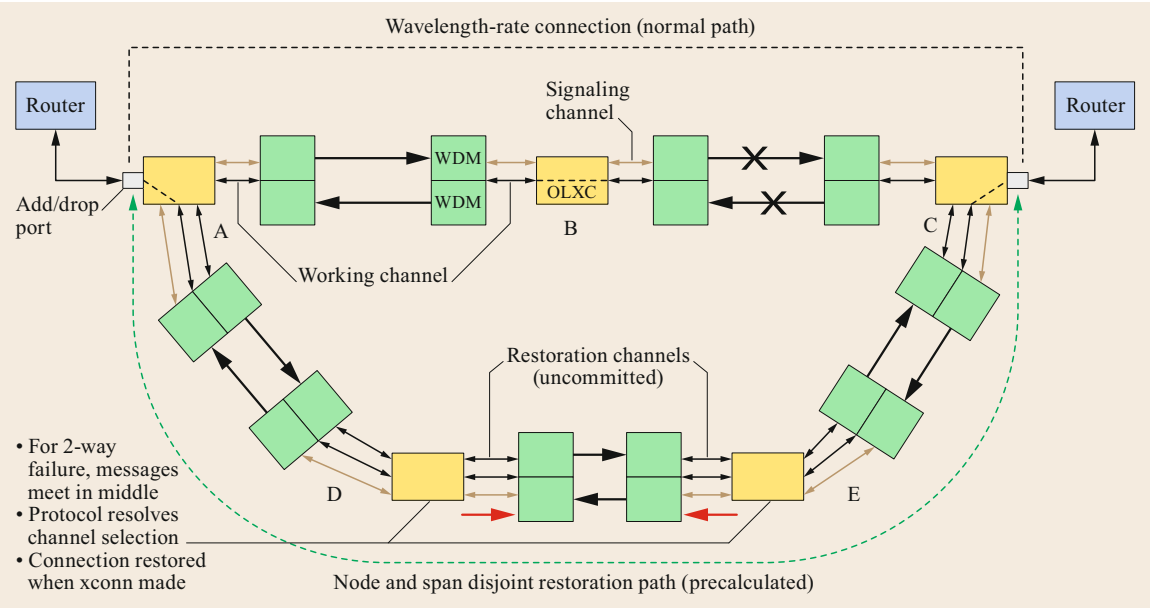

Fig. 11.17 Messages meet at middle node. ROLEX restoration: Signaling messages meet in the middle (after [11.45])

rate private-line services against these types of outages. Early phases of CORONET investigated simulation of the ROLEX protocol on the CORONET network with different sets of demands with varying traffic intensities. Phase-1 CORONET only evaluated the capability of the ROLEX control-plane protocol to converge properly and evaluate convergence times on reasonable controller hardware platforms at each optical node. Surprisingly, Phase I CORONET found that the control-plane portion of the optical-layer restoration method generally achieved the restoration time requirements within the hypothetical USA network. See [11.43, Sect. V.B.].

11.3.5 The Emergence and Dominance of IP-layer Restoration

One of the milestones in the evolution of resiliency in the metro-core and intermetro segments, is the migration away from lower layer resiliency of the past (mostly SONET/SDH-based architectures) to the situation of today where IP/MPLS is the principal layer where resiliency is provided. In this section, we will examine some of the motivations and realities that molded this evolution. But before we list these reasons, let us review a few key observations in the history of metro-core and intermetro evolution:

- At the time of their development and subsequent massive deployment around the world, SONET and SDH transport systems emerged as a standardized optical technology that solved most of the complex multiplex bundling problems as well as established a robust market for low-cost leasing of private-line circuits that could transport either voice trunks or links of emerging packet networks, the so-called *clear* un-channelized encapsulation protocols, such as clear DS1, $n \times$ DS1, DS3, $n \times$ DS3, E1, E3. In addition, SONET/SDH rings provided a resilient lower layer transport technology with very rapid restoration speeds (generally within 50–100 ms) and resulting high network availability.
- As data traffic increased, literally many orders of magnitude over decades, the SONET/SDH-based IOS switch technology provided a more capacity-efficient and provisioning-efficient alternative than SONET/SDH rings, although restoration speeds were slower.
- The OTN switch was a next-generation evolution of the IOS switch that provided significantly higher signal-rate capability, was compatible with the emerging OTN standards, provided the ability to seamlessly encapsulate multiple packet-based signal formats, and provided superior restoration capability than its predecessor IOS switch.
- As DWDM technology became common and wavelengths achieved higher rates, the DARPA CORONET project suggested a reasonable technology approach to provide optical-layer restoration.

Then, given all these seemingly attractive points, why does the intermetro segment of Fig. 11.3 show restoration capability at the IP/MPLS layer, but no restoration capability in the optical (DWDM) layer, plus a large arrow from the IP/MPLS Layer that skips the OTN layer? Most of the answers to this question lay buried in the internal decision making, network economics, and operations of large carriers; hence, there is no simple and quotable outside reference that we can offer to answer this question. However, we compiled a list of factors that we have derived from years of analyzing, architecting, and optimizing these networks.

Factor 1: DWDM-layer Restoration Was not Fully Proven as Viable in CORONET

While the CORONET Phase-1 ROLEX methodology appears to be a viable and attractive optical layer restoration alternative, one of the tasks of CORONET Phase-2 and Phase-3 was to suggest a path to commercialization of the ideas from Phase 1. However, as in all research projects, along the way new realities and directions emerged. In particular, while Phase-1 simulations demonstrated that the ROLEX control plane can achieve very fast restoration speed, it turned out harder to prove when the project attempted to introduce actual hardware devices whose optical cross-connect (provisioning) capability could match the speeds of the control plane. Essentially, a CORONET field trial explored the characteristics of existing ROADM technology connection (lightpath) provisioning that needed to be advanced to achieve these very rapid restoration times. These speed roadblocks included amplifier wavelength power balancing processes, laser tuning, and methods to filter out optical impairments in the transponders. Unfortunately, the results of this analysis were unpublished, but the findings were found to be consistent among most leading DWDM equipment vendors at the time. Another significant roadblock to advancing these characteristics was that from the point of view of carriers, the DWDM lightpath provisioning process was never developed to be rapid because it was part of a planning and provisioning process, the so-called *capacity provisioning process*, which historically was (and still is) generally interwoven with *operations support systems* (*OSS*) and human provisioning processes – but certainly never envisioned to occur on the order of a few seconds or less. To modify equipment and provisioning/control systems to solve these problems and perform subsecond provisioning along a path of ROADMs or optical switches requires significant equipment development, as well as streamlining of the OSS environment. Plus, an accompanying and convincing business case would be needed to motivate carriers to consequently push their DWDM vendors to enable such rapid features. This business model would have to show (1) business necessity for such rapid restoration/provisioning; (2) convince carriers that it could (even technically) be accomplished; and (3) be accomplished at small additional cost. After establishing these findings, CORONET Phase III determined to study an alternate path to optical-layer provisioning and resiliency.

Factor 2: Centralized Control Re-Emerges

The original CORONET requirement was for a restoration mechanism under distributed control, as evidenced in Figs. 11.15–11.17. However, before the CORONET project was initiated in 2006, distributed network control was *in vogue* in the Telecom industry, especially in government; but, during the time of the CORONET project (2006–2014), distributed control fell out of favor and yielded to SDN-based *centralized* control ideas. Given the above points and the lack of a strong business case for rapid, distributed wavelength-rate restoration, CORONET Phase-3 changed course and pursued a more fruitful approach to use the emerging SDN capabilities to craft a more attractive business case for bandwidth-on-demand of wavelength-rate services, as well as subrate (below wavelength rate) services. This is discussed again in Sect. 11.3.6.

Factor 3: It is More Efficient and Economical to Engineer Resilience in the IP/MPLS Layer than in Lower Layers

Studies at the time showed that it was more efficient and economical to engineer resilience in the IP/MPLS layer than in lower layers. This is a complex topic that requires the analytical techniques we described previously concerning cost-optimal network design, CoS/QoS modeling, and characteristics of the outage probability space complexities. Ultimately these became business decisions inside carriers. But without delving into mathematical network optimization and business cases, we list some the reasons:

1. To achieve high network availability, the reliability experience with router hardware, protocols, and required maintenance procedures (such as software upgrades) indicated that routers would have nontrivial downtime. Therefore, IP backbones are often designed with sufficient spare capacity to restore the network (or at least premium services) from the potential outage of an entire router, whether due to hardware/software failure, maintenance activity, or external event. To better understand this, note that no amount of the restoration capability in the lower layers (OTN or DWDM) can protect against a higher layer node outage (e.g., downed router). Therefore, as multiple studies showed, the installation of adequate packet-layer link capacity to restore against router outages also provides significant protection against nonsimultaneous outages of other types (e.g., router component equipment, optical-layer failures). Router/node coverage does not usually protect 100% against (say) single fiber outages, but optimal placement of a small amount of additional capacity does the trick. Placing DWDM layer capacity for this little bit of extra capacity was not cost-effective compared to placing it in the IP/MPLS layer.
2. IP/MPLS-layer links have discrete capacities defined by their line rate. Usually only a few critical links are at maximum QoS-threshold utilization (where *threshold* is defined as before to mean the level of maximum utilization that provides a desired packet QoS for the given classes of service); therefore, there is usually a large amount of such *marginal* capacity available in most links, even after potential traffic is rerouted over them to accommodate the worst-case outage. This effect, when combined with the above extra capacity for router outages, made the case against DWDM-layer restoration even stronger.
3. Finally, one of the strongest reasons is that, as mentioned, packet services can be prioritized into classes (CoS), each with its own QoS target. In fact, one of the key factors in determining the theoretical QoS of the premium class is how that traffic is treated during potential network outages or unexpected traffic surges. As an example, a common business practice in carriers is to allocate no extra IP/MPLS capacity for restoration of best-effort traffic. However, it is important to note that does this does NOT mean best-effort traffic gets clobbered at every outage. To the contrary, the lower class traffic usually only suffers when hit by one of the potential *worst-case* outages and even then some amount of best-effort traffic will likely not suffer. Without delving into probabilities and maximal potential link traffic flows, we can state this mathematical phenomenon as follows: to meet the desired network availability, the outages with the worst expected loss (probability times magnitude) generally dictate the main amounts of extra capacity needed for restoration. Stated (over) simply, the network is designed for the worst case. Thus, if an outage of less magnitude occurs, there is usually enough capacity for most traffic to be rerouted successfully. And when best effort and premium traffic are being rerouted over a common router link, priority queuing allocates the capacity first to the premium traffic. Thus, the effect is that the best-effort traffic either gets through without QoS degradation or some of it might experience delay or some loss during the worst outages. None of the methodology and nuances that we just described about the optimum handling of premium versus best-effort traffic during outages can be equivalenced by providing DWDM-layer restoration. This is because DWDM-layer restoration is brute force: it (coarsely) restores entire router links at full wavelength capacity by rerouting them over alternate DWDM links.

In summary, initial packet-layer networks were routed over SONET rings and then later some carriers routed them over IOS networks as multitudes of overlapping, overlaid SONET rings became impractical. But, as Internet bandwidth soared through orders-of-magnitude growth over the past two decades, the design of IP/MPLS-layer networks for reconfiguration started to dominate resiliency planning. MPLS fast reroute and capacity-sensitive Layer-2, Layer-3 routing were later installed to further improve this resiliency. Thus, for the reasons cited above, more IP/MPLS-layer links were provisioned directly onto the DWDM layer at the wavelength-rate and with no lower layer restoration provided.

Optical-Layer Restoration Ideas in the Literature

There is a plethora of published ideas to provide optical-layer (or integrated IP-over-optical-layer) resiliency, yet very few are implemented in commercial networks. To give the reader some practical feel for why this is so, we discuss a once popular idea in the Academia, *p-cycles*, pioneered in a paper by *Grover* and *Stamatelakis* [11.47]. Our analysis here is aided by the DARPA CORONET study, which analyzed it in Phase-1. P-cycles attempted to address a limitation of SONET/SDH rings. While they perform rapid restoration, they are closed topologies and cannot share restoration capacity among one another. This impact is significant when one considers a metro-core network with hundreds or even thousands of small ring subnetworks. Thus, the high-level appeal of a p-cycle is clear: to achieve the speed of rings, yet mitigate the restoration capacity penalty.

While we will not describe p-cycles in detail, the p-cycle idea removes the rigid hardware identity of an ADM-based ring (such as a BLSR). The p-cycle idea is to precalculate a set of diverse paths and reserved restoration channels that route over a shared set of fiber links. A p-cycle identifies a set of reserved, restoration channels that are fully cross-connected in one big, closed loop. When a link of the cycle (consisting of many channels, including both in-service/working and restoration) detects an outage, for each (working) connection that routes over that link, the p-cycle node breaks (i.e., disconnects or un-cross-connects) its bidirectional cross-connects at the two end nodes of the link, then breaks the cross-connects of a restoration channel (on the cycle) at the same end nodes, and then cross-connects the channels of the working connection into those of the restoration loop. This implements a *loop-back* around the other direction of the p-cycle. Another feature of the idea is that a more *mesh-like* restoration strategy occurs for connections that route over a *straddling span* that is not on a p-cycle itself. This connection can choose to loop-back in either direction of the p-cycle. In fact, two straddling connections can be restored on the same numbered channels of the p-cycle by routing in opposite directions along the p-cycle.

The inaugural paper on p-cycles launched hundreds of follow-up papers in a extensive reference tree; consequently, many manifestations of this idea emerged in the literature [11.48]. Yet, the p-cycle idea was never implemented in commercial, production equipment. To help understand why, we temporarily regress to again examine the SONET/SDH BLSR. Analogously, even though the BLSR is appealingly simple at a high level, it took years to overcome operational difficulties. Some of these include: accurately detecting transitory failure states, maintaining a consistent topology view among all ADMs, correctly rerouting connections under multiple link outages, and reliably handling and reporting revertive/nonrevertive states.

In a BLSR, each ADM must keep careful track of the surviving topology. For, when two noncoincident links fail the ring becomes disconnected and no restoration should occur. However, if two coincident links fail (e.g., an ADM failure due to a power outage or other serious outage in the Tree in Fig. 11.8), loop-back is still possible for a limited set of connections. Because each ADM operates somewhat independently, no restoration should take place until the alarms have settled, otherwise mis-cross-connection and contention can occur. For example, consider the BLSR of Fig. 11.13b. Label the nodes (ADMs) starting from top left and moving around the ring clockwise, as A, B, C, D. Consider two 1-hop (1 link in length) connections: connection #1 routes over A–B and connection #2 routes over A–D. Since they do not overlap, these two connections can both be assigned to channels with the same number, $j \leq (n/2)$, where n is the total channels of the high-speed link (e.g., $n = 192$ for an OC-192 SONET ring). However, if node A fails, nodes B and D should not start restoration loop-back cross-connection procedures, else the messages will contend for the same restoration channel, $(n/2)+j$. Thus, the other nodes must kill all the connections that originate or terminate at node A, else two separate connections could either be mis-cross-connected or experience a channel-contention deadlock. To avoid this possibility, the SONET and SDH standards built in a messy feature called *squelch tables*.

The reason we described the complexities of a node outage in a BLSR is to illustrate how difficult it is to implement restoration ideas in a commercial network, no matter how seemingly simple, yet maintain the desired high level of resiliency. For, to achieve a five nines state of BLSR availability, one must carefully analyze,

handle, and test such corner cases. Turning back to the p-cycle idea, one problem is that a SONET/SDH BLSR ring does not precross-connect restoration channels. So, the idea of a fully cross-connected restoration loop (ready to be broken into and recross-connected) was never proven to be feasible in an actual SONET/SDH environment. Because of the much more complex mesh network topology of the p-cycle, potential impacts to connections is far riskier and needs significant error handling to establish its resiliency in a real network. Like SONET/SDH rings, a significant operational problem can occur when multiple links fail. To avoid mis-cross-connection and channel contention, the p-cycle idea requires that every possible state of multiple link outage be precalculated, and the desired path and restoration channel usage stored. Furthermore, if a network outage condition occurs that is not represented by one of the precalculated network outage states, bad network conditions or contention could arise. In addition, this requires that a complex optimization problem be run every time a connection is provisioned in the network. See [11.49] and [11.50] for some of the CORONET study optimization results.

To further complicate this situation, we note that links do not necessarily go down in unison. Fibers do not always break cleanly and complex outage states can occur if they go through *staging*, where one link goes down and then another soon follows upon accumulating bit errors. Also, a link might be taken down intentionally for network maintenance. During this maintenance window, if another link outage occurs, the network must transition from the original outage state to a new one (not just jump to a precalculated multiple link outage state). In addition, how to detect when an alarm has *cleared* and how to reset the network afterwards is a very complex problem, even with the BLSR. Thus, when putting all these issues together under a wide set of realistic network conditions and recovery procedures, the CORONET project determined that the p-cycle method is logistically too difficult and risky (or perhaps even infeasible) to implement and it concluded not to pursue p-cycles beyond Phase-1.

To emphasize the difficult problem with precalculating detailed cross-connection responses to potential complex outage states, let us look back at mesh-restoration with the OTN switch. The main (again, alluringly simple) idea is based on storing a fiber-diverse backup path for all working connections. However, if the backup path fails for a set of given connections due to some of the multiple outage states we discussed above, once the link-state messages have settled the nodes revert to a slower dynamic process to calculate and cross-connect new paths on the surviving network for each downed connection. By falling back on a dynamic process for the un-restored connections, the method does not have to rely on precalculated paths that can foul up under complex outages. Even this took almost a decade of lab and in-network evaluation and modification to fully implement and provide confidence that it could reliably handle all network anomalies and corner cases.

11.3.6 Emerging Network Resiliency Architecture and Techniques

Over the many years we have seen the philosophy of network control vacillate between distributed versus centralized control. For example, at the beginning of the Internet (ARPANET), the US government was mostly interested in a network protocol that was rapidly survivable; consequently, distributed control was emphasized. Also, early restoration architectures under centralized control eventually proved too slow, such as [11.34]. Thus, we see the evolution of features of IETF protocols, such as various Interior Gateway Protocols (IGP) and associated protocols. Controls in an IP packet-layer network are mostly high-level *controls*, such as link weights/costs, timers, flooding mechanisms, and distributed topology generation. In contrast, Telecom companies in the past emphasized mostly centralized control via OSSs, and process-oriented procedures, such as circuit provisioning. However, many carriers began to show more interest in distributed mechanisms with philosophies such as *the network is the database* or quasidistributed (i.e., when compared to OSSs) within vendor control structures, such as element management systems, a construct which also arose in ITU-T *telecommunications management network* (*TMN*) concepts [11.51]. However, the tide has recently swung again in favor of centralized network management concepts. In this section, we explore emerging ideas for network resiliency while still mostly concentrating on actual network implementations.

CORONET BoD

The original CORONET Phase 1 requirement was for a restoration mechanism under distributed control, an example of which is shown in Fig. 11.15. However, as previously mentioned, as the project evolved, SDN concepts began to arise and, thus, centralized control had come into vogue again in the Telecom industry. Given the above points and the lack of a strong business case for rapid, distributed wavelength-rate restoration, CORONET Phase-3 changed course and pursued a more commercially fruitful approach to use the emerging SDN capabilities to craft a more attractive business case for bandwidth-on-demand of wavelength-rate services. CORONET Phase-3 demonstrated lab

prototypes with the ability to reroute optical layer connections upon demand using more modern control interfaces, SDN controllers, and associated *network orchestration capability* [11.52]. This also provided a more provable carrier business model for a more dynamically controlled optical layer, which was focused at private networks connecting large datacenters. As we noted previously, much of the connectivity for intermetro-segment private networks is leased, even by the large Internet enterprises. These customers tend to lease dark fiber between their massive core datacenters but then tend to connect their more numerous, peripheral datacenters and customer locations with a mixture of dark fiber and leased lower layer circuits.

The CORONET team found that the most pressing use-case for such a service was datacenter backup at another (distant) datacenter. For, today's large datacenters are so massive that private network overlays with circuits at rates less than the wavelength rate (e.g., less than 100, 400 Gb/s) cannot practically support datacenter backup. The CORONET BoD architecture and experiments enable circuits to be setup as needed at full-wavelength rate for regular backup activities. This created a more focused (in terms of features and capability) and tractable form of wavelength provisioning, rather than the very broad dynamic DWDM layer proposed in CORONET Phase 1. This service is attractive to many of the private-network Enterprise customers compared to more primitive existing procedures for backing up datacenters, such as using portable RAID (redundant array of independent discs) discs that are physically transported to another city. In addition, for some of the major environmental outages described in Fig. 11.8, bandwidth on demand (BoD) was found to be a useful resiliency mechanism to backup datacenters for replication in anticipation of a major environmental event [11.53].

SDN Integration of IP-over-Optical-Layers in Large Carriers

Many carriers are studying how to incorporate SDN ideas into their network management processes. An example can be found in [11.54–56] where an SDN controller is being built for an IP/MPLS network that will eventually work interactively with a more rapid bandwidth-on-demand provisioning process for the DWDM-layer (ROADM) network. The IP/MPLS layer generally follows the *two-phase* resiliency architecture we outlined for intermetro-segment networks in Sect. 11.2.2, wherein MPLS fast reroute (FRR) is used to achieve rapid restoration for their highest priority packet flows following a network outage. Then, after a network settling time, a second phase implements a form of IGP/MPLS reconfiguration where capacity-sensitive traffic engineering is used to reroute the MPLS tunnels to better handle the best-effort traffic and achieve more efficient routing. Network capacity is designed in the network planning process to meet the QoS of each CoS under various outage states. The SDN controller could possibly provide the following added advantages to this process:

- By monitoring the traffic changes more efficiently and providing the opportunity to optimize the routing of the MPLS LSP tunnels, the SDN controller can also be used to better adapt the MPLS tunnels to changing traffic, namely, the *unexpected traffic pattern change* subtree of Fig. 11.8, but also to a lesser degree take advantage of various time-of-day load differences.
- By incorporating the actual optical-layer routing (SRLG) information for each IP/MPLS-layer link, the SDN controller can also compute and download the FRR paths more rapidly and more efficiently than the crude methods current industry router vendors provide to auto-compute them in a distributed manner. For example, vendor methods usually include the ability to set via *command line interface* (*CLI*) or other network management protocol for each packet link a list of *link bundling* IDs. Then the FRR paths are computed in a distributed fashion by the routers to avoid certain paths using the link bundling information. Different vendor products offer other methods to control the FRR paths in a distributed manner, as well.
- As pointed out earlier, most of the extra/spare capacity in carrier IP/Layer router-router links is placed to handle worst-case restoration during a network outage or unexpected traffic pattern change. This amount of extra capacity turns out to be quite high, sometimes as high as 100% more than the peak-hour capacity required to meet QoS when the network is in a nonoutage state. This can be reduced by better capacitating and routing the resulting MPLS tunnels after an outage to more accurately achieve the QoS for each CoS in the second phase after an outage. For example, most of the savings can be achieved by carefully optimizing the best-effort traffic. Without the SDN controller and its associated traffic measurement modules, these tunnels are defined based on average traffic measurements and simplified built-in IETF routing and capacitating algorithms.
- By integrating the IP/MPLS tunnel definition process with ROADM layer provisioning, the SDN controller can utilize the large pool of spare wavelength capacity in the DWDM layer to adapt the underlying capacity of its router-router links. For

example, most intermetro ROAD-to-ROADM links have available 80–100 spare wavelengths upon initial provisioning. These wavelengths/channels are slowly put into service over time, thus enabling on average a large store of spare wavelengths. By reusing the DWDM-layer transponders on an existing lightpath or using preinstalled spare transponders, a rapid lightpath provisioning (or rerouting) process can be implemented using more advanced, or *open* network management interfaces to the ROADMS, such as using a REST interface with an information model based on a Yang protocol.

As an example of the last bullet about integrated IP-over-optical-layer coordination, if a router-router link between routers at CO A and CO D routes through ROADM links A–B, B–C, C–D (where A, B, C, D are COs where ROADMs are installed) and suppose an outage occurs along the fiber path of the B–C link (thus the ROADM B–C link goes down), then by using the same router interfaces and ROADM transponders on the ends of the existing lightpath (A and D), the SDN controller can optically reroute the lightpath on an alternate path of ROADMs between A and D. For example, it can bypass link B–C by reprovisioning the lightpath through alternate ROADM nodes E and F, with path = (A–B, B–E, E–F, F–C, C–D). Assuming no intermediate transponders are required (a nontrivial assumption), then the SDN controller can achieve this simply by disconnecting the A–D existing lightpath at A and D and then reconnecting through the alternate path with basic optical cross-connect commands to each ROADM, which are implemented in the ROADMs by laser tuning at the endpoints, WSS optical cross-connect processes and power balancing (the latter being the more challenging of the tasks).

This of course assumes that spare wavelengths (with the same wavelength/channel number) exist on each link of the alternate route which, as noted above, is quite likely given on average the large number of spare wavelengths per ROADM link. However, it is important to note that from the previous discussion about DARPA CORONET studies, this reprovisioning will not likely occur in subsecond time due to power balancing, laser tuning, and other optical signal quality necessities. However, considering that two-phase IP/MPLS resiliency is applied, for the example outage FRR has already occurred and it is now in the second phase of network reconfiguration. Since the network was planned for fast restoration of the premium CoS traffic, the lower priority traffic *may* be impacted in a worst-case type of outage. In such a case, the QoS expectation for that traffic class assumes it will take longer to restore it to its full throughput. Therefore, a slower reprovisioning process for the affected lightpaths may be tolerable. If so, such an integrated multilayer restoration capability provides the greatest opportunity to save total IP/MPLS-layer capacity.

However, with greater advantage often comes greater complexity. A first step of integrated IP-over-optical-layer network management is to target rapid initial lightpath provisioning for new IP/MPLS-layer links and to avoid OSS cost and complexity. The next step, to enable coordinated interlayer network restoration in a functioning commercial network, is a technically difficult application of SDN and still needs practical development before it reaches maturity in commercial carriers.

Large Enterprise Private Networks

As we noted, there are many large enterprises who own very large datacenters, usually along with a larger number of smaller, *outlying* (or *remote* or *peripheral*) datacenters that home on the larger datacenters. Some of the largest of these enterprises are the Internet-based corporations, for example, those who sell CDN, search capability, video content, web content, enterprise-cloud services, or sell advertising associated with these services. Some of these outlying datacenters can be datacenters owned by (or provided for) their enterprise customers (enterprise customer of the large enterprises). For example, if a large enterprise offers *Internet-as-a-service* (*IaaS*) or *computing-as-a-service* (*CaaS*), or *software-defined wide-area network* (*SD-WAN*) from its portfolio of cloud services, then they may connect to smaller datacenters owned by (or provided for) their cloud customers. The large enterprises tend to deploy large private networks whose major purpose is to transport traffic among their datacenters, called an *inter-datacenter network*. Furthermore, they tend to operate their datacenters themselves, e.g., within a network-supporting business unit.

Given an outlying datacenter in one of the enterprise access networks, there is a slim metro-core component to connect the datacenter to an intermetro network. However, we note that as we discussed in Sect. 11.2.4, to achieve close to the preferred five nines of availability of the private network, the datacenter has to be diversely connected to the intermetro point of presence and in fact is often *dual-homed* into two different points-of-presence (here, a *point-of-presence* is a boundary node between the metro-core- and intermetro-network segments). However, ignoring this metro-core component, most of the interesting aspects of resiliency are in the intermetro segment. Furthermore, almost all such Internet-based corporations lease dark fiber from a large intermetro-segment carrier and install their own lower layer transport equipment, although such equipment is

usually installed, provisioned and maintained by a third party, including sometimes the intermetro carrier itself. However, these corporations also deploy leased, high-bandwidth circuits over a portion of their network, especially to connect the outlying datacenters to their larger, core datacenters. In fact, one can think of the organization within such a large enterprise that runs its interdatacenter network as a type of internally owned carrier. Thus, many of the concepts we discussed earlier will apply to this situation.

Because these large Enterprises usually control and manage both the traffic (typically from their servers), as well as the interdatacenter network, they can customize more forward-looking networking capabilities than a commercial carrier, who must sell connectivity to many different customers. This creates a unique advantage in that such an enterprise can mold and shape its traffic, CoS, and QoS in conjunction with the transport of that traffic. We note, however, that as intriguing as these independent capabilities sound, most of them do not get standardized into the general commercial carrier world.

There is quite a diversity of implementations in the published literature of large enterprise private network implementations. We mention one here to illustrate this point. Google is an example of one such large Internet-based enterprise with truly massive core datacenters scattered around the world (at last count, six in the US alone). Google has adapted some ideas from the *open networking foundation* (*ONF*) [11.57]. In particular, OpenFlow is a centralized method to microcontrol the routing of IP traffic versus the IETF distributed IGP that is implemented in most commercial carriers. Google has furthermore developed its own SDN controller to load-balance its traffic across the large DWDM links that connect its core datacenter gateway switches (routers), as well as to provide alternative routing in case of outages. To illustrate how Google can customize both its traffic and network using traffic engineering ideas for CoS, at a high level it roughly classifies its traffic as *delay-sensitive* and *delay-insensitive*, the latter being an extremely large amount of traffic. The delay-insensitive traffic, such as information gathered from background Internet search-bots, can be queued in case of network congestion, such as would occur from a network outage. This keeps the network utilization very high and cost efficient. In contrast, commercial carriers cannot implement this type of tight CoS to control customer traffic in coordination with generic network control of network routing and performance. Furthermore, the Google SDN controller can execute extremely rapid and time-sensitive load balancing across links. These capabilities enable very rapid restoration with minimal packet loss, perhaps even better than MPLS Fast Reroute, but with more efficient implementation. See the following sources for more detail [11.58–61].

There are major differences among how these large Internet-based Enterprises manage both their large, core datacenters and their interdatacenter private networks. Above is just one example. See [11.62] for another example. Therefore, it is doubtful that any of these customized implementations for large Enterprise networks will carry over in a general way to large commercial carriers.

RENs and ON Labs

In this chapter, we have focused mostly on implementation of resiliency in commercial carriers. In contrast, Research and Education Networks are networks where more experimentation and forward-looking ideas can be trialed and evaluated in a network setting. RENs are typically fully or partially subsidized by various government entities, for example by direct subsidization or study grants. They usually also involve heavy collaboration with (or sponsorship by) academic institutions. However, RENs can serve multiple functions, such as a testbed for experiments in advanced networking, as well as small carriers for working, day-to-day traffic among universities, government agencies, and some private research groups. This latter function provides a more realistic environment to experiment and evaluate with network resiliency ideas than a controlled lab. But, because of their wide research emphasis, covering the myriad of restoration and resiliency ideas across hundreds of world-wide RENs is beyond our scope.

ESnet is an example of a larger REN, a network mostly funded by the US Department of Energy. ESnet has installed an intermetro network with many 100-Gb/s wavelength-rate links that spans from coast-to-coast. Part of the task of this REN is not only to provide a sandbox to try out new networking ideas, but also to provide very high rate connections that allow bandwidth-hungry science experiments to exchange and process voluminous data that could either be technically impossible or unaffordable via a purely commercial carrier. Examples are high-speed collider experiments, neural networks for brains, and assembling and synthesizing distant astronomical views by coalescing data from many different telescopes around the world. Furthermore, RENs from different countries often link via high-speed links (including undersea). For example, ESnet partners (peers) with GEANT (pan-European backbone R&E network), NORDUnet (Nordic countries REN), CANARIE (Canada), and LHCONE (an overlay REN in Europe, North America,

and Southeast Asia). A key point is that ESnet has an SDN testbed that implements OpenFlow [11.63]. OpenFlow is very popular in Academia because it enables detailed control of packet routing. As we have seen, routing is integral to network resiliency. Furthermore, as we illustrated in Sect. 11.3.6, *SDN Integration of IP-over-Optical-Layers in Large Carriers*, the ability to implement integrated control over multiple network layers can be beneficial to network restoration and potentially enable more efficient use of packet-layer and DWDM-layer capacity. In fact, as we pointed out numerous times in this chapter, literally every resiliency technique basically involves some attempt to reroute traffic/connections around bad things.

We finally note that along with centralization becoming more *in vogue* in the academic world and in some private networks, the idea of using open networking software has also been heavily advertised, especially in the area of *open platforms*. In fact, use of open software, software infrastructure, and more flexible computing environments is also being vigorously pursued in large carriers. See [11.64] for an example of open networking in ROADMs. That said, we have seen many networking ideas come and (mostly) go over many decades in the Telecom industry (see more about this in the last section). To what effect these new ideas stand the test of time in commercial networks is for future historical assessment.

11.4 Summary and Future Directions

We help to summarize our chapter via a brief question-and-answer format.

11.4.1 Summary

We first attempted to answer the principal question *how are today's terrestrial carrier-based networks architected?* We then provided a high-level view of the three major network segments, along with the technology layers within each segment. The next major question was: *how is resiliency provided in each layer today?* To answer that question, we went into a detailed analysis of the types of QoS degradations that tend to confound networks and their services, including a class of degradations called *outages*. With those degradations established, we then described the various types of remediation provided at each segment and layer. At that point, someone unfamiliar with the evolution of the carriers, business climate, and telecommunication technology, would likely be mystified by the *end state* of the seemingly odd combination of network technologies, network sectoring, and restoration/resiliency methodologies. Therefore, to help clarify this we asked the next question: *what factors led to the current evolution of network layers, resiliency, and resulting network performance and availability?* Potential answers would be even more befuddling if the reader sought answers from the publication world in these related fields. For, very few of the published ideas (many of which are derived in theoretical/abstract network settings) have been implemented in commercial, carrier networks. To understand why this is so, we examined a few restoration methodologies that have been implemented or attempted to be implemented and provided insight into how difficult it is to successfully implement these ideas in a large, commercial carrier. Furthermore, one cannot explain this evolution via telecommunications technologies, protocols, and restoration ideas alone. In that regard, we delved into the business side of commercial networks, especially the metro-access segment, where business, government, and regulatory considerations and constraints dominate the networking architectures that have evolved.

To further help clarify the above answers, we introduced another important question: *how do the current evolved network architectures, restoration methodologies, and network management practices impact network performance and availability on an* end-to-end *service basis*. We answered this by carefully examining how overall network availability is impacted by the network layers, segments and services (e.g., business versus residential) and how *the weak link* is so critical to understanding the business side of this long evolution.

11.4.2 Key Enablers for Future Work

The Telecommunications industry and academia has many efforts underway for improving network reliability and resiliency in optical and related networks. In fact, we could devote an entire section/chapter to discuss all these different directions. In the spirit of this chapter, we will instead funnel this down to a few key, practical directions, which are dominated by work in advanced network control and management. However, we caution that the network management field has in the past hailed how it was going to achieve improved network performance and cost via advanced network management capabilities, only to become awash with modeling complexity, layers of protocols, and bureaucracy. For example, ITU-T TMN (Sect. 11.3.6) CMISE/CMIP

is an excellent example of such a failure of expectation [11.65]. To illustrate this over-expectation, we quote from [11.66]:

> Many benefits are expected from standards-based integrated network management. By making all internal network management functions available through standardized interfaces, service providers will achieve more rapid deployment of new services and maximum use of automated functions. Powerful new service management capabilities will be offered to customers by the interconnection of service provider and user management infrastructures. Vendors of network elements will offer specialized systems known as *element managers* which will integrate readily into a service provider's larger management hierarchy. Groups of service providers will enter into 'business level agreements' and deploy resource sharing arrangements which will be administered automatically through interoperable interfaces.

In all fairness, element management systems did emerge over this period, but failed to achieve the standardization or advantages claimed by CMISE/CMIP modeling. In fact, some claim that the advent of element management systems stalled the evolution of advanced network management modeling that is needed today. There are other examples, such as CORBA (common object request broker architecture) and distributed network management, that also did not achieve the stated goals or where the industry changed directions. Furthermore, element management systems and standardized network/object modeling for packet-layer switches did not manifest over this period. For example, many systems still use SNMP (simple network management protocol) MIBs (management information bases) for alarm reporting with limited configuration management capabilities, which are far from achieving the objectives of the above quote. Still today most hard configurations (*configs*) for packet-layer switches are set via vendor-proprietary CLI (Sect. 11.3.6).

With this dubious network management background in mind and to make future directions more meaningful, we will concentrate on the historically persistent problem areas in network management that must be improved before the plethora of future efforts can make substantive progress in commercial carrier networks.

11.4.3 Streaming Analytics, Cognitive Systems, Machine Learning

One of the major areas of pursuit is faster and more organized reporting of network metrics, followed by faster and more powerful network state analysis, and then followed by more rapid and automatic network remediation. In this regard, when referring to new protocols, network updates and network management techniques, *Najam Ahmad*, VP of Network Engineering at Facebook said that it used to take them a year to test and then deploy new network capabilities for their datacenter networks and interdatacenter networks [11.67]. The business logic was that this was needed to prevent something from going wrong because it is so hard to detect, analyze, and then remedy network outages and dysfunctionalities. Furthermore, even when one does so much extensive pretesting and evaluation against potential outages and problems, is it possible to predict all the possible problems in a fully operational network? Clearly, this previous approach imposed a large cost to do such long evaluations, plus it delayed important network reliability and/or new features. However, Ahmad claimed recently that now they move to deploy much more rapidly because Facebook is moving more towards rapid outage detection and root cause analysis. And by *rapid*, he emphasized the ability of the network management software to automatically detect and react to such outages and then make automatic network corrections and restoration. This is in contrast to past practice where personnel in the NOC manually collect data, perform root cause analysis and then override the network settings to remediate a service-disrupting event. This new approach gives the NOC and developers time to instead concentrate on making needed network, software, and product updates.

Of course, this strategy sounds great in theory, but it is not so easy to accomplish. One of the perennial impediments has been the classical alarm reporting and NOC methodologies of filtering through voluminous and mysterious syslogs and alarm reporting to filter down to critical information, let alone figuring out how to remedy it. As one can see from the details of this chapter, given the layering complexity of networks, figuring out the source of a problem from narrowly focused equipment logs makes this task difficult, if not impossible. Older alarm-reporting protocols such as switch SNMP traps, ITU OTN termination point models (or even SONET/SDH-based) alarm reporting have proven inadequate to accomplish the above goal. We instead need a more sophisticated network modeling capability and advanced alarm reporting protocol. Work on *streaming analytics and cognitive systems* [11.68] has the goal of modernizing the reporting of network state in complex networks. For example, some in this field are pursuing network models and protocols such as OpenConfig to better represent the different network states in modern network equipment, along with more straightforward and flexible object-oriented data structures and interfaces that can better represent the relationships of network objects. Furthermore, this ap-

proach supports better focused network metrics to accomplish rapid root cause analysis.

To enhance this approach, machine learning and AI combine with improved data structures for network metrics reporting to more rapidly pin down network/service disruptions and then automatically recommend remediation. Stated more simply, the intent of this new approach is to put more investment and *muscle* into analysis and remediation and less into costly preventative measures and overbuilding of the network. We have already described in the previous section how advanced network management and control systems, based on approaches such as SDN, can be used to aid in some of the remedial phase after the enabling of advanced analytics. A more recent reference on how to possibly use machine learning to better perform root cause analysis can be found in [11.69].

11.4.4 Network Discovery

One of the key failures of the earlier approaches was abstract (generic, nonspecific) network modeling, protocols, and data models; but, they missed the inside knowledge of the real complex interactive structures of networks, restoration methods, outage characteristics, and traffic, such as we presented earlier. As one can discern after reading this chapter, it is difficult to accomplish automatic root cause analysis and automatic remediation in such networks without having a good, detailed model of their layered structure. For, even the most sophisticated AI or machine-learning algorithms will find it impossible to discern the needed detail and inter-relationships about these network constructions, unless these specific relationships are correctly and properly modeled. The missing ingredient today is automatic discovery of these complex, layered network relationships and restoration mechanisms, as illustrated in Fig. 11.3. A principal impediment in large commercial carriers has been that the lower layer relationships must be discerned from operations support systems and network capacity provisioning data. A further complicating factor is that much of this data is replete with errors and omissions. For example, the pointers between higher layer links and lower layer connections are often incomplete or missing. See [11.11] for a discussion of some of these issues. We note that although this reference is a bit dated compared to the present chapter, unfortunately much of this situation persists in large carriers (perhaps less in the private networks of some large Internet service enterprises). We conclude that having spent a large part of our career developing network discovery algorithms, the field of network discovery (including discovery of interlayer relationships) needs to significantly evolve before the future directions described above can evolve fully.

11.4.5 Predictive Network Availability and Performance

Finally, we briefly mention the historical problem area of predictive network availability and performance. As we have stated, assessing the availability and performance of a network under the onslaught of potential QoS degradations is more art than science. In almost all practical cases, networks are fine-tuned to meet network performance objectives via experience, i.e., reactive network planning and management. The largest impediments to doing this more predictively are the areas of automatic network discovery and better alarm reporting and isolation, as described above, plus the ability to better model the effects of network restoration. As previously discussed in Sect. 11.2.1, an example of how to put all these complex pieces together to perform predictive network availability is found in [11.20]. We add that this methodology (applied to a totally different study network than presented in [11.20]) was used to accurately predict network availability for extending the national backbone IPTV network of a commercial carrier to a new area of the United States. The results were used to fine-tune the network topology (both IP and optical layers) and their restoration methods to achieve the predicted network availability. To reenforce our previous points about the need to advance the fields of network discovery and streaming analytics, the network topology data for this study was gathered manually from provisioning information and historical statistics. For example, mean time to repair (MTTR) and mean time between failures (MTBF) were gathered from carrier outage equipment historical data and vendor FIT rates (Sect. 11.2.1). That is, since automatic network discovery and streaming analytics were not available and given our comments about the difficulty of acquiring lower network-layer data and correlations, this aspect of the study required intense modeling work. However, given that such advanced capabilities might eventually exist, the reader will find future predictive approaches in [11.69].

Finally, harkening back to our initial comments from the chapter introduction, the results of the above study remain unpublished. To help the reader understand why carriers keep these sorts of studies proprietary, consider if they were published: some people (not necessarily friendly to the carrier) might claim the study results are a guarantee of QoS for the given service. Given the potential differences that we described between theoretical QoS predictions versus actual experience, this might lead to law suits, negative publicity, and even frivolous claims of IPR (intellectual property rights) infringement, which are quite prevalent in any large carrier.

r.d.doverspikeconsulting@gmail.com

Robert Doverspike has a PhD from Rensselaer Polytechnic Institute. He has worked at Bell Labs, Bellcore-Telcordia, been Executive Director AT&T Network Evolution Research, and founded Network Evolution Strategies (consulting with Google). He is an INFORMS Fellow, an IEEE Fellow, and the OFC Program/General Chair. He has 35 patents, is a world-renowned expert on network restoration and optimization, and has helped design some of the world's largest networks.

12. Routing and Wavelength (Spectrum) Assignment

Jane M. Simmons, George N. Rouskas

Routing a connection from its source to its destination is a fundamental component of network design. The choice of route affects numerous properties of a connection, most notably cost, latency, and availability, as well as the resulting level of congestion in the network. This chapter addresses various algorithms, strategies, and tradeoffs related to routing.

At the physical optical layer, connections are assigned a unique wavelength on a particular optical fiber, a process known as wavelength assignment (WA). Together with routing, the combination of these two processes is commonly referred to as RWA. In networks based on all-optical technology, WA can be challenging. It becomes more so when the physical properties of the optical signal need to be considered. This chapter covers several WA algorithms and strategies that have produced efficient designs in practical networks.

A recent development in the evolution of optical networks is flexible networking, where the amount of spectrum allocated to a connection can be variable. Spectrum assignment is analogous to, though more complex than, wavelength assignment; various heuristics have been proposed as covered in this chapter. Flexible (or elastic) networks are prone to more contention issues as compared to traditional optical networks. To maintain a high degree of capacity efficiency, it is likely that spectral defragmentation will be needed in these networks; several design choices are discussed.

B. Mukherjee et al. (Eds.), *Springer Handbook of Optical Networks*, Springer Handbooks, https://doi.org/10.1007/978-3-030-16250-4_12

Routing a connection (or circuit) from its source to its destination is a fundamental component of network design. The choice of route affects numerous properties of a connection, most notably cost, latency, and availability. Furthermore, from a more macro perspective, routing determines the resulting level of congestion in a network, which may impact the amount of traffic that ultimately can be carried. This chapter addresses various algorithms, strategies, and tradeoffs related to routing. While much of the discourse applies to networks in general, the emphasis is on routing in the physical optical layer. Relevant network terminology and some of the fundamentals of optical systems are introduced in Sect. 12.1.

Network routing is a well-researched topic. Several commonly used routing algorithms have been developed to find an optimal path through the network with respect to a particular property. These algorithms are reviewed in Sect. 12.2. For a connection of relatively low criticality, it is sufficient to calculate a single path from source to destination. However, a failure that occurs along that path will bring the connection down. To guard against such failures, more critical connections are established with some level of protection. Some commonly used protection schemes rely on calculating two or more diverse paths between the source and destination. Optimal disjoint-path routing algorithms exist for this purpose as well, as covered in Sect. 12.3.

As noted above, the routing strategy that is utilized affects the congestion level in the network. Poor routing may lead to unbalanced load in the network, with some sections heavily utilized whereas others are lightly loaded. Such imbalances result in premature blocking in the network where it may not be possible to accommodate a new connection request due to insufficient capacity in portions of the network. Various routing strategies and their effect on network load are discussed in Sect. 12.4.

If multiple connections are being routed at once, then the order in which they are processed may also affect the blocking level. For example, it may be desirable to give precedence to geographically longer connections or connections that must traverse congested areas of the network, as it is likely more challenging to find a suitable path for these connections. Selecting the routing order is, in general, an arbitrary procedure; with rapid design runtimes, several orderings can be tested and the best result selected. Routing order is covered in Sect. 12.5.

Historically, connections in telecommunications networks have been unicast, with a single source and a single destination. However, with services such as video distribution growing in importance, connections directed from one source to multiple destinations are desirable. Establishing a multicast tree from the source to the set of destinations is more capacity efficient than utilizing multiple unicast connections. Furthermore, the optical layer is well suited for delivering multicast services. Section 12.6 discusses routing algorithms that find the optimal, or near-optimal, multicast tree.

The end-to-end path is the high-level view of how a connection is carried in the network. When examined more closely at the physical optical layer, it is necessary to assign a portion of the electromagnetic spectrum to carry the connection at each point along its path. Optical networks typically employ wavelength-division multiplexing (WDM) technology, where connections are assigned a unique wavelength on a particular optical fiber and the various wavelengths are multiplexed together into a single WDM signal on that fiber. Selecting the wavelengths to assign to each connection is the process known as *wavelength assignment*; this topic is introduced in Sect. 12.7. The combination of the routing and wavelength assignment processes is commonly referred to as RWA.

The underlying optical system technology determines the level of difficulty involved with wavelength assignment. With one class of technology, known as optical-electrical-optical (O-E-O), where connections repeatedly go from the optical domain to the electrical domain and back, the wavelengths assigned to connections on one link have no impact on the wavelengths that can be assigned on any other link. With such technology, wavelength assignment is a simple process. O-E-O technology, however, does have numerous drawbacks, as is outlined in Sect. 12.1.

In contrast, optical-optical-optical (O-O-O), or *all-optical*, technology potentially enables connections to remain in the optical domain from source to destination. While there are many advantages to this technology, it does lead to challenges in the wavelength assignment process. In practice, most networks fall somewhere in between pure O-E-O and O-O-O, where connections enter the electrical domain at intermediate points of the path, but do so infrequently. It is common practice to refer to these networks as all-optical, despite this term being a misnomer; this chapter makes use of this naming convention as well. The respective properties of O-E-O and all-optical networks drive the routing and wavelength assignment processes and are discussed further in Sect. 12.1.

Poor wavelength assignment in all-optical networks can lead to blocking, where the capacity exists to carry a new connection but no wavelength is free to assign to that connection. This is known as *wavelength contention*. Various wavelength assignment heuristics that are simple to implement yet effective in minimizing

wavelength contention have been developed, as outlined in Sect. 12.8.

Another important design decision is whether routing and wavelength assignment should be treated as separate processes or whether they should be combined into a single operation. This dichotomy is discussed in Sect. 12.9.

In an all-optical network, there are numerous practical challenges of wavelength assignment that are tied to the physical optical system. Some of the more important effects are introduced in Sect. 12.10.

A recent development in the evolution of optical networks is *flexible networking*, introduced in Sect. 12.11. In traditional optical networks, there is a fixed number of wavelengths that can be carried on each optical fiber, and each such wavelength occupies a fixed amount of spectrum. In contrast, with flexible (or elastic) networks, the amount of spectrum allocated to a connection can be variable, potentially leading to a more efficient use of the fiber capacity. Selecting the portion of the spectrum to assign to a given connection is known as *spectrum assignment*. As elucidated in Sect. 12.12, spectrum assignment is analogous to, though more complex than, wavelength assignment. Various heuristics have been proposed to specifically address the nuances of spectrum assignment.

Flexible networks tend to lead to more contention issues as compared to traditional optical networks. This is especially true if the network is dynamic, such that connections are frequently established and then torn down. Dynamism is expected to result in fragmented spectrum utilization where many small blocks of unutilized spectrum exist as opposed to large contiguous blocks of free spectrum. To maintain a high degree of capacity efficiency, it is likely that *spectral defragmentation* would need to be performed on a periodic basis, where connections are shifted to different regions of the spectrum (and possibly rerouted) to create larger chunks of available spectrum. Defragmentation techniques are discussed in Sect. 12.12.

Network design can be performed on different time scales. In *long-term* network planning, there is sufficient time between the planning and provisioning processes such that any additional equipment required by the plan can be deployed. The planning emphasis is on determining the optimal strategy for accommodating a set of demands; the runtime of the design algorithms is not critical. In *real-time* operation, there is little time between planning and provisioning. It is assumed that the traffic must be accommodated using whatever equipment is already deployed in the network, even if that sacrifices optimality. Any design calculations must be performed quickly (milliseconds to minutes time scale, depending on the requirements of the network). The long-term and real-time dichotomy is also referred to in the literature as *offline* and *online* design, respectively. Methodologies for both time scales are discussed in this chapter.

A number of algorithms are introduced in this chapter. Implementation of many of these algorithms, using the C programming language, can be found in [12.1].

12.1 Terminology

Network terminology that is relevant to the topics of this chapter is defined here. Additionally, a high-level comparison of O-E-O and all-optical networks is provided, with an emphasis on the aspects that affect routing and wavelength assignment.

Network nodes are the sites in the network that source, terminate, and/or switch traffic. Sites that serve only to amplify the optical signal are not considered nodes. Network nodes are depicted as circles in the figures contained here. *Network links* are the physical optical fibers that run between the nodes, with the fibers typically deployed in pairs. Links are almost always bidirectional, with one fiber of the pair carrying traffic in one direction and the other fiber carrying traffic in the opposite direction. Network links are depicted in figures as a single line. In discussions on routing, links are often referred to as *hops*.

The interconnection pattern among the nodes represents the *network topology*. The *nodal degree* is the number of fiber-pairs incident on a node. The nodal degree may also be defined as the number of links incident on a node. A link may be populated with multiple fiber-pairs, such that the two definitions are not always equivalent.

In a network that employs O-E-O technology (i.e., an O-E-O network), the connection signal is carried in the optical domain on the links but is converted to the electrical domain at each node that is traversed by the connection. An end-to-end path looks as depicted in Fig. 12.1a. The process of O-E-O conversion at each node cleans up the signal; more precisely, the signal is re-amplified, re-shaped, and re-timed. This is known as *3R regeneration*. (Note that passing a signal through a line optical-amplifier is considered *1R regen-*

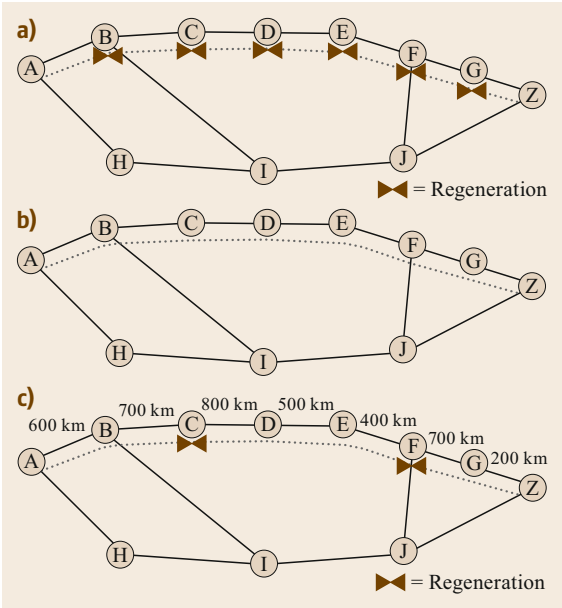

Fig. 12.1a–c The connection path from node A to node Z is shown by the *dotted line*. **(a)** In an O-E-O network, regeneration occurs at each node along the path of the connection. **(b)** In a true all-optical network, there is no regeneration along the path. The connection remains in the optical domain from end to end. **(c)** With an optical reach of 2000 km and the link distances as shown, two regenerations are required for the connection. (© Monarch Network Architects LLC)

eration, as it only re-amplifies the signal.) Regeneration equipment is needed for each individual signal that traverses a node; i.e., the WDM signal is demultiplexed into its constituent wavelengths and each one of the wavelengths that is routed through the node is passed through a regenerator. (Terminal equipment, as opposed to a regenerator, is used for a wavelength that is destined for the node as opposed to being routed *through* the node; a regenerator often comprises back-to-back terminal equipment, as discussed further in Sect. 12.7.1.) Thus, a network node may be equipped with hundreds of regenerators. (Limited *multiwavelength regeneration* has been demonstrated but is still in the early stages of research.)

The large amount of equipment required for regeneration poses drawbacks in terms of cost, power consumption, reliability, and space requirements. In O-E-O networks, regeneration is the major contributor to these factors in the optical layer. Minimizing the number of nodes that a signal must traverse is desirable, as it minimizes the number of regenerations.

Conversely, a true all-optical signal that remains in the optical domain is illustrated in Fig. 12.1b. No regenerations are present along the end-to-end path. The network nodes are equipped with elements such as *reconfigurable optical add/drop multiplexers* (ROADMs) that allow the signal to remain in the optical domain. This is known as *optical bypass* of the node.

An important property of all-optical networks is the *optical reach*, which is the distance that an optical signal can travel before it needs to be regenerated. (In practice, there are numerous factors other than distance that affect where regeneration is required [12.1]. For simplicity, we only consider distance here.) Most optical-bypass-enabled systems have an optical reach on the order of 1500–3000 km. If the length of the end-to-end path is longer than the optical reach, then the signal needs to be regenerated, possibly more than once, as illustrated in Fig. 12.1c. This is more often the case in core networks (also known as backbone networks, long-haul networks, or cross-country networks), where some of the end-to-end paths may be a few thousand kilometers in extent.

Regeneration is almost always performed in a network node as opposed to at an intermediate point along a link. Thus, regeneration typically occurs prior to the signal traveling exactly a distance equal to the optical reach. This may lead to more regeneration being required than predicted by the connection distance. For example, in Fig. 12.1c, the total end-to-end path distance is 3900 km, but with an optical reach of 2000 km, two regenerations are required, not one. Furthermore, a study performed on several realistic backbone networks indicated that the shortest path was not the path with the fewest number of required regenerations for roughly 1% of the source/destination pairs in those networks [12.1].

Taking advantage of extended optical reach and ROADMs to remove all, or at least most, of the required regeneration provides significant advantages in terms of cost, power consumption, reliability, and space. The drawback is that if a signal traverses a node in the optical domain, then it must be carried on the same wavelength into and out of the node. This is known as the *wavelength continuity constraint*. (Wavelength conversion in the optical domain is possible; however, it is costly and complex and has not been widely commercialized.) Thus, the presence of optical bypass creates an interdependence among the links of a network, where the wavelength assigned to a connection on one link affects the wavelengths that can be assigned to connections on other links. This leads to wavelength assignment being a critical aspect of network design in all-optical networks. Note that such an interdependence does not exist in O-E-O networks where regeneration at every node along a path allows the wavelengths to be assigned independently on each link.

12.2 Shortest-Path Routing Algorithms

We first consider algorithms that find a single path that is the shortest between a given source and destination [12.2]. If multiple paths are tied for the shortest, then one of the paths is found. Depending on the algorithm used, ties may be broken differently.

The class of shortest-path algorithms discussed here assumes that each link is assigned a cost metric and that the metric is additive. With an additive metric, the metric for a path equals the sum of the metrics of each link composing that path. Furthermore, there can be no cycles in the network where the sum of the link metrics around the cycle is negative. With these assumptions, a shortest-path algorithm finds the path from source to destination that minimizes the total cost metric.

These algorithms can be applied whether or not the links in the network are bidirectional. A link is bidirectional if traffic can be routed in either direction over the link. Different metrics can be assigned to the two directions of a bidirectional link. However, if the network is bidirectionally symmetric, such that the traffic flow is always two-way and such that the cost metric is the same for the two directions of a link, then a shortest path from source to destination also represents, in reverse, a shortest path from destination to source. In this scenario, which is typical of telecommunications networks, it does not matter which endpoint is designated as the source and which is designated as the destination.

There are numerous metrics that are useful for network routing. If the link metric is the geographic distance of the link, then the shortest-path algorithm does, indeed, find the path with the shortest distance. If all links are assigned a metric of unity (or any constant positive number), then the shortest-path algorithm finds the path with the fewest hops. Using the negative of the logarithm of the link availability as the metric produces the most reliable path, assuming that the failure rate of a path is dominated by independent link failures. (Note that the logarithm function can be used in general to convert a multiplicative metric to an additive metric.) Other useful metrics for routing in an all-optical network are the link noise figure and the link optical signal-to-noise ratio (OSNR) [12.1].

In spite of the link metric not necessarily being associated with distance, these algorithms are commonly still referred to as shortest-path algorithms.

12.2.1 Dijkstra Algorithm

The best known shortest-path algorithm is the Dijkstra algorithm [12.2]. The algorithm works by tracking the shortest path discovered thus far to a particular node, starting with a path length of zero for the source node. It considers the resulting length if the path is extended to a neighboring node. If the path to the neighboring node is shorter than any previously discovered paths to that node, then the path to that neighbor is updated. Dijkstra is classified as a greedy algorithm because it makes the optimal decision at each step without looking ahead to the final outcome. Unlike many greedy algorithms, it is guaranteed to find the optimal solution; i.e., the shortest path from source to destination.

12.2.2 Breadth-First-Search Algorithm

An alternative shortest-path algorithm is breadth-first search (BFS) [12.3]. It works by discovering nodes that are one hop away from the source, then the nodes that are two hops away from the source, then the nodes that are three hops away from the source, etc., until the destination is reached.

As with Dijkstra, BFS produces the shortest path from source to destination. Additionally, if there are multiple paths that are tied for the shortest, BFS breaks the tie by finding the one that has the fewest number of hops. This can be useful in all-optical networks where the likelihood of wavelength contention increases with the number of hops in a path. Note that Dijkstra does not have a similar tie-breaking property; its tie-breaking is somewhat more arbitrary (e.g., it may depend on the order in which the link information is stored in the database).

12.2.3 Constrained Shortest-Path Routing

A variation of the shortest-path problem arises when one or more constraints are placed on the desired path; this is known as the *constrained shortest path* (CSP) problem. Some constraints are straightforward to handle. For example, if one is searching for the shortest path subject to all links of the path having at least N wavelengths free, then prior to running a shortest-path algorithm, all links with fewer than N free wavelengths are removed from the topology. As another example, the intermediate steps of the BFS shortest-path algorithm can be readily used to determine the shortest path subject to the number of path hops being less than H, for any $H > 0$ (similar to [12.4]). However, more generally, the CSP problem can be difficult to solve; for example, determining the shortest path subject to the availability of the path being greater than some threshold, where the availability is based on factors other than distance. Various heuristics have been proposed to address the CSP problem [12.5]. Some heuristics have been developed

to specifically address the scenario where there is just a single constraint; this is known as the *restricted shortest path* (RSP) problem. Additionally, a simpler version of the multiconstraint problem arises when *any* path satisfying all of the constraints is desired, not necessarily the shortest path; this is known as the *multiconstrained path* (MCP) problem. An overview, including a performance comparison, of various heuristics that address the RSP and MCP problems can be found in [12.6].

12.2.4 *K*-Shortest-Paths Routing Algorithms

Routing all connection requests between a particular source and destination over the shortest path can lead to network congestion, as is discussed more fully in Sect. 12.4. It is generally advantageous to have a set of paths to choose from for each source/destination pair. A class of routing algorithms that is useful for finding a set of K possible paths between a given source and destination is the *K-shortest-paths algorithm*. Such an algorithm finds the shortest path, the second shortest path, the third shortest path, etc., up until the K-th shortest path or until no more paths exist. A commonly used K-shortest-paths algorithm is Yen's algorithm [12.7]. As with shortest-path algorithms, the link metrics must be additive along the path.

It is important to note that the K paths that are found are not necessarily completely diverse with respect to the links that are traversed; i.e., some links may appear in more than one of the K paths. K-shortest-paths routing is typically used for purposes of load balancing, not for protection against failures. Explicitly routing for failure protection is covered in Sect. 12.3.

12.2.5 Shortest-Distance Versus Minimum-Hop Routing

As stated earlier, a variety of link metrics can be used in a shortest-path algorithm. Two of the most common metrics in a telecommunications network are link distance and unity (i.e., *1*), producing the path of shortest geographic distance and the path of fewest hops, respectively. The most effective metric to use depends on the underlying network technology.

With O-E-O networks, the cost of a connection in the optical layer is dominated by the number of required regenerations. Regeneration occurs at every node that is traversed by the connection. Thus, utilizing *1* as the metric for all links in order to find the path with the least number of hops (and hence the fewest traversed nodes) is advantageous from a cost perspective. This is illustrated in Fig. 12.2 for a connection between nodes A and Z. Path 1 is the shortest-distance path at

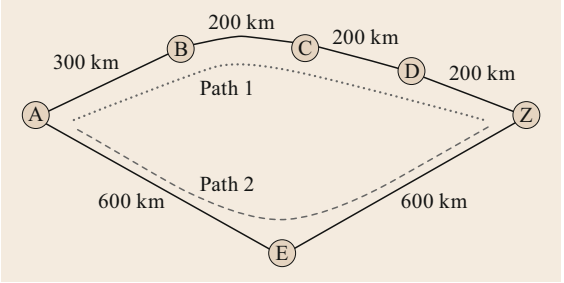

Fig. 12.2 Path 1, A–B–C–D–Z, is the shortest-distance path between nodes A and Z, but Path 2, A–E–Z, is the fewest-hops path. In an O-E-O network, where the signal is regenerated at every intermediate node, Path 2 is typically the lower-cost path (© Monarch Network Architects LLC)

900 km but includes four hops. Path 2, though it has a distance of 1200 km, is typically lower cost in an O-E-O network because it has only two hops and, thus, requires fewer regenerations.

Selecting a metric to use with all-optical networks is not as straightforward. Assuming that the number of regenerations required for a connection is dominated by the path distance, then searching for the shortest-distance path will typically minimize the number of regenerations. However, wavelength assignment for a connection becomes more challenging as the number of path hops increases. For all-optical networks, one effective strategy is to generate candidate paths by invoking a K-shortest-paths algorithm twice, once with distance as the link metric and once with *1* as the link metric. Assuming that link load is not a concern, the most critical factor in selecting one of the candidate

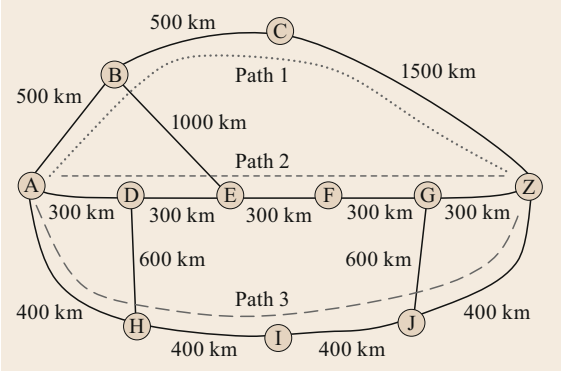

Fig. 12.3 Assume that this is an all-optical network with an optical reach of 2000 km. Path 1, A–B–C–Z, has the fewest hops but requires one regeneration. Path 2, A–D–E–F–G–Z, and Path 3, A–H–I–J–Z, require no regeneration. Of these two lowest-cost paths, Path 3 is preferred because it has fewer hops (© Monarch Network Architects LLC)

paths is typically cost. Thus, the candidate path that requires the fewest number of regenerations is selected. If there are multiple paths tied for the fewest regenerations, then the one with the fewest number of hops is selected.

This strategy is illustrated in Fig. 12.3. Three of the possible paths between nodes A and Z are: Path 1: A–B–C–Z of distance 2500 km and three hops; Path 2: A–D–E–F–G–Z of distance 1500 km and five hops; and Path 3: A–H–I–J–Z of distance 1600 km and four hops. Assume that the optical reach is 2000 km, such that there can be no all-optical segment that is longer than this distance. With this assumption, Path 1 requires one regeneration, whereas Paths 2 and 3 do not require any regeneration. Of the latter two paths, Path 3 has fewer hops and is, thus, more desirable despite it being longer than Path 2 (again, assuming that link load is not a factor).

12.3 Disjoint-Path Routing for Protection

Network customers desire a certain level of *availability* for each of their connections. Availability is defined as the probability of being in a working state at a given instant of time. The desired availability is typically specified contractually in the *service level agreement* (SLA) with the network provider. A common cause of connection failure is the failure of one or more links in the end-to-end path. Link failures are typically caused by fiber cuts or optical amplifier failures. Being able to route around the failed link allows the connection to be restored to the working state.

In some protection schemes, it is necessary to first identify which link has failed; the detour route around that failed link is then utilized. Determining the location of a failure can be time consuming. To expedite the restoration process and improve availability, network providers often utilize protection schemes where the same backup path is utilized regardless of where the failure has occurred in the original (i.e., primary) path. This allows the protection process to commence prior to the completion of the fault location process. In order to implement such a failure-independent protection scheme, also known as *path protection*, it is necessary that the backup path be completely link-disjoint from the primary path. If a very high level of availability is desired for a connection, then it may be necessary to protect against node failures in addition to link failures. In this scenario, the backup path must be completely link and node disjoint from the primary path. However, it should be noted that node failures occur much less frequently than link failures, such that node disjointness is often not required.

Shortest-path algorithms find the single shortest path from source to destination. With path protection, it is desirable to find two disjoint paths where the overall sum of the link metrics on the two paths is minimized. One of the paths is used as the primary path (typically the shorter one) with the other serving as the backup path.

It may seem reasonable to find the desired two paths by invoking a shortest-path algorithm twice. After the first invocation, the links (and intermediate nodes if node disjointness is also required) composing the first path are removed from the network topology that is

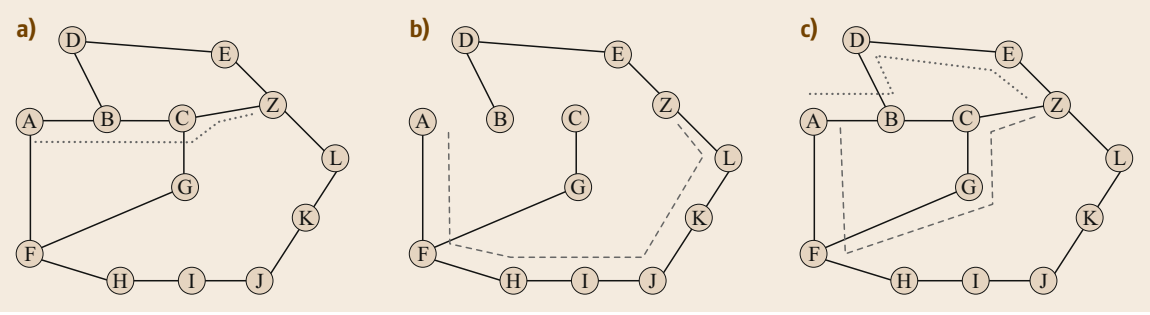

Fig. 12.4a–c The pair of disjoint paths with the fewest number of total hops is desired between nodes A and Z. **(a)** The first call to the shortest-path algorithm returns the path shown by the *dotted line*. **(b)** The network topology after pruning the links composing the shortest path. The second call to the shortest-path algorithm finds the path indicated by the *dashed line*. The total number of hops in the two paths is ten. **(c)** The shortest pair of disjoint paths between nodes A and Z is shown by the *dotted* and *dashed lines*; the total number of hops in these two paths is only eight (© Monarch Network Architects LLC)

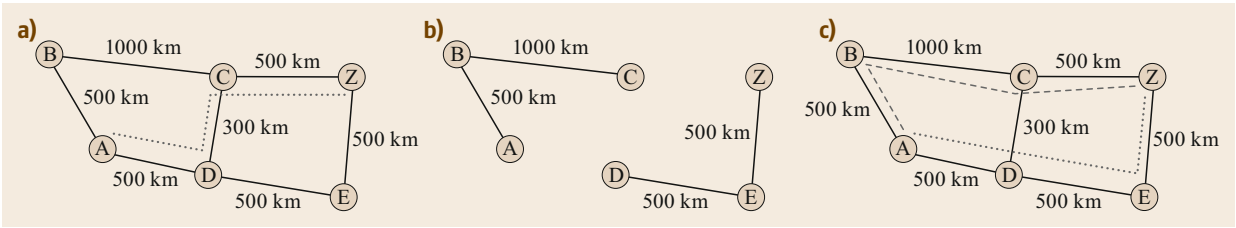

Fig. 12.5a–c The shortest pair of disjoint paths is desired between nodes A and Z. **(a)** The first call to the shortest-path algorithm returns the path shown by the *dotted line*. **(b)** The network topology after pruning the links composing the shortest path. The second call to the shortest-path algorithm fails, as no path exists between nodes A and Z in this pruned topology. **(c)** The shortest pair of disjoint paths between nodes A and Z, shown by the *dotted* and *dashed lines* (© Monarch Network Architects LLC)

used in the second call of the algorithm. Clearly, if a path is found by the second invocation, then that path is guaranteed to be disjoint from the first path that was found.

Although this strategy may appear to be reasonable, there are potential pitfalls. First, it inherently assumes that the shortest disjoint pair of paths includes the shortest path. As shown in Fig. 12.4, this is not always the case. In this example, the source is node A and the destination is node Z. Assume that this is an O-E-O network, with all links assigned a metric of *1*. The shortest path (i.e., the fewest-hops path) is A–B–C–Z, as shown in Fig. 12.4a. If the links of this path are removed and the shortest-path algorithm is invoked again, then the resulting path is A–F–H–I–J–K–L–Z; see Fig. 12.4b. The sum of the metrics of these two paths is 10. However, the shortest disjoint pair of paths is actually A–B–D–E–Z and A–F–G–C–Z, as illustrated in Fig. 12.4c; this pair of paths has a total metric of 8. Note that the shortest path, A–B–C–Z, is not part of the optimal solution.

Not only may the two-invocation method produce a suboptimal result, it may fail completely. This is illustrated in Fig. 12.5. Assume that this is an all-optical network, and the metric is the physical distance as shown next to each link. In this figure, the shortest path from A to Z is A–D–C–Z, as shown in Fig. 12.5a. If the links of this path are removed from the topology, as shown in Fig. 12.5b, then no other paths exist between nodes A and Z. Thus, the process fails to find a disjoint pair of paths despite the existence of such a pair, as shown in Fig. 12.5c: A–B–C–Z and A–D–E–Z. This type of scenario, where the two-invocation methodology fails despite the existence of disjoint paths, is called a *trap topology*.

Rather than using the two-invocation method, it is recommended that an algorithm specifically designed to find disjoint paths be used. The two most commonly used shortest-disjoint-paths algorithms are the Suurballe algorithm [12.8, 9] and the Bhandari algorithm [12.3]. Both algorithms make use of a shortest-path algorithm; however, extensive graph transformations are performed as well to ensure that the shortest pair of disjoint paths is found, assuming such a pair exists. Both algorithms require that the link metric be additive and both algorithms are guaranteed to produce the optimal result. They can be utilized to find the shortest pair of link-disjoint paths or the shortest pair of link-and-node-disjoint paths. The runtimes of the Suurballe and Bhandari algorithms are about the same; however, the latter may be more easily adapted to various network routing applications. We focus on its use here.

The Bhandari algorithm is readily extensible. For example, a mission-critical connection may require a high level of availability such that three disjoint paths are needed, one primary with two backups. If a failure occurs on the primary path, the first backup path is used. If a failure occurs on the backup path prior to the primary path being repaired, then the connection is moved to the second backup path. The Bhandari algorithm can be used to find the shortest set of three disjoint paths, if they exist. More generally, the Bhandari algorithm can be used to find the shortest set of N disjoint paths, for any N, assuming N such paths exist. (In most optical networks, however, there are rarely more than just a small number of disjoint paths between a given source and destination, especially in a backbone network.)

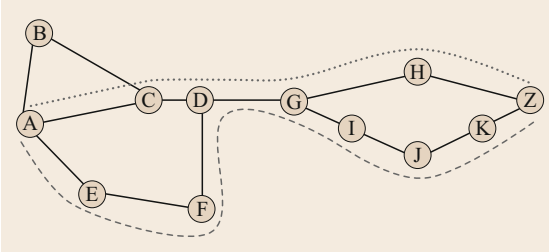

Fig. 12.6 There is no completely disjoint pair of paths between nodes A and Z. The set of paths shown by the *dotted* and *dashed lines* represents the shortest maximally-disjoint pair of paths. The paths have nodes D and G, and the link between them, in common (© Monarch Network Architects LLC)

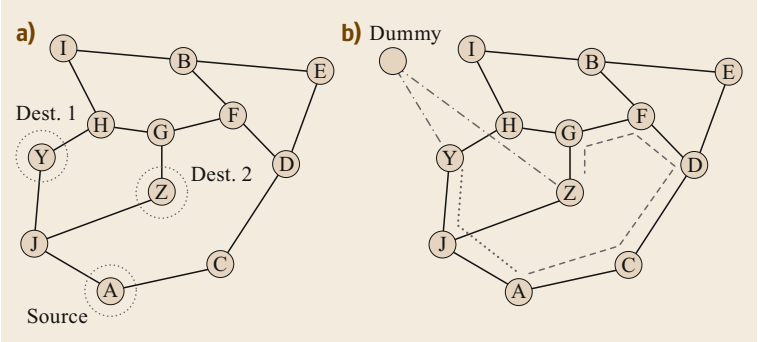

Fig. 12.7 **(a)** A disjoint path is desired between one source (node A) and two destinations (nodes Y and Z). **(b)** A dummy node is added to the topology and connected to the two destinations via links that are assigned a metric of zero. A shortest-disjoint-paths algorithm is run between node A and the dummy node to implicitly generate the desired disjoint paths, as shown by the *dotted line* and the *dashed line* (© Monarch Network Architects LLC)

In some scenarios, completely disjoint paths between the source and destination do not exist. In such cases, the Bhandari algorithm can be utilized to find the shortest *maximally-disjoint* set of paths. The resulting paths minimize the number of links (and optionally nodes) that are common to multiple paths. This is illustrated in Fig. 12.6, where the shortest maximally-disjoint pair of paths is A–C–D–G–H–Z and A–E–F–D–G–I–J–K–Z. Note that link DG is common to both paths.

12.3.1 Disjoint-Path Routing with Multiple Sources and/or Destinations

An important variation of the shortest-disjoint-paths routing problem exists when there is more than one source and/or destination, and each of the source/destination paths must be mutually disjoint for protection purposes. (Note that this is different from multicast routing, where the goal is to create a tree from one source to multiple destinations.) This protection scenario arises, for example, when backhauling traffic to multiple sites, utilizing redundant data centers in cloud computing, and routing through multiple gateways in a multidomain topology [12.1]. The example of Fig. 12.7a is used to illustrate the basic strategy. We assume that this is a backhauling example, where node A backhauls its traffic to two diverse sites, Y and Z. (Backhauling refers to the general process of transporting traffic from a minor site to a major site for further distribution.) Additionally, it is required that the paths from A to these two sites be disjoint.

In order to apply the shortest-disjoint-paths algorithm, a dummy node is added to the network topology as shown in Fig. 12.7b. Links are added from both Y and Z to the dummy node, and these links are assigned a metric of 0. The shortest-disjoint-paths algorithm is then run with node A as the source and the dummy node as the destination. This implicitly finds the desired disjoint paths as shown in the figure.

A similar strategy is followed if there are D possible destinations, with $D > 2$, and disjoint paths are required from the source to M of the destinations, with $M \leq D$. Each of the D destinations is connected to a dummy node through a link of metric 0. An extensible shortest-disjoint-paths algorithm such as the Bhandari algorithm is invoked between the source and the dummy node to find the desired M disjoint paths. Note that this procedure implicitly selects M of the D destinations that produce the shortest such set of disjoint paths.

If the scenario is such that there are multiple sources and one destination, then the dummy node is connected to each of the sources via links with a metric of 0. The shortest-disjoint-paths algorithm is then run between the dummy node and the destination. If there are both multiple sources and multiple destinations, then two dummy nodes are added, one connected to the sources and one connected to the destinations. The shortest-disjoint-paths algorithm is then run between the two dummy nodes. The algorithm does not allow control over which source/destination combinations will result.

12.3.2 Shared-Risk Link Groups

One challenge of routing in practical networks is that the high-level network topology may not reveal interdependencies among the links. Consider the network topology shown in Fig. 12.8a and assume that it is desired to find the shortest pair of disjoint paths from node A to node Z. From this figure, it appears that the paths A–B–Z and A–Z are the optimal solution. However, the fiber-level depiction of the network, shown in Fig. 12.8b, indicates that links AB and AZ are not fully

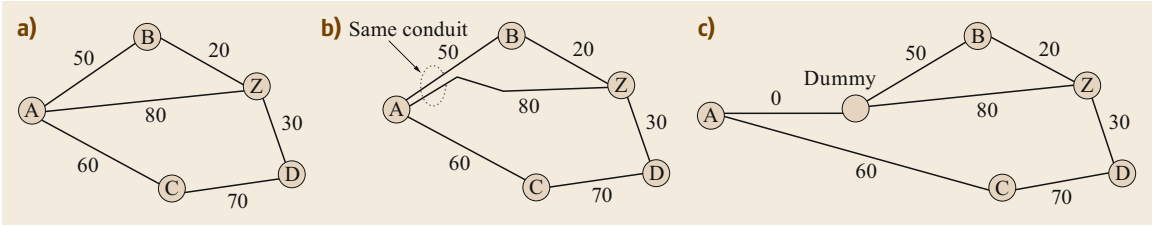

Fig. 12.8 **(a)** In the link-level view of the topology, links AB and AZ appear to be disjoint. **(b)** In the fiber-level view, these two links lie in the same conduit exiting node A and are, thus, not fully diverse. A single cut to this section of conduit can cause both links to fail. **(c)** Graph transformation to account for the SRLG extending from node A (© Monarch Network Architects LLC)

disjoint. The corresponding fibers partially lie in the same conduit exiting node A such that a rupture to the conduit likely causes both links to fail. These two links are said to constitute a *shared-risk link group* (SRLG). Links that are a member of the same SRLG are not fully disjoint. It is desirable to avoid a solution where an SRLG link is in the primary path and another link in that same SRLG is in the backup path.

For the SRLG configuration depicted in Fig. 12.8b, it is straightforward to find truly disjoint paths. First, a graph transformation is performed as shown in Fig. 12.8c, where a dummy node is added and each link belonging to the SRLG is modified to have this dummy node as its endpoint instead of node A. A link of metric 0 is added between node A and the dummy node. The shortest-disjoint-paths algorithm is run on the modified topology to find the desired solution: paths A–B–Z and A–C–D–Z. (While it is not necessary in this example, for this type of SRLG graph transformation, the shortest-disjoint-paths algorithm should be run with both link and node disjointness required [12.1].)

The scenario of Fig. 12.8 is one class of SRLG, known as the *fork configuration*. There are several other SRLG configurations that appear in practical networks [12.1, 3]. There are no known computationally efficient algorithms that are guaranteed to find the optimal pair of disjoint paths in the presence of any type of SRLG. In some cases, it may be necessary to employ heuristic algorithms that are not guaranteed to find the optimal (shortest) set of disjoint paths [12.10].

12.4 Routing Strategies

Monitoring network load is an essential aspect of network design. If too much traffic is carried on a small subset of the links, it may result in an unnecessarily high blocking rate, where future connections cannot be accommodated despite the presence of free capacity on most network links. The routing strategy clearly affects the network load. We discuss three of the most common routing strategies here.

12.4.1 Fixed-Path Routing

The simplest routing strategy is known as *fixed-path routing*. One path is calculated for each source/destination pair, and that path is utilized for every connection request between those two nodes. If any link along that path has reached its capacity (e.g., 80 connections are already routed on a link that supports 80 wavelengths), then further requests between the source/destination pair are blocked.

This strategy is very simple to implement, as it requires no calculations to be performed on an ongoing basis; all calculations are performed up front. Routing is a simple binary decision: either all links of the precalculated path have available capacity for the new connection, or they do not.

The drawback to fixed-path routing is that it is completely nonadaptive. The same path is selected regardless of the load levels of the links along that path. Such load-blind routing typically leads to uneven load distribution among the links, which ultimately may lead to premature blocking.

Despite this drawback, fixed-path routing is employed by many (if not most) network service providers, where the shortest-distance path is the one path selected for each source/destination pair. The rationale for this strategy is that it minimizes the latency of the connection. (Latency is the propagation delay from source to destination; in the optical layer, latency is typically dominated by the distance of the path.) While there are some network customers where latency differences on the order of microseconds can be critical (e.g., enterprises involved with electronic financial trad-

ing [12.11]), for most applications, a tolerance of a few extra milliseconds is acceptable. In most realistic networks, it is possible to find alternative paths that are very close in distance to the shortest path such that the increase in latency is acceptably small. By not considering such alternative paths, fixed-path routing is overly restrictive and can lead to poor blocking performance.

12.4.2 Alternative-Path Routing

A second routing strategy is *alternative-path routing*. In contrast to fixed-path routing, a set of candidate paths is calculated for each source/destination pair. At the time of a connection request, one of the candidate paths is selected, typically based on the current load in the network. For example, the candidate path that results in the lowest load on the most heavily loaded link of the path is selected. This enables adaptability to the current load levels in the network.

It is well known that alternative-path routing can lead to lower blocking levels as compared to fixed-path routing [12.12, 13]. One study performed by a service provider on its own large backbone network demonstrated one to two orders of magnitude lower blocking probability using alternative-path routing, even when limiting the length of the alternative paths for purposes of latency [12.14].

Furthermore, a large number of candidate paths is not required to achieve significant blocking improvements. Generating on the order of three candidate paths is often sufficient to provide effective load balancing. The key to the success of this strategy lies in the choice of the candidate paths. There is typically a relatively small set of links in a network that can be considered the *hot links*. These are the links that are likely to be in high demand and, thus, likely to become congested. An effective strategy to determine the expected hot links is to perform a design for a typical traffic profile where all connections in the profile follow the shortest path. The links that are the most heavily loaded in this exercise are generally the hot links.

With knowledge of the likely hot links, the candidate paths for a given source/destination pair should be selected such that the paths exhibit diversity with respect to these links. It is not desirable to have a particular hot link be included in all of the candidate paths, if possible, as this will not provide the opportunity to avoid that link in the routing process. Note that there is no requirement that the candidate paths for a given source/destination be *completely* diverse. While total path disjointness is necessary for protection, a less severe diversity requirement is sufficient for purposes of load balancing [12.15].

For completeness, we mention one variation of alternative-path routing known as *fixed alternative-path routing*. In this scheme, a set of candidate paths is generated and ordered. For each connection request, the first of the candidate paths (based on the fixed ordering) that has free capacity to accommodate the request is selected. Thus, load balancing is implemented only after one or more links in the network are full, thereby providing limited benefit as compared to fixed-path routing.

12.4.3 Dynamic Routing

With dynamic routing, no routes are precalculated. Rather, when a connection request is received by the network, a search is performed for a path at that time. Typically, path selection is based on cost and/or load. For example, consider assigning each link in an O-E-O network a value of LARGE $+ L_j$, where LARGE is a very large constant and L_j is a metric that reflects the current load level on link j. (Any load-related metric can be used, as long as the metric is additive.) Running a shortest-path algorithm with these link values will place the first priority on minimizing the number of hops in the path, due to the dominance of the LARGE component. In an O-E-O network, minimizing the number of hops also minimizes the number of regenerations required. The second priority is selecting a path of minimal load, as defined by the metric. Once the network contains several full or close-to-full links, the priorities may shift such that each link j is assigned a metric of simply L_j. With this assignment, the path of minimal load is selected regardless of the number of hops.

Dynamic routing clearly provides the most opportunity for the path selection process to adapt to the current state of the network. This may appear to be the optimal routing strategy; however, there are important ramifications in an all-optical network. By allowing any path to be selected as opposed to limiting the set of candidate paths to a small set of precalculated paths, connections between a given source/destination pair will tend to follow different paths. This has the effect of decreasing the network *interference length*, which can potentially lead to more contention in the wavelength assignment process. The interference length is the average number of links shared by two paths that have at least one link in common [12.16]. In addition, if the all-optical network makes use of wavebands, where groups of wavelengths are treated as a single unit, then the diversity of paths produced by a purely dynamic strategy can be detrimental from the viewpoint of efficiently packing the wavebands. Note that wavebands may be required with some of the technology that has been proposed for

achieving large fiber capacity in future networks, as is discussed in Sect. 12.12.5 [12.17, 18].

Another drawback to dynamic routing is the additional delay inherent in the scheme. This is especially true in a centralized architecture where any route request must be directed to a single network entity (e.g., a *path computation element* (PCE) [12.19, 20]). Delays incurred due to communication to and from the PCE, as well as possible queuing delays within the PCE, may add tens of milliseconds to the route calculation process. For dynamic applications that require very fast connection setup, this additional delay may be untenable.

To summarize this section on routing strategies, studies have shown that alternative-path routing provides a good compromise between adaptability and calculation time, and is more amenable to wavelength assignment in an all-optical network. If all candidate paths between a source/destination pair are blocked, then dynamic routing can be invoked.

12.5 Routing Order

In real-time network operation, connection requests are processed as soon as they are received. Thus, the routing process typically consists of searching for a path for just one connection (if batched routing is employed, then there may be a small number of connections to be routed at one time). In contrast, with long-term network design, routing is likely to be performed on a large traffic matrix comprising hundreds of connections. The order in which the connections are routed may have a significant impact on the ultimate level of network loading and blocking.

An effective ordering approach is to give routing priority to the source/destination pairs for which finding a path is likely to be more problematic. Thus, factors such as the relative locations of the two endpoints, whether or not a disjoint protection path is required for the connection, and whether or not the candidate paths for the connection contain a large number of *hot links* should be considered when assigning the routing order. For example, finding a path for a source/destination pair that is located at opposite ends of a network is likely to be more difficult than finding a path between an adjacent source and destination. It is typically advantageous to route such a connection early in the process when the links are relatively lightly loaded to minimize the constraints. Similarly, requiring disjoint paths for purposes of protection is already a significant constraint on the possible number of suitable paths. Giving priority to routing connections that require protection may enhance the likelihood that a feasible pair of disjoint paths can be found.

One enhancement of this strategy is to combine it with a metaheuristic such as *simulated annealing* [12.21]. A baseline solution is first generated based on the priority ordering method described above. The ordering that generated the baseline result is passed to the simulated annealing process. In each step of simulated annealing, the orderings of two connections are swapped, and the routing process rerun. If the result is better (e.g., less blocking or lower levels of resulting load), this new ordering is accepted. If the result is worse, the new ordering is accepted with some probability (this allows the process to extricate itself from local minima). The probability threshold becomes lower as the simulated annealing process progresses. If simulated annealing is run long enough, the overall results are likely to improve as compared to the baseline solution.

Other ordering schemes can be found in [12.1]. With rapid design runtimes, several orderings can be tested and the best result selected.

12.6 Multicast Routing

Video distribution is one of the major drivers of traffic growth in networks. Such services are characterized by a single source delivering the same traffic to a set of destinations. One means of delivering these services is to establish multiple unicast connections between the source and each of the destinations. Alternatively, a single multicast tree that includes each of the destinations can be established [12.22]. These two options are illustrated in Fig. 12.9. The multicast tree eliminates duplicate routing on various links of the network (e.g., link QR in Fig. 12.9) and is thus more capacity efficient. One study in a realistic backbone network showed that multicast provides a factor of roughly two to three improvement in capacity as compared to multiple unicast connections, where capacity was measured as the average number of wavelengths required on a link [12.1].

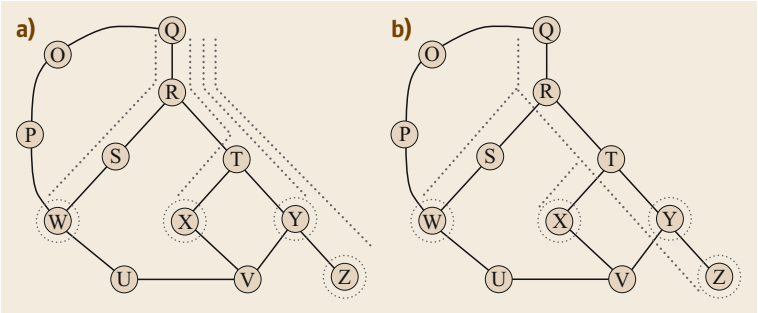

Fig. 12.9 **(a)** Four unicast connections are established between the source Q and the destinations W, X, Y and Z. **(b)** One multicast connection is established between node Q and the four destinations (© Monarch Network Architects LLC)

A tree that interconnects the source to all of the destinations is known as a *Steiner tree* (where it is assumed that all links are bidirectionally symmetric; i.e., two-way links with the same metric in both directions). The *weight* of the tree is the sum of the metrics of all links that compose the tree. As with point-to-point connections, it is often desirable to find the routing solution that minimizes the weight of the tree. Finding the Steiner tree of minimum weight is, in general, a difficult problem to solve unless the source is *broadcasting* to every node in the network. However, several heuristics exist to find good approximate solutions to the problem [12.23]. Two such heuristics are *minimum spanning tree with enhancement* (MSTE) [12.24, 25] and *minimum paths* (MP) [12.26]. Examples of these heuristics, along with their C-code implementation, can be found in [12.1]. Based on studies utilizing realistic backbone networks, MP tends to produce better results, although the relative performance of MSTE improves as the number of destinations increases [12.1]. In the case of broadcast, an algorithm such as Prim's or Kruskal's can be used to optimally find the tree of minimum weight [12.2].

The multicast algorithms enumerated above provide a single path from the source to any of the destinations. If a failure occurs along that path, connectivity with that destination is lost. Furthermore, due to the tree topology, a link failure along the tree often disconnects several destinations. Providing protection for a multicast tree, where connectivity with all destinations is maintained regardless of any single link failure, can be cumbersome and may require a large amount of protection resources.

Various strategies have been devised for providing multicast protection [12.27–29]. One approach common to several of these strategies is to make use of segment-based protection, where the multicast tree is conceptually partitioned into segments, and each segment is protected separately. A very different concept that has been applied to multicast protection is *network coding* [12.30–32]. With this approach, which has applications beyond just multicast protection, the destinations receive independent, typically linear, combinations of various optical signals rather than the individual optical signals that originated at the source. Processing at one or more nodes is required to create these signal combinations. The processing is preferably performed in the optical domain, but electrical processing may be required to generate more complex signal combinations. With proper processing of the received data, the destination can recreate the original signals. For protection purposes, the transmissions are sent over diverse paths and the signal combinations are such that if one signal is lost due to a failure, it can be recovered (almost) immediately from the other signals that are received. To mine the full benefits of network coding, there must be multiple signals that can be advantageously combined, as is often the case when routing a large amount of multicast traffic. Network coding *may* result in a more efficient use of network resources; however, even if the amount of required capacity is approximately the same as in a more conventional shared-mesh restoration approach, the recovery time is typically much faster.

Another important design aspect of multicast routing in an all-optical network is the selection of regeneration sites, where judicious use of regeneration may reduce the cost of the multicast tree. For example, it may be advantageous to favor the branching points of a multicast tree for regeneration. Refer to the tree of Fig. 12.10, where the source is node Q, and the multicast destinations are nodes W, X, Y, and Z. Assume that the optical reach is 2000 km. In Fig. 12.10a, the signal is regenerated at the furthest possible node from the source without violating the optical reach. This results in regenerations at nodes S and T. If, however, the regeneration occurs at the branching point node R as in Fig. 12.10b, then no other regeneration is needed, resulting in a lower cost solution.

12.6.1 Manycast Routing

In one variation of multicast routing, only N of the M destinations must be reached by the multicast tree,

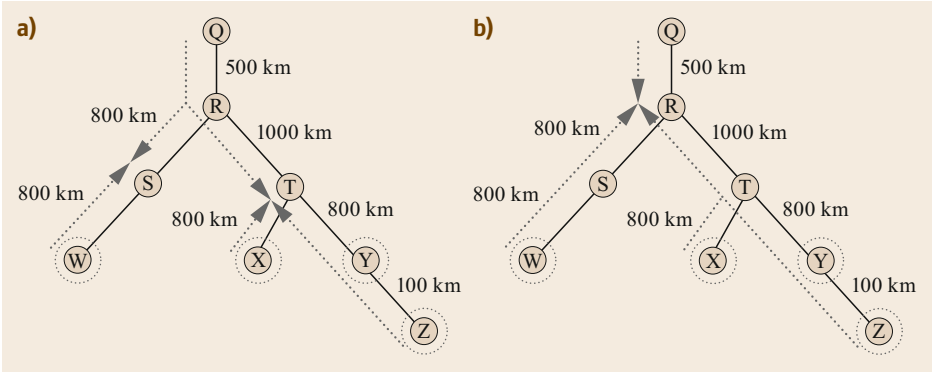

Fig. 12.10a,b Assume that the optical reach is 2000 km. **(a)** Regeneration at both nodes S and T. **(b)** Regeneration only at node R (© Monarch Network Architects LLC)

where $N < M$. The routing goal is still to produce the lowest-weight multicast tree; however, the routing algorithm must incorporate the selection of the N destinations as well. This scenario is known as *manycast*.

Manycast is useful in applications such as distributed computing. For example, there may be M processing centers distributed in the network, but an end user requires the use of only N of the processors. The goal of the end user is typically to minimize latency; it does not have a preference as to which N data centers are utilized. Optimal, or near-optimal, manycast routing, where the link metric is distance, is useful for such a scenario.

Various heuristic algorithms have been proposed for manycast routing, where the goal is to find the manycast tree of lowest weight. One effective heuristic in particular is a variation of the MP multicast algorithm [12.33].

12.7 Wavelength Assignment

Routing is one critical aspect of network design. Another important component is wavelength assignment, where each routed connection is assigned to a portion of the spectrum centered on a particular wavelength. Each time a connection enters the electrical domain, the opportunity exists (typically) to change the wavelength to which the connection has been assigned. The wavelength assignment process must satisfy the constraint that no two connections can be assigned the same wavelength on a given fiber. If this constraint were to be violated, the connections would occupy the same portion of the spectrum and interfere with each other. Note that when a link is populated with multiple fiber pairs, there can be multiple connections carried on the same wavelength on the link as long as each of the connections is routed on a different fiber.

12.7.1 Interaction Between Regeneration and Wavelength Assignment

As discussed in Sect. 12.1, all traffic that is routed through a node in an O-E-O network is regenerated. Regeneration is most commonly accomplished through the use of two back-to-back *transponders*, as shown in Fig. 12.11. A signal enters and exits a transponder in the optical domain but is converted to the electrical domain internally. The transponders interface to each other on a common wavelength (typically 1310 nm) through what is known as the *short-reach interface*. At the opposite end, the transponder receives and transmits a WDM-compatible wavelength, where the wavelength is generally in the 1500 nm range. The WDM-compatible wavelengths that are received/transmitted by the two transponders (i.e., λ_j and λ_k in Fig. 12.11) can be selected independently, thereby enabling wavelength conversion. (Wavelengths are also referred to as *lambdas*, with wavelength j represented by λ_j.)

Because of the flexibility afforded by regeneration, wavelengths can be assigned arbitrarily in an O-E-O network as long as each connection on a fiber is

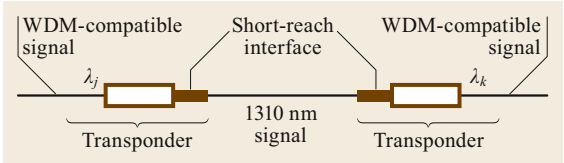

Fig. 12.11 Regeneration through the use of back-to-back transponders. The WDM-compatible signals associated with the two transponders, λ_j and λ_k, do not have to be the same, thereby enabling wavelength conversion (© Monarch Network Architects LLC)

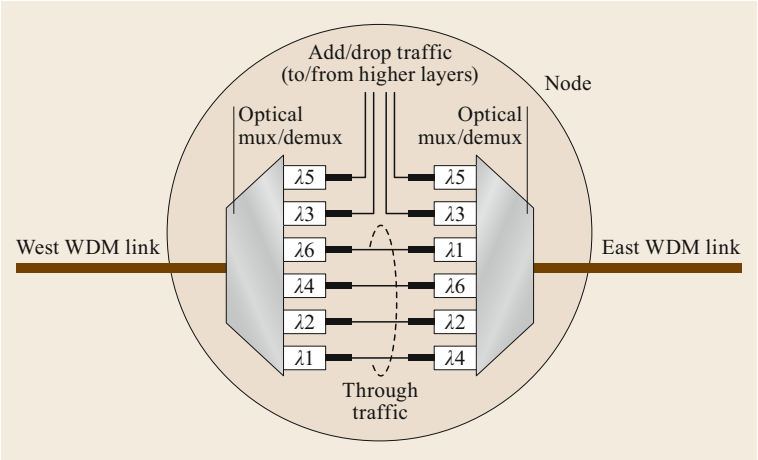

Fig. 12.12 A representative node in an O-E-O network. Wavelengths can be assigned independently to the connections on each link as long as each wavelength assigned on a fiber is unique. The lower-most connection is carried on λ_1 on the West link and carried on λ_4 on the East link (© Monarch Network Architects LLC)

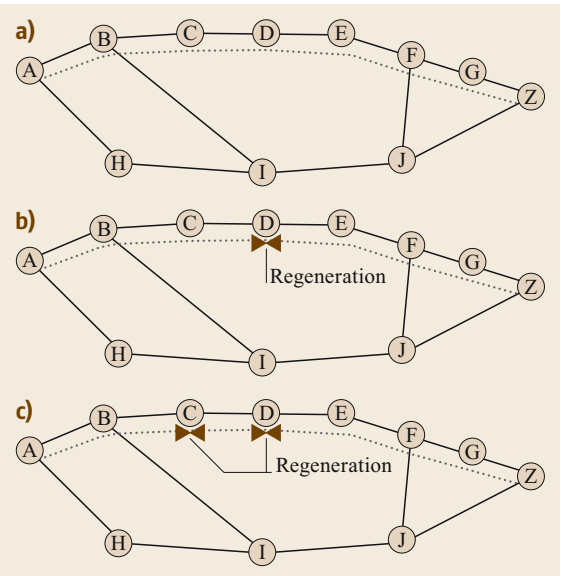
assigned a unique wavelength. This is illustrated in Fig. 12.12, where the lower most connection enters the node from the *West* link on wavelength 1 and exits the node on the *East* link on wavelength 4. In the reverse direction, wavelength 4 is converted to wavelength 1. (By convention, the nodal fibers at a degree-two node are referred to as West and East; it may have no correlation to the actual geography of the node.) There is no requirement that the wavelength must be changed. As shown in Fig. 12.12, another connection enters and exits the node on λ_2.

In contrast, signals in an all-optical network are not regenerated at every node along the path. It is only required that a signal be regenerated prior to it traveling a distance that is longer than the system's optical reach.



If a signal is not regenerated at a node (i.e., it traverses the node in the optical domain), then it is carried on the same wavelength into and out of the node. More generally, if the signal traverses N consecutive nodes in the optical domain, then it is carried on the same wavelength on $N+1$ links. The wavelength assignment process consists of finding a single wavelength that is available on each of these links. We use the term *all-optical segment* to refer to a portion of a connection that rides in the optical domain without any conversion to the electrical domain.

The difficulty of assigning wavelengths clearly depends on two factors: the number of links in an all-optical segment and the utilization level on those links. As the number of links in an all-optical segment increases, the difficulty in finding a wavelength that is free on each one of the links typically increases as well. Similarly, as the utilization level of a link increases, fewer wavelengths are available, thus making it less likely that a free wavelength can be found on the entire all-optical segment.

This presents an interesting tradeoff. Each regeneration requires the deployment of two transponders, adding to the cost, power consumption, and failure rate

Fig. 12.13 **(a)** The entire end-to-end connection is carried in the optical domain. The same wavelength must be available on all seven links traversed by the connection. **(b)** The connection is regenerated at node D, creating two all-optical segments: AD and DZ. These two segments can be assigned a different wavelength. **(c)** Assume that an available wavelength cannot be found from A to D, but λ_j is available from A to C, and λ_k is available from C to D. An additional regeneration can be added at node C to make wavelength assignment feasible for this connection (© Monarch Network Architects LLC) ◄

of the associated connection. However, wavelength assignment becomes simpler the more regeneration that is present. This is illustrated in Fig. 12.13. Figure 12.13a shows a true all-optical connection that remains in the optical domain from node A to node Z. In order to find a suitable wavelength to assign to this connection, the same wavelength must be available on all seven links that compose this end-to-end path. Figure 12.13b shows that same connection with an intermediate regeneration at node D. The presence of regeneration simplifies the wavelength assignment process. One needs to find a wavelength that is free on the three links from node A to node D and a wavelength that is free on the four links from node D to node Z. There is no requirement that these two wavelengths be the same.

If wavelength assignment fails for a connection, where a suitable wavelength cannot be found for one or more of the all-optical segments composing the connection's path, then at least four design options exist. First, the connection request can be blocked. Second, it may be possible to select different regeneration locations for the connection, thereby producing a different set of all-optical segments. Wavelength assignment may be feasible on this alternate set of segments. For example, in Fig. 12.1c (this figure appeared in Sect. 12.1), the two required regenerations are chosen to be at nodes C and F, producing the all-optical segments AC, CF, and FZ. Alternatively, the two regenerations could be placed at nodes B and E without violating the optical-reach constraint (there are other alternatives as well). This choice produces a completely different set of all-optical segments: AB, BE, and EZ. If moving the regenerations does not produce a feasible wavelength assignment, or if there are no regenerations for the connection, then a third option is to route the connection on a different path and re-attempt the wavelength assignment process on the new path. As a fourth option, the connection can remain on the same path, but one or more regenerations can be added even though they are not required due to optical-reach concerns, thus incurring greater cost. This last option is illustrated in Fig. 12.13c. Assume that a wavelength is available along the DZ segment, but no single wavelength is available on all of the links of the AD segment. Furthermore, assume that λ_j is available on the links from node A to node C, and λ_k is available on the link between node C and node D. By adding a regeneration at node C (and its attendant costs), wavelength assignment for this connection becomes feasible.
