33.1 WHAT IS A NETWORK AND HOW CAN WE STUDY BRAIN NETWORKS?

The human nervous system can be characterized at many levels of organization, from molecules to neurons to systems. The systems level is most amenable to studying the brain's network architecture using human neuroimaging techniques. Strictly speaking, a network is a set of well-defined items with well-defined pairwise relationships between those items. Network analysis, which is based on graph theory, allows for the quantification of those relationships. Graph theory is a branch of mathematics concerned with modeling the pairwise relationships (edges) between items (nodes). It allows for the formal measurement of many properties of networks, such as between-ness centrality, which is a measure of the frequency by which the shortest paths between all other nodes in the network pass through a given node, and modularity, which is a measure of clustering of nodes into subcommunities within a network (for a review, see Bullmore & Sporns, 2009). The ability to formalize and quantify network properties in this way makes graph theory highly attractive for measuring network properties in the brain. Hence, the number of studies in which graph theory tools are applied to brain imaging data is growing exponentially. Specifically at the systems level, recent investigations have utilized graph theory to measure and quantify relationships between brain regions, where nodes in the graph represent specified

brain regions or voxels, and edges in the graph represent the pairwise relationships between the brain regions. The analytic method is not dependent on the type of data used; therefore, network organization can be characterized using structural and functional brain imaging measures. It is worth keeping in mind that applying graph theory to brain imaging data is subject to some methodological limitations relative to other types of network data (e.g., transportation networks and social networks). Because brain networks are represented as graphs of correlations (representing the relationships between brain regions), certain graph metrics may be biased; for example, the number of edges that a node has can be biased by network size. Reviews of the literature on structural brain networks and the development of structural networks can be found in Alexander-Bloch, Giedd, and Bullmore (2013) and Giedd and Rapoport (2010). Here, we focus our discussions on functionally defined brain systems, primarily emphasizing studies that implement resting state functional connectivity (RSFC) magnetic resonance imaging (MRI) (Figure 33.1).

RSFC is a technique that measures spontaneous low-frequency blood oxygen level-dependent (BOLD) activity while a subject is "at rest" (i.e., lying awake quietly, often with eyes open and foveating on a centrally positioned crosshair). Functional connectivity is defined as the temporal correlation (measured as a Pearson's r) in the high amplitude, low-frequency spontaneously generated BOLD signal between voxels

FIGURE 33.1 Functional brain network architecture derived using network analysis of RSFC data between every pair of voxels in the brain. Adapted from Power et al. (2013) with permission from the publisher.

(cubic “pixel” in a three-dimensional brain image) or brain regions (Fox & Raichle, 2007). Functional connectivity is spatially constrained by anatomy but does not necessarily reflect monosynaptic anatomical connections. For example, RSFC is high between homotopic nonfoveal V1 visual cortex regions despite the lack of direct callosal connections (Vincent et al., 2007). Thus, RSFC provides a measure of functional brain connectivity that may contain different information than strict anatomy. For example, it has been posited to reflect a “Hebbian-like” history of co-activation between brain regions (Dosenbach et al., 2007; Kelly et al., 2009; Lewis, Baldassarre, Committeri, Romani, & Corbetta, 2009; Wig, Schlaggar, & Petersen, 2011). Figure 33.1 shows results from the application of graph theory methods, specifically modularity, to RSFC correlations across every pair of voxels in the adult brain. Different functional systems (or networks) are indicated by different colors. The BOLD timecourses in distributed yet functionally related brain regions are correlated with each other; these region sets correspond to known functional systems, including sensorimotor (e.g., somato-motor; turquoise and orange colors in Figure 33.1), auditory (fuchsia in Figure 33.1), visual (blue in Figure 33.1), and higher-level control systems (e.g., frontoparietal [yellow in Figure 33.1] and dorsal attention [chartreuse in Figure 33.1]) (Biswal, Yetkin, Haughton, & Hyde, 1995; Dosenbach et al., 2007; Lowe, Mock, & Sorenson, 1998). RSFC has also enabled the discovery and interrogation of the default mode system (red in Figure 33.1) (Fox et al., 2005; Greicius, Krasnow, Reiss, & Menon, 2003; Raichle et al., 2001). Thus, the

temporal correlations measured with RSFC provide a quantifiable metric suitable for network analysis.

In the functional MRI literature, the term “network” is often used to refer to a set of brain regions that co-activate or deactivate under certain task conditions, without consideration of the pairwise relationships between the regions. Designating networks in this sense is incomplete and can potentially misrepresent the true architecture of brain networks. Such misapprehension of network structure is common in the RSFC literature, with “resting state networks” or task activation networks being labeled without a sufficient examination of the pairwise relationships between brain regions. Some of the approaches commonly used to study these “networks,” although valuable, stop short of true network analysis. One such approach is seed-based analysis, in which statistical maps are generated across the whole brain, representing the correlations between the BOLD timecourse of a “seed” region of interest and the BOLD timecourses of every other voxel in the brain. The resulting map displays regions (collections of voxels) with timecourses similar to the seed’s, but without reflecting the relationships among all those regions. Similarly, independent component analysis approaches are commonly used to define resting state systems without accounting for the relationships between all the regions within a system or with other systems. Independent component analysis identifies voxels with shared temporal (and spatial) BOLD signal variance and separates them as orthogonal components. However, investigators most often stop at the point of identifying components and do not proceed to explore the relationships among regions within and

between components. The statistical constraints of independent components analysis requiring zero correlation between components and not explicitly modeling the strength of relationships between nodes within each component could result in incomplete or distorted descriptions of functional networks (Wig et al., 2011). Thus, these approaches leave an incomplete depiction of the complex relationships within and between systems. Graph theory, by contrast, provides a framework with which to analyze networks in the true sense of the term. For RSFC data, the pairwise correlations comprise the edges in the graph. Thus, network properties can be quantified with respect to functional connectivity between regions (collection of voxels) or individual voxels.

33.2 ORGANIZATION OF THE BRAIN'S FUNCTIONAL NETWORK ARCHITECTURE

Investigating systems across the whole-brain is a sizeable task. Although many studies have examined particular targeted brain systems (e.g., frontoparietal and default mode), considering the whole brain's network architecture is key for obtaining a complete picture of brain organization. There have been a small number of studies aimed at characterizing whole-brain network organization using RSFC methods (Power et al., 2011; Yeo et al., 2011). These studies have effectively identified whole-brain network schemes that map reasonably well onto known functional systems. Utilizing graph theoretic approaches (Power et al., 2011), we have identified communities (modules, sub-networks, subgraphs) corresponding to sensorimotor systems (e.g., visual, auditory, and somato-motor), control systems (e.g., frontoparietal, involved in moment-to-moment control, and cingulo-opercular, involved in sustained task control) (Dosenbach, Fair, Cohen, Schlaggar, and Petersen (2008), attention systems (e.g., dorsal attention, involved in goal-directed attentional orienting, and ventral attention system, involved in orienting to relevant exogenous stimuli) Corbetta, Patel, and Shulman (2008), and others (e.g., salience and default mode) (Figure 33.1). Graph metrics allow for interrogation of network properties, revealing some intriguing findings that could only be gleaned by network analysis. For example, the default mode system has certain network properties that most closely resemble those of lower level processing systems in contrast to higher level control systems. Specifically, the default mode system has high local efficiency and low participation coefficients, such that it is relatively isolated from other systems but well-integrated within itself (Power, Schlaggar,

Lessov-Schlaggar, & Petersen, 2013). Control systems, such as the cingulo-opercular, show the converse: low local efficiency and high participation coefficients, properties expected for systems whose putative role is to integrate information across systems (Power, Schlaggar, et al., 2013).

33.3 IS THERE A LANGUAGE NETWORK?

Descriptions of the brain's functional network architecture lead one to ask, what system(s) supports the uniquely human capacity for language? Some of the results from work using seed-based functional connectivity analysis have been interpreted as evidence for the presence of several language networks. One study used six left hemisphere regions that consistently activate in word reading tasks as seeds (inferior occipital gyrus, fusiform gyrus, superior temporal gyrus, temporoparietal junction, dorsal precentral gyrus, and inferior frontal gyrus) in RSFC connectivity analysis (Koyama et al., 2010). The whole-brain connectivity maps of each of these seeds differed substantially from each other, which was interpreted as evidence for the existence of six reading systems. Conjunction analysis aimed at identifying voxels that were significantly correlated with all of the seed regions showed that voxels in left posterior inferior frontal gyrus and left posterior middle temporal gyrus were common to five of the six correlation maps, suggesting that these regions are places of "functional interaction among the reading networks." Left inferior frontal and middle temporal gyrus regions were used as seeds in an investigation of functional connectivity of task-evoked activation data during acquisition of meaning of new nouns (Yeo et al., 2011). Based on the functional connectivity patterns of the two seeds across task conditions, the authors proposed the existence of two systems of meaning acquisition: one system that includes left inferior frontal gyrus, middle cingulate cortex/supplementary motor area, left inferior parietal lobule, thalamus, bilateral caudate, and bilateral middle frontal gyrus that subserves mapping meaning onto new words; and a second system that includes the left middle temporal gyrus, anterior and posterior cingulate cortex, and bilateral middle frontal gyrus that subserves semantic integration. Bilateral middle frontal cortex was functionally connected to both seed regions, implicating working memory processing as a shared domain between the two systems. However, no analysis was performed to examine the functional connectivity within each of the proposed system regions to test directly whether they belong to a separable network. Another study used task data but regressed out task-evoked activation to examine

functional connectivity with left posterior superior temporal sulcus (Lohmann et al., 2010). They found this region to be correlated with seeds in Broca's area, a brain region commonly conceptualized as supporting language production, and with closely positioned left frontal operculum in data from language tasks but not in data from control tasks, possibly identifying language-specific temporal-frontal connectivity. It is important to reiterate that seed-based functional connectivity analysis does not constitute a true network analysis because, although it effectively identifies the seed's neighbors, it does not characterize the pairwise relationships between the regions that comprise the system of interest.

Our group has taken seed-based and network approaches to study reading-related brain regions. Seed-based RSFC analysis was used to examine the putative visual word form area in left occipitotemporal cortex and showed that it is functionally connected to regions comprising the dorsal attention system and not to other regions presumed to be involved in reading (Vogel et al., 2012). These results support a role for attention processing in reading and counter the idea that the putative visual word form area is functionally related to reading-related regions. We then asked whether a dedicated reading system could be identified and, if so, whether it changes over the course of development from age 7 years to young adulthood. We used RSFC data to perform a network analysis of 83 reading-related regions assembled from meta-analyses in adults and from developmental studies of reading. Results demonstrated that these regions segregated into previously reported systems, as in Figure 33.1, including visual, somato-motor, cognitive control, and default mode (Vogel et al., 2013). Regions most commonly identified in reading studies were part of communities in the left hemisphere and included the visual cortex (putative visual word form area), inferior frontal cortex, inferior temporal cortex, supramarginal gyrus, and angular gyrus, largely considered core regions of the default mode system. However, two left supramarginal gyrus regions, left inferior frontal cortex, and a few other regions (right medial superior parietal gyrus, left medial supplementary motor area, right temporal gyrus, and mesial thalamus) could not be definitively assigned to one of the known systems. Interestingly, left supramarginal gyrus and inferior frontal cortex have been singled out as comprising a language-related system in the task-based seed-based analyses discussed (Koyama et al., 2010; Lohmann et al., 2010; Yeo et al., 2011), suggesting some convergence in findings across different levels of analysis. We found no evidence for developmental effects of the network structure of reading-related regions (Vogel et al., 2013).

Most recently, a whole-brain RSFC study in a large dataset found that a language system could be reliably identified at the level of the individual brain (Hacker et al., 2013). This language system was composed of superior and middle temporal cortex and inferior frontal gyrus bilaterally, left supramarginal/angular gyrus, left dorsal premotor cortex, and right cerebellum. Interestingly, the language system emerged at much later iterations of the learning algorithm that was used to identify resting state networks than other systems such as the default mode network. The authors suggested that finer (more hierarchical) levels of analysis might be necessary to detect a language network. In our most recent efforts of mapping functional brain systems (Figure 33.1), bilateral inferior frontal gyrus, left dorsal premotor cortex areas along with relatively smaller areas in left inferior parietal lobule (including in the supramarginal and angular gyri), and left medial dorsal cortex were assigned to the ventral attention system (teal color in Figure 33.1). These areas closely overlap with areas considered to be part of the language and ventral attention systems in the study by Hacker et al. (2013). Bilateral superior temporal cortex (light pink in Figure 33.1) was not part of any system that we identified, raising the possibility that with higher order analysis, it could have integrated with areas of the ventral attention system into a language system.

It is also plausible and intriguing that language emerges from elements of other brain systems. Support for this idea comes from recent evidence for brain regions or "hubs" that sit at the intersection of multiple systems. Hubs are considered to be nodes with particularly important network properties, akin to high-traffic, densely connected airports. One property that has received considerable attention is the node "degree," which is defined as the number of edges (connections) on a node. The more edges a node has, the higher its degree and the more interconnected it is with other nodes. High-degree nodes have been identified within the default mode system, implying that the default mode system contains "hubs" of the human brain (Buckner et al., 2009). However, we have argued that degree-based nodes are confounded by the size of the system in which they belong in correlation-based systems (Power, Schlaggar, et al., 2013). Because the default mode system, with respect to the total volume of cerebral cortex devoted to it, is one of the largest systems in the brain, high-degree nodes within it may reflect membership in the largest system, rather than true hub-like qualities. True hubs in the brain would be expected to support and/or integrate multiple types of information and to cause widespread disruption if compromised. From this perspective, we have investigated regions in the brain that possess two

properties related to but different from node degree. One property is referred to as “participation coefficient” and captures the number of regions in different systems to which a node is functionally connected; a second property is referred to as “articulation points,” which captures voxels where multiple brain systems are represented. Convergence between these two properties identified candidate hub regions located in the anterior insula, dorsal medial prefrontal cortex, dorsal prefrontal cortex, lateral occipitotemporal cortex, and superior parietal cortex.

Intriguingly, some of the putative hub regions identified in [Power, Schlaggar, et al. \(2013\)](#) are positioned in locations of the cortex that overlap with, or are near, canonical language areas. In particular, hub-like regions identified in the posterior part of the superior temporal sulcus overlap with standard localization of Wernicke’s area, a brain region commonly conceptualized as supporting language comprehension. Other hubs located in the anterior insula/frontal operculum are situated near the inferior frontal gyrus and the general region of Broca’s area. Thus, locations in the brain with these hub-like features may support language function, suggesting the confluence of multiple brain systems for language. These hub-like regions may be susceptible to substantial disruption in brain function, including disruption in language domains, because of their location at the intersection of multiple brain systems. It has been shown that patients with focal lesions that included nodes located at the intersection of several networks showed significant decrease in modular organization of four tested networks, whereas patients with focal lesions that included nodes located within networks did not show decrease in network modularity ([Gratton, Nomura, Pérez, & D’Esposito, 2012](#)).

33.4 DEVELOPMENT OF BRAIN NETWORKS

Understanding how brain network organization develops from childhood to adulthood has been the focus of much study in the past decade. Initial efforts to investigate the development of brain systems resulted in some principles that were, unfortunately, confounded by an insidious movement artifact, resulting from sub-millimeter movements, that was not addressed by industry standards for dealing with movement. For a complete review of the literature on network development up until the discovery of the motion confound, see [Power, Fair, Schlaggar, and Petersen \(2010\)](#) and [Power, Barnes, Snyder, Schlaggar, and Petersen \(2012\)](#). Several groups, including ours, initially found two key results. First, within-network connectivity increased while between-network connectivity decreased over

development, leading to more segregation of brain networks into adulthood ([Fair et al., 2008, 2007; Supekar, Musen, & Menon, 2009](#)). Second, development was associated with increased strength in long-range connections and decreased strength in short-range connections ([Dosenbach et al., 2010; Fair et al., 2007; Supekar et al., 2009](#)). Although these studies followed the best practices at the time for accounting for movement (e.g., frame-by-frame image realignment, excluding BOLD runs or subjects with average motion estimates exceeding set thresholds, matching groups on average motion estimates), they suffered from a previously unknown effect of motion on RSFC data. Head motion, even sub-millimeters in amplitude, that does not affect average motion estimates can cause spurious yet systematic changes in RSFC correlations ([Power et al., 2012; Van Dijk, Sabuncu, & Buckner, 2012](#)). Specifically, head motion increases the correlation strength between proximate brain regions and decreases the correlation strength between distant brain regions. Thus, if one compares RSFC correlations between two groups, a group with more micromovements will appear to have stronger short-range connections and weaker long-range connections, precisely mapping onto the “developmental” effect that we and others observed. Unfortunately, children move more than adults, patients move more than controls, and aging adults move more than younger adults, making it difficult to separate real group differences in RSFC correlations from motion artifacts.

The discovery of motion artifacts in RSFC correlation has prompted the development of data processing strategies to better account for motion ([Power, Mitra, et al., 2014; Satterthwaite, Elliott, et al., 2013; Satterthwaite, Wolf, et al., 2013; Yan et al., 2013](#)); however, there is no agreed-on standard. Still, these strategies have been shown to reduce significantly the spurious correlation between motion and BOLD signal intensity, thus mitigating some of the effects of motion-induced artifact. Studies that incorporate improved motion correction strategies support the first main finding of earlier studies: increased network segregation over the course of development defined by increased within-network connectivity and decreased between-network connectivity ([Fair et al., 2012; Satterthwaite, Wolf, et al., 2013](#)). Recent findings provide evidence that motion correction may even strengthen these effects ([Satterthwaite, Wolf, et al., 2013](#)). Earlier findings that a significant amount of the variance in brain maturation (55%) measured using whole-brain RSFC can be explained by chronological age ([Dosenbach et al., 2010](#)) are also supported using improved motion correction methods ([Fair et al., 2012; Satterthwaite, Wolf, et al., 2013](#)), with evidence that the variance in brain maturation attributable to age may

actually increase after motion correction (Fair et al., 2012). Using seed-based analysis of four default mode system regions, one study showed that the increased positive correlations between these four regions across age were eliminated after movement artifact correction (Chai et al., 2014). At the same time, the amplitude of the negative correlations between default mode regions and attention-related regions increased over the course of development. Specifically, these correlations changed from positive in 8- to 12-year-olds to negative in 13- to 17-year-olds to strongly negative in 18- to 24-year-olds, and these effects were robust to motion correction. These results, suggesting age-related increases in between-system functional connectivity for negative correlations, are the first to our knowledge to examine the development of negative correlations.

The second developmental finding in earlier studies—increased connectivity of long-range connections and decreased connectivity of short-range connections, implying increased complexity of functional brain organization over development—seems to be almost entirely explained by the motion artifact (Power et al., 2012; Satterthwaite, Wolf, et al., 2013). There is still some evidence, however, for integration of distant anterior and posterior regions into the same system and for segregation of closely located regions into separate systems across development. In movement-corrected data, integration of regions in the frontoparietal and default mode systems was seen from childhood (ages 6–14 years) to young adulthood (ages 21–29 years), whereas segregation of medial and lateral visual system regions was seen across these age groups (Vogel et al., 2013). These results suggest that some changes do occur in the strength of the correlations in long-range and short-range connections, consistent with the original ideas (Fair et al., 2008, 2007; Supekar et al., 2009). The idea of increased complexity over the course of development is also supported by analyses of structural MRI data. A large study of 5- to 18-year-olds showed that gray matter intensity in seed regions in sensorimotor, salience, executive control, and default mode systems, as well as language-related regions, was correlated with age in a larger number of voxels across the brain (Zielinski, Gennatas, Zhou, & Seeley, 2010). Expansion of the seed-based structural connectivity was particularly dramatic between ages 12 and 14 years, with the exception of speech and executive control systems, where the largest expansion was seen in the oldest age group (16- to 18-year-olds). Of note, this study was a seed-based analysis that does not meet the definition of network analysis, as we have pointed out. In addition, with some exceptions (Rose et al., 2012), the impact of motion artifact on structural connectivity analysis has not been rigorously

investigated at this time and will likely become an active area of research in the near future.

In contrast, motion correction of RSFC data is an active area of research and there is, at present, no standard approach to dealing with this issue. The details of the debate regarding optimizing data quality through removing movement artifact are beyond the scope of this chapter. The reader is directed to several recent publications on this topic (Chai et al., 2014; Power, Mitra, et al., 2014; Saad et al., 2012; Satterthwaite, Elliott, et al., 2013).

We have implemented an approach that includes, among other steps, censoring high movement volumes in RSFC data (Power et al., 2012; Power, Mitra, et al., 2014). One significant side effect of such an approach is substantial data loss (Yan et al., 2013), which could result in the inability to perform planned analyses. Data loss may be especially problematic for already collected developmental data that rely on *post hoc* statistical motion correction. In comparison with large datasets (Satterthwaite, Wolf, et al., 2013) or meta-analysis of data from multiple sites (Fair et al., 2012), smaller studies examining brain system development are at a relative disadvantage for showing robust effects. Efforts to minimize motion should be prioritized at the time of data collection, when study participants can be more rigorously secured and acquisition sequences can be optimized (Craddock et al., 2013). Collecting RSFC data for longer periods of time can also mitigate data loss by providing greater probability for sufficient data per subject to allow stringent movement correction.

33.5 IMPLICATIONS OF DEVELOPMENT OF BRAIN NETWORKS TO LANGUAGE-RELATED BRAIN REGIONS

We noted earlier that the seed-based whole-brain connectivity map of the putative visual word form area in adults parallels the dorsal attention system (Vogel et al., 2012). The same analysis in a sample of 7- to 9-year-old children showed a much reduced extent of putative visual word form area functional connectivity across the brain with positive correlations in visual cortex and negative correlations in superior frontal cortex (Vogel et al., 2012). Comparisons between children and adults matched on movement showed generally elevated connectivity in adults, although the matched sample was small ($n = 13$ adults, 6 children) and lacked statistical power. As mentioned, subsequent network analysis of 83 reading-related regions using movement-corrected data did not find a reading system in children and instead showed that reading-related regions largely segregated into known brain systems, including

visual, sensorimotor, cognitive control, default mode, subcortical, and temporal. Although there was some modest evidence for integration (e.g., frontal and parietal regions of the frontoparietal cognitive control system) and segregation of regions (e.g., visual cortex into medial and lateral communities) across development, there was no evidence for regions that comprise a reading community in children (Vogel et al., 2013). To the extent that brain regions that serve as “hubs” for information processing include language-related regions, hub architecture so far appears to be largely stable across development from ages 10 to 20 years (Hwang, Hallquist, & Luna, 2013).

33.6 FUTURE DIRECTIONS

Investigating the development of the brain’s functional network architecture is a highly active research area with rapidly evolving analytical methods. Some of the most important current challenges involve correcting resting state functional MRI data for submillimeter amplitude subject movements and applying network analysis methods that probe network architecture in the true sense of the word, considering all pairwise relationships between brain regions (collection of voxels) or individual voxels in a given analysis. Although the presence of a brain system uniquely devoted to language is still a subject of investigation, it is entirely possible that continued development of network analysis methods and increasing understanding of brain network architecture could uncover communities within the larger network structure, with language comprising one such community (Hacker et al., 2013). Considering the relatively recent evolutionary emergence of language for our species, it is also plausible that language and its development are the products of the interaction of multiple brain systems.

Bilingual Development and Age of Acquisition

Arturo E. Hernandez

Department of Psychology, University of Houston, Houston, TX, USA

34.1 INTRODUCTION

Development by definition involves changes in age. The topic of maturational changes and effects due to critical periods in language has a long-standing tradition in the literature (Lenneberg, 1967; Pinker, 1994). This approach has also held true in the bilingual literature that has, in part, focused on the differences between adult and child language learners (Johnson & Newport, 1989). The traditional view in a purely maturational model would view language learning as being easiest early in life, with learning becoming progressively more difficult across the lifespan. Despite the evidence for such a view, there are findings that contradict a simple version of the critical period hypothesis. It has become increasingly clear that a classical view of development fails to capture some of the exceptions to this rule (Au, Knightly, Jun, & Oh, 2002; Oh, Au, & Jun, 2010; Oh, Jun, Knightly, & Au, 2003; Pallier et al., 2003; Ventureyra, Pallier, & Yoo, 2004). In this chapter, the nature of age effects in bilingual language development is considered. First, the ways in which age of acquisition (AoA) affects processing in monolinguals are described. This discussion involves the same effects within the bilingual population. Finally, the chapter concludes with a brief discussion of the theoretical implications of this review (for a longer discussion see Hernandez, 2013).

34.2 AGE OF ACQUISITION

In 2007, Hernandez and Li proposed that AoA is related to sensorimotor processing (Hernandez & Li, 2007). The clearest marker of this can be seen in brain

development. Neurological changes that serve as markers of this development include neuronal proliferation, neuronal death, and dendritic pruning. Early in development, there is neuronal proliferation along with extensive dendritic connections between neurons. Over time neuronal death and dendritic pruning lead to a great reduction in the number of neurons and connections between them. At the same time, the density of the myelin sheath that helps speed up the electrical signal sent by the axons grows thicker (Campbell & Whitaker, 1986).

Interestingly, these changes during neural development do not occur at the same rate across all areas of the brain, at least not in humans. Unlike many other animal species, humans show a disjointed form of brain maturation. Neurons mature earlier at central points and then fan out to areas that are further and further away. In an attempt to consolidate all available data of the rate at which different brain regions mature, Best (1988) proposed that growth occurs in three different ways: right-to-left, primary-to-secondary-to-tertiary, and basal-to-cortical (from the middle of the brain out to the cortex).

More recent studies using a variety of techniques have confirmed the importance of these axes of brain development. In infants, sensory cortices are the earliest to develop in life. The development of sensory cortex is followed by development of association areas in the parietal lobe and motor cortex in the frontal lobe. The most anterior regions of the brain in the prefrontal cortex are known to develop the latest. Changes in brain structure continue into middle childhood, across adolescence and adulthood, and through older adulthood. These findings have been confirmed by studies using direct observation of brain tissue as well as those using indirect methods of measuring the brain such as

magnetic resonance imaging (MRI) and functional magnetic resonance imaging (fMRI).

Neuronal changes that occur across development were first investigated by observing the anatomy of neurons in the brains of a few individuals under a microscope (Huttenlocher, 1990, 1994; Huttenlocher & Dabholkar, 1997; Huttenlocher & de Courten, 1987; Huttenlocher, De Courten, Garey, & Van der Loos, 1982a, 1982b). These studies were resonant with the pattern discussed here. Differential development of areas under the microscope revealed changes in the production of synapses, in later synaptic pruning, and in myelination. Production of synapses is strongest in the occipital lobe (i.e., visual regions) of the cortex between 4 and 8 months of age (Huttenlocher & de Courten, 1987). In the frontal lobe, synapse production reaches its peak at 15 months of age (Huttenlocher & Dabholkar, 1997). The lag in the frontal lobes' overproduction of synapses is also observed in the reduction of synapses via pruning (Huttenlocher, 1994).

The advent of newer neuroimaging techniques has allowed researchers to look at brain development *in vivo*. Work using these newer techniques has found evidence that developmental changes in brain areas can be seen as involving both left–right gradient, anterior–posterior gradient, and primary-to-secondary-to-tertiary gradient. Recent neuroimaging studies of single word processing in children have shown changes in the magnitude of neural activity in adults and children centered in areas of the frontal lobe (Schlaggar et al., 2002), the area that has been found to reach adult levels of synaptic connectivity the latest. This is consistent with the view that children have less developed frontal lobes relative to adults.

In a groundbreaking study, Sowell et al. (2003) examined the gray matter density of high-resolution structural MRI scans in a group of individuals who ranged between 7 and 87 years of age. Results revealed a linear decrease in gray matter density across age. Regions in the frontal lobe showed decreases in gray matter density from ages 7 and beyond. The authors attribute some of this to an increase in myelination up until age 40, with a decrease in neural density ensuing into older adulthood. An interesting deviation from this general trend was observed in the left temporal regions (particularly the posterior portions of the middle and superior temporal gyrus), which revealed an increase in gray matter density until age 40. These studies converge with previous work that had found continued changes in left temporal cortices well into adulthood. The late maturation of the temporal lobes, particularly in the superior and posterior parts, is an example of primary-to-secondary-to-tertiary development. In this particular case, it would involve extensions of auditory processing into language processing.

Development affects both the patterns of neural specialization and brain anatomy. The notion of development has also played an interesting role in the bilingual literature as well as the monolingual word recognition literature. In the bilingual literature, it has been used to consider how second language processing differs from first language processing. The development of early sensorimotor effects and later developing frontal lobe functions can also be seen in the word recognition literature. First, we consider the literature with monolinguals before moving on to the bilingual literature in subsequent sections.

34.3 AoA IN A SINGLE LANGUAGE

Catriona Morrison and Andrew Ellis (Morrison & Ellis, 1995) asked participants to read or identify a visual stimulus as a word (i.e., shave) or not (i.e., mave) in a set of visually presented stimuli. They performed two separate manipulations. In one set of experiments, they chose a set of early-learned (fairy) and late-learned words (wharf) that were matched for lexical frequency. In a second set of experiments, they chose a set of high-frequency (market) and low-frequency (pigeon) words that were matched on AoA. By doing this, they could measure to what extent frequency of use or AoA influenced the speed with which a word was read or decisions were made. The results revealed effects of AoA but no effect of word frequency.

These findings were somewhat controversial at the time, because they called into question the results of previous research that had focused extensively on word frequency. These studies had identified word frequency as the primary determinant of speed and accuracy in word recognition experiments (Besner & Smith, 1992; Grainger, 1990; Ostergaard, 1998). Follow-up studies found that AoA and word frequency played a role in speed of picture naming (Meschyan & Hernandez, 2002). Thus, behavioral data, at least in some cases, indicate that word frequency may play a role independently of word AoA.

A second study, in collaboration with Christian Fiebach, Angela Friederici, and Sonja Kotz, sought to investigate the neural correlates associated with lexical AoA. The effect of frequency led to increased neural activity within the inferior frontal gyrus (IFG), a finding that was in line with previously published studies. What was most surprising was the effect of AoA (Fiebach, Friederici, Muller, von Cramon, & Hernandez, 2003). Words learned in early childhood led to activity in Heschl's gyrus and brain areas involved in the processing of speech sounds. Words learned in late childhood relied, to a greater extent, on

brain areas in the lower portions of the inferior frontal lobe. These areas have been associated with the effortful access to a word's meaning (Badre, Poldrack, Pare-Blagoev, Insler, & Wagner, 2005; Bookheimer, 2002; Poldrack et al., 1999; Wagner, Maril, Bjork, & Schacter, 2001; Wagner, Pare-Blagoev, Clark, & Poldrack, 2001).

The divide between early-learned and late-learned words in the brain images bears an interesting resemblance to the way in which the brain develops. As discussed, areas in sensory cortex are the earliest to develop and those in the prefrontal cortex develop later. The results from the fMRI study investigating AoA at the word level were fascinating because they suggest that, even as adults, words are accessed in the way that they were learned. Adults were "sounding out" early-learned words in their heads. For late-learned words, their brains revealed that people were using meaning-based links to access their meaning.

34.4 THE RELATIONSHIP BETWEEN AoA AND SENSITIVE PERIODS

The rapid maturation of sensory and motor cortices has also been tied to the long-standing literature regarding the nature of critical periods. Evidence of AoA effects has been found in many nonlinguistic domains. For example, it is well-known that early deprivation or alteration of sensory input leads to impaired sensory perception in many species. This is known from the pioneering work of Hubel and Wiesel, two neurophysiologists who were interested in uncovering how the visual cortex develops. In a series of papers, they outlined how visual deprivation affected the neural structure of both the lateral geniculate nucleus of the thalamus and the primary visual cortex. This work found that young kittens had a sensitive period during which deprivation of visual input would lead to long-term visual impairments (Hubel & Wiesel, 1963; Wiesel & Hubel, 1963a, 1963b). Interruption of visual input in one eye, however, did not impair vision in adult cats. Since Hubel and Wiesel's groundbreaking findings, researchers in the field have found evidence of a sensitive period in cats, monkeys, rats, mice, ferrets, and humans (Banks, Aslin, & Letson, 1975; Fagiolini, Pizzorusso, Berardi, Domenici, & Maffei, 1994; Harwerth, Smith, Duncan, Crawford, & von Noorden, 1986; Huang et al., 1999; Issa, Trachtenberg, Chapman, Zahs, & Stryker, 1999; Olson & Freeman, 1980). Similar research also reveals critical period effects in the calibration of the auditory map by visual input (Brainard & Knudsen, 1998).

Sensory deprivation can also lead to problems in the motor system. For example, disruption of binocular experience can lead to problems that adversely affect smooth pursuit of moving objects and can lead to eyes

drifting when viewing stationary targets (Norcia, 1996). Hence, problems in the sensory domain lead to abnormalities of motor function.

The effects of AoA have also been seen in the learning of birdsongs, which has been conceptualized as involving three phases, sensory, sensorimotor, and crystallized (Brainard & Doupe, 2002). During the sensory period, a bird listens to the song of a tutor to form a template. Lack of exposure to an adult song during this phase leads to irregular songs that contain some species-specific characteristics. In the second sensorimotor phase, the bird learns to match the song to the template. During this phase, songbirds fine-tune their songs through practice. Auditory feedback is crucial during this time. In the final crystallized phase, birds are mature and can produce the species-specific song but may no longer be able to learn other songs. In short, learning of birdsongs also points to a sensorimotor basis for this early form of learning followed by a longer period in which a bird is no longer able to produce different types of songs.

Finally, differences in AoA have also been observed in higher-level nonlinguistic functions. Work with musicians has found effects of AoA at both the behavioral and neural levels. There is evidence that absolute pitch can only be learned by speakers of nontonal languages before the age of 7 (Deutsch, Henthorn, Marvin, & Xu, 2006; Trainor, 2005). In addition, the ability to synchronize motor responses to a visually presented flashing square has been found to differ significantly between groups of professional musicians as a function of AoA, even when these groups are matched for years of musical experience, years of formal training, and hours of current practice (Watanabe, Savion-Lemieux, & Penhune, 2007). Work using fMRI has found that there is evidence that early musical training correlates with the size of the digit representation in motor regions of the cortex (Elbert, Pantev, Wienbruch, Rockstroh, & Taub, 1995). In a similar vein, Schlaug, Jancke, Huang, Staiger, and Steinmetz (1995) found the anterior corpus callosum (one of two tracts that connects the right and left hemispheres) to be larger in musicians than nonmusicians, and largest for those who learned to play before the age of 7. Hence, the effects of AoA on behavior as well as neural representations in the music domain can be viewed as reflecting sensorimotor processing.

34.5 AoA AND SECOND LANGUAGE LEARNING

So far, I have considered how reliance on sensorimotor processing changes as a function of AoA. Results from a number of studies have found that as

brain maturation expands from primary to tertiary areas within sensorimotor cortex and extends into the frontal lobe, individuals begin to process information differently. The neurological changes that occur are also accompanied by changes in the concomitant behavior. This is captured in the way that researchers have conceptualized the learning of grammar as being based on the sounds of a particular language. It is also seen in the fact that sensitive periods during early development are observed mostly in basic sensory and motor functions. In the case of language, it involves multiple levels of processing that build on each other.

The fact that different aspects of language are differentially sensitive to age has also appeared in the second language learning literature. Second language learners often struggle learning to master the phonology and grammar of a new language. Furthermore, this effect changes as a function of age. The following section considers to what extent the effects of AoA on second language learning can also be conceptualized as involving sensorimotor processing.

34.6 PHONOLOGY IN A SECOND LANGUAGE

A number of studies have found that accent is related to the age of L2 acquisition. Asher and Garcia (1969) conducted a seminal study in this respect. A group of Cuban adults who had come to the United States between the ages of 6 and 19 were recorded as they spoke in English. A set of raters then decided how native-like their accents were. The results revealed a strong relationship between degree of nativeness and age of L2 learning. Since then, a number of studies have been conducted that show a clear linear relationship between AoA and second language accent (Piske, MacKay, & Flege, 2001).

If phonological development continues to occur across childhood and results in systems that are less and less able to adapt to a nonnative speech sound system, then we should expect that adults will also show these developmental effects. To investigate the link between language learning history and development of second language phonology, Susan Guion and colleagues have conducted a series of studies investigating the production of sounds. Guion's findings indicate that the independence of vowel categories in bilingual adults is dependent on when they learn their second language (Guion, 2003). In an early study, a group of Quichua–Spanish bilinguals were asked to pronounce a series of vowels in both languages. Quichua is a native dialect spoken in the area near Quito, Ecuador. Spanish has five vowels, a, e, i, o, and u. Quichua only has three vowels, which

correspond to the Spanish a, i, and u. There are also differences in the ways in which these vowels are spread out. Figures of these vowels reveal a triangular shape, with each vowel in Quichua corresponding to each vertex. To accommodate two additional vowels, Spanish stretches the i and u further away, making space for an e and an o. This results in a compressed vowel space in Quichua relative to Spanish.

Not surprisingly, monolinguals of each language will speak their non-native language with an accent either because they are spreading the vowels out too far away or because they are constricting them too much. Quichuan accents will appear in Spanish because of the fact that the latter has more vowels. They will tend to produce a Spanish e and i or an o and u using a sound that lies between these two categories. Similarly, Spanish speakers will tend to slur Quichuan vowels by spreading them too far. In the case of Quichua and Spanish, accents appear either because of the fact that too many vowels are trying to be constrained into a space or because too few vowels are trying to be expanded into the same space.

Guion tested a group of Quichuan–Spanish bilinguals who had learned Spanish at various ages. The results revealed a strong relationship between the AoA of each language and a particular participant's ability to pronounce the vowels. Simultaneous bilinguals were able to pronounce vowels in both languages accurately. Bilinguals who learned a second language between the ages of 5 and 7 were close to native-like for both languages. As the age of second language increased, the ability to represent both sets of speech sounds diminished. The most extreme case of this was in the individuals who learned a second language between ages 15 and 25. In this group, there was a strong bias toward using the first language to guide pronunciation of vowels in the second language. That is, late learners tend to build their second language sound system around an already established first language system. Hence, the second language is more dependent on the first language in late learners.

Results from Guion's studies revealed that independence of the two systems is greatest in simultaneous bilinguals but much less so in sequential bilinguals. Specifically, those who learned a second language after 5 years of age exhibit differing amounts of dependence on the first language, depending on the age at which the L2 was learned. Childhood bilinguals show a mild dependence of L2 on L1, whereas the late bilinguals' L2 vowel categories are very dependent on L1. In short, the older an individual is at the age when beginning to learn a second language, the more the first language sound system is entrenched.

So far, evidence that exposure to an L2 is driven by AoA has been presented. Infant learners show

incredible plasticity in the phonological system (Eimas, Siqueland, Jusczyk, & Vigorito, 1971; Kuhl et al., 2008; Werker & Curtin, 2005). They can learn to recognize sounds from another language even when that speech sound was lost during the first year (Kuhl, Tsao, & Liu, 2003). Children who learn a second language have softer accents than adult learners. One question that arises is how this dependence may play out in the recognition of phonemes by people with different second language AoAs.

Despite this early entrenchment, there is considerable evidence that later learners can recognize sounds in a second language (Flege). In one study, Flege, Munro, and MacKay (1995) tested a group of Italians who immigrated to Canada between the ages of 2 and 13 (early learners) or between the ages of 15 and 26 (late learners). The results revealed that early learners, in general, could distinguish English vowel sounds better than late learners. However, there was considerable variability. For example, early learners who used Italian often were found to differ from native speakers, whereas those who used it seldom were not. Furthermore, some of the late learners were able to distinguish these vowel sounds. Thus, early acquisition does not appear to be a guarantee that native-like L2 performance will be observed when recognizing speech sounds. Furthermore, it does appear that some late learners can learn to distinguish these sounds. The question is how late learners achieve speech recognition in their second language.

To uncover the mechanisms that differentiate early and late learning of a language, Archila-Suerte and colleagues asked a group of Spanish speakers who learned English at different points in childhood to rate whether two sound pairs were similar or different (Archila-Suerte, Zevin, Bunta, & Hernandez, 2012). The sounds were chosen such that some English sounds were similar to sounds in Spanish (SAF and SEF) and others were much less similar (SOF and SUF). Pairs of sounds were presented and people had to decide how similar the two sounds were using four different buttons that were marked as really similar, somewhat similar, somewhat different, or really different. Age of learning played a role when our participants had to decide that two items from the same category (SAF–SAF) were the same. Early learners, those who learned English before the age of 5, like monolinguals, showed four tight clusters for each sound. However, intermediate learners, who acquired English between ages 6 and 9, showed distinct but blurry clusters. Late learners, who acquired English after the age of 10, showed even blurrier clusters. Early learners, like monolinguals, were able to ignore slight variations in a sound to form a single sound category. Late learners used a very different strategy;

they used a relative comparison strategy to compare different sounds. Hence, like Flege and MacKay noted, late learners can be quite good at distinguishing between different phonological categories. However, the processes that late learners use for L2 speech sound recognition differ from those seen in early learners and monolinguals.

34.7 AoA AND THE BILINGUAL BRAIN

One of the first studies looking at bilinguals using positron emission tomography (PET) was conducted by Daniela Perani and colleagues. In this study, a group of late Italian–English bilinguals were asked to listen to stories in Italian, in English, or in an unknown language. When listening to stories in Italian, the native language, participants revealed larger areas of activity that extended from the temporal lobes up into Broca’s area. Many of the same areas were active when participants listened to the second language, English. However, the extent of this activation was reduced. Perani et al. suggest that later learned languages engage a smaller network than native languages when bilinguals listen to speech. Hence, the age at which an individual learns a particular language results in brain activity differences observed using PET.

In 1997, Kim and colleagues used fMRI to look at the nature of second language AoA in bilinguals *Nature* (Kim, Relkin, Lee, & Hirsch, 1997). While in the scanner, they were asked to say “in their head” what they had done the day before. They were given a cue that would tell them to think about something that happened at a particular time of day (morning, afternoon, or evening) and in a particular language (first or second). Researchers observed neural activity in both Broca’s and Wernicke’s areas to look at whether each language showed two distinct areas of activity or just one glob.

In Wernicke’s area, both languages showed an overlapping area of activity in all the people tested whether they learned their second language early or late in life. Kim et al., however, found something different when comparing neural activity in Broca’s area for early and late learners. In early bilinguals, brain activity for both languages was mostly overlapping. Brain activity for late bilinguals, however, showed two adjacent but clearly separate areas of activity. The findings from the study by Kim et al. have implications for results that we discussed previously. Specifically, the authors suggest that different areas of Broca’s area may be a reflection of the specialization in producing language at an early age. Hence, early bilinguals may come to represent the motor programs for each language in overlapping areas because of the fact that they learn to speak

both languages early in life. Late bilinguals learn one system first and then a second. The findings of Kim et al. support the view that once a first language is already firmly established, the second language builds around it in adjacent but clearly distinct areas.

The results from the Kim et al. study leave us with a few unanswered questions. The most important of these is, what aspect of the task leads to differences in neural activity across these two groups? The task used by Kim et al., with participants reciting to themselves what they did the day before, could involve a number of aspects of cognitive processing that go beyond simple motor planning. This task involves a memory component in that each participant had to recall activities of the previous day in a particular language. This task also involved self-talk in each language. Because we do not have a recording of exactly what each participant was saying, it is possible that participants may have produced a different amount or quality of speech in each language. Furthermore, it is unclear whether the retrieval of a memory in conjunction with having to turn it into a verbal code might have been responsible for the differences across groups. Finally, participants were producing sentences in each language. It is possible that differences in the way in which sentences were put together might have differed across groups and languages. Hence, we are not sure what aspect of language may have differed across languages. One possibility is that it was grammatical processing that differed, a point that we turn to next.

34.8 GRAMMATICAL PROCESSING AND AoA

The influence of AoA on grammatical processing has also been approached using neuroimaging methods. One of the earliest studies was performed by [Weber-Fox and Neville \(1996\)](#). In that study, a group of second language speakers who had learned English between the ages of 2 and 16 using electroencephalography (EEG) were recruited. Weber-Fox and Neville sought to test whether two EEG components might differ in learners who differed in their age of second language acquisition. The first component is a wave that peaks at approximately 200 msec after a stimulus has been presented. This early negative wave appears over left frontal sites and is hence termed the early left anterior negativity ([Friederici, Hahne, & Mecklinger, 1996](#); [Friederici & Meyer, 2004](#)). It is commonly seen when listeners are presented with sentences that have phrase structure violations such as “The pizza was in the eaten.” ([Friederici et al., 1996](#); [Friederici & Meyer, 2004](#)). The second wave, a positivity that peaks at approximately 600 msec, has been found to occur in sentences

that have grammatical violations and also in sentences that temporarily lure the reader into the wrong interpretation ([Osterhout & Holcomb, 1992](#); [Osterhout, Holcomb, & Swinney, 1994](#)). For example, the sentence “The broker persuaded to sell the stock was tall” leads people astray because a noun is expected after persuaded (i.e., persuaded me, the audience, or the seller).

Weber-Fox and Neville asked participants to read sentences that had grammatical violations such as “The scientist criticized Max’s **of** proof the theorem.” These sentences were designed to go wrong at the bolded word. Not surprisingly, learning English later in childhood modulated the size of early and late component EEG waves relative to monolinguals. The early negativity that appears in sentences with blatant errors in the parts of speech used (i.e., The scientist criticized Max’s **of** proof the theorem) was reduced in all second language learners, even when the age of L2 immersion occurred during the first 3 years of life. Furthermore, there was no indication of the brain signatures associated with reanalysis in individuals older than age 11. For those who learned the language between the ages of 1–10, however, this later component was present. The presence of a later component suggests that individuals who learn a second language during early or middle childhood perform reanalysis in a manner similar to that of monolinguals. In short, the early components of the brain waves were reduced in all second language learners. The late components were reduced in those who learned a second language after the age of 10.

In 2011, Eric Pakulak and Helen Neville followed-up this study by looking at the brain waves associated with grammatical errors in a group of late learners of English (who learned English between ages 10 and 12) who were matched to native English speakers in proficiency. Results revealed that native speakers showed both an early negativity and a late positivity for grammatical errors. Late learners, however, did not show such an early negativity. Furthermore, the late positivity showed a widespread pattern across the brain and extended for a longer time than that seen in native speakers. Similar results have also been observed by [Manolo Carreiras, Horacio Barber, and colleagues \(Dowens, Vergara, Barber, & Carreiras, 2010\)](#). These two studies confirm that late learners use other mechanisms to process grammar relative to native speakers.

Taken together, these three studies suggest that learning a second language, even during childhood, does not lead to a native-like pattern of electrical brain activity. The complete lack of an early negativity regardless of second language (L2) AoA suggests that automatic computation of grammatical processing may not occur in second language learners (for an alternative finding see [Rossi, Gugler, Friederici, & Hahne, 2006](#)).

Finally, one study that looked at artificial grammar learning showed that late learners are more likely to show an anterior negativity-P600 pattern of response after encountering a grammatical error when they have achieved relatively higher proficiency in that language (Morgan-Short, Steinhauer, Sanz, & Ullman, 2012). The use of a language that has the same phonotactics of the learners' language circumvents some of the difficulties associated with natural language acquisition. At the same time, phonological processing has been thought to play a role in early grammatical development (Demuth, Patroliia, Song, & Masapollo, 2012; Morgan & Demuth, 1996). Hence, the use of these artificial grammars may eliminate the varying source that distinguishes native and non-native speakers. It is important to note that learners of an artificial grammar did not reveal early negativity. The most common pattern across the majority of studies reveals that late learners do show later components of reanalysis necessary for controlled grammatical processing. Thus, detecting grammar errors in a second language relies to a greater extent on later components instead of early computation. Finally, there is some evidence that learning a second language later in life is associated with electrical activity in a larger brain network during reanalysis of grammatical errors relative to the network seen in native speakers.

In 2003, my colleague Isabell Wartenburger along with a group of other researchers, including Daniela Perani, wondered whether AoA might also influence the nature of brain activity using fMRI (Wartenburger et al., 2003). Building on Perani's previous work (Perani et al., 1998), Wartenburger compared groups of Italian–German bilinguals who had learned their second language either late or early in life. Participants were shown sentences that had errors of case, number, or gender in German as well as errors in number or gender in Italian. The results revealed increased activity for late bilinguals relative to early bilinguals in the prefrontal cortex in a region that was just above Broca's area. This superior portion of Brodmann area 44 is typically associated with the need to retrieve the speech sounds of a word (Poldrack et al., 1999). Hence, it appears that late learners appeared to access the speech sound of the article of a word to check whether it was correct. The early learners, however, showed no difference in the brain's blood metabolism when shown sentences with grammatical errors.

34.9 ISOLATING AoA

One issue that arises with studies that have looked at the brain bases of bilingualism is that AoA is often confounded with language proficiency. In the case of

two studies reviewed earlier, the Perani et al. study involving language comprehension and the Kim et al. study involving production, there are potential confounds with language proficiency. Traditionally, researchers have used two complimentary approaches to isolate effects of proficiency. The first approach involves the use of a statistical method in which the effect is minimized by using regression. The second approach is to create two groups that differ in their second language AoA but are identical in proficiency. This was the approach used by Wartenburger and colleagues.

Both of these comparisons have some limitations. When comparing monolinguals and bilinguals, we are left with the possibility that any differences in the latter group have to do with speaking two languages and not with having learned one language later. That is, it is unclear if the difference between these groups might simply be due to the comparison between individuals who learned a second language with those who did not. In addition, comparing second language learners with different AoAs does not resolve the question of whether a first and second language differ due to AoA. An important complementary approach would be to compare performance in a second language with that of a first language while equating for language proficiency across groups in both languages. Although Pakulak and Neville did this with event-related potentials (ERPs) in 2011, there has been very little work exploring this approach using fMRI.

Work by Hernandez and colleagues had picked up on a different pattern of English dominance in a very different group of subjects. For many years, data had revealed that when testing Spanish native speakers who became bilingual in childhood but became dominant in their second language, English. This dominance in English was found in tasks such as picture naming or word reading (Hernandez, Bates, & Avila, 1996; Hernandez & Kohnert, 1999; Hernandez & Reyes, 2002). In addition, Hernandez and colleagues were able to find a group of late Spanish learners who were highly proficient. This allowed the comparison of two groups who showed very similar language proficiency profiles but differed in AoA.

34.10 AoA EFFECTS DURING GRAMMATICAL PROCESSING

The nature of grammatical processing in bilinguals had been a topic considered by Elizabeth Bates and colleagues during the 1980s and 1990s. Of particular interest was uncovering how different languages differed in their grammatical properties. For example, we could take a sentence like "The dog are kicking the

cows” and ask native English speakers to choose the actor or subject of the sentence. The results reveal that even though there is a grammatical violation in subject–verb agreement, the majority of English speakers still choose the dog as the actor. Why is this? English is highly reliant on word order to indicate the subject of a sentence. There are some exceptions to this rule, but for the most part English speakers use the position of a noun in the sentence to determine its role.

Not all languages are built the same. Romance languages rely, to a much greater extent, on the verb to indicate the subject of a sentence. Other languages have particular case markings on a noun or its determiner to indicate a noun’s role. In addition, morphology is particularly vulnerable even in languages that utilize it frequently for grammatical purposes (Bates, Friederici, & Wulfeck, 1987). The variability across languages leads to a complex mapping issue in which grammatical functions appear to be senseless to those outside of the language. Because of this variability and the complexity of mapping across languages, it is very difficult to show transfer from the grammar of one language to the other (MacWhinney, 2004).

One example that captures this complexity well is grammatical gender. For an English speaker, the notion that grammatical items are masculine or feminine is grounded purely in semantics. The tendency to break-up the world into masculine and feminine categories extends beyond nouns that refer to sex-based gender. Interestingly, this bias also appears in children who have a tendency to judge artificial categories (i.e., buildings, elevators, and cars) as masculine and natural categories (flowers, trees, and birds) as feminine (Sera, Berge, del Castillo Pintado, 1994). The conceptual basis of nongrammatical gender also appears across languages (Boroditsky, Schmidt, & Phillips, 2003; Konishi, 1993). Finally, semantic gender may also be marked explicitly on personal pronouns (he, she, and it) or on nouns such as waiter and waitress.

However, certain languages extend the semantic nature of gender further. In romance languages, for example, the gender of a noun can be masculine or feminine and must agree with an adjective that qualifies it. This can be seen in Spanish phrases such as *el carro rojo*, which translates as the_{masc} car_{masc} Red_{masc}. People who speak nongender-marked languages such as English often wonder why grammatical gender even exists. Liz Bates argued that gender allowed a speaker to identify a noun without mentioning it (Bates, Devescovi, Hernandez, & Pizzamiglio, 1996; Bates, Devescovi, Pizzamiglio, D’Amico, & Hernandez, 1995). Spanish speakers may point to a pencil and a pen while exclaiming, *pasamela*, pass it to me. With enough proficiency, a Spanish speaker would pass the person a pen, *la pluma*, and not the pencil, *el lapiz*.

In short, for a speaker of a gender-marked language, gender helps to reduce the search space of possible nouns.

The final dimension of interest is that grammatical gender, at least in Spanish, also has a regularity dimension to it. Nouns with regular gender carry an -o ending for masculine nouns (i.e., *carro*), and others carry an -a ending for feminine nouns (i.e., *casa*). However, other words that end in other letters (such as s, t, z, n, r, e) are much less regular. These words can be masculine or feminine. For example, *la fuente* (the fountain) is feminine, whereas *el puente* (the bridge) is masculine. The regularity of these mappings allows researchers to see whether the lack of direct connection between ending and gender mattered.

In a first study, a group of monolingual Spanish speakers judged whether a noun in Spanish was masculine or feminine while being scanned with fMRI (Hernandez et al., 2004). In every block of items, half of the items were masculine and half were feminine. In addition, we had blocks with regular gender signaled by an -a or -o ending and blocks with irregular gender markings that were signaled by words ending in s, z, n, r, t, z, or e.

Gender decisions for irregular nouns in Spanish led to increased neural activity in three distinct areas, the anterior insula, as well as a superior and inferior portions of Broca’s area, relative to regular nouns. In addition, there was increased activity in the anterior cingulate gyrus, an area that is involved in tasks that require increased cognitive effort. The role of the anterior insula in articulation has been well-documented. Studies with patients who have difficulty with articulation, the physical movements associated with speech, have found that all of them have damage in the anterior insula, which lies just inside the surface of the cortex adjacent to Broca’s area (Bates et al., 2003; Dronkers, 1996). Broca’s area has also been associated with different aspects of speech. The lower portion has traditionally been associated with motor planning of speech (Broca, 1988; Graves, 1997). The upper portion has been found to be active in tasks that require people to access the speech sounds of a word. This area showed more activity when German native speakers were asked to produce the article (masculine, feminine, or neuter) when looking at the picture of a noun (Heim, Opitz, & Friederici, 2002).

From a psycholinguistic point of view, subjects were engaged in deeper phonological retrieval and more complex motor planning while using more cognitive effort. Irregular items are more difficult because they require monolingual Spanish speakers to create a small noun phrase when deciding whether a word is masculine or feminine. This involves accessing the speech sounds, planning a motor response, and preparing to articulate the word as revealed by the neural activity

in the superior and inferior portions of Broca's area as well as the anterior insula. Finally, there was increased activity in the anterior cingulate gyrus that served as an indicator of the added cognitive effort required in this irregular condition. Hence, the brain signature associated with irregular items is substantially different than that observed for regular items. This is true even in speakers who have only been exposed to one language in their lives.

34.11 COMPARING FIRST AND SECOND LANGUAGES

Grammatical gender does not come easily to English speakers, although it can be learned (Morgan-Short, Sanz, Steinhauer, & Ullman, 2010). One interesting question is whether grammatical gender can also be learned by those who have uneven exposure to a language. To assess the influence of early exposure, Au and colleagues tested a group of overhearers who had been exposed to a language in childhood but never spoke it (Oh et al., 2010, 2003). This group showed sensitivity to speech sounds above those seen in individuals who had never been exposed to a language. Subsequent studies explored grammatical processing in this population by presenting two objects (a red cow or some red cows) and asking a group of overhearers to form a sentence with them (Au, Oh, Knightly, Jun, & Romo, 2008). Au made this task challenging because grammatical agreement in Spanish involves both number and gender. For example, the red cows would be *las vacas rojas*. Although the plural extends beyond the noun in Spanish, notice that it is marked by an -s, similar to the way it is done in English. However, overhearers also had to match the gender of the determiner, noun, and adjective. By looking at these two different ways to signal grammar, Au et al. could determine whether early exposure benefits grammatical functions that are not present in the dominant language. Interestingly, overhearers, like low-proficiency non-native speakers, were unable to correctly identify gender errors (*la vaca rojo*) but were able to identify errors in number (*las vacas roja*). These results show that early overhearing may help with the basic elements of a sound system in a particular language. However, hearing a language does not help with all aspects of a language. In this case, grammatical rules that are particular to a language are not learned when a child is exposed to that language in a passive way during early childhood.

Work in my laboratory sought to exploit the difference between English and Spanish to understand AoA effects better. Because gender does not exist in its grammatical form in English, the experience of non-native

speakers would have differed substantially from that of native speakers. Specifically, native speakers would have early exposure to the grammatical rule, whereas native English speakers who learned Spanish in early adolescence would not. Hence, the fact that **grammatical** gender did not transfer easily from one language to the other allowed us to test the effects of AoA on grammar directly (MacWhinney, 2004).

In addition to the native English speakers who learned Spanish in adolescence, a group of early Spanish–English bilinguals was also recruited. This group had early exposure to Spanish at home but extensive exposure to English at school. Over time, education and immersion in the second language led to better language proficiency in English. This allowed us to match both early and late learners regarding English and Spanish proficiency. The greatest contributor to differences in brain activity would be the age at which Spanish was learned and not the particular proficiency in either language.

The results revealed increased activity for irregular items compared with regular items in the inferior portions of Broca's area. The surprising part was that both areas were adjacent to each other. The early Spanish learners showed activity in the area that was seen in monolinguals, one that is thought to be involved in motor planning. The late Spanish learners showed activity just below this. The activity was so extensive in the late learners that it spread into an adjacent portion that shows activity when people engage in retrieving the meaning of words.

These neural signatures clearly show that when a second language is learned, it has very different effects on people, even when ability in that language is matched across groups. For early learners, processing of gender involves more extensive motor planning much like monolingual Spanish speakers. Late learners, however, need to engage in a network that is involved in meaning retrieval. The problem is that this semantic extension is a less efficient way to represent grammatical gender. In short, English speakers appear to take advantage of existing language representations that they already have and then adapt them to learn Spanish during adolescence. The late learners tested in this study did not differ behaviorally from our early learners. Therefore, late learners can manage to retrieve gender correctly. However, their brains have to work harder and differently than that of native speakers.

34.12 AoA AND DEVELOPMENT

Earlier theoretical work in collaboration with Ping Li had suggested that early learning was associated with sensorimotor processing. There is clear evidence

to support this view. Processing of sensorimotor information is more privileged early in life. Lack of exposure to certain types of sensory information can lead to lifelong deficiencies. In a similar vein, deprivation in the motor domain can also lead to lifelong deficiencies, but only when it occurs early in life. One implication of this fits nicely with emergentist views of language development (Elman, 1995; Elman, Bates, Johnson, & Karmiloff-Smith, 1996; MacWhinney, 1999, 2002a, 2002b, 2004). Specifically, these views suggest that development provides the tools with which to build from the bottom up. Children learn language differently than adults; hence, early acquisition can lead to a different pattern of bilingualism relative to late acquisition. The interesting part is that late acquisition does occur and can be quite successful. Adults have both the bottom-up route used by children that is based on sensorimotor processing and a top-down route that involves declarative forms of memory (Ullman, 2001, 2005) as well as cognitive control mechanisms (Abutalebi, 2008; Green & Abutalebi, 2008). Hence, we could define this as the difference between sensorimotor processing and controlled processing across development. It is mapping out how these two different types of processing interact across time that will continue to yield interesting results for language development and for the nature of bilingual language processing (for a longer discussion see Hernandez, 2013).

35.1 INTRODUCTION

The ability to use two languages at will often marvels monolingual speakers and, at the same time, comes naturally to bilingual speakers who appear to do so without difficulty. The critical issue in this context refers to the cognitive processes and brain basis involved in controlling the two languages. In other words, what are the brain mechanisms that allow bilingual speakers to focus on one language while preventing interference from the non-response language?

This issue has been extensively explored by studying the ability of bilingual speakers to switch between languages. The ability to switch back and forth between languages according to the needs of the interlocutor is perhaps the activity that most often strikes monolingual speakers. In this chapter, we review some of the most relevant available evidence regarding the time course and the brain basis of language switching and how this information can inform models of language control. In doing so, we particularly focus on the studies exploring language switching in speech production and on how certain variables, such as language proficiency level, affect the brain network sustaining language switching.

35.2 LANGUAGE SWITCHING: INSTANTIATING THE PARADIGM

Language switching studies in language production usually involve participants naming aloud a series of stimuli (pictures, digits, etc.). There are two main instantiations of this paradigm. In the first one (trial-by-trial switching task), the language in which a given stimulus

has to be named is signaled by a cue (e.g., the picture's color) and the response language is randomly assigned to the stimuli. Crucially, there are two main types of trials: trials in which a picture is named in the same language as the language used in the immediately preceding trial (nonswitch trials) and trials in which the target language is different from the one used in the immediately preceding trial (switch trials). The so-called "language switch cost" is computed by comparing the performance in switch versus non-switch trials. In the second instantiation (blocked switching task), the language in which a given picture has to be named is "blocked," that is, participants name a series of pictures in only one language, and then a new block starts in which the other language is used. In the second instantiation, the "language switch cost" is calculated by comparing naming latencies between the different blocks. The argument is that if speech production in a given language (e.g., language A) affects the successive naming in the other language (e.g., language B), then comparing the same language (language B) after and before the use of the other language (language A) should incur cognitive and neural costs. To investigate this question, some authors compared the behavioral performance and the neural effects elicited by naming in language B in a first block of tasks versus naming in language B in a second block of tasks (i.e., after naming in language A in the first block) (Branzi, Martin, Abutalebi, & Costa, 2014).

Both the first and the second instantiations of the language switching task allow computing the "after-effects" of naming in one language on the performance of the other language (Branzi et al., 2014; Guo, Liu, Misra, & Kroll, 2011). However, the majority of the studies on bilingual language control used the trial-by-trial

instantiation of the language switching¹ task, sometimes accompanied by entire blocks of naming in dominant (L1) and non-dominant (L2) language (blocked conditions) (Christoffels, Firk, & Schiller, 2007).

It has been argued that the use of these two different naming contexts (mixed and blocked) allowed for testing different types of language control (“local” versus “global” control) and various timing aspects of the control processes (“transient” versus “sustained” control). In fact, it has been proposed that language control might be implemented in different ways (Green, 1998). The first one would act through a control process that globally adapts the activation levels of all lemmas in both languages (increasing activation for lexical representations of the target language and decreasing those of the non-target language). The second mechanism would act by locally suppressing the activation of any (specific) non-target language lemmas that escape the global inhibition process (see De Groot & Christoffels, 2006). Thus, bilinguals may use a whole-language control process to suppress a complete language subsystem affecting all lexical representations in that language (“global control”) and an additional control process that affects a restricted set of items (“local control”).

Beyond the representational scope of bilingual language control, there are also different processes related to the timing of such control (Christoffels et al., 2007). “Transient control” refers to reactive trial-by-trial control applied during the continuous switching between languages/tasks, and it is generally measured through “switch costs.” Conversely, “sustained control” refers to an proactive control influenced by the context in which a given language has to be produced. This type of control is applied for maintaining language/task sets throughout the whole task, and it is measured through the so-called “mixing cost”, that is, by comparing non-switch trials² in mixed versus blocked naming contexts (Braver, Reynolds, & Donaldson, 2003; Christoffels et al., 2007). It has been suggested that both “sustained” and “transient” components of control might be crucial for bilingual language production. In fact, many studies reported these two components as being differently involved in the control of L1 and L2 production.

Before explaining these issues in detail, we first describe the two different instantiations of language switching paradigm and the main relevant findings.

At the behavioral level, trial-by-trial switching paradigm reveals slower response times (RTs) for switch trials than for non-switch trials, indicating that switching

languages incurs a behavioral cost (Christoffels et al., 2007; Jackson, Swainson, Cunningham, & Jackson, 2001). Interestingly, however, several studies have revealed that the magnitude of the language switch cost depends, to some extent, on the relative proficiency of the two languages involved in a switching task. When there is a difference between the proficiency in the two languages, switch costs tend to be larger for the stronger language (i.e., L1) than for the weaker language (i.e., L2) (Meuter & Allport, 1999). That is, switching into the easy task (stronger language, L1) is more costly than switching into the difficult task (weaker language, L2). This pattern resembles that observed in domain-general switching tasks in which little language is involved (Martin, Barceló, Hernández, & Costa, 2011; Nagahama et al., 2001; Rubinstein, Meyer, & Evans, 2001) and has been taken to reveal the participation of inhibitory processes in bilingual language control. The Inhibitory Control model (see IC model by Green, 1998) explicitly predicts such inhibitory effects: because both languages are active even when naming in only one language (Colomé, 2001; Costa, Miozzo, & Caramazza, 1999; Kroll, Bobb, & Wodniecka, 2006), a control mechanism suppresses the activation of non-target lexical items, and this suppression is proportional to the amount of activation and potential interference of a given language. To be more specific, speaking in the weaker language (i.e., L2) requires engaging inhibitory control mechanisms that reduce or suppress the activation of the more ready representations of the stronger language (i.e., L1). Consequently, if in the next trial a response in the stronger language (i.e., L1) is required, then the speaker needs to overcome the lingering effects of the inhibition applied in the preceding trial, therefore delaying production (see *Task-set inertia* hypothesis in Allport, Styles, & Hsieh, 1994). Given that inhibitory processes are supposed to be proportional to strength of the language (Green, 1998), one would expect the stronger language (i.e., L1) to be more inhibited than the weaker language (i.e., L2), therefore leading to the asymmetrical switch cost (Meuter & Allport, 1999). Importantly, however, when participants are asked to switch between languages in which they have similar proficiency, then the asymmetrical switch cost goes away and the switch costs for both languages are of similar magnitude when switching not only between L1 and L2 but also between L1 and a much weaker L3 (e.g., Calabria, Hernández, Branzi, & Costa, 2012; Costa, Santesteban, & Ivanova, 2006).

¹The second instantiation (i.e., the “blocked switching task”) is very recent (Branzi et al., 2014; Guo et al., 2011; Misra et al., 2012; Strijkers et al., 2013).

²In the literature, “mixing costs” have been assessed by computing either the difference between mixed (switch and non-switch trials) and blocked conditions. (Koch, Prinz, & Allport, 2005; Los, 1996) or the difference between non-switch trials in mixed versus blocked conditions. (Rubin & Meiran, 2005).

These sorts of studies have been rather influential when trying to understand the cognitive processes behind bilingual language control and have highlighted how proficiency may affect such processes. The interpretation of the asymmetrical switch costs in terms of inhibition inflicted on the L1 has been one of the fundamental results used to support the IC model proposed by Green (1998). However, somewhat problematic for the IC account is that symmetrical switch costs have been reported not only for highly proficient bilinguals but also for unbalanced bilinguals during voluntary switching and with long preparation times (cue-stimulus intervals) (Christoffels et al., 2007; Gollan, & Ferreria, 2009; Verhoef, Roelofs, & Chwilla, 2009). Moreover, some other results (Runnqvist, Strijkers, Alario, & Costa, 2012) showed that semantic effects appear to survive language switching, suggesting that words from the non-used language are not inhibited during language production in the other language. Henceforth, alternative explanations that do not rely (or do not only rely) on inhibitory processes have been put forward (e.g., L2 overactivation account,³ for a review see Koch, Gade, Schuch, & Philipp, 2010, but also “L1 repetition benefit hypothesis” in Verhoef et al., 2009). At any rate, this sort of language switching instantiation is the kind that has been used most often in neuroscientific studies on bilingual language control.

As previously hinted, the use of the other instantiation of the language switch paradigm is very recent and has given special attention to the “after-effects” of naming in one language on the successive use of the other language without mixing the two languages in the same block. In this paradigm, naming latencies are usually compared across groups of participants. For example, while group 1 starts naming a block of pictures in L1 and then names them in L2, another group starts in L2 and subsequently does so in L1. The critical issue here is whether naming performance in the second block departs from naming performance in the first block while keeping the languages constant. Responses in an L2 do not seem very affected by whether they are given in the first block or rather after having named the pictures in an L1 (hence, the second block). However, responses in L1 are actually affected by the order of presentation. L1 naming is hindered after having named the pictures in an L2 (Branzi et al., 2014; Misra, Guo, Bobb, & Kroll, 2012). This effect appears to find a ready explanation in terms of inhibitory processes (see IC model,

Green, 1998), according to which naming the pictures in the weaker language entails a strong inhibition of the corresponding representations in the L1, inhibition that then affects negatively subsequent naming in the L1 (see also Meuter & Allport, 1999 for similar explanation in the trial-by-trial language switching task).

Regardless of whether the inhibitory account of these effects is the correct one, these results highlight two important factors to consider when exploring the brain basis of language switching and the corresponding links to bilingual language control. First, the neural correlates of language switching need to be considered in the context of the language proficiency of the bilingual speaker. That is, it is likely that the neural substrates of language switching and, consequently, those of bilingual language control depend on the proficiency level attained by the bilingual speaker in the two languages (Costa & Santesteban, 2004). Second, for cases in which language proficiency is very different in the two languages, special attention needs to be given to the direction of the language switch. That is, it could be that the brain networks involved in switching into the weaker language are different from those involved in switching into the stronger language. It is worth mentioning that besides language proficiency, other sociolinguistic variables such as language exposure and/or frequency of language switching have been shown to affect somehow bilingual language control (Christoffels et al., 2007; Perani et al., 2003; Prior & Gollan, 2011). Therefore, such factors also need to be taken into consideration when assessing the behavioral and neural effects related to bilingual language control in switching tasks.

In the next sections, we review some relevant studies that describe the time course and the neural correlates of bilingual language control.

35.3 EVIDENCE FROM ELECTROPHYSIOLOGY

During the past decade, the event-related potentials (ERPs) technique has been largely used to study the time course of bilingual language control. Behavioral differences between L1 and L2 processing can be explained by calling into account different control mechanisms (e.g., L1 inhibition, L2 overactivation). Hence, ERP studies were designed to reveal whether such behavioral differences between L1 and L2 were due to the

³According to “proactive interference” accounts, switch costs would primarily reflect the passive *after-effects* of previous active control processes (i.e., *task-set inertia*), which result in both positive and negative priming of task sets (Allport et al., 1994; Allport & Wylie, 1999; Wylie & Allport, 2000). Hence, regarding the origin of switch costs and related asymmetries, there are at least two equally good explanations within the “proactive interference” accounts (Allport et al., 1994; Allport & Wylie, 1999; Wylie & Allport, 2000). One is that switch costs origin because of previous task inhibition (Green, 1998; Meuter & Allport, 1999). The other possibility is that at the origin of switch costs and related effects, there is a carryover effect of the activation of the previous task on the successive one.

implementation of qualitatively different control mechanisms (as reflected by different effects at different ERP components) or rather to the recruitment of the same control mechanisms but to a different extent (as reflected by smaller or larger effects at the same ERP component).

The most common ERP component associated with language control mechanisms is the so-called N200 component (Christoffels et al., 2007; Jackson et al., 2001; Misra et al., 2012; Verhoef et al., 2009). This negative deflection (peaking at approximately 250–350 ms after stimulus onset) has been generally described as an index of general control processes (Nieuwenhuis, Yeung, & Cohen, 2004). Even though it is still unclear whether the N200 component reflects inhibitory control processes (Falkenstein, Hoormann, & Hohnsbein, 1999) or response conflict monitoring (Bruin, Wijers, & Van Staveren, 2001; Donkers & van Boxtel, 2004; Nieuwenhuis, Yeung, van den Wildenberg, & Ridderinkhof, 2003), in language switching studies it has been often attributed to inhibitory control applied during bilingual speech production (Christoffels et al., 2007; Jackson et al., 2001; Misra et al., 2012; Verhoef et al., 2009).

As previously described, at the behavioral level trial-by-trial language switching paradigm reveals slower RTs for switch trials than for non-switch trials, indicating that switching languages incurs a behavioral cost. An additional observation is that this switch cost becomes asymmetrical when the L2 proficiency is quite different from that of the L1 (Meuter & Allport, 1999). Hence, if the linguistic switch cost originates from the suppression of the non-target language (see IC model, Green, 1998), a greater ERP N200 negativity for switch than for non-switch trials would be expected. Regarding the asymmetries of switch costs, if the switch-related modulation of the N200 component is associated with response suppression during language switching, then there should be an increased modulation (switch–non-switch difference) of this negativity on L2 trials (when the L1 response needs to be inhibited) compared with L1 trials. Interestingly, this result was observed by Jackson et al. (2001), along with longer RTs to switch to L1 than to switch to L2.

In detail, Jackson et al. (2001) studied a group of unbalanced bilinguals who were presented with digits to be named in either their L1 or their L2 in a predictable fashion. The language to be uttered was signaled by a visual cue (the color of the digit). Behavioral results revealed an asymmetrical pattern of switch costs, with larger costs for switching into the L1 than into the L2.⁴ ERP results showed an increased N200

negativity for switch versus non-switch trials only when responses were given in the L2.

These findings strongly suggest that inhibitory processes are involved in bilingual language control. However, this conclusion is undermined by the fact that subsequent ERP studies were not able to replicate these observations. In fact, these studies reported somewhat inconsistent results related to the N200 component. Sometimes the N200 effects have been found in the opposite direction, with more negative deflections for L1 non-switch versus switch conditions (Christoffels et al., 2007), whereas other studies failed to observe any modulation of the N200 component regarding switch cost effects (Martin et al., 2013; Verhoef et al., 2009).

In Christoffels et al. (2007), a group of moderately proficient German–Dutch bilinguals named pictures either in their L1 or in their L2 (blocked language conditions), or they switched between languages in an unpredictable manner (mixed language conditions). This experimental design allowed the dissociation of the effects of the “transient” and “sustained” components of language control. Behaviorally, “transient” processes for L1 and L2 were of the same magnitude, as revealed by symmetrical switch costs. ERP results relative to switch costs showed an increased N200 negativity for the L1 only (this effect was absent for the L2) in non-switch trials as compared with switch trials in mixed language conditions. Behavioral “mixing costs” reflecting “sustained” processes revealed an asymmetric pattern: naming latencies in L2 were not affected by naming contexts, whereas naming latencies in L1 were slower in the mixed condition. Furthermore, authors observed an enhanced N200 negativity in the ERPs for non-switch trials compared with blocked conditions, irrespective of the language in the first time-window (275–375 ms). Interestingly, in a second time-window (375–475 ms), authors found enlarged negative ERP amplitudes for blocked compared with non-switch trials (mixed language conditions) for L1, but not for L2. This “frontal negativity effect” found for L1, but not for L2 was taken to reflect that bilinguals control their two languages by adjusting selectively the availability of the L1 only. This result supported by behavioral mixing costs for the L1 only was taken as evidence of sustained inhibitory control (Green, 1998) applied to the L1 to favor L2 production. Conversely, the observation of symmetrical switch costs in RTs and relatively small effects of switching in the ERP data led authors to conclude that their results did not support the presence of reactive inhibition in bilingual language control (Green, 1998).

⁴Note that the asymmetrical pattern of switch costs was due to a difference between the L1 and the L2 for non-switch trials, with faster RTs for L1 than for L2. Instead, RTs for switch trials were identical between the L1 and the L2. Note that these data do not replicate exactly those reported previously by Meuter and Allport (1999). Specifically, Jackson et al. (2001) did not obtain the crossover interaction pattern (i.e., L1 RTs longer than L2 RTs for switch trials) obtained by Meuter and Allport (1999).

Verhoef et al. (2009) obtained a quite different pattern of results regarding the aforementioned studies. In this study, unbalanced Dutch–English bilinguals performed a language switching task where preparation time (cue-stimulus interval) was manipulated to test whether the asymmetries in switch costs were due to L1 slower RTs on switch trials (IC hypothesis, see Green, 1998) or rather to an L1 repeat benefit on nonswitch trials (L1 repeat benefit hypothesis). The results revealed that the occurrence of asymmetrical or symmetrical switch costs did not depend on language proficiency, but rather on preparation time (short preparation times elicited asymmetrical switch costs whether long preparation times elicited symmetrical switch costs), and that the modulation of the N200 ERP component, previously taken as the expression of language inhibition (Jackson et al., 2001), was only sensitive to preparation times. Based on these results, the authors concluded that bilinguals could use inhibition as a strategy during language switching but do not need inhibition to control their language use. In accord with this conclusion, Martin et al. (2013) tested two groups of bilinguals (early and late Catalan–Spanish bilinguals) and failed to reveal any modulation of the N200 component in relation to linguistic switch costs.

The evidence reviewed indicates a complex scenario. The behavioral patterns of switch costs and the ERP components related to inhibition seem to be modulated by other up-to-date unknown factors besides language proficiency. This observation suggests that some caution should be exercised when drawing strong conclusions from these nonsystematic observations.

At present, just a few ERP studies revealed the time course of the effects related to language control by using the other instantiation of language switching. Misra et al. (2012) used a “blocked switching task” to investigate how performance in one language is affected by the previous use of a different language. Hence, two groups of unbalanced bilinguals took part in the study. The first one named a set of pictures in the L1 (two blocks of naming) and, subsequently, the same set of pictures in the L2 (two blocks of naming). The second group instead named a set of pictures in the L2 (two blocks of naming),

and then the same pictures in the L1 (two blocks of naming). Therefore, to assess whether naming in one language was affected by previous use of the other language, authors compared across the two groups the third versus the first block of naming in the same language. Results indicated that naming in L1 was slowed by previous naming in the L2 as compared with naming in L1 without previous use of any language (i.e., first block). Conversely, the L2 was not negatively affected by the previous use of the L1. This asymmetrical pattern of RTs, which resembles that of trial-by-trial language switching tasks, was accompanied by ERP effects in the N200 time-window (Figure 35.1). Specifically, it was found that naming in L1 after naming in L2 elicited an enhancement of the N200 component, as compared with naming in L1 in the first block. In contrast, naming in L2 after L1 did not modulate the N200 component. Overall, these results have been taken as evidence of inhibition of the L1 during naming in the L2, with this inhibition having a negative after-effect when naming the same pictures later in L1.

A recent study with highly proficient bilinguals (Branzi et al., 2014) revealed a pattern of RTs similar to that found by Misra et al. (2012), that is, naming in L1 was hindered by previous use of the L2. Interestingly, this was found for both pictures that had to be named in the two languages or only in one (i.e., repeated and unrepeated pictures), suggesting that language control is applied globally on the whole non-target language set. However, differently from what was reported by Misra et al. (2012), the ERP effects of language control occurred in an earlier time-window than the N200, that is, in the P200 time-window. The ERP P200 component has been associated with the ease of lexical access (Costa, Strijkers, Martin, & Thierry, 2009; Strijkers, Baus, Runnqvist, Fitzpatrick, & Costa, 2013; Strijkers, Costa, & Thierry, 2010; Strijkers, Holcomb, & Costa, 2011) rather than with inhibitory control processes. In accord with other recent findings (Strijkers et al., 2013), these results suggest that the way language control applies in bilingual speakers might be different for highly and low-proficients. Specifically, language control might not rely on inhibition in the first case.

FIGURE 35.1 Grand average ERPs for naming pictures in L1 (left panel) and in L2 (right panel). First block (in green) represents the first time that pictures were named in L1 or in L2. Third and fourth blocks (blue and red) represent the third and the fourth times that pictures were seen. In these blocks pictures were named in L1 or in L2, after naming in L2 and in L1 (in the first two blocks), respectively. Note that negative is plotted up. Adapted from Misra et al. (2012) with permission from the publisher.

An interesting aspect of the studies presented refers to the fact that similar patterns of behavioral results may be related to qualitatively different control processes driven by L2 proficiency.

It is evident that when taking into account more variables, the image drawn from these reviewed studies becomes quite complex. As already mentioned, one such variable is language proficiency. Different patterns of behavioral and ERP effects between groups of bilinguals with different levels of L2 proficiency suggest that this factor may influence the way in which bilinguals control their languages. However, given that many of these studies were conducted with bilinguals with low or medium proficiency in the second language, much research is needed to address whether this is the case.

Besides proficiency, other variables may influence the way in which bilingual language control is applied. One of them is the “frequency of language switching” in daily life (Prior & Gollan, 2011). As previously hinted, Christoffels et al. (2007) revealed that bilinguals who were moderately proficient in their second language showed symmetrical switch costs between their L1 and their L2. This pattern, typically observable in highly proficient bilinguals, has been the argument for language-specific control mechanisms driven by L2 proficiency (Costa et al., 2004, 2006). Because bilingual participants in Christoffels et al. (2007) were only moderately proficient in L2, the authors hypothesized that the symmetrical pattern of switch costs was due to the fact that these participants were accustomed to switch frequently between languages in daily life. Hence, in addition to L2 proficiency and, daily experience with language switching may also boost the language control system and influence how language control mechanisms are applied.

It has also been proposed that some differences in the experimental designs could explain the different outcomes in these studies. For example, Christoffels et al. (2007) suggested that the different ERP results obtained in comparison with those of Jackson et al. (2001) could be explained by differences in the experimental design. That is, in Christoffels et al. (2007), participants had to switch between the L1 and the L2 in an unpredictable manner, whereas in Jackson et al. (2001) the occurrence of switch trials was totally predictable (e.g., every second trial). Even though the effect of predictability of language switches on the ERP components has yet to be established, the N200 component is particularly sensitive to context (Nieuwenhuis et al., 2003). Hence, this aspect could have influenced the way in which the N200 ERP component related to language control was modulated in these two studies (see also Martin et al., 2013).

Verhoef et al. (2009) provided an example of how experimental design manipulations could affect the

pattern of behavioral and ERP results. In fact, authors revealed that preparation times influenced not only the pattern of switch costs but also the effects at the N200 time-window. These results suggested that the behavioral pattern of switch costs was not proficiency-dependent, unlike what Costa and Santesteban (2004) proposed, given that in a group of unbalanced bilinguals short–long preparation times elicited different patterns of switch costs. Even if this result suggests that high proficiency in an L2 is not a necessary prerequisite for symmetrical switch costs, the fact that the N200 component was sensitive to preparation times but not to language switching effects makes it difficult to establish whether this component has a key role in bilingual language control.

Overall, the current set of ERP findings does not provide consistent evidence and leaves open the question of the mechanisms involved in bilingual language control. Importantly, we believe there is still a need to address the weights of different factors (i.e., language proficiency, daily frequency of language switching) in modulating the ERP components and behavioral effects related to bilingual language control in language switching tasks.

The neuroimaging findings represent an important source of evidence to understand the functional significance of the ERP components related to language control. For example, the N200 component has been related to a specific neural generator: the anterior cingulate cortex (ACC) (Ladouceur, Dahl, & Carter, 2007; Van Veen & Carter, 2002). This brain structure has also been found to be involved in many language switching tasks and has been referred to as specific language control mechanisms (Wang, Xue, Chen, Xue, & Dong, 2007). In the next section, we review the most important functional magnetic resonance imaging (fMRI) studies in the language switching literature, which describe how proficiency level can affect the brain network sustaining language switching.

35.4 THE NEURAL CORRELATES OF LANGUAGE CONTROL: A FRONTAL, PARIETAL, AND SUBCORTICAL NETWORK

A number of neuropsychological studies have presented patients showing selective linguistic alterations and/or pathological language switching (Abutalebi, Miozzo, & Cappa, 2000; Fabbro, Skrap, & Aglioti, 2000; Paradis, 2001). These cases suggest the existence of specific brain areas involved in language control. With the complementary aid of neuroimaging techniques, brain areas such as the left caudate, the ACC, the lateral prefrontal cortex, and the left inferior parietal cortex have been proposed to conform the language

control network (Abutalebi & Green, 2007). These brain areas were not specifically dedicated to this aim but acquired a specific role in language control as a part of its general function.

The brain lesion most frequently related to pathological language switching in bilinguals is that affecting the left basal ganglia (Abutalebi et al., 2000; Adrover-Roig et al., 2011; Aglioti & Fabbro, 1993). The general role of this area is to integrate information from multiple brain regions to shape motor learning. In the case of bilinguals, this area is required to establish the adequate motor language program including language planning, selection, and switching. A second area involved in language control is the ACC, which participates in the monitoring of different response alternatives during conflict processing (e.g., Botvinick, Braver, Barch, Carter, & Cohen, 2001; Botvinick, Cohen, & Carter, 2004; Braver, Barch, Gray, Molfese, & Snyder, 2001). In the case of bilinguals, the ACC may participate in the control process of L1 or L2, and in error detection and selective attention during language monitoring. Consistent with this role, Fabbro et al. (2000) reported a case of pathological language switching after a lesion in the left ACC. A third area involved in language control is the left lateral prefrontal cortex including the dorsolateral and ventrolateral parts. These parts exert general executive control functions over behavior in response to stimuli. For instance, when bilinguals named pictures or read words aloud in their L2, this area was more activated in highly proficient bilinguals than in monolinguals (Jones et al., 2012). Thus, the left lateral prefrontal cortex participates actively in the language control network by exerting a role in response selection and inhibition and in working memory. The last part of the brain proposed to participate in the network is the left inferior parietal lobe that participates in the maintaining of language representations in working memory.

The language control network described seems to be somehow affected by the language proficiency level in the second language. For example, bilinguals with high proficiency in the two languages (Garbin et al., 2011) engage different brain areas when switching between L1 and L2 as compared with low-proficient bilinguals (Wang et al., 2007). Note also that the language control network seems to be functionally influenced by sociolinguistic aspects other than language proficiency. For example, Perani et al. (2003) examined the role of age acquisition and language exposure/usage in early and highly proficient Catalan-Spanish bilinguals by means of a fluency task performed in the two languages. Authors revealed the lexical retrieval in the language acquired earlier in life was associated with less extensive activation in the brain. Language exposure/usage modulated the brain areas involved in lexical retrieval. In fact, in one of two groups of participants, those who

were less exposed to the L2 showed larger activations during L2 lexical retrieval. These results indicated that in addition to language proficiency, also age of language acquisition and language exposure/usage are crucial factors in determining the neural pattern during lexical processing in bilinguals. This conclusion is in accord with recent ERP evidence suggesting that different linguistic experiences (early versus late acquisition of the L2) in bilinguals may affect the way in which the brain recruits language control (Martin et al., 2013).

Taken together, the network described, which consists of the prefrontal cortex, the ACC, the posterior parietal cortex, and the basal ganglia, constitutes an efficient brain network for language selection and control. In the next section, we describe how this network is specifically engaged when bilinguals have to switch between languages, because language switching relies heavily on cognitive control (Monsell, 2003) and how L2 proficiency can influence this activity.

35.4.1 The Neural Correlates of Language Switching

Neuroimaging techniques like positron emission tomography (PET) and fMRI have been used during the past 20 years to measure brain activity. They provide accurate information about time course of brain activity, and especially about brain localization of this activity. Initial studies on bilingualism were more focused on the representation problem, that is, in knowing whether both languages were represented in the same or different parts of the brain (Kim, Relkin, Lee, & Hirsch, 1997; Perani et al., 2003). Once the great overlapping in the brain activity for L1 and L2 representations was determined, the remaining question was to investigate how language control is exerted in the brain (i.e., how these overlapping brain areas are recruited for language selection, language inhibition, and language switching).

As in the ERP studies, the different fMRI experiments conducted to investigate language switching have been designed to investigate “sustained” and/or “transient” control mechanisms in language control. As previously introduced, both “sustained” and “transient” control processes are important for language control and both processes may be best characterized in a qualitatively different way and subserve different aspects of language control (Christoffels et al., 2007).

“Sustained” activity was studied by Hernandez, Martinez, and Kohnert (2000) and Hernandez, Dapretto, Mazziotta, and Bookheimer (2001) by comparing brain activation in early and highly proficient Spanish–English bilinguals during naming blocks in one language with naming in mixing blocks in either L1 or L2 (fixed order). Mixed compared with blocked naming conditions

increased the activation of the left inferior frontal cortex and the bilateral dorsolateral prefrontal cortex for the two languages. These results suggest that switching between languages requires the extra participation of executive control areas. Similar results (bilateral activation of dorsolateral prefrontal cortex) were obtained by Wang, Kuhl, Chen, and Dong (2009) in late, low-proficient, Chinese–English bilinguals using a single digit naming task in mixed and blocked conditions. Also, they found an additional activation in the supplementary motor area (SMA) (see Guo et al., 2011 for similar results in low-proficient bilinguals). Interestingly, Wang et al. (2009) revealed some dissociation between the two languages for sustained control. The mixed condition elicited the activation of the left middle frontal gyrus and right precuneus relative to blocked naming in L1 (Chinese). The mixed condition as compared with the blocked naming in L2 (English) instead revealed the activation of a large network of brain areas: the bilateral middle frontal gyri, the cerebellum, the left inferior frontal gyrus, and the SMA. This recruitment of frontal areas for both languages may reflect proactive processes necessary to regulate the activation level of the two languages when the interference is high (i.e., mixed condition) (Braver et al., 2003). In accord with this observation, Ma et al. (2014) have explored sustained control in a group of Chinese–English unbalanced bilinguals, relatively highly proficient in their L2. In detail, authors revealed that switching between languages (mixed condition) as compared with naming in L1 (blocked L1 condition) elicited the activation of two large clusters. The first one included the left inferior frontal gyrus, the SMA bilaterally, the left insula, and the basal ganglia (including caudate and putamen portions). The second big cluster peaked into the left inferior parietal gyrus and extended to the left supramarginal gyrus and the angular gyrus and precuneus. Switching between languages (mixed condition) as compared with naming in L2 (blocked L2 condition) elicited activations mainly in the left inferior frontal gyrus, the bilateral precentral gyrus and SMA, the bilateral inferior parietal gyrus, the bilateral fusiform, the left lingual gyrus, the left inferior temporal gyrus, as well as the hippocampus bilaterally. These results revealed a neural dissociation that suggests that the sustained mechanisms for L1 and L2 involve different levels of control demands. This may be taken to reflect that when competition increases because of the need to alternate the two languages, the level of activation of the L1 needs to be reduced to favor L2 production. According to Ma et al. (2014), this might be achieved through the coupling between the frontal and basal ganglia brain regions.

These evidences suggest that language proficiency may affect the way in which sustained control processes are applied to regulate the availability of words of the two languages during speech production.

In a different study, Abutalebi et al. (2008) studied highly proficient bilinguals (university students of the Translation Department) using a similar procedure with a random presentation of cues to name in the L1 or in the L2. Besides the activation of left Broca's area, it was reported that naming in L1 in the bilingual context (where subjects had to select L1 or L2 nouns following a cue) compared with monolingual contexts (where subjects had to select L1 nouns or L1 verbs following a cue) induced an increased activation in the left prefrontal cortex and specifically engaged the left caudate and the ACC. Strikingly, this pattern of activity was absent for the same L1 nouns when the same subjects were placed in a monolingual context, therefore highlighting the crucial role of these neural structures in language control and particularly in language switching.

As in ERPs, different studies have used the first instantiation of the language switching paradigm designed to study “transient” effects. For example, Wang et al. (2007) applied this paradigm to a group of late Chinese–English bilinguals. The overall switching condition when compared with non-switching condition activated the language control network, including the left and right dorsolateral prefrontal cortex, the right ACC, and right caudate. When considering directional changes, the authors observed an asymmetry in behavioral switch costs, such as a larger cost present when switching to the L1 than when switching to the L2. The notion that there is competition between languages predicts that increased executive processes are recruited to allow L2 production compared with L1, especially in the case of low-proficient bilinguals. In line with this prediction, Wang et al. (2007) observed that switches from L1 to L2 (“forward switching”) activated the left ACC/SMA, whereas the switches from L2 to L1 (“backward switching”) did not activate any brain area within the language control network (Figure 35.2).

In a subsequent study, Wang et al. (2009) studied “transient” changes of language in low-proficient bilinguals using a single digit naming task. They replicated behavioral asymmetries of switch costs (larger switch cost to L1 than to L2) and that switching from L1 to L2 (“forward switching”) activated the language control network (left SMA, left dorsolateral prefrontal cortex, and left inferior parietal lobe), but the results for overall switches and switches from L2 to L1 (“backward switching”) did not show activations in areas of the language control network. In a further study using the first instantiation of language switching paradigm, Garbin et al. (2011) studied a group of early and highly proficient bilinguals and found a different pattern of results. Switches from L1 to L2 (“forward switching”) activated the left caudate, whereas switches from L2 to L1 (“backward switching”) activated the SMA/ACC (Figure 35.3).

FIGURE 35.2 Brain regions involved in “forward switching” (from L1 to L2) relative to L2 non-switching (left panel) and in “backward switching” (from L2 to L1) relative to L1 non-switching (right panel).

FIGURE 35.3 Brain regions involved in “forward switching” and “backward switching.” From Garbin et al. (2011) with permission from the publisher.

At the neural level, different brain areas appear to be engaged during language switching and, interestingly, functional data indicate that the nature of this may alter with L2 proficiency, consistent with a change from controlled to more automatic L2 processing (Abutalebi & Green, 2007).

Abutalebi et al. (2012, 2013) used a different strategy based on the comparison of the process of language switching in bilinguals to a within-language switching task in monolinguals. The first study focused on the ACC and described this brain area as tuned by bilingualism to resolve cognitive and language conflicts (Abutalebi et al., 2012). The second study compared multilinguals with high proficiency in the L2 and poor proficiency in the L3 with monolinguals⁵ while performing the first instantiation of the language switching paradigm twice (once with L1 and L2, and the other with L1 and L3). In this study, authors were particularly interested in evaluating how language proficiency modulates the brain network of bilingual language control during a language switching task. The crucial finding of this study is that the pre-SMA/ACC participated in language switching regardless of individual proficiency, whereas the left caudate only was active when switching from L1 to the less

proficient language (L3). Contrasting with these results, no neural significant differences were found in this study when comparing direction of switches within the multilingual group.

These studies suggest that language proficiency has an important role in determining how brain areas are recruited for language control, both for the “sustained” and “transient” components.

Besides these adaptations of the switching behavioral paradigms, other studies have used perceptive tasks. Crinion et al. (2006) used a classical semantic priming procedure to compare neural activation when the prime and the target belong to the same language or to different languages. Results showed an activation of the left caudate during language switching compared with nonlanguage switching trials across three different groups of highly proficient bilinguals. A different perceptive task was used by Abutalebi et al. (2007) in a sample of early, highly proficient bilinguals with more experience in L2. They used narratives that included unpredictable changes of languages that might be regular or irregular depending on the respect or violation of the constituents of sentence structure. The comparison of switch and nonswitch trials activated more language areas, including the left inferior frontal gyrus and

⁵The switching task for monolinguals required to switch between two different categories of naming in the same language: nouns and verb forms.

middle temporal gyrus. Switches into L1 (the less exposed language) activated the left caudate and the ACC, whereas switches into L2 did not activate the language control network.

In general terms, the reviewed studies provide an acceptable uniformity of the results highly consistent with brain areas proposed to form the language control network. This uniformity is greater if we attend to the special role played by variables, such as the type of task and proficiency of bilinguals. The studies designed to investigate “sustained” processes in language control showed consistent activations in the dorsolateral prefrontal cortex and the SMA/ACC, whereas those more related to the “transient” process circumscribed the neural basis of language switching to the SMA/ACC. As in other conflict processes, the language conflict seems to require the participation of ACC that may exert the functions of monitoring and resolution. The dorsolateral prefrontal cortex would remain a global cognitive control mechanism of language conflicts. The role of the left caudate seems to be restricted to language in early and highly proficient bilinguals in tasks that involve language production and comprehension (see Ma et al., 2014 for involvement of caudate in late bilinguals more proficient in L2). Even though its specific role is not clear because in some studies it participated in “backward switching” and in others it appeared to be more related to “forward switching,” the diverse studies were consistent in showing a role in detection of language switching when both languages were acquired early. Finally, the left inferior parietal lobe is the brain area of the language network less often detected, probably due to the low working memory demands of the used paradigms. The activation of this area has only been found in tasks using the same stimuli (i.e., numbers) and responses. Maybe its role would be more prominent in translation tasks (Price, Green, & Von Studnitz, 1999).

35.5 CONCLUSION

In this chapter we reviewed the main literature on bilingual language control, giving special attention to the studies that have made use of language switching paradigms. When combining behavioral, electrophysiological, and neuroimaging evidence, it is evident that some sociolinguistic variables, such as language proficiency, appear to influence the way in which language control is applied. This aspect is well-supported by both behavioral and neuroimaging evidence. However, more research is needed to determine how other sociolinguistic variables, besides language proficiency, can shape language control ability in bilinguals. Also, a distinction between different components of attentional control appears to be crucial within the

linguistic domain. “Sustained” and “transient” components of attention show dissociable effects in the control of the two languages of a bilingual, as reflected by the recruitment of different brain areas.

36.1 INTRODUCTION

Signed languages used in deaf communities are naturally occurring human languages that exhibit the full range of linguistic complexity found in spoken languages. Just as there are a multitude of spoken language communities around the world (e.g., speakers of Quechua, Farsi, Portuguese, and English), there are many different sign language communities (e.g., signers of Langue des Signes du Québec [LSQ], Deutsche Gebärdensprache [DGS], Taiwan Ziran Shouyu [TZS], and British Sign Language [BSL], to name but a few). Although the histories and geographies of signed languages are less well-documented, it is known that signed languages arise spontaneously, over several generations, from isolated communities that have a preponderance of deaf individuals. Such situations are not as rare as one might think because genetic influences on the transmission of deafness are well-attested (Groce, 1985; Sandler, Meir, Padden, & Aronoff, 2005).

The comparison of signed and spoken human languages provides a unique opportunity for investigating the biological substrates of human language. The existence of two fundamentally different forms of human language, one expressed by manual and body articulations and perceived by the visual system, and one expressed by the vocal system and perceived by the auditory system, allows researchers to identify neural systems that are common to all forms of human linguistic communication from those that reflect a language modality of expression.

Neurolinguistic studies of life-long signers have documented patterns of sign language disturbances after acute brain damage and have helped to identify brain regions that are critical for sign language processing. These studies indicate remarkable parallels between left hemisphere regions that support signed language

processing and left hemisphere regions that support spoken language processing. Collectively, the pattern of hemispheric asymmetries found in language holds independently of whether the language involved is signed or spoken. These studies point toward a common network of brain regions that support the human capacity for linguistic communication. Moreover, these studies have helped advance our understanding of the homologies between the linguistic properties of spoken and signed languages. Research using neuroimaging and electrophysiology has confirmed and extended our understanding of the neuroanatomical and functional relationships between signed and spoken languages and has raised new questions about the similarities and the modality-specific differences observed. More recently, neurolinguistic studies of signed language have helped us to evaluate the role of *mirror neuron*–inspired theories of language understanding, a central theme in embodied accounts of human language and cognition.

36.2 SIGN LANGUAGE APHASIA

Case studies of deaf signing individuals with acquired brain damage provide evidence for the contribution of left hemisphere perisylvian regions in the mediation of signed language. Deaf signers, like hearing speakers, exhibit distinct language disturbances when left hemisphere cortical regions are damaged, and these disturbances vary systematically depending on lesion locus (Hickok, Love-Geffen, & Klima, 2002; Marshall, Atkinson, Smulovitch, Thacker, & Woll, 2004; Poizner, Bellugi, & Klima, 1987; for a review see Corina, 1998a, 1998b). One of the most interesting facts about the realization of aphasic deficits in right-handed deaf signers is that language errors are often realized on the ipsilesional limb, (i.e., the left hand in

cases of left hemisphere damage). This indicates that the observed language errors are not an artifact of motoric weakness due to contralesional hemiplegia. Rather, these deficits reflect a central disorder of linguistic control mediated by the left hemisphere.

36.2.1 Broca-Like Signing

In spoken languages, language production impairments are typically associated with left hemisphere frontal anterior lesions that involve the lower posterior portion of the left frontal lobe (e.g., Broca's area, Brodmann area 44/45). These lesions often extend in depth to the periventricular white matter (Goodglass, 1993; Mohr et al., 1978). The anterior insula has also been implicated in chronic speech production problems (Dronkers, Redfern, & Knight, 2000). Two well-documented cases of sign language aphasia after left hemisphere frontal damage demonstrate this familiar structure–function relationship for signed languages. The case study of patient G.D., reported in Poizner et al. (1987), documents a profound expressive nonfluent sign language aphasia after large left frontal lobe lesion that encompassed Broca's territory including BA 44/45. The subject presented with halting dysfluent sign articulation and an agrammatic language profile—American Sign Language (ASL) sentence structure was greatly simplified (i.e., telegraphic) and signs did not show required movement modulations that signal morpho-syntactic inflection. In contrast to her expressive deficits, G.D.'s comprehension was well within normal limits.

Case study R.S. had a left inferior frontal lesion that was more restricted to classically defined Broca's territory (Hickok, Kritchevsky, Bellugi, & Klima, 1996). This lesion involved inferior motor cortex and extended anteriorly to involve most of the par opercularis and inferiorly involved anterior and superior insula. Subcortically, this lesion undercut most of the par triangularis and involved subcortical white matter deep to the lower motor cortex. During the acute phase of this stroke, the patient showed a marked expressive aphasia with nonfluent effortful production. Sign repetition was also affected. Sign language comprehension, however, was intact. Over time, the expressive aphasia largely resolved with lingering problems of word finding. As discussed, an unusual feature of R.S.'s signing was formational paraphasia. These impairments were not attributable to motor weakness, nor did this patient show signs of limb apraxia.

36.2.2 Wernicke-Like Signing

Spoken language comprehension deficits are well-attested after left hemisphere temporal lobe damage

(Damasio, 1992; Dronkers & Baldo, 2009; Naeser, Helm-Estabrooks, Haas, Auerbach, & Srinivasan, 1987). For example, Wernicke's aphasia, which is expressed as impaired language comprehension accompanied with fluent but often paraphasic (semantic and phonemic) output is often associated with damage to the posterior regions of the left superior temporal gyrus. More recent work has suggested the contribution of posterior middle temporal gyrus in cases of chronic Wernicke's aphasia (Dronkers, Redfern, & Knight, 2000; Dronkers, Redfern, & Ludy, 1995). Signers with left hemisphere posterior lesions also evidence fluent sign aphasia with associated comprehension deficits. However, as discussed, there is some controversy regarding whether anatomical locations of lesions that result in sign language comprehension deficits are fully comparable with those seen in users of spoken languages.

Subject L.K. described in Chiarello, Knight, and Mandel (1982) and in Poizner et al. (1987) had a left anterior parietal lesion in the region of the supramarginal and angular gyri. The inferior frontal operculum (areas 44 and 45) and the posterior superior temporal plane (areas 41, 42, and 22) were spared by the lesion. She presented with motorically facile signing, but with phonemic paraphasia and severe anomia. She had difficulty in grasping test instructions and was unable to perform two- or three-part commands. She experienced profound and lasting sign comprehension impairment. Subject P.D., reported in Poizner et al. (1987), had a left subcortical lesion deep to Broca's area, extending posteriorly beneath the parietal lobe. His signing, while fluent, exhibited numerous grammatically inappropriate signs (paragrammatism). His expression of sentence-level grammatical roles was disturbed. ASL syntax relies heavily on the use of an imaginary horizontal plane in front of the signer, which the signer may use to locate nominal referents. The movements of verb and predicate sign forms between these locations can signal subject and object relations; pronominal reference also makes use of this signing space convention. P.D. showed a lack of consistency in spatial agreement required of ASL syntax (Bellugi, Poizner, & Klima, 1989). That is, he would establish nominal referents in space, but he was inconsistent in maintaining co-reference to these previously established locations.

36.2.2.1 Comprehension Deficits

Group-level analyses have helped assess the structure–function relationships implicated in sign language comprehension deficits. In two reports, one on ASL and one on BSL (a completely distinct language from ASL), damage to the left hemisphere was observed to factor in sign comprehension deficits

(Atkinson, Marshall, Woll, & Thacker, 2005; Hickok et al., 2002). These studies report an increasing gradation of impairments for single signs, verb meaning, and simple sentence understanding (e.g., sentence verification and token test commands) in patients with left hemisphere damage but not right hemisphere damage.

There is, however, controversy with respect to degree of anatomical overlap observed in comprehension problems in spoken and signed languages. Whereas the study by Hickok et al. (2002) highlights the role of the left posterior temporal lobe in sign comprehension deficits, others have remarked on the potentially unique role of the left inferior parietal region in sign processing (Chiarello et al., 1982; Corina, 1998a, 1998b; Corina, Lawyer, & Cates, 2013; Leischner, 1943; Poizner et al., 1987). For example, in the group study data presented by Hickok et al. (2002) comparing the sign language comprehension abilities of signers with damaged left and right hemispheres, signers with left hemisphere posterior temporal lobe damage were found to perform worse than any other group. Although the authors emphasize the involvement of the damaged temporal lobe in these comprehension deficits, in all cases lesions of these subjects additionally extend into the parietal lobe. It is noteworthy that in the cases of L.K. and P.D. described, neither appears have to temporal lobe lesions. Case study W.L. (Corina et al., 1992) exhibited fluent aphasia with severe comprehension deficits. Lesions once again did not occur in cortical Wernicke's area; rather, this lesion undercuts frontal and inferior parietal areas, including the supramarginal gyrus. These observations have led some to suggest that sign language comprehension may be more dependent than speech on left hemisphere inferior parietal areas traditionally associated with somatosensory and visual motor integration, whereas spoken language comprehension might weigh more heavily on posterior temporal lobe association regions whose input includes networks intimately involved with auditory speech processing.

In summary, although it is clear that sign language comprehension suffers after left hemisphere damage, the contributions of the temporal and parietal lobes warrant further investigation. This controversy illustrates a theoretical difference between a modality-influenced view of language comprehension and an a-modal account. Proponents of a modality-influenced model would claim that cortical regions such as the IPL that support associative visual and motoric properties of sign language processing are intimately connected with language comprehension, whereas the a-modal perspective views the posterior temporal lobe

as a unifying computational stage in language understanding, independent of language modality (see Hickok et al., 2002 for some discussion). Additional studies are needed to fully assess these competing hypotheses.

36.2.2.2 Sign Language Paraphasia

Language breakdown after left hemisphere damage is not haphazard, but it affects independently motivated linguistic categories. An example of the systematicity in sign and spoken language breakdown is illustrated through consideration of paraphasic errors (Corina, 2000). Paraphasia refers to the substitution of an unexpected word for an intended target. Semantic paraphasias often have a clear semantic relationship to the desired word and represent the same part of speech (Goodglass, 1993). In contrast, phonemic or "literal" paraphasia refers to the production of unintended sounds or syllables in the utterance of a partially recognizable word (Blumstein, 1973; Goodglass, 1993). Sound substitutions in phonemic paraphasia may result in the production of a real word related in sound, but not in meaning (e.g., telephone becomes television). Also attested are cases in which the erroneous word shares both sound characteristics and meaning with the target (broom becomes brush; Goodglass, 1993).

Sign language paraphasias are produced by signers with aphasia and have clear parallel forms found in spoken languages. For example, subject P.D. (Poizner et al., 1987) produced semantic paraphasias, signing BED for CHAIR, DAUGHTER for SON, and QUIT for DEPART. ASL semantic paraphasias tend to overlap in meaning and lexical class with the intended target. Semantic paraphasias, whether in sign or speech, suggest that the mental lexicon is structured according to semantic principles, whereby similar semantic items share a representational proximity. In this view, coactivation of closely related representations and/or an absence of appropriate inhibition from competing lexical entries may lead to substitutions and blends.

Descriptions of formational or literal paraphasias in aphasic signing provide insight into the structural properties of signed language. ASL formational errors may encompass both *phonological* and *phonetic* levels of impairment (see Corina, 2000 for some discussion).¹ *A priori*, we may expect to find phonological errors affecting the four major formational parameters of ASL phonology: handshape, movement, location, and orientation. However, the distribution of these paraphasic errors appears to be unequal; handshape configuration errors are the most widely reported, whereas sign

¹The use of the terms phonology and phonetics in the present context refer to the abstract structural and articulatory properties of a sign, respectively.

errors affecting movement and especially location, although attested, are far less frequent. The aphasic signer WL described produced numerous *phonemic* errors, nearly all of which were errors involving substitutions of handshape. For example, he produced the sign TOOTHBRUSH with a Y handshape rather than the required G handshape. He produced the sign SISTER with an F handshape rather than the required L handshape (Figure 36.1).

Data from rare clinical cases of cortical stimulation mapping (CSM) performed in deaf and signing neurosurgical patients provide important clues to neural regions involved in semantic and phonemic paraphasia. Corina et al. (1999) reports the effects of left hemisphere cortical stimulation on sign language production in a deaf individual, patient S.T., undergoing an awake CSM procedure. Stimulation to two anatomical sites, one in the frontal operculum and one in the parietal operculum, led to consistent naming disruption. The errors, however, were qualitatively different.

Stimulation to the frontal opercular region of Broca's area (BA 44) resulted in errors involving the motor execution of signs. These errors were characterized by a laxed articulation of the intended sign, with nonspecific movements (repeated tapping or rubbing) and a reduction in handshape configurations to a lax closed fist handshape. Interestingly, there was no effort on the part of S.T. to self-correct these imperfect forms. In addition, such errors were observed during trials of sign and nonsign repetition. These results suggest that the posterior portion of Broca's area is involved in the motoric execution of complex articulatory forms, especially those underlying the phonetic level of language structure.

FIGURE 36.1 In ASL paraphasia, the correct sign Sister is made with an “L” handshape; in the error, the aphasic subject produced this form with an “F” handshape. From Corina et al. (1992) with permission from the publisher.

The sign errors observed with stimulation to the supramarginal gyrus (BA 40) resulted in both formational and semantic errors. Formational errors were characterized by repeated attempts to articulate the intended targets, and successive approximations of the target sign were common. For example, the sign PEANUT is normally signed with a closed fist with an outstretched thumb. During the movement of the sign, the thumb is flicked off the front of teeth. Under stimulation, this sign began as an incorrect, but clearly articulated, X handshape (closed fist with a protruding bent index finger) articulated at the correct location (in front of the mouth), but with an incorrect inward rotation movement. In two successive attempts to correct this error, S.T. first corrected the handshape and then went on to correct the movement as well. Notably, we do not find the laxed and reduced articulations characteristic of the signs seen with stimulation to Broca's area. Instead, these examples suggest problems involving the selection of the individual components of sign forms (i.e., handshape, movement, and, to a lesser extent, location). Moreover, although stimulation to the frontal operculum triggered errors in both sign and pseudosign production, pseudosign repetition was unaffected with stimulation to the supramarginal gyrus (SMG).

Semantic errors were also observed with stimulation to the SMG. Interestingly, many of these errors involve semantic substitutions that were formationally quite similar to the intended targets. For example, in one instance the stimulus picture “pig” elicited the sign FARM. The signs PIG and FARM differ in movement but share an identical articulatory location (the chin), and each is made with similar handshapes. This formational-semantic similarity is similar to the blended spoken paraphasia (e.g., *broom* → *brush*). Thus, in patient S.T., stimulation to the ventral portion of Broca's area had a global effect on the motor output of signing, whereas stimulation to the supramarginal gyrus affected the correct selection of the linguistic elements of a sign (including both phonological and semantic components).

The higher incidence of handshape errors is interesting, and linguistic analyses of ASL have argued that the parameter of handshape has autosegmental properties. Autosegmental representations are used to capture the independence of phonological features and posit representations in which features appear on separate tiers. This approach has been useful in capturing phonological phenomena in cases where phonological features span domains greater than the traditional segment, for example, in the cases of tone in tonal languages (Goldsmith, 1990). In many linguistic accounts of signed languages, handshape specifications are represented on an independent tier in a phonological

representation (Sandler & Lillo-Martin, 2006). The independent vulnerability of handshape specifications in ASL formational paraphasia may be evidence for the psychological reality of this abstract linguistic representation. In spoken language phonemic paraphasias, a curious asymmetry exists; the majority of phonemic paraphasias involve consonant rather than vowel distortions. In sign language, handshape errors are far more common than path movement errors. What is striking is that in some analyses, handshape specifications are suggested to be more consonantal in nature, whereas movement components of ASL signs may be more analogous to vowels (see Corina & Sandler, 1993, for some discussion). Collectively, these errors demonstrate how functionally similar language categories (i.e., *consonants*, *vowels*) may be selectively vulnerable to impairment across signed and spoken languages. Although the surface manifestations differ, the underlying disruption may be related to a common abstract modality-independent level of representation.

Although compelling commonalities exist in the expression of paraphasic errors in spoken and signed language, one might also expect errors that reflect a language's modality of expression. For example, errors affecting the feature of voicing may not have any direct parallel in a signed language, so this type of error is likely modality-specific. The control of the articulators for speech and sign has different processing requirements. For signed languages, low-level motor control of the limbs is contralateral, whereas low-level motor control of the vocal tract is largely bilaterally. The processing requirements for two-handed articulations may place qualitatively different demands on the linguistic system and result in the expression of modality-conditioned errors.

Patient R.S., described previously, exhibited paraphasia restricted to two-handed signs. In signs that require two hands to assume different handshapes and/or move independently, R.S. would incorrectly move one of her hands. In other cases, R.S. would fail to preserve the required spatial relationships between the two hands. Moreover, during one-handed signing, R.S. mirrored the movements and handshapes of the dominant hand on the nondominant hand, but somewhat reduced in degree of movement. This mirroring was not seen during nonlinguistic movements and appears different from mirror movements seen in some cases of hemiparesis. This case is important for our understanding of neurobiology of language because it indicates that the modality of the linguistic system can place unique demands on the neural mediation and implementation of language. These errors may be taken as evidence of modality-dependent linguistic impairment.

36.3 RIGHT HEMISPHERE DAMAGE

Studies of deaf signers with right hemisphere damage often exhibit visual-spatial deficits, but evidence only subtle language problems, similar to those observed in hearing nonsigners. The case study of J.H., a deaf signer with a large right hemisphere lesion involving frontal, temporal, and parietal cortex, shows a remarkable sparing of sign language comprehension with severely compromised visual-spatial abilities (Corina, Kritchevsky, & Bellugi, 1996). J.H. exhibited persistent left-neglect, an attention disorder that causes patients to ignore contralesional spatial locations.

Formal testing showed that even in cases of face-to-face signing, where the perception of a two-handed sign such as DEER (the right and left hands, finger spread, are placed on each side of the forehead like antlers) could easily be perceived as the well-formed one-handed sign FATHER (only the dominant hand, fingers spread, is placed in the forehead). J.H. showed little to no evidence that this visual-spatial neglect affected his perception of ASL. In contrast, if two identical objects were presented for identification, one in J.H.'s left visual field and the other in the right visual field, J.H. would show consistent *extinction* for the physical object in his left visual field (see Corina et al., 1996 for a discussion).

36.3.1 Discourse Abilities

The disruption of discourse abilities is well-attested in hearing individuals with right hemisphere damage (Brownell, Simpson, Bihrlé, Potter, & Gardner, 1990; Kaplan, Brownell, Jacobs, & Gardner, 1990; Rehak et al., 1992). Similar patterns of discourse impairment are seen in right hemisphere-damaged (RHD) users of signed language. Analysis of language use in subjects with right hemisphere lesions, J.H. and D.N. (Emmorey, 1993; Emmorey, Corina, & Bellugi, 1995; Poizner & Kegl, 1992), reveal contrasting disruptions. Lesion sites differed in these two patients; J.H.'s stroke involved cortical regions in the distribution of the right middle cerebral artery, whereas D.N.'s lesion was predominantly medial and involved the upper part of the occipital lobe and superior parietal lobule. In everyday signing and in picture description tasks, J.H. showed occasional nonsequiturs and abnormal attention to details, behaviors that are typically found in the discourse of hearing patients with right hemisphere lesions. Subject D.N. showed a different pattern of discourse disruption: one that affected the discourse cohesion. Spatial indexing is a commonly used device for pronominal reference in signed languages. Signers will point to the spatial location of a previously signed

nominal, in essence re-referencing this previously introduced concept. Although her within-sentence spatial indexing was unimpaired, her use of space across sentences was inconsistent. That is, she did not consistently use the same index points to refer to individuals throughout a discourse.² To salvage intelligibility, D.N. used a compensatory strategy in which she restated the noun phrase in each sentence, resulting in an overly repetitive discourse style. Taken together, the cases of J.H. and D.N. suggest that right hemisphere lesions in signers can differentially disrupt discourse content (as in the case of JH) and discourse cohesion (as in the case of DN) (see also Hickok et al., 1999).

Signed languages are unique in their ability to spatially represent prepositional relationships between objects such as *on*, *above*, *under*, and others. These concepts are often conveyed via the depiction of the physical relation itself rather than encoded by a discrete lexical item. For example, an ASL translation of the English sentence “The pen rests on a book” may, in part, involve the use of the two hands, whereby one hand configuration with an outstretched finger (representing the pen) is placed on the back of a flat open hand (representing the book). This configuration encodes the spatial meaning “on” but without the need for an explicit lexical preposition.

Many signed languages express spatial relationships and events in this manner and have discrete inventories of highly productive grammatical forms, often referred to as “classifiers” or “classifier predicates,” which participate in a wide range of depictive constructions. These highly productive forms play an important linguistic function in signed languages (Supalla, 1982; see also Emmorey, 2003 and papers therein) and their theoretical status remains a point of vibrant discussion and debate (for contrastive views see Dudis, 2007; Liddell, 2003; Sandler & Lillo-Martin, 2006).

The linguistic status of these classifier forms and their conventions of use have important implications for our understanding of neurolinguistics of signed languages. Several studies have found differential disruptions in the use and comprehension of sentences that involve these spatial-depictive forms. For example, Atkinson and colleagues conducted a group study of left-hemisphere-damaged and right-hemisphere-damaged signers of BSL (Atkinson et al., 2005). They devised comprehension tests that examined a wide range of sentence types including simple and complex argument structures and semantically reversible sentences. They also included a test of classifier placement, orientation, and rotation. Their findings indicated that left hemisphere damaged BSL signers relative to age-matched control subjects exhibited

deficits on all comprehension tests. Right hemisphere damaged signers did not differ from controls on single sign and single predicate-verb constructions, nor on sentences that ranged in argument structure and semantic reversibility. However, RHD signers (like left hemisphere–damaged [LHD] signers) were impaired on tests of locative relationships expressed via classifier constructions, and on the test of classifier placement, orientation, and rotation (see also Hickok, Pickell, Klima, & Bellugi, 2009).

One interpretation offered for this pattern of responses is that the comprehension of classifier constructions requires not only intact left hemisphere resources but also intact right hemisphere visual-spatial processing mechanisms. Atkinson et al. states “the deficits stem from the disruption of processes which map nonarbitrary sign locations on the real-world’s spatial position.” That is, whereas both LHD and RHD signers show comprehension deficits, the RHD signer’s difficulties stem from a more general *extralinguistic* visual-spatial deficit rather than linguistic malfunction *per se*. However, depictive forms are used to refer to not only real-world events but also imaginary and nonpresent events as well. Thus, a theoretical question arises as to how specific these visual-spatial deficits must be to be deemed *extralinguistic*. The broader point is whether aphasic deficits should solely be defined as those that have clear homologies to the left hemisphere maladies that are evidenced in spoken languages, or whether the existence of sign languages will force us to reconsider the conception of linguistic deficits. As discussed in the case of R.S., who showed evidence of modality-specific linguistic paraphasias in language production and in the realm of language comprehension, we may need to acknowledge modality-specific linguistic deficits. These sign language impairments may implicate neural regions such as left parietal areas and right hemisphere regions that lie well beyond traditionally defined perisylvian language areas that support properties of spoken languages.

In summary, aphasia studies to date provide ample evidence for the importance of the left hemisphere in mediation of sign language. After left hemisphere damage, sign language performance breaks down in a linguistically significant manner. In addition, there is growing evidence for the role of the right hemisphere in aspects of ASL discourse, classifier use, and syntactic comprehension. Case studies of deaf signers with aphasia have been useful in illuminating the nature of aphasic breakdown in signed languages as well as raising new questions concerning the neurobiology of linguistic processing.

²Contrast this impairment with left hemisphere subject P.D. who showed a lack of spatial agreement within single sentences.

36.4 NEUROIMAGING

Functional imaging studies of deaf signers provide additional evidence for left hemisphere specialization of signed language and provide an opportunity to explore more targeted questions regarding neurobiology of signed languages. Early studies often emphasized the overlap of activation between regions subserving sign processing and those regions traditionally thought to mediate speech processing (Bavelier et al., 1998; McGuire et al., 1997; Neville et al., 1998; Nishimura et al., 1999; Petitto et al., 2000; Söderfeldt et al., 1997). For example, Petitto et al. (2000) and McGuire et al. (1997) reported significant activation in left inferior frontal regions, specifically Broca's area (BA 44 and 45) and anterior insula during overt and covert tasks of sign generation. Subsequent work using more refined cytoarchitectonic references have indicated that BA 45 is activated during both sign and speech, and it can be differentiated from complex oral/laryngeal and limb movements, resulting in more ventral activation of BA 44. This interpretation accords well with the cortical stimulation finding reported in Corina et al. (1997). Overall, this research speaks to the modality independence of the pars triangularis (BA 45) (Horwitz et al., 2003), a region that has been traditionally considered a "speech-motor" region.

Studies have also reported that processing of signs in deaf signers can lead to activation in the temporal lobe. Petitto et al. (2000) and Nishimura et al. (1999) reported significant activation in left superior temporal cortex, a region often associated with auditory processing, in response to the perception of single signs. MacSweeney, Woll, Campbell, McGuire, et al. (2002) also observed the activation of auditory association areas in deaf and hearing native signers of BSL. Their findings revealed relatively greater activation for deaf native signers than hearing native signers in the left temporal auditory association cortex during the perception of signed sentences (see also Kassubek, Hickok, & Erhard, 2004). These findings are taken as evidence of cross-modal plasticity whereby auditory cortex and auditory association cortex may be modified in the absence of auditory input to become specialized for visual language input. Although this left hemisphere auditory activation is presumed to reflect linguistic processing, the functional significance of these activations is not well-understood. For example, several studies have reported activation of primary auditory cortex in deaf individual in response to low-level (nonlinguistic) visual stimulation (Fine, Finney, Boynton, & Dobkins, 2005; Finney, Clementz, Hickok, & Dobkins, 2003; Scott et al., 2014). The findings that auditory cortex is responsive to visual information is perhaps not that surprising given recent evidence that

auditory cortex supports silent speech reading and audiovisual integration (Calvert et al., 1997; Calvert & Campbell, 2003; Kauramäki, 2010; Okada et al., 2013).

In studies of ASL verb generation in which subjects are required to generate a verb in response to a given noun, San José-Robertson, Corina, Ackerman, Guillemin, and Braun (2004) reported left-lateralized activation within perisylvian frontal and subcortical regions commonly observed in spoken language generation tasks. In an extension of this work, Corina, San Jose-Robertson, Guillemin, High, and Braun (2003) reported the left-lateralized pattern was not significantly different when the production of a repeat-generate task was conducted with a signer's right dominant or left nondominant hand. This finding is consistent with the fact that left-hemisphere-damaged aphasic signers will evidence linguistic errors while using their nondominant hand.

36.4.1 Sign Language Production

Neuroimaging studies of sign language production reveal further commonalities in the neural systems underlying core properties of language function in sign and speech. In a large-scale analysis of deaf signers and hearing nonsigners engaged in object naming tasks, Emmorey, Mehta, and Grabowski (2007) reported areas of overlap in neural activation for sign production in the deaf subjects and word production in the hearing subjects. This analysis identified regions supporting modality-independent lexical access. Common regions included the left mesial temporal cortex and the left inferior frontal gyrus. Emmorey et al. suggest that left temporal activation reflects conceptually driven lexical access (Indefrey & Levelt, 2004). In this view, for both speakers and signers, activation within the left inferior temporal gyrus may reflect prelexical conceptual processing of the pictures to be named, whereas activation within the more mesial temporal regions may reflect lemma selection, prior to phonological code retrieval. These results argue for a modality-independent frontotemporal network that subserves both sign and word production.

Differences in activated regions in speakers and signers were also observed. Within the left parietal lobe, two regions were more active for sign than for speech: the supramarginal gyrus and the superior parietal lobule. As discussed, parietal regions may be linked to modality-specific output parameters of sign language. Specifically, activation within left SMG may reflect aspects of phonological processing in ASL (e.g., selection of hand configuration and place of articulation features), whereas activation within the superior parietal lobule (SPL) may reflect proprioceptive monitoring of motoric output.

A study of discourse production in ASL-English native bilinguals further underscores the similarities between speech and sign. In this study, spontaneous generation of autobiographical narratives in ASL and English revealed complementary progression from early stages of concept formation and lexical access to later stages of phonological encoding and articulation. This progression proceeds from bilateral to left-lateralized representations, with posterior regions—especially posterior cingulate, precuneus, and basal-ventral temporal regions—activated during encoding of semantic information (Braun, Guillemin, Hosey, & Varga, 2001).

36.4.2 Sentence Comprehension

Studies of sentence processing in signed languages have repeatedly reported left-hemisphere activations that parallel those found for spoken languages (Figure 36.2). These activation patterns include inferior frontal gyrus (including Broca's area and insula), pre-central sulcus, superior and middle temporal cortical regions, posterior superior temporal sulcus (STS), angular gyrus (AG), and SMG (Lambertz, Gizewski, de Greiff, & Forsting, 2005; MacSweeney, Woll, Campbell, Gemma, et al., 2002; MacSweeney et al., 2006; Newman, Bavelier, Corina, Jezzard, & Neville, 2002; Neville et al., 1998; Petitto et al., 2000; Sakai, Tatsuno, Suzuki, Kimura, & Ichida, 2005). The majority of

functional imaging studies of sign language confirm the importance of the left hemisphere in sign processing and emphasize the similarity of patterns of activation for signed and spoken languages.

In addition to the more familiar left hemisphere activations, imaging studies of sentence processing in sign language have also noted significant right hemisphere activation. For example, activations in right hemisphere superior temporal, inferior frontal, and posterior parietal regions have been reported (MacSweeney, Woll, Campbell, McGuire, et al., 2002; MacSweeney et al., 2006; Neville et al., 1998; Newman et al., 2002). The question of whether these patterns of activation are unique to sign has been the topic of debate (Corina, Neville, & Bavelier, 1998; Hickok, Bellugi, & Klima, 1998). Mounting evidence suggests that some aspects of this right hemisphere activation may be attributable to the processing of facial information, which factors significantly in the sign signal. Studies of auditory and audiovisual speech have observed right hemisphere activations that appear similar to those reported in signing (Capek et al., 2004; Davis & Johnsruide, 2003; Schlosser, Aoyagi, Fulbright, Gore, & McCarthy, 1998).

However, as hinted, right hemisphere posterior parietal and temporal lobe regions may play a unique role in the mediation of signed languages. In a study by Newman et al. (2002), deaf and hearing native signers, hearing nonsigners, and hearing late learners of ASL viewed sign language sentences contrasted with sign gibberish. Deaf and hearing native signers showed significant activation in right hemisphere posterior parietal and posterior temporal regions. These activation patterns were not seen in nonsigners, nor were they observed in hearing late learners of sign language. A group analysis of hearing participants confirmed that only hearing native users of ASL, but not late learners who had learned ASL after puberty, recruited the right angular gyrus during this task. Newman and colleagues suggested that the activation of this neural region may be a neural signature of sign language being acquired during the critical period for language.

MacSweeney, Woll, Campbell, Gemma, et al. (2002) compared the role of left and right parietal cortices in an anomaly detection task in BSL. They tested deaf and hearing native signers in a paradigm that utilized BSL sentence contexts that either made use of spatial-topographic signing space or did not require spatial mapping. Similar to the findings reported by Newman et al. (2002), native deaf signers in the MacSweeney et al. study also showed activation in the right angular gyrus (BA 39). Parietal activation in the hearing native signers, however, was modulated by accuracy on the task, with more accurate subjects showing greater activation. This finding suggests that proficiency, rather

FIGURE 36.2 (A) Regions activated by BSL sentence comprehension in deaf native signers. (B) Regions activated by audiovisual English sentence comprehension in hearing nonsigners (voxelwise $p < 0.00005$). Both language inputs were contrasted with a low-level baseline: perception of the still model and a low-level target detection task (visual for deaf; auditory for hearing). Activation up to 5 mm beneath the cortical surface is displayed. From MacSweeney, Capek, Campbell, and Woll (2008) with permission from the publisher.

than age of acquisition, may be a critical determinant of right hemisphere engagement. Importantly, activation in right hemisphere temporal-parietal regions was specific to BSL and was not observed in hearing nonsigners watching audiovisual English translations of the same sentences.

Neuroimaging studies of working memory processes in users of sign language have also reported modality-specific activations in response to the perception and maintenance of sign-based information. These activations typically include bilateral temporal-occipital activations and posterior parietal cortex (Buchsbbaum et al., 2005; Pa, Wilson, Pickell, Bellugi, & Hickok, 2008; Ronnberg, Rudner, & Ingvar, 2004).

In an electrophysiological study of ASL sentence processing, Capek et al. (2009) reported left anterior negativity (i.e., LAN) syntactic verb-agreement violations in ASL. However, in a condition where the ungrammaticality was signaled by a spatially inflecting verb that lacked an overtly specified object, anterior negativity (200–360 ms) that was largest over the right lateral frontal sites was observed.

Many researchers have speculated that right hemisphere parietal activation in signers is associated with the linguistic use of space in sign language, and recent studies have sought to clarify the contributions of spatial processing in ASL signing to observed right hemisphere activations. A positron emission tomography (PET) study by Emmorey et al. (2002) is noteworthy in this regard. Emmorey et al. (2002) required deaf subjects to examine line drawings of two spatially arrayed objects and produce either a classifier description or a description of the spatial relationship using ASL lexical prepositions. This study found evidence for right hemisphere SMG activation for both prepositional forms and classifiers compared with object naming; however, the direct comparison between classifier constructions and lexical prepositions in sign revealed only left hemisphere inferior parietal lobule activation. This counterintuitive finding suggests that right hemisphere activation must be related to some common process, perhaps the spatial analysis of stimulus to be described, rather than a special spatial-linguistic property of ASL classifiers *per se*. Note this finding would support the contention of Atkinson et al. that restricted right hemisphere comprehension impairments seen in some deaf aphasics may reflect more generalized disruptions of core mechanisms needed for spatial analysis.

36.5 SIGN LANGUAGE AND THE MIRROR NEURON SYSTEM

Studies of the neurobiology sign language have been called on to inform motor simulation theories of

language, particularly mirror neuron–based accounts of language evolution and language processing. Arbib (2005, 2008) and Rizzolatti and Arbib (1998), Rizzolatti and Craighero (2004) propose that a human analog of the bilateral frontoparietal macaque mirror neuron system that subserves action execution and action perception supports a variety of complex sociocognitive phenomena, most notably human action understanding and human language. Signed languages provide an important opportunity to examine hypotheses such as that sign language production requires the orchestration of complex manual gestural forms and its comprehension depends on the direct perception of these same gestures.

Data from lesion and neuroimaging studies place some limits on the feasibility of the mirror neuron account of sign language. For example, researchers have suggested that Broca's region is a likely homologue of Macaque F5, a frontal ventral region where neurons with mirroring properties have been observed (Gallese, Fadiga, Fogassi, & Rizzolatti, 1996). Yet, as discussed, studies of aphasic patients show that damage to left frontal ventral and opercular regions do not result in comprehension deficits in signers, as would be predicted from a mirror neuron account of human language. Recent group-level analyses of signing aphasics reinforce this point (Rogalsky et al., 2013). In addition, case studies of deaf signers have shown compelling dissociations between nonlinguistic pantomime and sign language abilities. Patient W.L., for example, produced and comprehended pantomime normally but demonstrated marked deficits in sign language production and comprehension (Corina et al., 1992). His gestures were clearly intended to convey symbolic information that he ordinarily would have imparted with sign language. Marshall et al. (2004) reported on the dissociation of sign and gesture in Charles, an aphasic user of BSL. His ability to use nonlinguistic gesture was intact while sign language expression showed significant impairment. These accounts are difficult to reconcile within a human mirror neuron system view of action execution and perception that fail to distinguish between different classes of human actions. Data from neuroimaging studies that have directly compared the perception of different classes of human actions and signs in deaf signers also show little evidence of overlap in the neural system mediating the perception of transitive and intransitive human actions, pantomimes, and linguistic signs (Corina et al., 2007; Emmorey, Xu, Gannon, Goldin-Meadow, & Braun, 2010 but see also MacSweeney et al. 2004). In these studies, activation patterns in response to sign language forms activate the now-familiar perisylvian language areas while nonlinguistic human actions and pantomimes show prominent activation in the inferior occipital-temporal

regions in deaf signers. One explanation for these differences is that deaf signers may show a greater reliance on top-down processing in the recognition of signs, leading to a more automatic and efficient early visual processing of highly familiar linguistic features. In contrast, nonlinguistic gesture detection may be driven by bottom-up processing, in which preliminary visual analysis is crucial to interpretation of these forms.

Some support for the involvement of a unified action perception/action execution system for sign language comes from consideration of the functional role of the parietal lobes in sign language behaviors. Mirror neuron system accounts of language processing hold that one and the same region should participate both in the production and comprehension of language forms. In a review, [Corina and Knapp \(2006\)](#) compiled neuroimaging data from studies of sign language production and sign language comprehension and examined regions that showed significant overlap. One region that showed compelling overlap was in the left SMG of the inferior parietal lobe. Recall that lesion studies have shown evidence for sign comprehension deficits with damage to left inferior parietal regions, and both lesion and stimulation mapping studies have shown impairment in sign production implicating the SMG. This is a region that is often observed in studies sign language working memory ([Buchsbau et al., 2005](#); [Pa et al., 2008](#); [Ronnberg et al., 2004](#)). In hearing individuals, this region is considered a polymodal association region with involvement in tasks that range from phonological short-term memory ([Jacquemot & Scott, 2006](#)), to judgments of hand gestures ([Hermsdorfer et al., 2001](#)), to motor attention to limb movements ([Rushworth, Krams, & Passingham, 2001](#)), and to phonological agraphia ([Alexander, Friedman, Loverso, & Fischer, 1992](#)). Given this multiplicity of functions of the SMG, it is perhaps not surprising that aspects of sign comprehension and sign production are subserved by this region. Whether individual neurons within this region exhibit mirror properties remains an important question (see [Chong, Cunnington, Williams, Kanwisher, & Mattingley, 2008](#), for example).

In summary, functional imaging studies have largely replicated and helped extend the findings of lesion studies in deaf signers. These studies point to the importance of the left hemisphere in sign language production and comprehension, and have helped illuminate the modality-independent regions of the left hemisphere perisylvian language network. Functional imagining studies typically permit more directed inquiry than lesion studies. As such, these investigations have begun to address more subtle issues related to the modality-dependent contributions of the left and right parietal lobes in sign language processing and have proved to be an important source of data for constraining contemporary theories of biological basis of language.

36.5.1 Morphometric Studies

A small number of morphometric studies have been conducted to examine the presence of anatomical differences in the brains of deaf and hearing subjects. Two studies have reported reduced white matter in the left posterior superior temporal gyrus adjacent to language cortex in deaf subjects, but no difference in gray matter volume of temporal auditory and speech areas ([Emmorey, Allen, Bruss, Schenker, & Damasio, 2003](#); [Shibata, 2007](#)). It is speculated that the reduced white matter volume may indicate a hypoplasia in the development of specific tracts related to speech. The finding that auditory cortices show no differences in gray matter volume has been taken as evidence for preserved functionality of these regions, perhaps in the form of cross-modal plasticity. As noted previously, several studies have shown activation of auditory cortex in response to the perception of visual stimuli and visual language. It is also interesting to note that in the Shibata study, deaf subjects showed trends for larger gray matter differences in superior frontal gyrus (BA 6) thought to reflect differences related to the use of manual language in this right-handed cohort of signers. In a study examining morphology of the insula in deaf and signing populations, Allen et al. reported volumetric differences attributed to both auditory deprivation and sign experience. Deaf subjects exhibited a significant increase in the amount of gray matter in the left posterior insular lobule, which may be related to dependence on lip-reading and articulatory (rather than auditory-based) representation. In contrast to nonsigners, both deaf and hearing signers exhibited increased volume in white matter in the right insula. This latter difference may be attributed to increased reliance on cross-modal sensory integration in sign compared with spoken languages ([Allen, Emmorey, Bruss, & Damasio, 2008](#)).

36.6 CONCLUSION

Patterns for deficits seen in deaf signers following left and right hemisphere lesions show great commonalities to the deficits seen in users of spoken languages. Functional imaging studies of sign language comprehension and production in deaf and hearing signers provide further evidence for the uniformity in the neural systems underlying spoken and signed languages. Taken together, these studies provide evidence for a core neurobiological system that underlies human language, regardless of the modality of expression ([Fedorenko, Behr, & Kanwisher, 2011](#)). At the same time, and as might be expected, studies of sign language have also revealed instances in which the

properties of sign languages invoke neural processing resources that differ from those observed for spoken languages. These instances force us to acknowledge the possibility of language specificity of linguistics impairment (and whether these fall under the purview of aphasic deficits) and illuminate the intimate connections between language modality and brain structures for language. Neurolinguistics studies of signed languages have been used to motivate and constrain models of language evolution and language biology offered by mirror neuron system accounts of language understanding. Structural imaging studies of deaf signers have begun to observe and differentiate the roles of sensory and language experience in sculpting cortical connections. Studies of signed languages and the experiences of deaf individuals provide an important means to advance our understanding of the neurobiology of human language.

PERCEPTUAL ANALYSIS
OF THE SPEECH SIGNAL

This page intentionally left blank

Phoneme Perception

Jeffrey R. Binder

Department of Neurology, Medical College of Wisconsin, Milwaukee, WI, USA

Human vocalizations include the set of sounds called phonemes, which are the basic linguistic units of speech. Phonemes are approximately equivalent to the set of vowel and consonant sounds of a language. For example, the word *cat* comprises the three phonemes (here transcribed in International Phonetic Alphabet notation) /k/, /æ/, and /t/. Changing any one of these phonemes, such as substituting /p/ for /k/, results in a different word. Thus, a phoneme is often defined as the smallest contrastive speech unit that brings about a change of meaning. Phonemes are also the product of complex motor acts involving the lungs, diaphragm, larynx, tongue, palate, lips, and so on. The actual sounds produced by this complex apparatus vary from one instance to the next, even for a single speaker repeating the same phoneme. They are also altered by the context in which the act occurs, resulting in allophonic variations such as the difference in the middle “t” sound of *night rate* and *nitrate*. Phoneme realizations also show large variations across geographical and social groups, resulting in regional and class accents. Therefore, a phoneme is best viewed as an abstract representation of a set of related speech sounds that are perceived as equivalent within a particular language. The main task of phoneme perception systems in the brain is to enable this perceptual equivalence.

The acoustic analysis of phonemes is a relatively recent science, becoming systematic only with the development of acoustic spectral analysis in the 1940s using analog filter banks (Koenig, Dunn, & Lacy, 1946). Accordingly, the standard classification of phonemes refers mainly to the motor gestures that produce them. “Manner” of articulation refers to the general type of gesture performed. Examples of distinct manners of articulation include: transient complete closure of the vocal tract, called a stop or plosive (example: p, d, k); sustained constriction of the vocal tract resulting in turbulent air flow, called a fricative (example: f, th, s); lowering of the soft palate and relaxation of the upper pharynx during occlusion of the oral

tract to allow air flow and resonance in the nasal cavity, called a nasal (example: m, n, ng); and relatively unobstructed phonation using the tongue and lips to shape the resonant properties of the oral tract, resulting in a vowel. “Place” of articulation refers to the location in the vocal tract at which maximal restriction occurs during a gesture. Examples include: restriction at the lips, referred to as bilabial (example: b, p, m); restriction with the tip of the tongue against the teeth or alveolar palate, referred to as coronal (example: th, d, s); and restriction with the body of the tongue against the soft palate, called velar (example: g, k). Finally, the consonants are divided into two “voicing” categories on the basis of whether the vocal folds in the larynx are made to vibrate during or very close to the time of maximal articulation. When phonatory muscles in the larynx contract, the vocal folds vibrate due to periodic build-up of air pressure from the lungs, resulting in an audible pitch or voice. When this vibration is present during maximal articulation, the consonant is “voiced” (example: b, z, g). When no vocal fold vibration is present, the consonant is “unvoiced” (example: p, s, k). For stop consonants followed by a vowel, voicing is largely determined by the time that elapses between release of the stop and the onset of vocal fold vibration, referred to as voice onset time (VOT).

Although derived originally from motor descriptions, each of these distinctions is associated with corresponding acoustic phenomena (Figure 37.1). Vocal cord vibrations produce a periodic sound wave at a particular rate, called the fundamental frequency of the voice (F0), as well as harmonics at multiples of the fundamental. The relative intensity of these harmonics is determined by the shape of the vocal tract, which changes dynamically due to movement of the tongue and other articulators, altering the resonant (and antiresonant) properties of the tract. Resonant harmonics form distinct bands of increased power in the spectrum, called formants (numbered F1, F2, etc.), and the center frequency and

FIGURE 37.1 Acoustic waveforms (top row in each pair) and time-frequency displays (“spectrograms”) showing spectral power at each point in time (bottom row in each pair) for the syllables /bæ/ and /pæ/ (as in “bat” and “pat”). Vertical striations seen in both displays are due to vocal cord vibrations at the fundamental frequency of the speaker’s voice. Dark horizontal bands in the time-frequency displays are formants (labeled F1, F2, and F3 on the /bæ/ display) caused by resonances related to the shape of the oral cavity. The first 50–60 ms of /bæ/ is the period of formant transition, during which the jaw opens and the spectral position of the formants changes rapidly. Unvoiced /pæ/ differs from voiced /bæ/ in that the period of formant transition is replaced in /pæ/ by a period of aspiration noise (indicated by “VOT”) during which there are no vocal cord vibrations. The absence of voicing also greatly shortens the formant transition duration and raises the starting frequency of F1 for /pæ/.

bandwidth of these formants change as the vocal tract changes shape. Stop consonants are characterized by abrupt changes in tract shape as the jaw, tongue, and lips open or close, resulting in rapid changes (typically occurring over 20–50 ms) in the center frequencies of the formants (called formant transitions), as well as rapid changes in overall intensity as air flow is released or stopped. Fricatives are characterized by sustained, high-frequency broadband noise produced by turbulent air flow at the point of vocal tract constriction. Nasal consonants are characterized by a prominent nasal formant at approximately 250–300 Hz (the “nasal murmur”) and damping of higher-frequency oral formants.

The acoustic correlates of consonant place of articulation were a central focus of much early research in acoustic phonetics, in large part due to the difficulty in identifying invariant characteristics that distinguished stops in different place categories. Place distinctions among stops are associated with differences in the direction and slope of formant transitions, but it was quickly noticed that these parameters are context-dependent. For example, the second formant rises during articulation of syllable-initial /d/ when the following vowel is “ee,” but it falls during articulation of the same segment when

the following vowel is “ah” or “oo” (Delattre, Liberman, & Cooper, 1955). Such context dependency, which is ubiquitous in speech, proved challenging to explain and even led to a prominent theory proposing that phoneme identification depends on activation of an invariant motor representation (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967), although exactly how this could occur if the acoustic signal is uninformative was never fully specified. Later studies showed that overall spectral shape at the time of stop release and change in overall shape just after release provide a context-invariant acoustic cue for place of articulation (Kewley-Port, 1983; Stevens & Blumstein, 1981). Similarly, place of articulation for fricatives and nasal consonants is cued primarily by gross spectral shape (Hughes & Halle, 1956; Kurowski & Blumstein, 1987).

Phoneme perception is often based on multiple interacting acoustic cues. The cues signaling stop consonant voicing are a clear case in point. Although VOT is the most prominent cue, with VOT values longer than 25–30 ms generally creating a strong unvoiced percept, unvoiced stops (i.e., p, t, and k) are also characterized by aspiration (i.e., noise from the burst of air that accompanies release of the stop), a higher center

frequency of the first formant at the onset of voicing, and a shorter formant transition duration, among other cues (Lisker, 1986) (Figure 37.1). Studies using synthesized speech show that these cues jointly contribute to voicing discrimination in that reduction of one cue can be compensated for by an increase in others (e.g., reduction of VOT can be “traded” for an increase in aspiration amplitude or first formant onset frequency to maintain the likelihood of an unvoiced percept) (Summerfield & Haggard, 1977).

As mentioned, a major task of the phoneme perception system is to detect these acoustic cues despite extensive variation in their realization. In addition to variation due to phonetic context (i.e., preceding or following phonemes), speaker accent, and a host of purely random factors, speakers vary in overall speed of production and in the length and size of their vocal tracts, producing variation in the absolute value of fundamental and formant center frequencies. Two types of mechanisms are thought to mitigate this problem. The first are normalization processes that adjust for variation in vocal tract characteristics and articulation speed. Evidence suggests, for example, that although absolute formant frequencies for any particular phoneme vary between speakers, the ratios of formants are more constant and therefore provide more invariant cues (Miller, 1989). Similarly, there is evidence that listeners automatically apply a temporal normalization process that adjusts for variation in speed of production within and across speakers (Sawusch & Newman, 2000).

A second mechanism for dealing with acoustic variation is known as categorical perception. This term refers to a relative inability to perceive variation within a set of items belonging to the same perceptual category. The phenomenon is most strikingly demonstrated using synthesized speech continua that vary in acoustically equidistant steps from one phoneme category to another, such as from /b/ to /p/ (Liberman, Harris, Hoffman, & Griffith, 1957). Listeners fail to perceive changes in VOT from 0 to 20 ms, for example, but can easily perceive a change from 20 to 40 ms. The 0-ms and 20-ms VOT sounds are both perceived as the same voiced stop consonant, whereas the 40-ms VOT sound is perceived as unvoiced and, therefore, a different phoneme. Importantly, the phenomenon is not simply attributable to response bias or limited availability of response labels, because it is observed using alternative forced-matching (e.g., ABX) tasks as well as labeling tasks. Categorical perception indicates that the phoneme perception system has an automatic (i.e., subconscious) mechanism for “suppressing” acoustic detail of a speech sound, leaving behind, in consciousness, mainly the abstract identity of the phoneme. Which specific details are suppressed, however, depends on the phoneme categories to which one is exposed during

early linguistic experience. Speakers of English, for example, cannot appreciate distinctions between the dentoalveolar and (postalveolar) retroflex stops of Hindi and other Indo-Aryan languages, whereas these are distinct phonemes with categorical perceptual boundaries for Hindi listeners (Pruitt, Jenkins, & Strange, 2006). It thus appears that the phoneme perceptual system becomes “tuned” during language development through bottom-up statistical learning processes that reflect overrepresentation of category prototypes in the language environment (Kuhl, 2000; Werker & Tees, 2005). The phoneme categories that result from this tuning process can be thought of as “attractor states” (Damper & Harnad, 2000) or “perceptual magnets” (Kuhl, 1991) that “pull” the neural activity pattern toward a target position in phoneme perceptual space regardless of small variations in the acoustic input.

Before moving on to a consideration of relevant neurobiological data, two additional core aspects of phoneme perception should be mentioned. The first involves the integration of visual and auditory input. Many of the articulatory movements used in speaking are visible, and because this visual information is strongly correlated with the resulting acoustic phenomena, it is useful for phoneme perception. For people with normal hearing, visual information is particularly helpful in noisy environments (Sumbly & Pollack, 1954). For people with little or no hearing, visual information alone can often provide enough information for phoneme recognition (Bernstein, Demorest, & Tucker, 2000). Auditory and visual information are “integrated” at a relatively early, preconscious level during phoneme perception, as shown by the McGurk illusion, in which the perceived identity of a heard phoneme is altered by changing the content of a simultaneous video display (McGurk & MacDonald, 1976).

A final point is that phoneme perception should not be thought of as an entirely bottom-up sensory process. As with all perceptual recognition tasks, identification of the sensory input is influenced by knowledge about what it is most *likely* to be. One illustration of this phenomenon is the influence of lexical status on phoneme category boundaries (Ganong, 1980; Pitt & Samuel, 1993). A sound that is acoustically near the VOT boundary between /b/ and /p/, for example, is likely to be heard as /b/ after the stem /dræ/, thereby forming a word (drab) rather than a nonword (drap), whereas the same sound is likely to be heard as /p/ after the stem /træ/ (again, favoring a real word over a nonword). The connectionist model of phoneme perception called TRACE instantiates this top-down influence using feedback connections from lexical to phoneme representations (McClelland & Elman, 1986). Although feedback from higher levels provides one biologically plausible account of lexical effects on phoneme perception, it may

not be strictly necessary (Norris, McQueen, & Cutler, 2000). Another example of “top-down” effects in phoneme perception is the phenomenon of “perceptual restoration,” in which a phoneme is perceived within a word despite the fact that the actual phoneme has been replaced by a segment of noise or other nonspeech sound (Samuel, 1997; Warren & Obusek, 1971). An extreme example of such “top-down restoration” is the successful perception of phonemes in sounds constructed of three or four pure tones that represent only the center frequency and intensity of the formants in the original speech. Naïve listeners initially perceive such “sine wave speech” as nonverbal “chirps” or “electronic sounds,” but they are then immediately able to hear phonemes on being told that the sounds are speech (Remez, Rubín, Pisoni, & Carrell, 1981). Such phenomena vividly illustrate the general principle that what we perceive is determined as much by what we expect as by what is available from sensory input.

37.1 NEUROPSYCHOLOGICAL STUDIES

As described in the preceding section, phoneme perception in the healthy brain is influenced by stored lexical and phonetic knowledge. However, neuropsychological studies amply demonstrate that phoneme perception and higher lexical processes are often differentially affected by focal lesions. For example, patients with transcortical sensory aphasia have severe impairments of word comprehension but are perfectly able to repeat words they do not understand (Berthier, 1999). Intact repetition indicates preserved perception of phonemes, and thus the word comprehension deficit must be due to either an impairment in mapping the phonemes to a lexical representation or an impairment at the semantic level. Conversely, patients with “pure word deafness” (PWD) are unable to recognize or repeat spoken words but have normal understanding of written language and normal language production, suggesting a relatively specific impairment at the level of phoneme perception (Buchman, Garron, Trost-Cardamone, Wichter, & Schwartz, 1986). This well-documented double dissociation should be kept in mind when encountering ambiguous terms such as “speech comprehension” and “intelligibility,” which unnecessarily conflate different levels of processing involving distinct kinds of information.

Early studies of PWD provided the first hard evidence that speech sounds are processed in the temporal lobe. The work of Salomon Henschen, in particular, distinguished lesions causing specific phoneme perception impairment from lesions causing other forms of “word deafness” (at the time, this term was used to designate any speech comprehension impairment),

linking the former to damage in the superior temporal gyrus (STG) (Henschen, 1918–1919). Lesion data from patients with PWD strongly suggest some degree of bilateral phoneme processing, because the vast majority of cases have bilateral STG lesions (Buchman et al., 1986; Poeppel, 2001). Particularly compelling in this regard are those who have a unilateral STG lesion with no symptomatic speech perception impairment and then develop PWD only after the contralateral STG is affected (Buchman et al., 1986; Ulrich, 1978). Also relevant to the issue of bilateral representation is evidence from intracarotid amobarbital (Wada) testing that shows that patients maintain much of their ability to discriminate phonemes even after anesthetization of the language-dominant hemisphere (Boatman et al., 1998; Hickok et al., 2008). Taken as a whole, these data suggest that phoneme perceptual processes are much more bilaterally represented than are later stages of speech comprehension. Nevertheless, PWD after unilateral damage is occasionally reported, and the damage in these instances is nearly always on the left side, suggesting a degree of asymmetry in the bilateral representation (Buchman et al., 1986; Poeppel, 2001).

PWD is a misnomer for several reasons. The deficit involves perception of phonemes, not words; therefore, sublexical phoneme combinations and other nonword stimuli are affected at least as much as real words. More appropriate designations include “phoneme deafness” and “auditory verbal agnosia.” The “purity” of the deficit is also highly variable. Although patients with PWD have normal pure tone hearing thresholds, most cases show impairments on more complex auditory perceptual tasks that do not involve speech sounds, such as recognition of nonspeech environmental sounds, pitch discrimination and other musical tasks, and various measures of temporal sequence perception (Buchman et al., 1986; Goldstein, 1974). The variety and severity of such nonverbal perceptual impairments are generally greater in patients with bilateral lesions than in those with unilateral left lesions. Two patients with unilateral left temporal lesions, for example, showed relatively circumscribed deficits involving perception of rapid spectral changes, including impaired consonant but spared vowel discrimination (Stefanatos, Gershkoff, & Madigan, 2005; Wang, Peach, Xu, Schneck, & Manry, 2000).

37.2 FUNCTIONAL IMAGING STUDIES

Phoneme perception has been the focus of many functional imaging studies. The loud noises produced by rapid gradient switching present a challenge for fMRI studies of auditory processing, because these noises not only mask experimental stimuli but also activate many of the brain regions of interest, limiting the

dynamic range available for hemodynamic responses. Most auditory fMRI studies avoid these problems by separating successive image volume acquisitions with a silent period during which the experimental stimuli are presented (Hall et al., 1999). If the acquisitions are separated by a sufficient amount of time (i.e., >7 seconds), then the measured BOLD responses primarily reflect activation by the experimental stimuli rather than the noise produced by the previous image acquisition.

Compared with a silent baseline, speech sounds (whether syllables, words, pseudowords, or reversed speech) activate most of the STG bilaterally (Binder et al., 2000; Wise et al., 1991). Although this speech–silence contrast is sometimes advocated as a method of “mapping Wernicke’s area” for clinical purposes (Hirsch et al., 2000), the resulting activation is typically symmetric and is unrelated to language lateralization as determined by Wada testing (Lehéricy et al., 2000). The activated regions include Heschl’s gyrus and surrounding dorsal STG areas that contain primary and belt auditory cortex (Rauschecker & Scott, 2009), suggesting that much of the activation is due to low-level, general auditory processes. A variety of nonspeech control stimuli (frequency-modulated tones, amplitude-modulated noise) were introduced to identify areas that might be more speech-specific (Binder et al., 2000; Jäncke, Wüstenberg, Scheich, & Heinze, 2002; Mummary, Ashburner, Scott, & Wise, 1999; Zatorre, Evans, Meyer, & Gjedde, 1992). The main finding in these studies was that primary and belt regions on the dorsal STG respond similarly to speech and simpler nonspeech sounds, whereas areas in the ventral STG and superior temporal sulcus (STS) respond more to speech than to simpler sounds (see DeWitt & Rauschecker, 2012 for an activation likelihood estimation [ALE] meta-analysis). The pattern suggests a hierarchically organized processing stream running from the primary auditory cortex on the dorsal surface to higher-level areas in the lateral and ventral STG, a pattern very reminiscent of the core-belt-parabelt organization in monkey auditory cortex (Kaas & Hackett, 2000).

The tone and noise controls used in the studies just mentioned are far less acoustically complex than speech sounds, leaving open the possibility that the observed ventral STG/STS activation reflects general acoustic complexity rather than phoneme-specific processing. The degree to which speech perception requires “special” mechanisms has been a contentious topic for many decades (Diehl & Kluender, 1989; Liberman et al., 1967; Liberman & Mattingly, 1985; Lotto, Hickok, & Holt, 2009). This unresolved issue motivated functional imaging researchers to begin the search for auditory cortical areas that respond selectively to speech phonemes compared with nonphonemic sounds of equivalent spectrotemporal complexity.

Scott, Blank, Rosen, and Wise (2000) addressed this problem using spectrally “rotated” speech. In this manipulation, the instantaneous auditory spectrum at each point in time is rotated about a central frequency axis, such that high frequencies become low frequencies and vice versa (Blessner, 1972). The rotation preserves overall spectrotemporal complexity (though the long-term spectrum and spectral distribution of dynamic features are both greatly altered) while reducing phoneme intelligibility. The contrast between speech and rotated speech produced activation of the left middle and anterior STS. A number of subsequent studies using similar methods have replicated this initial finding (Davis & Johnsrude, 2003; Friederici, Kotz, Scott, & Obleser, 2010; Narain et al., 2003; Okada et al., 2010). One difficulty with interpreting these results arises from the fact that the stimuli were sentences and therefore contained considerable semantic and syntactic information. Phoneme perception would have been perfectly correlated with engagement of semantic and syntactic processes. Thus, what is sometimes referred to as an “acoustically invariant response to speech” may simply reflect semantic or syntactic processing independent of phoneme perception per se. This would explain the somewhat anterior location of the activation compared with prior speech studies, because semantic and syntactic integration at the sentence level is thought to particularly engage the anterior temporal lobe (DeWitt & Rauschecker, 2012; Humphries, Binder, Medler, & Liebenthal, 2006; Humphries, Swinney, Love, & Hickok, 2005; Pallier, Devauchelle, & Dehaene, 2011; Spitsyna, Warren, Scott, Turkheimer, & Wise, 2006; Vandenberghe, Nobre, & Price, 2002; Visser, Jefferies, & Lambon Ralph, 2010).

Subsequent work focused more specifically on phoneme perception using a variety of controls for spectrotemporal complexity. Liebenthal, Binder, Spitzer, Possing, and Medler (2005) created synthetic nonphonemic syllables by inverting the direction of the first formant (F1) transition in a series of stop consonants. Stops are characterized acoustically by a rising F1 trajectory that results from opening the closed vocal tract and sudden enlargement of the oral cavity (Fant, 1973). Inverting the F1 trajectory results in speech-like sounds that have no phoneme identity. Brain activity was measured during ABX discrimination along a synthetic continuum ranging in equal steps from /b/ to /d/ (accomplished by gradual shift of the F2 transition from rising to falling) and along an otherwise similar nonphonemic continuum with inverted F1 transitions. Participants showed typical categorical perception behavior (superior discrimination across the category boundary compared with within category) for the phoneme continuum, but a flat discrimination function for the nonphonemic items, verifying that the latter stimuli failed to evoke a phoneme percept. The conditions were matched on overall accuracy (i.e.,

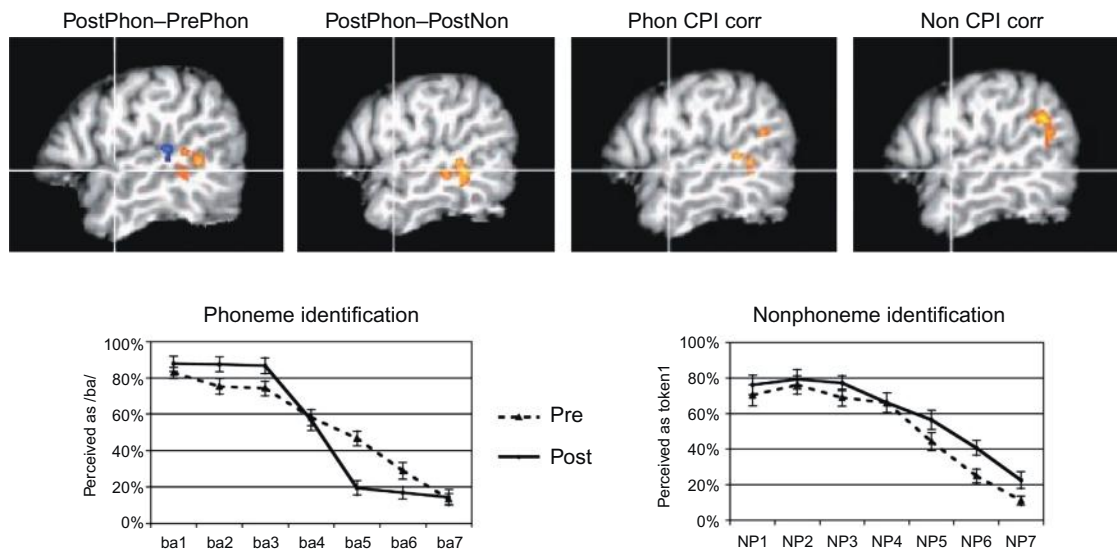

FIGURE 37.2 Left posterior temporal activation correlated with perception of phonemes in sine wave speech. The first upper panel (PostPhon–PrePhon) shows left posterior STS areas engaged only after the phonemic stimuli were perceived as /ba/ and /da/ as a result of training. The second upper panel (PostPhon–PostNon) shows selective activation of this region by phonemic relative to nonphonemic stimuli after training. Graphs in the lower panels show group average identification functions for the phonemic (left) and nonphonemic (right) continua, and the selective induction of categorical labeling for the phonemic stimuli after training. The third upper panel shows areas where increased activation for the phonemic stimuli from before (Pre) to after (Post) was correlated with individual change in slope of the phoneme identification function from Pre to Post (phonemic categorical perception index). The final upper panel shows areas where increased activation for the nonphonemic stimuli from Pre to Post was correlated with individual change in slope of the nonphonemic identification function from Pre to Post (nonphonemic CPI). Adapted from [Desai et al. \(2008\)](#) with permission from the publisher.

discriminability) and reaction time. A contrast between the phonemic and nonphonemic conditions showed activation localized in the mid-to-posterior left STS (peaks at Talairach coordinates $-60, -8, -3$ and $-56, -31, 3$). The spectrotemporally matched control condition effectively rules out auditory complexity as an explanation for this effect. This portion of the left STS thus appears to be a location where complex auditory information activates phoneme category representations.

[Liebenthal et al. \(2010\)](#) replicated this result using the same stimuli together with a labeling task. Event-related potentials data were obtained simultaneously with fMRI, showing that the difference between phonemic and nonphonemic processing begins at approximately 180 ms after stimulus onset and peaks at approximately 200 ms, manifesting as a larger P2 deflection in the phonemic condition.

[Dehaene-Lambertz et al. \(2005\)](#) and [Möttönen et al. \(2006\)](#) addressed the problem of spectrotemporal complexity confounds by comparing activation to sine wave speech presented before and after training subjects to perceive the sounds as phonemes. In both studies, participants performed a discrimination task in the naïve state during which they reported hearing the sounds as nonspeech. After explicit instruction that the sounds contained particular phonemes and after training in the scanner with explicit phoneme

identification tasks, the participants were scanned again. [Dehaene-Lambertz et al.](#) included a manipulation of across-category versus within-category discrimination and demonstrated a specific improvement in across-category discrimination after training. In both studies, a left posterior STS region showed stronger activation after training compared with before training. The clusters were somewhat more posterior along the STS than in the [Liebenthal](#) studies ([Dehaene-Lambertz et al.](#) peaks: $-60, -24, 4$ and $-56, -40, 0$; [Möttönen et al.](#) peak: $-61, -39, 2$), although both overlap with the posterior aspect of the [Liebenthal et al.](#) clusters.

[Desai, Liebenthal, Waldron, and Binder \(2008\)](#) combined these approaches by comparing sine wave syllables and nonphonemic sine wave stimuli before and after training. The nonphonemic items were created by inverting the initial trajectory of the sine tone representing “F1,” analogous to the approach followed by [Liebenthal et al.](#) with their speech sounds. The question the authors addressed was whether the expectation of hearing phonemes after training is sufficient in itself to activate the left STS, or if it is necessary for the stimulus to contain phonemic information. The main results ([Figure 37.2](#)) suggest that both top-down expectation and bottom-up phoneme input are necessary to activate the left STS region observed in the prior studies, and that the same region is activated whether

comparing phoneme sounds after versus before training (replicating the Dehaene-Lambertz et al. and Möttönen et al. studies) or phonemic and nonphonemic sounds after training. Desai et al. also obtained labeling data for the phonemic and nonphonemic continua before and after training and used a logistic function to model the slope of the boundary region as an index of categorical perception. This index increased significantly for the phoneme continuum after training but not for the nonphonemic continuum (Figure 37.2, bottom), and activation in the left STS was correlated with individual variation in the size of this increase in categorical perception.

It is noteworthy that in all of these studies in which phonemic stimuli were contrasted with nonphonemic stimuli of equal spectrotemporal complexity, the phoneme-specific responses were strongly left-lateralized. In contrast to the data from Wada testing and patients with PWD, discussed previously, these fMRI studies suggest that, at least in the intact brain, the left auditory system performs most of the computation related specifically to phoneme perception. The issue of lateralization of phoneme perception is discussed further in the final section of this chapter.

A major unanswered question from these fMRI studies is the extent to which the left STS response is necessarily exclusive to phoneme sounds. Phonemes are, by definition, highly familiar sounds for which behaviorally relevant perceptual categories have developed as a result of extensive experience. Would the left STS respond similarly during categorical perception of nonphoneme sounds? Does the response depend on the particular acoustic properties of phonemes, or does it reflect a more general process of auditory category perception? Desai et al. addressed this issue using individual variation in the categorical perception index they derived from their nonphonemic labeling functions (Figure 37.2). Although the participants, on average, showed no increase in categorical perception of these sounds after training, the small variation in the categorical perception index across participants actually predicted the level of activation in a small region in the left supramarginal gyrus and posterior STS. This cluster was somewhat posterior and dorsal to the one activated by phoneme perception (Figure 37.2). The authors proposed that the left posterior STS serves a general function of auditory category perception, and that small differences in the location of activation for phonemic and nonphonemic sounds reflect differences in familiarity between these types of categories.

Desai et al. (2008) provided only minimal perceptual training with their nonphonemic continuum. In a follow-up study, Liebenthal et al. (2010) asked whether more extensive training that induced stronger categorical perception of nonphonemic sounds would result in a similar recruitment of left posterior STS regions by

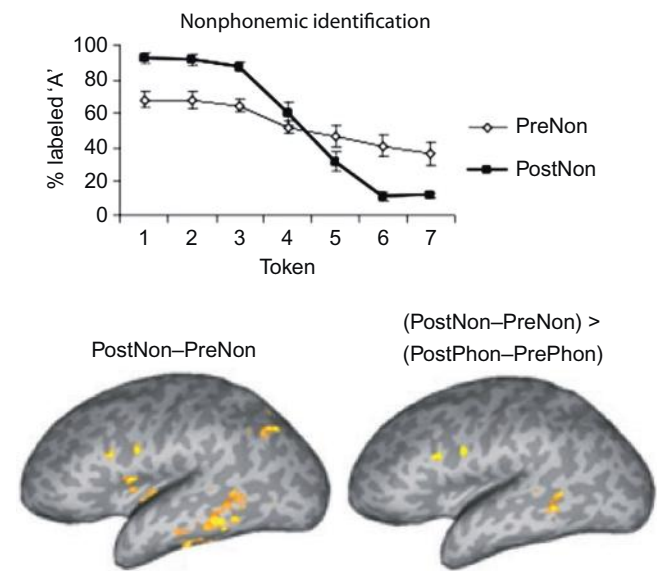

FIGURE 37.3 Coding of novel speech categories in the posterior left STS. The top graph shows induction of categorical labeling of nonphonemic consonant-like speech sounds after four training sessions. Training resulted in recruitment of a large left middle temporal region (lower left) and a more focal region of posterior left STS that was recruited more by learning novel nonphonemic categories than by similar training with familiar phonemic categories (/ba/ and /da/). Adapted from Liebenthal et al. (2010) with permission from the publisher.

phonemic and nonphonemic sounds after training. Participants participated in four sessions in which they were taught to label items in the nonphonemic speech continuum developed by Liebenthal et al. (2005) using two (arbitrary) category names. Identification functions became more categorical after training (Figure 37.3, top). Activation in the left mid-STS, which had been stronger for phonemic sounds prior to training, showed no difference between phonemic and nonphonemic stimuli after training, and a large region in left posterior middle temporal gyrus (MTG) and STS showed stronger responses to the nonphonemic sounds after training compared with before training (Figure 37.3, bottom). An interaction analysis showed that the left posterior STS was recruited by training specifically for the nonphonemic sounds (Figure 37.3, bottom right).

These five studies paint a somewhat complex picture of phoneme processing in the left STS, summarized in Figure 37.4. Highly familiar phonemes, for which strong and overlearned perceptual categories exist, selectively engage the mid-portion of the left STS compared with closely matched acoustic control stimuli. Sine wave speech phonemes engage a slightly more posterior region of left STS compared with the same sounds heard as non-speech. Finally, perception of newly learned nonphonemic speech categories engages still more posterior regions in the left STS, MTG, and supramarginal gyrus.

FIGURE 37.4 Summary of five controlled studies of phoneme and matched nonphoneme perception. Red markers indicate peaks in two studies comparing phonemic (/ba/-/da/) with spectrotemporally matched nonphonemic speech sounds (Liebenthal et al., 2005, 2010). Yellow markers indicate peaks from three studies examining induction of phoneme perception with sine wave speech (Dehaene-Lambertz et al., 2005; Desai et al., 2008; Möttönen et al., 2006). Blue markers indicate peaks in two studies examining acquisition of categorical perception with nonphonemic sine wave stimuli (Desai et al., 2008) and nonphonemic synthetic speech (Liebenthal et al., 2010).

One interpretation of this “familiarity gradient” is that it reflects a greater dependence on short-term auditory memory mechanisms in the case of less familiar sounds. As the mapping from spectrotemporal forms to categories becomes less automatic, the spectrotemporal information needs to be maintained in a short-term memory store. For speech sounds, this memory store likely constitutes the first stage in a supra-sylvian speech production pathway (Hickok & Poeppel, 2007; Wise et al., 2001), although the evidence obtained from nonphonemic categorization tasks (Desai et al., 2008; Liebenthal et al., 2010) indicates that these short-term auditory memory representations are not strictly speech-specific (Figure 37.4).

The perceptual integration of auditory and visual phoneme information has been examined in a number of studies, most of which manipulated the congruency or temporal synchrony of auditory and visual speech inputs (see Calvert, 2001 for an early review). These studies have generally implicated the left posterior STS and superior parietal regions such as the intraparietal sulcus in audiovisual integration of speech. Miller and D’Esposito (2005) used synchrony manipulation together with an event-related analysis of perceptual fusion judgments to separate brain responses due to successful perceptual fusion from responses reflecting the degree of synchrony. The left mid-STS (MNI coordinates $-46, -28, 0$) and left Heschl’s gyrus responded more strongly when the audiovisual stop consonants were successfully fused than when they were perceived as separate events.

A number of other regions, mainly nodes in the attention and cognitive control networks, showed the reverse pattern. The left STS response depended on successful perceptual fusion but showed no sensitivity to the degree of actual audiovisual synchrony.

Recent studies also implicate the left mid-STS in audiovisual integration processes underlying the McGurk illusion. Susceptibility to the McGurk effect is known to vary across individuals. Nath and Beauchamp (2012) divided their participant sample into low- and high-susceptibility McGurk perceivers, defined by their probability of perceiving “da” when presented with simultaneous auditory “ba” and visual “ga.” High-susceptibility perceivers showed stronger responses to these stimuli in a functionally defined audiovisual left mid-STS region of interest (ROI) (mean center-of-mass Talairach coordinates $-58, -28, 4$) compared with low-susceptibility perceivers. Across all participants, activation in this ROI was significantly correlated with individual susceptibility scores. In a complementary study, Beauchamp, Nath, and Pasalar (2010) showed that single-pulse transcranial magnetic stimulation (TMS) applied to a functionally defined audiovisual left mid-STS region disrupted the McGurk illusion in high-susceptibility perceivers, causing participants to report only the auditory stimulus. Taken together, these results suggest that a focal region in the left mid-STS integrates auditory and visual phoneme information, but that the visual input to this region is more variable across individuals and more easily disrupted.

37.3 DIRECT ELECTROPHYSIOLOGICAL RECORDINGS

Intracranial cortical electrophysiological recording (electrocorticography, or ECoG) offers a means of recording neural activity directly rather than indirectly via a hemodynamic response (as in positron emission tomography [PET] or fMRI). The technique provides much higher temporal resolution than fMRI and can also provide more precise spatial localization. Recent work has focused on induced changes in high gamma (>60 Hz) power, which is tightly correlated with local neural activity and the BOLD signal (Crone, Miglioretti, Gordon, & Lesser, 1998; Goense & Logothetis, 2008). The method usually involves a regularly spaced grid of electrodes draped on the surface convexity of the brain. One limitation of this approach is that the electrodes make contact with gyral crests and do not record from sulcal depths. Thus, most ECoG studies of phoneme perception provide data regarding the lateral STG but little or none regarding the STS.

ECoG studies suggest that overall spectrotemporal form is relatively well-preserved in the pattern of neural

activity on the left lateral mid-STG. The recorded spectrotemporal neural activity is sufficient to reconstruct intelligible speech waveforms (Pasley et al., 2012), indicating that the represented information is primarily, if not exclusively, acoustic rather than linguistic or symbolic in nature. Mesgarani, Cheung, Johnson, and Chang (2014) demonstrated that this region contains patches selective for different kinds of phonemes and phoneme features, with selectivity perhaps most closely reflecting manner cues such as overall spectral shape and dynamic changes in spectral shape. Thus, distinct groups of electrodes respond selectively to the following: plosive consonants, which are characterized by rapid changes over a broad frequency spectrum; sibilant fricatives, which have less dynamic and much more focused high-frequency energy; vowels, which have less dynamic and grossly bimodal frequency spectra; and nasals, which are characterized by prominent low-frequency energy. The fricative manner category includes both sibilant and nonsibilant (anterior) phonemes, and it is notable that the anterior voiced fricatives /v/ and /ð/ (as in “vee” and “thee”) did not pattern with the sibilant phonemes. This is further evidence that the patterns reflect spectrotemporal information, which is quite different for sibilant unvoiced fricatives and anterior voiced fricatives, rather than more abstract phonetic features like “fricative.”

Another notable finding from these studies is the combinatorial nature of responses in the lateral STG. For example, Mesgarani et al. report that areas sensitive to vowels show negatively correlated sensitivity to first and second formant values, indicating that they integrate information about F1 and F2 and respond optimally to particular F1/F2 combinations. Such combinatorial encoding not only is expected given the essential acoustic properties that distinguish vowels (Peterson & Barney, 1952) but also provides a probable mechanism for perceptual normalization across speakers with different vocal tract properties (Sussman, 1986).

ECog data also provide novel information about the timing of activation across the STG and STS during phoneme perception. Canolty et al. (2007) compared spoken word stimuli with nonphonemic sounds created by removing formant detail from the auditory waveform. High gamma responses were larger for words than for the nonphonemic sounds, and these differences emerged at 120 ms after stimulus onset in the posterior STG, at 193 ms in the mid-STG, and at 268 ms in the mid-STS. This timing is in good agreement with the findings of a larger scalp P2 response for phonemic compared with nonphonemic sounds peaking at approximately 200 ms (Liebenthal et al., 2010). The ECog data furthermore show the spread of activation over time from earlier posterior auditory areas to higher-level anterior and lateral STG cortex and, finally, to mid-STS, consistent with the

proposed hierarchical organization of this network (Binder et al., 2000; Kaas & Hackett, 2000).

These data add enormously to our understanding of spectrotemporal encoding in higher-level auditory cortex. They indicate a process of multidimensional acoustic feature representation from which subphonemic features arise through combinatorial processing. The extent to which such representations are specific to phonemes would require further testing with appropriate nonphonemic controls, but presumably identical subphonemic acoustic features would be represented by the same neurons in lateral STG regardless of whether they occurred in phonemes or nonphonemic sounds. As described in the preceding section, it appears likely that encoding of more abstract phonetic category percepts occurs at still higher levels of processing performed in the left STS.

37.4 THE ROLE OF ARTICULATORY REPRESENTATIONS IN PHONEME PERCEPTION

The role of motor speech codes in phoneme perception has been a long and heatedly debated topic. There are theories emphasizing that speech sounds arise from articulatory gestures, and that these gestures, or at the least the motor programs that underlie them, are less variable than the sounds they produce (Galantucci, Fowler, & Turvey, 2006; Liberman et al., 1967). According to such theories, motor programs provide an internal template (or “efference copy”) of the phoneme against which the auditory input can be matched. On the other side of the debate are purely auditory theories of phoneme perception in which motor templates have no necessary role (Diehl & Kluender, 1989; Lotto et al., 2009). An intermediate view is that motor templates are increasingly engaged and become more necessary as the auditory signal is more unfamiliar or degraded (Callan, Jones, Callan, & Akahane-Yamada, 2004). There seems little doubt that strong connections exist between speech perception and articulation systems, enabling auditory feedback to guide articulation during speech production (Guenther, Hampson, & Johnson, 1998; Tourville, Reilly, & Guenther, 2008). It therefore appears reasonable that these connections might operate in reverse during phoneme perception tasks.

Numerous fMRI and PET studies show activation in the left precentral gyrus (ventral premotor cortex) and inferior frontal gyrus (IFG) pars opercularis during speech perception tasks (Binder et al., 2000; Burton, Small, & Blumstein, 2000; Démonet et al., 1992), and show common activation in these areas during speech perception and production tasks (Callan, Callan, Gamez,

Sato, & Kawato, 2010; Callan et al., 2006; Tremblay & Small, 2011; Wilson & Iacoboni, 2006; Wilson, Saygin, Sereno, & Iacoboni, 2004). A persistent difficulty with interpreting these posterior frontal activations is the possibility that they may in some cases reflect decision, working memory, or other cognitive control processes rather than activation of motor codes (Binder, Liebenthal, Possing, Medler, & Ward, 2004). A more specific activation of motor representations is suggested by TMS studies showing enhancement of motor-evoked potentials in articulatory muscles during passive listening to speech (Fadiga, Craighero, Buccino, & Rizzolatti, 2002; Watkins, Strafella, & Paus, 2003) (see Yuen, Davis, Brysbaert, & Rastle, 2010 for related evidence). These findings suggest that merely listening to speech sounds activates motor speech areas sufficiently to lower the threshold for eliciting an evoked potential. Pulvermüller et al. (2006) presented fMRI evidence that this activation is articulator-specific. Premotor areas controlling tongue and lip movements were determined using motor localizer tasks. The tongue area was differentially activated by hearing the coronal stop /t/ relative to hearing the bilabial stop /p/, and conversely the lip area was more activated by /p/ compared to /t/.

As pointed out by many authors, the common activation in premotor areas by production and auditory perception of speech gestures is analogous to the cross-modal responsiveness of mirror neurons to execution and visual observation of other actions (Rizzolatti & Arbib, 1998; Rizzolatti & Craighero, 2004). In both cases the performer is simultaneously a perceiver and uses perceptual information to guide performance, presumably creating strong functional connections between perceptual and motor networks.

The possibility that motor cortex activation might be merely an epiphenomenon unrelated to the perceptual process itself was countered by several studies showing that repetitive TMS delivered to the articulatory motor cortex to produce a functional "lesion" reduces phoneme discrimination performance (D'Ausilio et al., 2009; Meister, Wilson, Deblieck, Wu, & Iacoboni, 2007; Möttönen & Watkins, 2009). In two of these studies, the effects on speech perception were specific to the place of articulation affected by TMS: identification of bilabial stops ("ba" and "pa") was selectively affected by TMS to the lip representation, whereas identification of lingual stops ("da" and "ta") was selectively affected by TMS to the tongue representation (D'Ausilio et al., 2009; Möttönen & Watkins, 2009). Such results provide rather compelling evidence for at least some contribution from motor codes to phoneme perception.

At issue is the extent to which this contribution is critical under typical listening circumstances. The

forementioned TMS lesion studies all used relatively difficult phoneme discrimination tasks with intelligibility compromised by adding noise or by manipulating the distinctiveness of synthetic formant transitions. Two other motor cortex TMS lesion studies showed no effect of TMS on perception of highly intelligible phonemes (D'Ausilio, Bufalari, Salmas, & Fadiga, 2012; Sato, Tremblay, & Gracco, 2009), suggesting that motor codes may only contribute to phoneme perception under adverse listening conditions. A more recent TMS study by Möttönen, Dutton, and Watkins (2013), however, provides evidence against this interpretation. They examined effects of motor cortex TMS on auditory mismatch negativity (MMN) responses to ignored speech. The MMN is a relatively preattentive auditory cortex response to infrequent deviant stimuli appearing within a sequence of repeating stimuli. Repetitive TMS to the motor lip representation reduced the magnitude of the MMN to deviant "ba" or "ga" syllables in a train of "da" syllables. This effect was specific to lip cortex stimulation and did not appear when the hand motor area was stimulated, when the lip cortex was stimulated and tone trains with intensity or duration deviants were used, or when the lip cortex was stimulated and syllable trains with duration deviants were used. One wrinkle in the results was that stimulation of the lip cortex also reduced the MMN to syllables with intensity deviations, which would be unexpected if the input from motor cortex reflects phoneme identity. Although these results do not imply that activation of motor cortex is necessary for successful conscious phoneme perception, they do demonstrate that input from motor areas involved in speech articulation reduces the ability of auditory cortex to process changes in phoneme input under noise-free listening conditions and in the absence of any attentional task.

Another notable aspect of the Möttönen and Watkins MMN study concerns the locus of motor activation effects. Activation of articulatory representations could affect perception in at least two distinct ways. According to the original Motor Theory of speech perception, articulatory representations are the actual targets of perception (Liberman et al., 1967). That is, perceptual decisions are based on activation of these codes rather than on auditory phoneme representations, and there is no role for feedback from motor to auditory codes. In contrast, most recent work assumes that motor codes provide feedback that assists phoneme recognition by the auditory system through a mechanism variously described as priming, prediction, or constraint. Suppression of the preattentive auditory MMN by motor cortex TMS suggests that a feedback mechanism from motor to auditory cortex plays at least some role.

37.5 HEMISPHERIC SPECIALIZATION IN PHONEME PERCEPTION

Speech contains much more than just phoneme information. Speech provides rich information about the age, gender, and specific identity of the speaker (based on fundamental frequency, voice quality and timbre, speed of articulation, accent, and other cues); emotional state of the speaker and affective content of the message (derived from emphasis cues and prosodic variation in fundamental frequency); and a variety of nonphonemic linguistic content (syllabic emphasis, semantic emphasis, sentential prosody). To refer to phoneme perception as “speech perception” is therefore both illogical and confusing, yet this usage is rampant and has contributed to some of the confusion regarding hemispheric lateralization of phoneme perception. As noted, speech sounds induce relatively symmetric bilateral activation of the STG compared with nonspeech sounds (tones and noise), which has contributed to a general sense that phoneme perception is symmetrically represented. Much of this right STG activation from speech, however, likely reflects processing of indexical and prosodic cues (Baum & Pell, 1999; Belin, Zatorre, Lafaille, Ahad, & Pike, 2000; Bonte, Hausfeld, Scharke, Valente, & Formisano, 2014; Latinus, McAleer, Bestelmeyer, & Belin, 2013; Lattner, Meyer, & Friederici, 2005; Ross, Thompson, & Yenkosky, 1997; Van Lancker, Kreiman, & Cummings, 1989; von Kriegstein, Eger, Kleinschmidt, & Giraud, 2003; Zatorre, Belin, & Penhune, 2002; Zatorre et al., 1992). With adequate controls for these cues, activation associated specifically with phoneme perception is much more strongly lateralized to the left STS (Dehaene-Lambertz et al., 2005; Desai et al., 2008; Liebenthal et al., 2005, 2010; Meyer et al., 2005; Möttönen et al., 2006).

Phoneme perception, however, does not depend solely on the left hemisphere. As noted, data from patients with focal brain lesions and patients undergoing Wada testing indicate that the right hemisphere has the capacity to perceive phonemes when the left hemisphere is compromised. Again, however, it is useful to note that unilateral left STG lesions occasionally produce phoneme perception deficits (this could depend on the extent of left STG and STS damage), and phoneme perception by the right hemisphere during Wada testing is not perfect (Hickok et al., 2008). Moreover, Boatman and colleagues demonstrated unequivocal phoneme perception deficits during unilateral electrical stimulation of the left mid-posterior STG (Boatman, Lesser, & Gordon, 1995). Perception was more impaired for consonant than for vowel discriminations (Boatman, Hall, Goldstein, Lesser, & Gordon, 1997). These mixed findings are difficult to

explain with models that propose either bilateral symmetric processing of phonemes or unilateral left hemisphere processing, despite the attractiveness of such models. As with many theories of brain function, the weight of the evidence suggests a less dichotomous state of affairs in which phoneme information is processed mainly but not exclusively by the left STG/STS, and lesions to this region cause varying degrees of phoneme perception deficit, depending on the type and extent of the lesion and the premorbid functional capacity of the individual’s right hemisphere.

Zatorre et al. proposed a theory of auditory hemispheric specialization in which the left auditory system excels at temporal resolution and the right auditory system excels at spectral resolution (Zatorre & Belin, 2001). Analogous to the trade-off in temporal versus spectral resolution that characterizes any time-frequency analysis, the left auditory system is proposed to integrate information across wide spectral bandwidths but over short time windows, whereas the right auditory system integrates across longer time windows in narrower spectral bands. As a general concept, the theory provides considerable explanatory power, accounting for right hemisphere specializations for prosody, melody, and suprasegmental linguistic perception, and left hemisphere specialization for perception of short-segment (i.e., <50 ms) phoneme cues. Specialization of the right auditory system for frequency discrimination and melody processing is now well-documented in functional imaging studies (Belin, Zilbovicius, Crozier, Thivard, & Fontaine, 1998; Brechmann & Scheich, 2005; Jamison, Watkins, Bishop, & Matthews, 2006; Schonwiesner, Rubsamen, & von Cramon, 2005; Zatorre & Belin, 2001; Zatorre et al., 2002), although the evidence supporting left hemisphere specialization for high temporal resolution is more mixed (Belin et al., 1998; Boemio, Fromm, Braun, & Poeppel, 2005; Jamison et al., 2006; Overath, Kumar, von Kriegstein, & Griffiths, 2008; Schonwiesner et al., 2005; Zaehle, Wustenberg, Meyer, & Jancke, 2004; Zatorre & Belin, 2001). McGettigan and Scott (2012) criticized the proposal on the basis that phoneme perception requires extensive spectral analysis; however, this criticism misses the central fact that the spectral resolution needed for phoneme perception is still very coarse. Discriminating place of articulation for stop consonants, for example, requires only an overall representation of spectral shape across a range of >1,000 Hz. Similarly, discriminating fricative place of articulation and voicing, voiced from unvoiced stops, and nasal from oral stops require only fairly coarse information about spectral shape over bandwidths of several hundred Hz (see Shannon, Zeng, Kamath, Wygonski, & Ekelid, 1995 for related evidence). In contrast, listeners can discriminate changes in F0 of 5 Hz or less (Klatt, 1973), which is

required for prosodic perception (and for singing in tune!) yet constitutes spectral resolution several orders of magnitude finer than is needed for phoneme discrimination. Changes of this magnitude in formant center frequencies have no effect on phoneme intelligibility (Ghitza & Goldstein, 1983). Vowels are a somewhat special case in which phoneme discrimination depends on a relatively fine-grained analysis of spectral shape (although still coarse by musical standards) and involves longer segments. This difference is consistent with broad evidence for relatively right-lateralized processing of vowel categories (Boatman et al., 1997; Bonte et al., 2014; Shankweiler & Studdert-Kennedy, 1970; Stefanatos et al., 2005; Wang et al., 2000).

Working from the principles articulated by Zatorre, Poeppel proposed a relationship between asymmetric time scales and corresponding brain oscillations (Poeppel, 2003). Gamma frequency oscillations (40 Hz and higher) were proposed as the physiological correlate of integration over short time windows (20–50 ms) and linked with processing of phonemes, whereas alpha–theta oscillations (4–10 Hz) were proposed as the physiological correlate of integration over longer time windows (150–250 ms) and linked with processing of syllables and suprasegmental frequency modulations. The theory is otherwise (to this reader, at least) identical to Zatorre’s. More recent versions of the theory emphasize the role of endogenous theta oscillations, which are proposed to be entrained by amplitude modulations at the syllable level in ongoing speech (Giraud & Poeppel, 2012). Entrainment of an endogenous theta rhythm enhances processing of nested gamma oscillations that sample the auditory input on a finer time scale to support processing of phoneme cues. Asymmetry arises because entrainment of theta oscillations dominates in the right auditory system, whereas gamma oscillations are more prominent in the left auditory cortex. Some support for this linkage comes from studies showing relative asymmetries of theta and gamma power at rest (Giraud et al., 2007; Morillon et al., 2010). The emphasis on syllabic rhythms reflects a current renewed interest in the role of syllabic organization in speech perception (Ghitza, 2012; Peelle & Davis, 2012; Stevens, 2002), which in turn reflects the dominant rate of articulator movements during production. However, entrainment by a syllabic rhythm cannot be critical for phoneme perception because phonemes can be perceived in isolated monosyllabic stimuli, which do not allow enough time for such entrainment (Ghitza, 2013). At present, the links between acoustic phonetic perception and endogenous neural oscillations is a topic of ongoing investigation.

38.1 OVERVIEW

Of all the signals the human auditory system has to process, the most relevant to the listener is arguably speech. Speech perception is learned and executed with automaticity and great ease even by very young children, but it is handled surprisingly poorly by even sophisticated automatic devices. Therefore, parsing and decoding speech can be considered one of the main challenges of the auditory system. This chapter focuses on how the human auditory cortex uses the temporal structure of the acoustic signal to extract phonemes and syllables, two types of events that need to be identified in connected speech.

Speech is a complex acoustic signal exhibiting quasiperiodic behavior at several timescales. The neural signals recorded from the auditory cortex using EEG or MEG also exhibit a quasiperiodic structure, whether in response to speech or not. In this chapter we present different models grounded on the assumption that the quasiperiodic structure of collective neural activity in auditory cortex represents the ideal mechanical infrastructure to solve the speech demultiplexing problem (i.e., the fractioning of speech into linguistic constituents of variable size). These models remain largely hypothetical. However, they constitute exciting theories that will hopefully lead to new research approaches and incremental progress on this foundational question about speech perception.

The chapter proceeds as follows. First, some of the essential features of natural and speech auditory stimuli

are outlined. Next, the properties of auditory cortex that reflect its sensitivity to these features are reviewed, and current ideas about the neurophysiological mechanisms underpinning the processing of connected speech are discussed. The chapter closes with a summary of speech processing models on a larger scale, attempting to capture most of these phenomena in an integrated vision.

38.1.1 Timescales in Auditory Perception

Sounds are audible over a broad frequency range between 20 and 20,000 Hz. They enter the outer ear and travel through the middle ear to the inner ear, where they provoke the basilar membrane to vibrate at a specific location, depending on the sound frequency. Low and high frequencies induce vibrations of the apex and base of the basilar membrane, respectively. The deformation of the membrane on acoustic stimulation provokes the deflection of inner hair cells, *ciliae*, and the emission of a neural signal to cochlear neurons, subsequently transmitted to neurons of the cochlear nucleus in the brainstem. Each cochlear neuron is sensitive to a specific range of acoustic frequencies between 20 Hz and 20 kHz. Because of their regular position along the basilar membrane, the cochlear neurons ensure the place-coding of acoustic frequencies, also called “tonotopy,” which is preserved up to the cortex (Moerel et al., 2013; Saenz & Langers, 2014).

Acoustic fluctuations <20 Hz are not audible. They do not elicit place-specific responses in the cochlea.

FIGURE 38.1 (A) Scale of perceived temporal modulation (modified from Joris, Schreiner, & Rees, 2004 and Nourski & Brugge, 2011). (B) Relevant psychophysical parameters (perceptual changes) of the spectrogram reflect the temporal constraints that superimpose on the structure of linguistic signals. (C) Temporal structure of linguistic features. (D) The length of linguistic features remarkably matches the frequency of oscillations that are observed at rest in the brain. Note that the frequency ranges at which auditory percepts switch from discrete (flutter) to continuous (pitch) roughly match the upper limit at which gamma rhythms can be entrained by the stimulus (~ 200 Hz).

Low frequencies <300 Hz are present in complex sounds, such as temporal fluctuations of audible frequencies, and are encoded through the discharge rate of cochlear neurons (Zeng, 2002). A range of frequencies from 20 to 300 Hz is both place-coded and rate-coded at the auditory periphery. Temporal modulation of sounds in these frequencies typically elicits a sensation of pitch. Figure 38.1A and 38.1B summarizes the correspondence between categories of perceptual attributes and the sound modulation frequency (see also Nourski & Brugge, 2011 for a review). When sounds are modulated at very slow rates <10 Hz, a sequence of distinct events is perceived. When modulations accelerate from 10 to approximately 100 Hz, distinct events merge into a single auditory stream, and the sensation evolves from fluctuating magnitude to a sensation of acoustic roughness (Figure 38.1B).

Speech sounds are complex acoustic signals that involve only the lower part of audible frequencies (20–8,000 Hz). They are called “complex” because both their frequency distribution and their magnitude vary strongly and quickly over time. In natural speech, amplitude modulations at slow (<20 Hz) and fast (>100 Hz) timescales are coupled (Figure 38.2), and slower temporal fluctuations modulate the amplitude of spectral fluctuations. Slow modulations (<5 Hz) signal word and syllable boundaries (Hyafil, Fontolan, Gutkin, & Giraud, 2012; Rosen, 1992), which are perceived as a sequence of distinct events. Phonemes (speech sounds) are signaled by fast spectrotemporal

modulations (<30 Hz). They can be perceived as distinct events when being discriminated from each other. Faster modulations, such as those imposed by the glottal pulse (100–300 Hz), indicate the voice pitch (Figure 38.1C). Figure 38.1D shows how these perceptual events relate to the different frequency ranges of the EEG.

38.1.2 The Temporal Structure of Speech Sounds

Figure 38.2 illustrates two useful ways to visualize the signal: as a waveform (38.2A) and as a spectrogram (38.2B). The waveform represents energy variation over time—the input that the ear actually receives. The outlined “envelope” (thick line) reflects that there is a temporal regularity in the signal at relatively low modulation frequencies. These modulations of signal energy (in reality, spread out across the “cochlear” filterbank) are <20 Hz and peak at a rate of approximately 4–6 Hz (Elliott & Theunissen, 2009; Steeneken & Houtgast, 1980). From the perspective of what auditory cortex receives as input, namely the modulations at the output of each frequency channel of the filterbank that constitutes the auditory periphery, these energy fluctuations can be characterized by the modulation spectrum (Chi, Ru, & Shamma, 2005; Dau, Kollmeier, & Kohlrausch, 1997; Kanedera, Arai, Hermansky, & Pavel, 1999; Kingsbury, Morgan, &

FIGURE 38.2 (A) Waveform and (B) spectrogram of the same sentence uttered by a male speaker. Some of the key acoustic cues in speech comprehension are highlighted in black.

Greenberg, 1998; McDermott & Simoncelli, 2011). At the shortest timescale (below 1 ms or equivalently above 1 kHz), the very fast temporal fluctuations are transformed into a spectral representation at the cochlea and the neural processing of these features is generally known as spectral processing. At an intermediate timescale (~ 70 Hz–1 kHz), the temporal fluctuations are usually referred to as the temporal fine structure. The temporal fine structure is critical to the perception of pitch and inter-aural time differences that are important cues for sound source localization (Grothe, Pecka, & McAlpine, 2010; Plack, Oxenham, Fay, & Popper, 2005). Temporal fluctuations on an even longer timescale (~ 1 –10 Hz) are heard as a sequence of discrete events. Acoustic events occurring on this timescale include syllables and words in speech and notes and beats in music. Of course, there are no clear boundaries between these timescales; the timescales are divided here based on human auditory perception.

The second analytic representation, the spectrogram, decomposes the acoustic signal in the frequency, time, and amplitude domains (Figure 38.2B). Although the human auditory system captures frequency information between 20 Hz and 20 kHz (and such a spectrogram is plotted here), most of the information that is extracted for effective recognition is below 8 kHz. It is worth remembering that speech transmitted over telephone landlines contains a much narrower bandwidth (200–3600 Hz) and is comfortably understood by normal listeners. A number of critical acoustic features can be identified in the spectrogram. The faintly visible vertical stripes represent the glottal pulse, which reflects the speaker's fundamental frequency, F0. This

can range from approximately 100 Hz (male adult) to 300 Hz (child; see Figure 38.1D). The horizontal bands of energy show where in frequency space a particular speech sound is carried. The spectral structure thus reflects the articulator configuration. These bands of energy include the formants (F1, F2, etc.) definitional of vowel identity; high-frequency bursts associated, for example, with frication in certain consonants (e.g., /s/, /f/); and formant transitions that signal the change from a consonant to a vowel or vice versa.

Notwithstanding the importance of the spectral fine structure, there is a big caveat: speech can be understood, in the sense of being intelligible in psychophysical experiments, when the spectral content is replaced by noise and only the envelope is preserved. Importantly, this manipulation is done in separate bands across the spectrum, for example, as few as four separate bands (Shannon, Zeng, Kamath, Wygonski, & Ekelid, 1995). Speech that contains only envelope but no fine structure information is called vocoded speech (Faulkner, Rosen, & Smith, 2000). Compelling demonstrations that exemplify this type of signal decomposition illustrate that the speech signal can undergo radical alterations and distortions and yet remain intelligible (Shannon et al., 1995; Smith, Delgutte, & Oxenham, 2002). Such findings have led to the idea that the temporal envelope, that is, temporal modulations of speech at relatively slow rates, is sufficient to yield speech comprehension (Drullman, Festen, & Plomp, 1994a, 1994b; Giraud et al., 2004; Loebach & Wickesberg, 2008; Rosen, 1992; Scott, Rosen, Lang, & Wise, 2006; Shannon et al., 1995; Souza & Rosen, 2009). When using stimuli in which the fine structure is compromised or not available at

all, envelope modulations below 16 Hz appear to suffice for adequate intelligibility. The remarkable comprehension level reached by most patients with cochlear implants, in whom approximately 15–20 electrodes replace 3,000 hair cells, remains the best empirical demonstration that the spectral content of speech can be degraded with tolerable alteration of speech perception (Roberts, Summers, & Bailey, 2011). A related demonstration showing the resilience of speech comprehension in the face of radical signal impoverishment is provided by sine-wave speech (Remez, Rubin, Pisoni, & Carrell, 1981). In these stimuli both envelope and spectral content are degraded, but enough information is preserved to permit intelligibility. Typically, sine-wave speech preserves the modulations of the three first formants, which are replaced by sine-waves centered on F0, F1, and F2. In summary, dramatically impoverished stimuli remain intelligible insofar as enough information in the spectrum is available to convey temporal modulations at appropriate rates.

Based on this brief and selective summary, two concepts merit emphasis. First, the extended speech signal contains critical information that is modulated at rates below 20 Hz, with the modulation peaking at approximately 5 Hz (Edwards & Chang, 2013). This low-frequency information correlates closely with the syllabic structure of connected speech (Giraud & Poeppel, 2012). Second, the speech signal contains critical information at modulation rates higher than, for example, 50 Hz. This rapidly changing information is associated with fine spectral changes that carry information about the speaker's gender or identity and other relevant speech attributes (Elliott & Theunissen, 2009). Thus, two surprisingly different timescales are concurrently at play in the speech signal. This important issue is described in the text that follows. In this chapter, we discuss the timescales longer than 5 ms (<200 Hz) with a focus on the timescale between 100 ms and 1 s (1–10 Hz). Temporal features that contribute to the spatial localization of sounds are not discussed (see Grothe et al., 2010 for a review).

38.2 CORTICAL PROCESSING OF CONTINUOUS SOUNDS STREAMS

38.2.1 The Discretization Problem

In natural connected speech, speech information is embedded in a continuous acoustic flow, and sentences are not "presegmented" in perceptual units of analysis. Recent work on sentence-level stimuli (i.e., materials with a duration exceeding 1–2 s) using experimental tasks such as intelligibility, suggests that long-term

temporal parameters of the acoustic signal are of major importance (Ghitza & Greenberg, 2009; Luo, Liu, & Poeppel, 2010; Luo & Poeppel, 2007; Peelle, Gross, & Davis, 2013). Online segmentation remains a major challenge to contemporary models of speech perception as well as automatic speech recognition.

Interestingly, a large body of psychophysical work studied speech perception and intelligibility using phrasal or sentential stimuli (see Miller, 1951 for a summary of many experiments and Allen, 2005 for a review of the influential work of Fletcher and others). Fascinating findings emerged from that work, emphasizing the role of signal-to-noise ratio in speech comprehension, but perhaps the most interesting feature is that connected speech has principled and useful temporal properties that may play a key role in the problem of speech parsing and decoding. Natural speech usually comes to the listener as a continuous stream and needs to be analyzed online and decoded by mechanisms that are unlikely to be continuous (Giraud & Poeppel, 2012). The parsing mechanism corresponds to the discretization of the continuous input signal into subsegments of speech information that are read out, to a certain extent, independently from each other. The notion that perception is discrete has been extensively discussed and generalized in numerous sensory modalities and contexts (Pöppel & Artin, 1988; VanRullen & Koch, 2003). Here, we discuss the hypothesis that neural oscillations constitute a possible mechanism for discretizing temporally complex sounds such as speech (Giraud & Poeppel, 2012).

38.2.2 Analysis at Multiple Timescales

Speech is a multiplexed signal, that is, it interlinks several levels of complexity, and organizational principles and perceptual units of analysis exist at distinct timescales. Using data from linguistics, psychophysics, and physiology, Poeppel and colleagues proposed that speech is analyzed in parallel at multiple timescales (Boemio, Fromm, Braun, & Poeppel, 2005; Poeppel, 2001, 2003; Poeppel, Idsardi, & van Wassenhove, 2008). The central idea is that both local-to-global and global-to-local types of analyses are carried out concurrently (multitime-resolution processing). This assumption adds to the notion of reverse hierarchy (Hochstein & Ahissar, 2002; Nahum, Nelken, & Ahissar, 2008) and other hierarchical models in perception, which propose that the hierarchical complexification of sensory information (e.g., the temporal hierarchy) maps onto the anatomo-functional hierarchy of the brain (Giraud et al., 2000; Kiebel, Daunizeau, & Friston, 2008). The principal motivations for extending such a hypothesis are two-fold. First, a single, short temporal window

that forms the basis for hierarchical processing, that is, increasingly larger temporal analysis units as one ascends the processing system, fails to account for the spectral and temporal sensitivity of the speech processing system and is difficult to reconcile with behavioral performance. Second, the computational strategy of analyzing information on multiple scales is widely used in engineering and biological systems, and the neuronal infrastructure exists to support multiscale computation (Canolty & Knight, 2010). According to the view summarized here, speech is chunked into segments of roughly featural or phonemic length, and then integrated into larger units, such as segments, diphones, syllables, and words. In parallel, there is a fast global analysis that yields coarse inferences about speech (akin to Stevens, 2002 “landmarks” hypothesis) and that subsequently refines segmental analysis. Here, we propose that segmental and suprasegmental analyses could be carried out concurrently and “packaged” for parsing and decoding by neuronal oscillations at different rates.

The notion that speech analysis occurs in parallel at multiple timescales justifies moving away from strictly hierarchical models of speech perception (Giraud & Price, 2001). Accordingly, the simultaneous extraction of different acoustic cues permits simultaneous high-order processing of different information from a unique input signal. That speech should be analyzed in parallel at different timescales derives, among other reasons, from the observation that articulatory–phonetic phenomena occur at different timescales. It was noted previously (Figure 38.1C and Figure 38.2) that the speech signal contains events of different durations: short energy bursts and formant transitions occur within a 20- to 80-ms timescale, whereas syllabic information occurs over 150–300 ms. The processing of both types of events could be accounted for either by a hierarchical model in which smaller acoustic units (segments) are concatenated into larger units (syllables) or by a parallel model in which both temporal units are extracted independently, and then combined. A degree of independence in the processing of long (slow modulation) and short (fast modulation) units is observed at the behavioral level. For instance, speech can be understood well when it is first segmented into units up to 60 ms and when these local units are temporally reversed (Greenberg & Arai, 2001; Saberi & Perrott, 1999). Because the correct extraction of short units is not a prerequisite for comprehension, this rules out the notion that speech processing relies solely on hierarchical processing of short and then larger units. Overall, there appears to be a grouping of psychophysical phenomena such that some cluster at thresholds of approximately 50 ms and below and others cluster at approximately 200 ms and above (a similar clustering is observed for temporal

properties in vision; Holcombe, 2009). Importantly, non-speech signals are subject to similar thresholds. For example, 15–20 ms is the minimal stimulus duration required for correctly identifying upward versus downward FM sweeps (Luo, Boemio, Gordon, & Poeppel, 2007). By comparison, 200-ms stimulus duration underlies loudness judgments. In summary, physiological events at related scales form the basis for processing at that level. Therefore, the neuronal oscillatory machinery (together with motor constraints related to speech production; Morillon et al., 2010) presumably imposed strong temporal constraints that might have shaped the size of acoustic features selected to carry speech information. This is consistent with the notion that perception is discrete and that the exogenous recruitment of neuronal populations is followed by refractory periods that temporarily reduce the ability to optimally extract sensory information (Ghitza, 2011; Ghitza & Greenberg, 2009). According to this hypothesis, the temporally limited capacity of gamma oscillations to integrate information over time possibly imposes a lower limit to the phoneme length. This also suggests that oscillatory constraints in the delta–theta range possibly constrained the size of syllables to be approximately the size of a delta–theta cycle. Considering that the average lengths of phoneme and syllable are approximately 25–80 and 150–300 ms, respectively (Figure 38.1 and Figure 38.2), the dual timescale segmentation requires two parallel sampling mechanisms, one at approximately 40 Hz (or, more broadly, in the low gamma range) and one at approximately 4 Hz (or in the theta range).

38.2.3 Neural Oscillations as Endogenous Temporal Constraints

Neural oscillations correspond to synchronous activity of neuronal assemblies that are both intrinsically coupled and coupled by a common input. It was proposed that these oscillations reflect modulations of neuronal excitability that temporally constrain the sampling of sensory information (Schroeder & Lakatos, 2009a). The intriguing correspondence between the size of certain speech temporal units and the frequency of oscillations in certain frequency bands (see Figure 38.1) has elicited the intuition that they might play a functional role in sensory sampling. Oscillations are evidenced by means of a spectrotemporal analysis of electrophysiological recordings (see Wang, 2010 for a review). The requirements for measuring oscillations and spiking activity are different. The presentation of an exogenous stimulus typically results in an increase of spiking activity (i.e., an increase of synaptic output relative to baseline spiking activity) in those brain areas that are functionally

sensitive to such sensory inputs. Neural oscillations, however, can be observed in local field potential recordings (LFPs), which reflect synchronized dendritic inputs into the observed area, even in the absence of any external stimulation. Exogenous stimulation, however, typically modulates oscillatory activity, resulting either in a reset of their phase and/or in a change (increase or decrease) in the magnitude of these oscillations (Howard & Poeppel, 2012).

Cortical oscillations are proposed to shape spike-timing dynamics and to impose phases of high and low neuronal excitability (Britvina & Eggermont, 2007; Panzeri, Brunel, Logothetis, & Kayser, 2010; Schroeder & Lakatos, 2009a, 2009b). The assumption that it is oscillations that cause spiking to be temporally clustered is derived from the observation that spiking tends to occur in specific phases (i.e., the trough) of oscillatory activity (Womelsdorf et al., 2007). It is also assumed that spiking and oscillations do not reflect the same aspect of information processing. Whereas spiking reflects axonal activity, oscillations are said to reflect mostly dendritic synaptic activity (Wang, 2010). Although both measures are relevant to address how sensory information is encoded in the brain, we believe that the ability of neural oscillations to temporally organize spiking activity support the functional relevance of neural oscillations to solve the discretization problem and to permit the integration of complex sensory signals across time.

Neuronal oscillations are ubiquitous in the brain, but they vary in strength and frequency depending on their location and the exact nature of their neuronal generators (Mantini, Perrucci, Del Gratta, Romani, & Corbetta, 2007). The notion that neural oscillations shape the way the brain processes sensory information is supported by a wealth of electrophysiological findings in humans and animals. Stimuli that occur in the ideal excitability phase of slow oscillations (<12 Hz) are processed faster and with a higher accuracy (Busch, Dubois, & VanRullen, 2009; Henry & Obleser, 2012; Lakatos, Karmos, Mehta, Ulbert, & Schroeder, 2008; Ng, Schroeder, & Kayser, 2012; Wyart, de Gardelle, Scholl, & Summerfield, 2012). However, gamma-band 40 Hz activity (low gamma band) can be observed at rest in both monkey (Fukushima, Saunders, Leopold, Mishkin, & Averbach, 2012) and human auditory cortex. In humans, it can be measured using EEG, MEG, concurrent EEG and fMRI (with more precise localization) (Morillon et al., 2010), and intracranial electroencephalographic recordings (sEEG, EcoG) in patients. Neural oscillations in this range are endogenous in the sense that one can observe a spontaneous spike clustering at approximately 40 Hz even in the absence of external stimulation. This gamma activity is thought to be generated by a ping-pong

interaction between pyramidal cells and inhibitory interneurons (Borgers, Epstein, & Kopell, 2005; Borgers, Epstein, & Kopell, 2008), or even just among interneurons that are located in superficial cortical layers (Tiesinga & Sejnowski, 2009). Exogenous inputs usually increase gamma-band activity in sensory areas, presumably clustering spiking activity that is propagated to higher hierarchical processing stages (Arnal & Giraud, 2012; Arnal, Wyart, & Giraud, 2011; Bastos et al., 2012; Fontolan, Morillon, Liegeois-Chauvel, & Giraud, 2014). By analogy with the proposal of Elhilali, Fritz, Klein, Simon, and Shamma (2004) that slow responses gate faster ones, it is interesting to envisage this periodic modulation of spiking by oscillatory activity as an endogenous mechanism to optimize the extraction of relevant sensory input in time. Such integration could occur under the patterning of slower oscillations in the delta–theta range.

38.2.4 Alignment of Neuronal Excitability with Speech Timescales

Experimental exploration of how speech parsing and encoding is performed by the brain is nontrivial. One approach has been to explore how neural responses can discriminate different sentences, assuming that the features of neural signals that are sensitive to such differences (e.g., frequency band, amplitude, and phase) should reveal the features that are vital to sentence decoding. Using this approach, it was shown that the phase of theta-band neural activity reliably discriminates different sentences (Luo & Poeppel, 2007). Specifically, when one sentence is repeatedly presented to listeners, the phase of ongoing theta-band activity follows a consistent phase sequence. When different sentences are played, however, different phase sequences are observed. Because the theta-band (4–8 Hz) falls around the mean syllabic rate of speech (~5 Hz), the phase of theta-band activity likely tracks syllabic-level features of speech (Doelling, Arnal, Ghitza, & Poeppel, 2014; Edwards & Chang, 2013; Giraud & Poeppel, 2012; Hyafil et al., 2012; Luo & Poeppel, 2007; Peelle et al., 2013). These findings support the notion that the syllabic timescale has adapted to a preexisting cortical preference for temporal information in this frequency range. At this point, however, it is not clear whether the phase-locking between speech inputs and neural oscillations is necessary for speech intelligibility. Sentences played backward (and therefore unintelligible) can similarly be discriminated on the basis of their phase course, which tempers the interpretation that these oscillations play a causal role in speech perception (Howard & Poeppel, 2011). However, two recent studies using distinct ways of

acoustically degrading speech intelligibility demonstrate that the temporal alignment between the stimulus and delta–theta band responses is higher when the stimulus is intelligible (Doelling et al., 2014; Peelle et al., 2013). This, again, supports the notion that those neural oscillations that match the slow (syllabic) speech timescales are useful (if not necessary) for the extraction of relevant speech information.

Neural oscillatory responses can also be entrained at much higher rates in the middle to high (40–200 Hz) gamma band (Brugge et al., 2009; Fishman, Reser, Arezzo, & Steinschneider, 2000). This could suggest that faster speech segments such as phonemic transitions could be extracted using the same encoding principle. High gamma responses in early auditory regions (Ahissar et al., 2001; Mesgarani & Chang, 2012; Morillon, Liegeois-Chauvel, Arnal, Benar, & Giraud, 2012; Nourski et al., 2009) reflect the fast temporal fluctuations in the speech envelope. A recent EcoG study succeeded at reconstructing the original speech input by using a combination of linear and nonlinear methods to decode neural responses from high gamma (70–150 Hz) activity recorded in auditory cortical regions (Pasley et al., 2012). Therefore, the decoding of auditory activity on a large spatial scale (at the population level) demonstrates that the auditory cortex maintains a high-fidelity representation of temporal modulations up to 200 Hz.

However, according to psychophysiological findings described previously, speech intelligibility mostly relies on the preservation of the low-frequency (<50 Hz) temporal fluctuations rather than on higher-frequency information. Therefore, whether it is necessary to maintain a representation of such acoustic features to correctly perceive speech remains unclear. The following section aims at clarifying the putative neural mechanisms underpinning the segmentation and the integration of auditory speech signals into an intelligible percept.

38.2.5 Parallel Processing at Multiple Timescales

Schroeder & Lakatos (2009a, 2009b) have argued that oscillations correspond to the alternation of phases of high and low neuronal excitability, which temporally constrain sensory processing. This means that low gamma oscillations at 40 Hz, which have a period of approximately 25 ms, provide a 10- to 15-ms window for integrating spectrotemporal information (low spiking rate), followed by a 10- to 15-ms window for propagating the output (high spiking rate; see Figure 38.3A for illustration). However, because the average length of a phoneme is approximately 50 ms on average, a 10- to 15-ms window might be too short for integrating

FIGURE 38.3 The temporal relationship between speech and brain oscillations. (A) Gamma oscillations periodically modulate neuronal excitability and spiking. The hypothesized mechanism is that neurons fire for approximately 12.5 ms and integrate for the rest of the 25-ms time window. Note that these values are approximate; we consider the relevant gamma range for speech to lie between 28 and 40 Hz. (B) Gamma power is modulated by the phase of the theta rhythm (approximately 4 Hz). Theta rhythm is reset by speech, resulting in maintaining the alignment between brain rhythms and speech bursts.

this information. Using a computational model of gamma oscillations generated by a pyramidal interneuron network (PING model; [Borgers et al., 2005](#)), [Shamir, Ghitza, Epstein, and Kopell \(2009\)](#) showed that the shape of a sawtooth input signal designed to have the typical duration and amplitude modulation of a diphone (~50 ms; typically a consonant–vowel or vowel–consonant transition) can correctly be represented by three gamma cycles, which act as a three-bit code. Such a code has the capacity required to distinguish different shapes of the stimulus and is therefore a plausible means to distinguish between phonemes. That 50-ms diphones could be correctly discriminated with three gamma cycles suggests that phonemes could be sampled with one or two gamma cycles. This issue is critical because the frequency of neural oscillations in the auditory cortex might constitute a strong biophysical determinant with respect to the size of the minimal acoustic unit that can be manipulated for linguistic purposes. In a recent extension of this model, the parsing and encoding capacity of coupled theta and gamma oscillating networks was studied ([Hyafil et al., 2012](#)). In combination, these modules succeed in signaling syllables boundaries and to orchestrate spiking within syllabic windows, so that online speech decoding becomes possible with a similar accuracy as experimental findings using intracortical recordings ([Kayser, Ince, & Panzeri, 2012](#)).

An important requirement of the computational model mentioned previously ([Shamir et al., 2009](#)) is that ongoing gamma oscillations are phase-reset, for example, by a population of onset excitatory neurons. In the absence of this onset signal, the performance of the model declines. Ongoing intrinsic oscillations appear to be effective as a segmenting tool only if they align with the stimulus. Several studies in humans and nonhuman primates have suggested that gamma and theta rhythms work together, and that the phase of theta oscillations determines the power and possibly also the phase of gamma oscillations (see [Figure 38.3B](#); [Canolty et al., 2006](#); [Csicsvari, Jamieson, Wise, & Buzsaki, 2003](#); [Lakatos et al., 2008, 2005](#); [Schroeder, Lakatos, Kajikawa, Partan, & Puce, 2008](#)). This cross-frequency relationship is referred to as “nesting.” Electrophysiological recordings suggest that theta oscillations can be phase-reset by several means, such as through multimodal corticocortical pathways ([Arnal, Morillon, Kell, & Giraud, 2009](#); [Lakatos, Chen, O’Connell, Mills, & Schroeder, 2007](#); [Thorne, De Vos, Viola, & Debener, 2011](#)) or through predictive top-down modulations, but most probably by the stimulus onset itself. The largest cortical auditory-evoked response measured with EEG and MEG, approximately 100 ms after stimulus onset, corresponds to a phase-reset and magnitude increase of theta activity

([Arnal et al., 2011](#); [Howard & Poeppel, 2012](#); [Sauseng et al., 2007](#); [Sayers & Beagley, 1974](#)). This phase-reset would align the speech signal and the cortical theta rhythm, the proposed instrument of speech segmentation into syllable/word units. Because speech is strongly amplitude-modulated at the theta rate, this would result in aligning neuronal excitability with those parts of the speech signals that are most informative in terms of energy and spectrotemporal content ([Figure 38.3B](#)). There remain critical computational issues, such as the means to get strong gamma activity at the moment of theta reset. Recent psychophysical research emphasizes the importance of aligning the acoustic speech signal with the brain’s oscillatory/quasi-rhythmic activity. [Ghitza and Greenberg \(2009\)](#) demonstrated that while comprehension was drastically reduced by time-compressing speech signals by a factor of 3, comprehension was restored by artificially inserting periods of silence. The mere fact of adding silent periods to speech to restore an optimal temporal rate—which is equivalent to restoring “syllabicity”—improves performance even though the speech segments that remained available are not more intelligible. Optimal performance is obtained when 80-ms silent periods alternate with 40-ms time-compressed speech signals. These time constants allowed the authors to propose a phenomenological model involving three nested rhythms in the theta (5 Hz), beta, or low gamma (20–40 Hz) and gamma (80 Hz) domains (for an extended discussion, see [Ghitza, 2011](#)).

38.2.6 Parallel Processing in Bilateral Auditory Cortices

There is emerging consensus, based on neuropsychological and imaging data, that speech perception is mediated bilaterally. [Poeppel \(2003\)](#) attempted to integrate and reconcile several of the strands of evidence. First, speech signals contain information on at least two critical timescales, correlating with segmental and syllabic information. Second, many nonspeech auditory psychophysical phenomena fall in two groups, with integration constants of approximately 25–50 and 200–300 ms. Third, both patient and imaging data reveal cortical asymmetries such that both sides participate in auditory analysis but are optimized for different types of processing in left versus right. Fourth, crucial for the present chapter, neuronal oscillations might relate in a principled way to temporal integration constants of different sizes. [Poeppel \(2003\)](#) proposed that there are asymmetric distributions of neuronal ensembles between hemispheres with preferred shorter versus longer

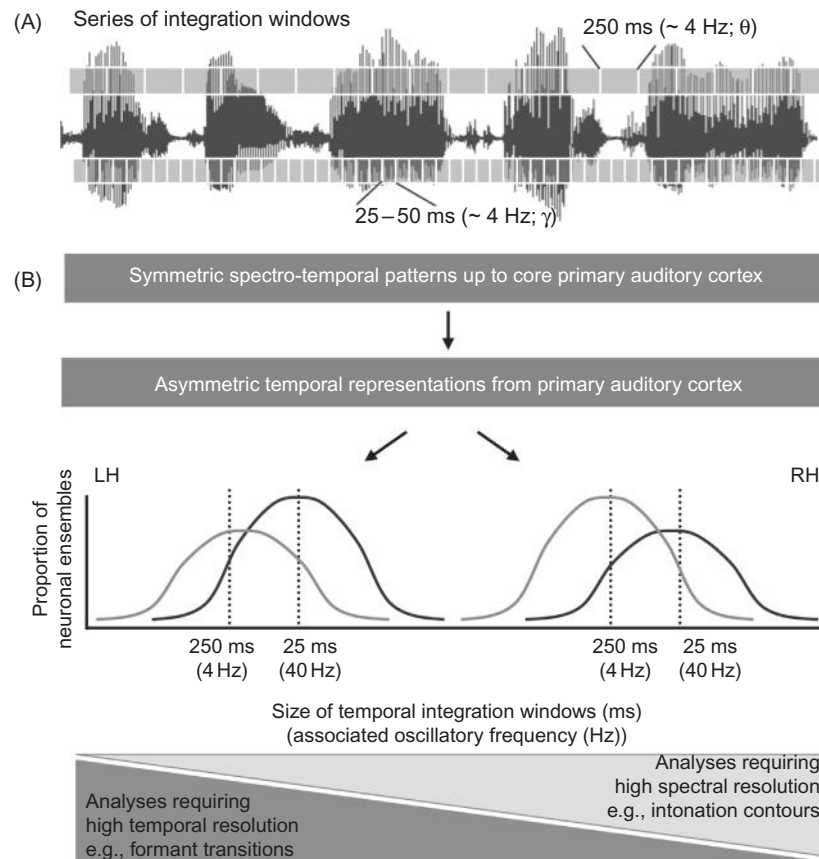

FIGURE 38.4 The AST hypothesis. (A) Temporal relationship between the speech waveform and the two proposed integration timescales (in milliseconds) and associated brain rhythms (in hertz). (B) Proposed mechanisms for asymmetric speech parsing: left auditory cortex (LH) contains a larger proportion of neurons able to oscillate at gamma frequency than the right one (RH).

integration constants; these cell groups “sample” the input with different sampling integration constants (Figure 38.4A). Specifically, left auditory cortex has a relatively higher proportion of short-term (gamma) integrating cell groups, whereas right auditory cortex has a larger long-term (theta) integrating proportion (Figure 38.4B). As a consequence, left hemisphere auditory cortex would be better equipped for parsing speech at the segmental timescale, and right auditory cortex would be better equipped for parsing speech at the syllabic timescale. This hypothesis, referred to as the asymmetric sampling in time (AST) theory, is summarized in Figure 38.4. It accounts for a variety of psychophysical and functional neuroimaging results that show that left temporal cortex responds better to many aspects of rapidly modulated speech content, whereas right temporal cortex responds better to slowly modulated signals, including music, voices, and other sounds (Warrier et al., 2009; Zatorre, Belin, & Penhune, 2002). A difference in the size of the basic integration window between left and right auditory cortices would explain speech functional asymmetry by better sensitivity of left auditory

cortex to information carried in fast temporal modulations that convey, for example, phonetic cues. A specialization of right auditory cortex to slower modulations would grant it better sensitivity to slower and stationary cues, such as harmonicity and periodicity (Rosen, 1992), which are important to identify vowels, syllables, and thereby speaker identity. The AST theory is very close, in kind, to the spectrotemporal asymmetry hypothesis promoted by Zatorre (Zatorre et al., 2002; Zatorre & Gandour, 2008). Although many psychophysics and neurophysiological experiments seem to support this idea (see Giraud & Poeppel, 2012; Poeppel, 2003; Poeppel et al., 2008 for reviews on the topic), there is a lot of work in progress regarding this unresolved question.

38.2.7 Dysfunctional Oscillatory Sampling

Additional evidence to support the notion that neural oscillations play an instrumental role in speech processing would be to show that dysfunctional oscillatory mechanisms result in speech processing impairments.

Dyslexia, which is a phonological deficit (i.e., a deficit in processing speech sounds), presumably is a good candidate to test this hypothesis. Temporal sampling mediated by cortical oscillations has recently been proposed to be a central mechanism in several aspects of dyslexia (Goswami, 2011). This proposal suggests that a deficit involving theta oscillations might impair the tracking of low temporal modulations in the syllabic range. In a complementary way, it was proposed recently that gamma oscillations might play a role in yielding an auditory phonemic deficit.

Interestingly, at approximately 30 Hz, the left-dominant phase-locking profile of auditory responses in MEG (auditory steady-state responses) was only present in subjects with normal reading ability (Lehongre, Ramus, Villiermet, Schwartz, & Giraud, 2011). Because this response is absent in dyslexic participants, the authors suggested that the ability of their left auditory cortex to parse speech at the appropriate phonemic rate was altered. Those with dyslexia had a strong response at this frequency in right auditory cortex and therefore presented an abnormal asymmetry between left and right auditory cortices. Importantly, the magnitude of the anomalous asymmetry correlated with behavioral measures in phonology (such as non-word repetition and rapid automatic naming). Finally, it was also shown that dyslexic readers had stronger resonance than controls in both left and right auditory cortices at frequencies between 50 and 80 Hz. This supports the notion that these participants had a tendency to oversample information in the phonemic range, with this latter effect being positively correlated with a phonological memory deficit. As a consequence, if dyslexia induces speech parsing at a wrong frequency, then phonemic units would be sampled erratically, without necessarily inducing major perceptual deficits (Ramus & Szenkovits, 2008; Ziegler, Pech-Georgel, George, & Lorenzi, 2009). As a consequence, the phonological impairment could take different forms, with a stronger impact on the acoustic side for undersampling (insufficient acoustic detail per time unit) and on the memory side for oversampling (too many frames to be integrated per time unit).

Although important, the observation that oscillatory anomalies co-occur with atypical phonological representations remains insufficient to establish a causal role of dysfunctional oscillatory sampling. Causal evidence that auditory sampling depends on intrinsic oscillatory properties (and is, as a consequence, determined by cortical columnar organization) could be obtained from knockout animal models comparing neuronal activity with continuous auditory stimuli in sites with various degrees of columnar disorganization. However, such animal work can only indirectly address a specific relation to speech processing.

38.3 BROADENING THE SCOPE: FUNCTIONAL MODELS

Although the perceptual analysis of speech is rooted in the different anatomic subdivisions of auditory cortex in the temporal lobe, speech processing involves a large network that includes areas in parietal and frontal cortices, the relative activations of which strongly depend on the task performed. Several reviews have synthesized the state of the art of functional neuroanatomy of speech perception (Hickok & Poeppel, 2000, 2004, 2007; Rauschecker & Scott, 2009; Scott & Johnsrude, 2003). Figure 38.5A summarizes the main consensus based on functional neuroimaging (fMRI; positron emission tomography [PET], MEG/EEG) and lesion data.

Departing from the classical model in which both a posterior (Wernicke's) and an anterior (Broca's) area form the anatomic network, it is now argued that speech is processed in parallel in at least two streams, a ventral stream for speech-to-meaning mapping (a "what" stream) and a dorsal stream for speech-to-articulation mapping (a "how" stream). Both streams converge on prefrontal cortex, with a tendency for the ventral pathway to contact ventral prefrontal cortex (BA 44/45, also referred to as Broca's area) and for the dorsal pathway to contact dorsal premotor regions (Hickok & Poeppel, 2007; Rauschecker & Scott, 2009). The dual path network operates both in a feedforward (bottom-up) and feedback (top-down) manner, highlighting the need for neurophysiologically grounded theories that have appropriate primitives to permit such bidirectional processing in real time.

38.3.1 An Oscillation-Based Model of Speech Processing

This chapter emphasizes a neurophysiological perspective and especially the potential role of neuronal oscillations as "administrative mechanisms" to parse and decode speech signals. Does such a focus converge with the current functional anatomical models? Recent experimental research has begun developing a functional anatomic model solely derived from recordings of neuronal oscillations. Based on analyses of the sources of oscillatory activity, that is, brain regions showing asymmetric theta/gamma activity at rest and under linguistic stimulation, Morillon et al. (2010) proposed a new functional model of speech and language processing (Figure 38.5B) that links to the textbook anatomy (illustrated in Figure 38.5A). This model is grounded in a "core network" showing left oscillatory dominance at rest (no linguistic stimulation, no task), encompassing auditory, somatosensory, and motor

(A) Dual stream functional neuroanatomical model

(B) Oscillation-based functional model

(C) Top-down predictions in the AC

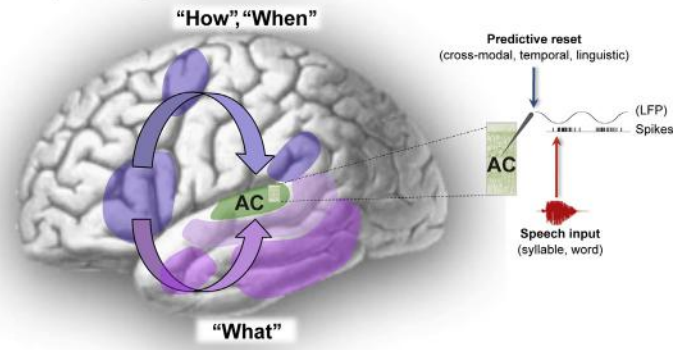

FIGURE 38.5 Three functional neuroanatomical models of speech perception. (A) Model based on neuropsychology and functional neuroimaging data (PET and fMRI; after Hickok & Poeppel, 2007). (B) Model based on the propagation of resting oscillatory asymmetry during an audiovisual linguistic stimulation (a spoken movie). (C) The Predictive (Bayesian) View on Speech Processing relies on the inversion of the dual-stream model to support the propagation of “what” and “when” predictions toward sensory regions.

cortices, and BA40 in inferior parietal cortex. The strongest asymmetries are observed in motor cortex and in BA40, which presumably play an important causal role in left hemispheric dominance during language processing. Critically, the proposed core network does not include Wernicke’s (BA22) and Broca’s (BA 44/45) areas, despite the fact that both are classically related to speech and language processing. Interestingly, whereas these areas show no sign of asymmetry at rest, they possibly “inherit” left-dominant oscillatory activity during linguistic processing from the putative core regions.

The model argues that posterior superior temporal cortex (Wernicke’s area) inherits its profile from auditory and somatosensory cortices, whereas Broca’s area inherits its profile from all posterior regions including auditory, somatosensory, Wernicke, and BA40. This model specifies that posterior regions share their oscillatory activity over the whole range of frequencies examined (1–72 Hz), whereas Broca’s area inherits only the gamma range of the posterior oscillatory activity. This might reflect that oscillatory activity in Broca’s area does not exclusively pertain to language. Finally, an

important feature of the model is the influence of the motor lip and hand areas on auditory cortex oscillatory activity on the delta/theta scale, which underlines the importance of syllable and co-speech gesture production rates, on the receptive auditory sampling, and its asymmetric implementation. This model is compatible with a hardwired alignment of speech perception and production capacities at a syllable but not at a phonemic timescale, suggesting that sensory/motor alignment at the phonemic timescale is presumably acquired. Using an approach entirely driven by oscillations, this model is largely consistent with the traditional one (Figure 38.5A), but it places a new emphasis on hardwired auditory–motor interactions and on a determinant role of BA40 in language lateralization, which remains to be clarified.

38.3.2 Predictive Models of Speech Processing

When processing continuous speech, the brain needs to simultaneously carry out acoustic and linguistic operations; at every instant there is both acoustic input to be processed and meaning to be calculated from the preceding input. Discretization using phases during which cortical neurons are either highly or weakly receptive to input is one computational principle that could ensure constant alternation between sampling the input and matching this input onto higher-level, more abstract representations. A Bayesian perspective on this issue would indicate that the brain decodes sounds by constantly generating descending (top-down) inferences about what is and will be said on the basis of the quickest and crudest neural representation it can make with an acoustic input (Poeppel et al., 2008). Consistent with this view, recent models of perception suggest that the brain hosts an internal model of the world that is used to generate, test, and update predictions about future sensory events. A proposal in very similar spirit is the "reverse hierarchy theory," a conceptualization developed to meet certain challenges in visual object recognition (Hochstein & Ahissar, 2002), and more recently extended to speech processing (Nahum et al., 2008).

Adding to the dual-stream model of perception that splits the processing of "what" and "how" information (Figure 38.5A), the predictive coding framework (Friston, 2005, 2010) posits that each stream also generates distinct types of predictions with regard to expected sensory inputs (Figure 38.5C). Top-down predictions that propagate throughout the ventral stream relate to the content of expected stimuli (the "what" aspect), whereas the dorsal stream generates predictions that pertain to the timing of events (the "when" aspect). Here we propose that in both cases, top-down expectations predictively

modulate neural oscillations to facilitate the sampling of predicted sensory inputs.

Audiovisual speech perception provides an ideal paradigmatic situation to test how the brain can use information from one sensory (visual) stream to derive predictions about upcoming events in another sensory (auditory) stream. During face-to-face conversation, because the onset of visual cues (oro-facial movements) often precedes the auditory onset (syllable) by approximately 150 ms, visual information can be used to predict upcoming auditory syllables (van Wassenhove, Grant, & Poeppel, 2005), speeding-up speech perception. A series of recent works have proposed that this predictive cross-modal mechanism relies on a corticocortical phase-reset from visual regions to auditory ones (Arnal et al., 2009, 2011; Luo et al., 2010). According to this hypothesis, a cross-modal visual-to-auditory phase-reset aligns ongoing low-frequency delta–theta oscillations in the auditory cortex in an ideal phase allowing for optimal sampling of expected auditory inputs (Schroeder et al., 2008). Therefore, during the perception of a continuous audiovisual speech stream, visual inputs would predictively entrain ongoing oscillations in the auditory cortex, which in turn facilitates the encoding of syllabic information (Zion Golumbic, Cogan, Schroeder, & Poeppel, 2013).

When presented to a rhythmic stream of events, the brain can also predict the temporal occurrence of future sensory inputs (Arnal & Giraud, 2012). Because the speech signal exhibits quasiperiodic modulations at the syllabic rate, the syllable timing is relatively predictable in time and could be predictively encoded by the phase of ongoing delta–theta (2–8 Hz) (Lakatos et al., 2008). The alignment of incoming speech signals with slow endogenous cortical activity and the resonance with neocortical delta–theta oscillations represents a plausible way to automatize predictive timing at an early, prelexical, processing stage (Ding & Simon, 2012; Henry & Obleser, 2012). However, the observation that the dorsal pathway (Figure 38.5A and 38.5C) is recruited during the perception of temporally regular event streams (e.g., during beat perception) suggests that the motor system also plays a role in the predictive alignment of ongoing oscillation in the auditory cortex (Arnal, 2012; Arnal & Giraud, 2012; Fujioka, Trainor, Large, & Ross, 2012). Consistent with the concepts of active sensing or active inference, motor efferent signals that are generated in synchrony with the beat may predictively modulate the activity in the auditory cortex and facilitate the processing of incoming events (Arnal & Giraud, 2012). In other words, the active entrainment of slow endogenous cortical activity via a periodic resetting from the motor system represents a plausible way to facilitate the

processing of expected auditory events at a low processing level. Such a mechanism is possibly at the origin of the attentional selection of the relevant streams in the cocktail party effect (Zion Golumbic, Ding, et al., 2013).

In summary, predictions play a major role in the encoding of temporal information in the auditory cortex. The ability to extract regularities and generate inferences about upcoming events primarily allows the periodic cortical activity to facilitate sensory processing, regardless of the informational content of forthcoming information. Additionally, when targeting specific neuronal populations, top-down signals could provide content-related priors. These two mechanisms are complementary at the computational level. Whereas temporal predictions (“when”) align neuronal excitability by controlling the momentary phase of low-frequency oscillations relative to incoming stimuli, content predictions target neuronal populations specific to the representational content (“what”) of forthcoming stimuli. The combination of these two types of mechanisms is again ideally illustrated by speech processing. Speech comprehension has long been argued to rely on cohort models in which each heard word preactivates a pool of other words with the same onset, until it reaches a point at which the word is uniquely identified. This model assumes that cognitive resources are used at the lexical level, where predictions are formed. Gagnepain and collaborators (Gagnepain, Henson, & Davis, 2012) recently demonstrated, however, that the predictive mechanisms in word comprehension involve segmental rather than lexical predictions, meaning that each segment is likely used to predict the next. Computationally, this observation supports the view that auditory cortex samples speech into segments using mechanisms that make them predictable in time, and that a representation of these segments is used to test specific predictions in a recurrent, predictable fashion.

38.3.3 Conclusion

Time is an essential feature of speech perception. No speech sound can be identified without integrating the acoustic input over time, and the temporal scale at which such integration operates determines whether we are hearing phonemes, syllables, or words. The central idea of this chapter is that, unlike subcortical processing that faithfully encodes speech sounds in their precise spectrotemporal structure, processing in primary and association auditory cortices results in the discretization of spectrotemporal patterns, using variable temporal integration scales. It is unlikely that speech representations are precise in both time and

space. The limited phase-locking capacity of the auditory cortex thus appears a likely counterpart to its spatial integration properties (across cortical layers and functional regions). Speech processing through and across cortical columns containing complex recurrent circuits bears a cost on the temporal precision of speech representations, and integration at the gamma scale could be a direct consequence of processing at the cortical column scale. In this chapter we argue that the auditory cortex uses gamma oscillations to integrate the speech auditory stream at the phonemic time-scale, and uses theta oscillations to signal syllable boundaries and orchestrate gamma activity. Although the generation mechanisms are less well-known for theta than for gamma oscillations, at present we see no alternative computational solution to the online speech segmentation and integration problem than invoking coupled theta and gamma activity. More research is needed to evaluate the detailed neural operations that are necessary to transform the acoustic input into linguistic representations, and it remains possible that other nonoscillatory mechanisms also contribute to these transformations.

Direct Cortical Neurophysiology of Speech Perception

Matthew K. Leonard and Edward F. Chang

Department of Neurological Surgery, University of California, San Francisco, CA, USA

39.1 INTRODUCTION

Language is among the most unique and complex human behaviors. Understanding how the brain coordinates multiple representations (e.g., for speech: acoustic–phonetic, phonemic, lexical, semantic, and syntactic) to achieve a seemingly unified linguistic experience is among the most important questions in cognitive neuroscience. This is not a new question (Geschwind, 1974; Wernicke, 1874); however, methodological developments in the past decade have provided a new perspective on its biological underpinnings. Combined with theoretical advances in linguistics (Poeppel, Idsardi, & van Wassenhove, 2008; also refer Chapters 12–14) and important discoveries in the fundamental mechanisms of neural communication and representation (Friston, 2010; Simoncelli & Olshausen, 2001), we are at a critical moment in the study of the neurobiology of language.

One challenging consequence of language being unique to humans is that we are more limited in our ability to observe the brain during linguistic tasks. Whereas sensory, motor, and even some cognitive abilities like decision-making can be studied in detail in animal models using methods that afford high spatial and temporal resolution, there are only limited opportunities for investigations at the same level of detail in humans. In this chapter, we consider how data acquisition methods that provide unparalleled spatiotemporal resolution, combined with new applications of multivariate statistical and machine learning analysis tools, have significantly advanced our understanding of the neural basis of language. In particular, we focus on a relatively rare and invasive recording method known as electrocorticography (ECoG) and its use in the direct study of the human auditory, motor, and speech

systems. ECoG has been in use for much longer than many noninvasive methods, including functional magnetic resonance imaging (fMRI), but recent advances in the design and manufacturing of electrode arrays, in addition to important discoveries on the frequency dynamics of neural signals recorded directly from the cortical surface, have enabled critical new insights into neural processing.

We argue that the ability to study language at the level of neural population dynamics (and in some cases, single neurons) is fundamentally necessary if we wish to understand how sensory input is transformed into the phenomenologically rich linguistic representations that are at the center of human communication and thought. Invasive electrophysiological methods are uniquely situated to examine these questions and, when interpreted in the context of the vast (and growing) knowledge gained from noninvasive approaches, allow us to move beyond the localization questions that have dominated the field for decades and toward an understanding of neural representations.

39.2 INVASIVE NEURAL RECORDING METHODS

39.2.1 Event-Related Neural Responses

Since soon after the discovery of the scalp electroencephalogram (EEG) 85 years ago (Berger, 1929), several aspects of neural population activity have been clear. The coordinated, stimulus-evoked responses of large groups of similarly oriented pyramidal neurons can be closely related to behavior. One of the most important examples in language research is the discovery of the N400 event-related potential (ERP) (Kutas & Federmeier, 2011). When

EEG subjects read or hear sentences that end with either contextually congruent (“I like my coffee with milk and *sugar*”) or contextually incongruent (“I like my coffee with milk and *bolts*”) endings, neural activity between approximately 200 and 600 ms after critical word onset is stronger for the incongruent condition. This finding, replicated hundreds of times in a variety of subject populations (Federmeier & Kutas, 2005) and stimulus modalities (Leonard et al., 2012; Marinkovic et al., 2003), suggests that activity in large groups of cells is sensitive to the linguistic features of the stimulus and to the context in which individual words occur.

Understanding how these effects arise from local neuronal firing requires more detailed information than is typically available from scalp recordings. Electrical currents from the brain are typically measured in microvolts, approximately 1.5 million-times weaker than the power of a standard AA battery. Furthermore, the electromagnetic inverse problem, where signals recorded at the scalp cannot unambiguously be localized in the brain, means that noninvasive recordings of electrical activity are unable to resolve separate neural populations (Pascual-Marqui, 1999). Compounding the

lack of an analytic solution to the inverse problem, the biophysical properties of the head, including the various layers of parenchyma, corticospinal fluid, meninges, skull, and scalp, mean that there is up to approximately 15 mm of tissue between the signal source and the recording electrode (Beauchamp et al., 2011). This tissue further smears the signal spatially and also acts as a low-pass filter, preventing the observation of oscillatory activity at higher frequencies.

ECoG does not suffer from these problems to the same extent because the recording electrodes are placed directly on the surface of the cortex during a surgical procedure that involves exposing the brain through either a Burr hole or a craniotomy (Figure 39.1A) (Penfield & Baldwin, 1952). Obviously, the methods for implanting electrodes limit the populations that can be studied to patients who require such invasive surgery for clinical reasons. In a small portion of the epilepsy patient population, anti-seizure medications are ineffective, and the clinicians determine that the severity of the seizures is sufficiently disabling that the best course of treatment is to identify and resect the epileptogenic tissue.

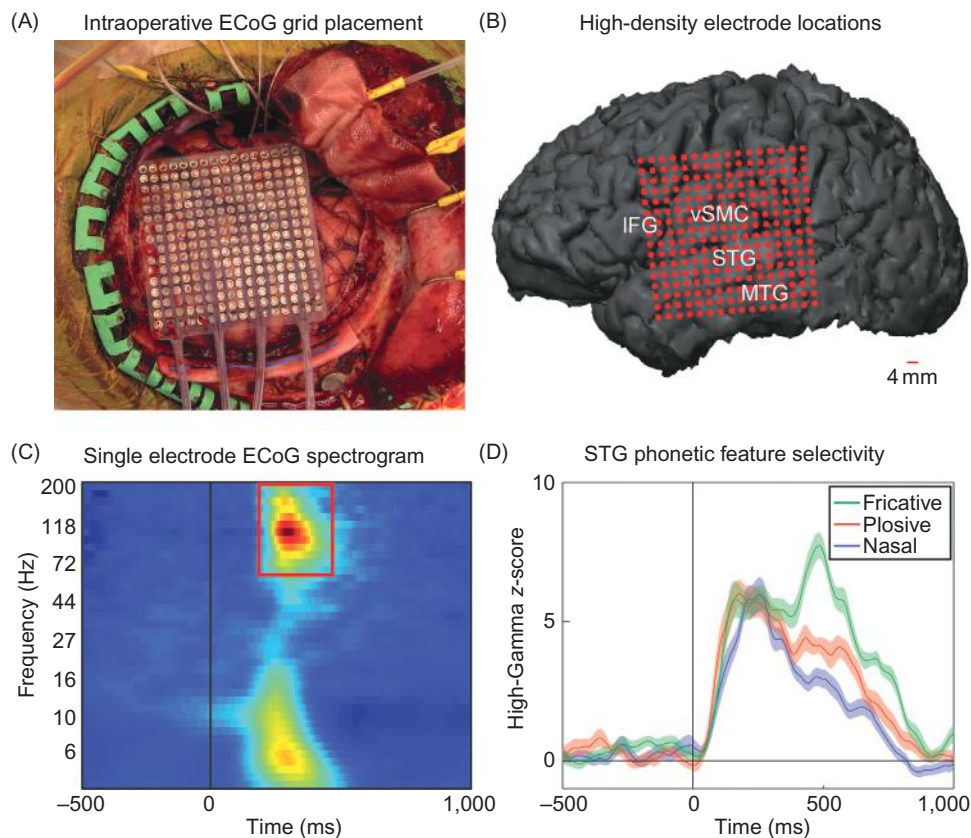

FIGURE 39.1 Invasive recording methods. (A) Intraoperative photo showing placement of high-density (4 mm pitch) ECoG grid on cortical surface. (B) Brain reconstruction showing coverage of ECoG grid. (C) Spectrogram of average speech-evoked neural activity from STG, with prominent high-gamma band responses (red box). (D) STG electrode showing high-gamma sensitivity to phonetic features (fricatives, plosives, nasals).

In many cases, localizing these foci can be done through a combination of behavioral and scalp EEG measures. However, in some cases, either because of the depth of the seizure focus or because of the inverse problem, it is only possible to identify the abnormal tissue through electrodes implanted directly in the brain (Crone, Sinai, & Korzeniewska, 2006). In these instances, the electrodes are placed according to the clinicians' best estimates of probable seizure foci, and the patient is kept in the epilepsy monitoring unit for a few days to several weeks, or however long it takes to record enough seizure activity to localize the source. If the patient has consented prior to surgery, then this hospitalization period provides a unique opportunity for researchers to collect neural data directly from the brain during a variety of experimental tasks.

The placement of ECoG electrodes often overlaps with peri-Sylvian areas of the brain that are critical for linguistic functions, particularly for speech. Electrode arrays can routinely obtain high-density coverage of the superior temporal gyrus (STG), middle temporal gyrus (MTG), ventral sensory-motor cortex (vSMC), and the inferior frontal gyrus (IFG), regions that are known to be involved in speech perception and production (Figure 39.1B).

Additionally, given that medial temporal lobe epilepsy is common in this patient population, activity is often recorded from the hippocampal and perihippocampal structures, which are also thought to be involved in the encoding of linguistic information (Halgren, Baudena, Heit, Clarke, & Marinkovic, 1994). These recordings are obtained by implanting penetrating depth electrodes, which reach these deep structures through basal or lateral cortical areas that are likely to be resected (Jerbi et al., 2009). Depth electrode recordings are difficult, both surgically and electrophysiologically; however, several research groups have pioneered these methods and obtained incredibly fruitful results.

It is also possible to record the activity of single neurons in the human brain. We present several examples of work that have examined the fundamental currency of neural computation, the spike. Although relatively less common, these studies provide a critical link between human cognitive neuroscience and animal models, where much more is known about the cellular and neurophysiological properties of neuronal function.

39.2.2 High-Frequency Oscillations

In addition to spatial (electrodes) and temporal (milliseconds) dimensions, neural population activity can be decomposed into the frequency dimension. One of Berger's initial observations in the scalp EEG was a dominant oscillation in the 8- to 12-Hz range, which he

referred to as the "alpha" band (Berger, 1929). Over the next several decades, more frequency bands were discovered and analyzed using a variety of techniques including Fourier decomposition, wavelet analysis, and the Hilbert transform (Bruns, 2004). Different frequency ranges have been associated with a variety of behavioral states and stimulus-related responses. For example, in speech, the theta band ($\sim 4\text{--}7$ Hz) is proposed to be a critical range for encoding the temporal structure of spoken input (Edwards & Chang, 2013; Poeppel, 2003).

However, the biophysics of the various media in the head prevents some of the higher frequencies from being observed at the scalp. Thus, one major advantage of ECoG is the ability to detect oscillations above approximately 70 Hz. Approximately 15 years ago, these frequencies were discovered in humans to contain highly coherent and reliable information about the stimulus (Crone, Boatman, Gordon, & Hao, 2001; Crone, Miglioretti, Gordon, & Lesser, 1998). Since then, the majority of studies that have examined speech processing using ECoG have focused on the high-gamma range, which is typically between 60 and 200 Hz (Figure 39.1C). Whereas the broadband local field potential ERP is dominated by low-frequency oscillations between approximately 2 and 20 Hz (in part due to the $1/f$ power law), the temporal resolution of high-gamma appears to carry critical information about speech, which is equally dynamic on a millisecond time scale. As we describe, it has been shown that high-gamma evoked activity correlates with acoustic-phonetic variability in primary and secondary auditory areas (Figure 39.1D) and with the coordinated movement of the articulators in motor regions during speech production. Perhaps of great interest to readers of this book is that high-gamma activity also carries information about higher level and abstract aspects of the speech signal, which suggests that it may be an important tool for understanding how both local and long distance neural networks give rise to rich linguistic representations and concepts from incoming sensory signals. Finally, high-gamma activity is well-suited to link animal models with human cognitive studies because it is strongly correlated with multiunit spiking activity (Ray & Maunsell, 2011; Steinschneider, Fishman, & Arezzo, 2008) and the blood oxygen level-dependent (BOLD) response in fMRI (Mukamel et al., 2005; Ojemann, Ojemann, & Ramsey, 2013).

39.2.3 Limitations of Invasive Methods

Before describing the scientific advancements that have been made using this set of tools, it is important to consider the limitations of invasive recording methods. First, the data are obtained from patient volunteers who

are undergoing surgical procedures for serious medical conditions. Therefore, all recordings are dictated by the willingness of the patient to participate in the hospital setting and by the areas of the brain that the clinicians deem relevant to their treatment. A related limitation is that although electrode arrays are becoming more advanced in their density and coverage (Insel, Landis, & Collins, 2013; Viventi et al., 2011), invasive methods necessarily under-sample the brain. Except in cases when it is clinically necessary, recordings are typically obtained only from the exposed surface of the cortex, which limits access to the sulci and deep structures. Additionally, because most epilepsy cases have unilateral seizure foci, simultaneous recordings from both cerebral hemispheres are rare, although there have been some bilateral cases (Cogan et al., 2014).

Finally, it is important to consider that recordings are obtained from patients who have abnormal brains. Many of these surgeries involve removing much of the anterior temporal lobe and hippocampal/amygdala complex, sometimes with only limited behavioral effects on the patients (Tanriverdi, Ajlan, Poulin, & Olivier, 2009). This suggests that these areas had only limited functionality, perhaps due to plastic reorganization around epileptogenic tissue. In practice, electrodes that show any sort of abnormal neurophysiological activity are excluded from analyses; however, this concern warrants caution in interpreting results.

Despite all of these caveats, invasive recording methods offer numerous advantages for advancing our knowledge of the neurobiology of language. Limited sampling of select brain regions precludes an understanding of the dynamics of large-scale inter-regional neural networks, but the frequency and spatiotemporal resolutions of the data obtained from these areas are unparalleled compared with noninvasive tools. Furthermore, results from invasive methods consistently agree with and extend findings from other techniques, despite the nature of the patient populations. As we argue in the rest of this chapter, ECoG, depth electrode, and single unit recordings must be interpreted in the context of the current understanding from other methodologies. Ultimately, it is a rare opportunity and a privilege to work with these patients, and their contributions to neuroscience and the neurobiology of language have been critical over the past several years.

39.3 INTRACRANIAL CONTRIBUTIONS TO THE NEUROBIOLOGY OF LANGUAGE

In this section, we present examples of how invasive recording techniques have provided new insights into the neural basis of language. Although this is not an

exhaustive review of the science, we hope to convey the contributions of these studies to the broader view of neurolinguistics. Thus, we consider these studies in the context of fMRI, EEG, and MEG studies, particularly those that are using analogous multivariate statistical and machine learning analysis methods. We also focus primarily on the sensory, acoustic–phonetic, and phonemic aspects of speech perception because implanted electrodes typically cover areas that are most closely associated with these functions. We also briefly argue that invasive methods are already proving useful for examining other aspects of language and linguistic encoding, particularly higher level abstract representations, such as those for lexical and semantic information (Leonard & Chang, 2014).

39.3.1 Sensory Encoding in Primary Auditory Cortex

We begin this section with a brief overview of sensory processing in the primary auditory cortex (A1). As shown in subsequent sections, downstream regions that encode acoustic–phonetic and phonemic information are highly sensitive to the spectrotemporal characteristics of the stimulus. Therefore, it is crucial to understand the inputs to these regions and to recognize that even the earliest cortical auditory areas show selective tuning that facilitates speech perception.

The ascending auditory system sends signals from the tonotopically organized cochlea through the lateral lemniscal pathway to an area on the posteromedial portion of Heschl's gyrus, which is the primary auditory cortex in humans (Hackett, 2011). Like the areas that precede it in the auditory hierarchy, A1 is tonotopically organized along at least one major axis, meaning that different neural populations are sensitive to different acoustic frequencies (Barton, Venezia, Saberi, Hickok, & Brewer, 2012; Baumann, Petkov, & Griffiths, 2013; also refer to Chapter 5). Following initial work by Celesia (Celesia, 1976) and Liégeois-Chauvel (Liégeois-Chauvel, Musolino, & Chauvel, 1991), researchers at the University of Iowa have provided a detailed description of human A1 using multicontact depth electrodes and have found that there are frequency-specific responses that are indicative of both rate and temporal coding of auditory stimuli both within and across neural populations (Brugge et al., 2009). These different coding mechanisms occur at different stimulus frequencies and may also contribute to the perception of pitch (Griffiths et al., 2010). Furthermore, narrow spectral tuning in human A1 is not just a feature of the population neural activity; it is also reflected in the selective responses of single neurons (Bitterman, Mukamel, Malach, Fried, & Nelken, 2008).

These depth electrode and single unit studies in Heschl's gyrus extend important work from noninvasive methods. Using machine learning analysis methods to relate the acoustic properties of natural sounds to changes in the BOLD response in fMRI, Moerel and colleagues have shown that A1 exhibits narrow spectral tuning in addition to tonotopic organization (Moerel, De Martino, & Formisano, 2012). The same researchers have also used high-field fMRI to show that individual neural populations have multipeak tuning at octave intervals, possibly facilitating the binding of complex sound features (Moerel et al., 2013). In agreement with temporal coding mechanisms giving rise to the perceptual phenomenon of pitch, it has also been shown with fMRI that A1 has spectrotemporal modulation transfer functions that track temporal modulations in the stimulus (Schönwiesner & Zatorre, 2009). The combined spatial organization of spectral and temporal modulation selectivity reveals multiple subfields of both primary and secondary auditory regions, suggesting a functional microstructure of the earliest cortical sensory areas that may contribute to the complex nonlinear representations of input like speech (Barton et al., 2012).

Sensitivity to spectral and temporal stimulus features in A1 most likely facilitates our ability to understand dynamic acoustic input like speech. However, it is not necessarily the case that this type of tuning reflects speech-specific or even speech-oriented specialization. In a recent study, Steinschneider and colleagues examined single-unit and multi-unit spiking activity in the primary auditory cortex of human epilepsy patients and macaques. For broadband auditory evoked potentials and high-gamma activity, both species showed similar spectrotemporal selectivity (Steinschneider, Nourski, & Fishman, 2013). Remarkably, this selectivity included acoustic aspects of speech, such as voice-onset-time and place of articulation (POA), which are critical for making phonetic distinctions. This suggests that speech-specific representations do not reside at the level of A1, although the tuning characteristics of this region allow us to parse spoken input efficiently.

39.3.2 Acoustic–Phonetic Representations in Lateral Superior Temporal Cortex

In humans, Heschl's gyrus is in close proximity and is densely connected to the lateral superior temporal cortex, in particular the STG (Hackett, 2011). In part because of the most common placement of ECoG electrode arrays, and also because of the functions of this area, STG is among the best characterized regions in the speech system. It is well known that STG is involved in phonological representation, because

neural activation is observed for most speech tasks (DeWitt & Rauschecker, 2012; Hickok & Poeppel, 2007; Rauschecker & Scott, 2009). In fMRI, a very productive paradigm has contrasted BOLD responses to speech and nonspeech sounds that preserve important spectral or temporal aspects of the signal (Davis & Johnsrude, 2003; Scott, Blank, Rosen, & Wise, 2000). Numerous studies have demonstrated stronger STG activation for speech, suggesting that this region encodes aspects of the stimuli that are intelligible and behaviorally relevant to the listener (Oblaser, Eisner, & Kotz, 2008). Recently, multivariate pattern analysis methods have been applied to fMRI data and have shown that STG (among other temporal lobe regions including superior temporal sulcus) are involved in representing meaningful aspects of the speech signal (Evans et al., 2013).

These results have been advanced using both invasive and noninvasive methods that afford high spatial and temporal resolution. Using MEG in healthy volunteers and ECoG in epilepsy patients, Travis and colleagues showed that STG responds preferentially to speech relative to a noise-vocoded control, which smoothes the speech spectrogram in the spectral axis, preserving the temporal and most of the frequency content but destroying intelligibility (Travis et al., 2012). This study also demonstrates that STG speech-selective responses observed in fMRI most likely reflect stimulus-evoked neural activity between approximately 50 and 150 ms, significantly earlier than activity in the same region that is associated with higher level linguistic encoding of lexical and semantic information. This demonstrates that at least at the level of nearby cortical columns, STG encodes multiple levels of acoustic–phonetic and abstract linguistic information.

What gives rise to this selectivity for meaningful aspects of the acoustic speech signal? Like A1, distinct STG neuronal populations encode the temporal structure of nonspeech acoustic input differently depending on the frequency content of the input (Nourski et al., 2013). Also like A1, populations are spectrally selective to ranges of frequencies, although they are more broadly tuned than in primary auditory regions (Nourski et al., 2012). These two ECoG studies with nonspeech tones and clicks are complemented by a set of speech ECoG studies using high-density electrode grids over STG. Spectrotemporal selectivity at single electrodes has important consequences for the representation of spoken words because it suggests that those acoustic inputs are represented as a complex pattern of activity across electrodes over time as the input unfolds. Using linear stimulus reconstruction methods, it is possible to generate a spectrogram from the population STG activity that corresponds closely to the original stimulus spectrogram (Pasley et al., 2012). This correspondence is particularly strong when the reconstruction model applies stronger

weights to the spectrotemporal aspects of the acoustic input that are relevant for speech intelligibility, including temporal modulation rates that correspond to syllable onsets and offsets.

This spectrotemporal representation across electrodes indicates that separate neural populations may be contributing sensitivity to particular features of the speech stimulus. Chang and colleagues presented ECoG participants with hundreds of naturally spoken sentences that contained a large number of examples of all English phonemes (Mesgarani, Cheung, Johnson, & Chang, 2014). This allowed the researchers to examine activity at the closely spaced ECoG electrodes in response to each phoneme. They found that individual electrodes responded selectively to linguistically meaningful phonetic features, such as fricatives, plosives, and nasals. For vowels, there was a similar feature-based representation for low-back, low-front, and high-front vowels, which arose from the encoding of formant frequencies, particularly the ratio of F1 and F2. These results provide crucial information about the role of STG in speech perception. It has been suggested that STG is involved in spectrotemporal (Pasley et al., 2012), acoustic–phonetic (Boatman, 2004), and phonemic (Chang et al., 2010; DeWitt & Rauschecker, 2012; Molholm et al., 2013) processing; however, the functional and spatial specificity of these features have not been described previously. Chang and colleagues showed that STG does represent acoustic–phonetic features (rather than individual phonemes, as single electrodes responded to multiple phonemes sharing a particular feature), but that this selectivity arises from tuning to specific spectrotemporal cues.

Similar results have been obtained at the single neuron level. Chan and colleagues collected neural responses from an epilepsy patient implanted with a Utah array, which consists of 100 penetrating electrodes with 20 micron tips, and recorded spiking activity from approximately 150 single and multiunits in anterior STG (Chan et al., 2013). They found neurons that responded selectively to specific phonemes that shared particular phonetic features (e.g., high-front vowels), but not to individual phonemes. Remarkably, they also demonstrated that responses are similarly selective to phonemes when they are heard and when they are read. This suggests that written words activate phonological representations and also that single neurons in the human STG are tuned to phonetic features, independent of the nature of the sensory input.

39.3.3 Population Encoding of Phonemic Information in STG

Spectrotemporally based phonetic tuning at individual neural populations may also give rise to more

complex representations of speech. Although single electrodes do not show sensitivity to specific phonemes (Mesgarani et al., 2014), the combined activity across electrodes generates a population code for complex sets of phonetic features. Two important higher level features that help distinguish phonemes are POA and voice onset time (VOT). POA refers to the configuration of the articulators and distinguishes different phonemes that share a particular feature, such as plosives (e.g., /ba/ vs. /ga/). VOT refers to the temporal delay between plosive closure and the onset of vibrations in the larynx, and distinguishes plosives that have the same POA (e.g., /ba/ vs. /pa/).

In an ECoG study, Steinschneider et al. (2011) examined how event-related high-gamma activity differed for sounds that differed parametrically in POA or VOT. They found that posterior STG electrodes correlated most strongly with changes in POA. VOT was also represented in both medial and posterior STG, and it tracked the timing of voice onset through latency shifts in the peaks of the average high-gamma waveforms. This demonstrates that understanding the encoding of complex stimulus features requires the ability to discriminate activity at local neural populations (spatial selectivity, achieved through high-density electrode arrays and high-gamma band filtering) and also to track neural activity on a millisecond level.

Another common method for examining the encoding of individual phonemes is through categorical phoneme perception. In this paradigm, a linear continuum of speech sounds varies in a particular acoustic parameter from one unambiguous extreme to another (e.g., F2 frequency, distinguishing POA for the plosives /b/, /d/, and /g/). The sounds are perceived nonlinearly, such that listeners hear one phoneme up to a particular point on the continuum, and then abruptly switch to perceiving a different phoneme; in other words, listeners fit acoustically ambiguous examples into established phoneme categories. This phenomenon has been localized using fMRI primarily to the lateral superior temporal cortex (Joanisse, Zevin, & McCandliss, 2007); however, these studies generally do not reveal how population neural activity enables this important perceptual effect.

ECoG has sufficient spatial and temporal resolution to address how nonlinear perceptual phenomena such as categorical perception are encoded in the brain. Using a continuum of synthesized speech sounds that varied linearly in F2 onset from /ba/ to /da/ to /ga/ (Figure 39.2A), it has been shown that high-gamma activity across electrodes can distinguish these sounds categorically (Chang et al., 2010). Distinct neural populations within the posterior STG generate neural activity patterns that correspond to each phoneme along

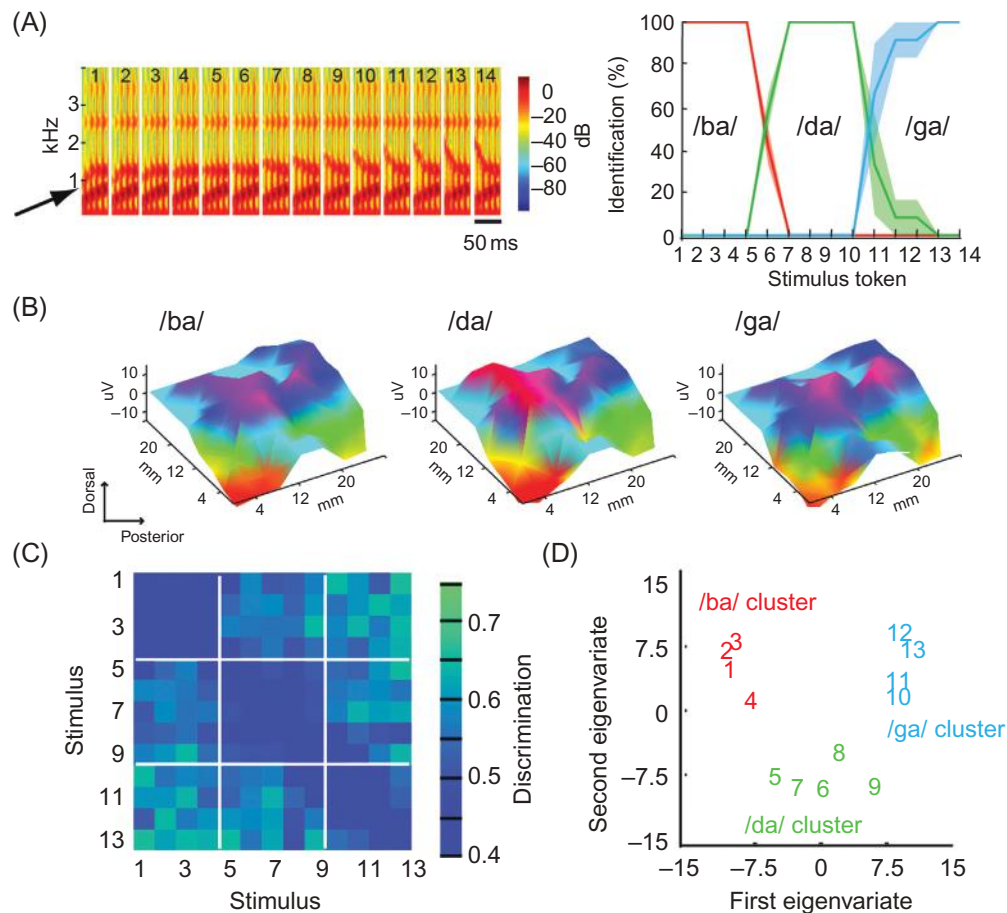

FIGURE 39.2 Speech representation in human STG. (A) Speech sounds synthesized along an acoustic continuum (stimuli 1–14, small increases in the second formant [arrow]) are perceived categorically rather than linearly in the behavior. (B) Spatial topography of evoked potentials recorded directly from the cortical surface of STG using ECoG is highly distributed and complex for each sound class. (C) Neural confusion matrix plots the pair-wise dissimilarity of neural patterns using a multivariate classifier. (D) Multidimensional scaling shows that response patterns are organized in discrete clustered categories along both acoustic and perceptual sensitivities. Adapted from *Chang et al. (2010)* with permission from the publisher.

the POA continuum, even within the space of only a couple of centimeters (Figure 39.2B). Using multivariate classification methods, stimulus-specific discriminability was observed in this activity (Figure 39.2C), which suggests that at the peak of neural pattern dissimilarity across categories (occurring at ~110 ms after stimulus onset), the perceptual effect arises from the activity at specific groups of electrodes. The timing of this discriminability is sufficiently early to suggest that categorical phoneme perception occurs *in situ* within the STG, rather than through top-down influences of other brain regions, although the limited sampling of brain areas with ECoG does not rule out the latter possibility. It is also important to note that, consistent with the evidence described for phonetic feature representations at individual STG electrodes (Mesgarani et al., 2014), categorical perception of the linear continuum in this study was organized along acoustic sensitivities. Specifically, the representations

of speech tokens were ordered according to F2 in one dimension (see ordering along the x -axis in Figure 39.2D), but the overall pattern was categorical in two dimensions (Figure 39.2D). This is a clear demonstration that nonlinear perceptual phenomena are encoded nonlinearly in the brain.

39.3.4 Cognitive Influences on Speech in STG

Intracranial recording methods have also recently proven useful for understanding how spectrotemporal, phonetic, and phonemic representations in STG are modulated by cognitive processes. For example, these methods have renewed an interest in the “cocktail party” problem, where listeners can selectively filter out irrelevant auditory streams in a noisy environment (Cherry, 1953). Several recent studies have examined neural responses to overlapping, multispeaker acoustic stimuli,

where listeners were directed to focus their attention on only one speaker (Ding & Simon, 2012; Kerlin, Shahin, & Miller, 2010; Sabri et al., 2008; Zion-Golumbic et al., 2013). Using ECoG, one study used stimulus reconstruction methods (Mesgarani, David, Fritz, & Shamma, 2009) to investigate how attention modulates the spectrotemporal representation of the acoustic input in STG (Mesgarani & Chang, 2012). Participants listened to two speakers simultaneously (Figure 39.3A and B) and were asked to report the content of just one of the speech streams, thus attending to only part of the acoustic input. Remarkably, the spectrotemporal representation of the

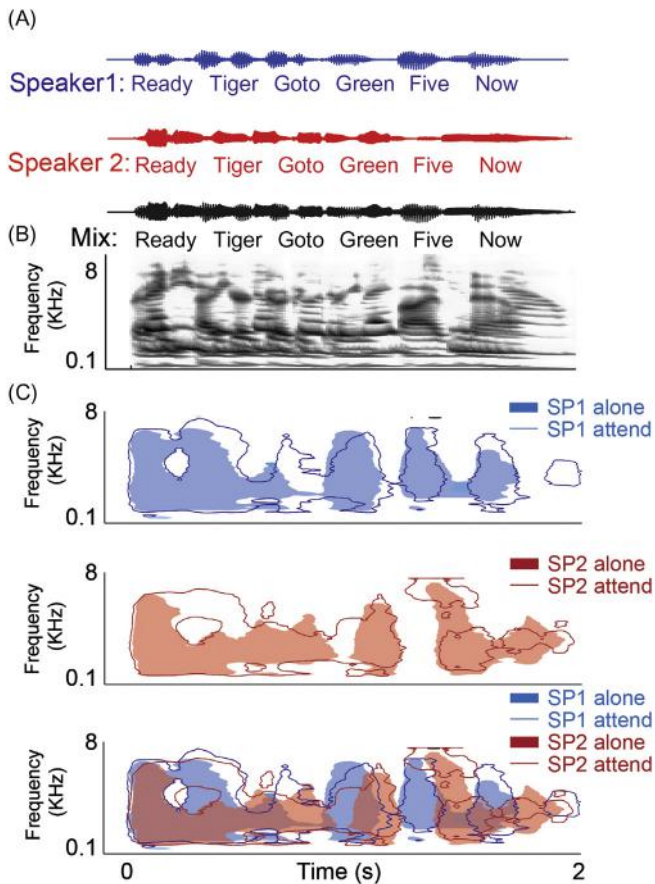

FIGURE 39.3 Attention modulates STG representations of spectrotemporal speech content. (A) ECoG participants listened to two speech streams either alone or simultaneously and were cued to focus on a particular call sign (“tiger” or “ringo”) and to report the color/number combination (e.g., “green five”) associated with that speaker. (B) The acoustic spectrogram of the mixed speech streams shows highly overlapping energy distributions across time. (C) Neural population-based reconstruction of the spectrograms for speaker 1 (blue) and speaker 2 (red), when participants heard each speaker alone (shaded area) or in the mixed condition (outline). Results demonstrate that in the mixed condition, attention to a particular speaker results in a spectrotemporal representation in STG as if that speaker were heard alone. Adapted from Mesgarani and Chang (2012) with permission from the publisher.

stimulus in STG only reflected the attended speech stream, as if the ignored speaker had not been heard at all (Figure 39.3C).

Using similar methods, Zion-Golumbic and colleagues extended these findings to show that this attentional modulation is reflected not only in high-gamma power changes but also in low-frequency phase over the course of several hundred milliseconds (Zion-Golumbic et al., 2013). They also demonstrated that the extent to which the ignored speech stream is represented changes as a function of brain region, specifically that higher level frontal and pre-frontal areas show less robust representation. There was also a stronger correlation between the attended stimulus and the neural response in STG for high-gamma power, whereas frontal regions showed stronger correlations with the low-frequency phase, implicating different frequency-dependent encoding mechanisms in different brain regions.

As described, there have also been attempts to characterize higher order representations of linguistic input using intracranial recording methods (Sahin, Pinker, Cash, Schomer, & Halgren, 2009). The N400 response, which reflects the degree of semantic contextual mismatch, has been localized to left anterior, ventral, and superior temporal cortex (Halgren et al., 1994). Recent work has further shown that responses within STG are sensitive to semantic context, independent of lower level acoustic features (Travis et al., 2012). ECoG and depth electrode recordings have also revealed that ventral temporal regions (including perirhinal cortex) show semantic category selectivity for words, regardless of whether they are written or spoken, suggesting that abstract semantic and conceptual representations are resolvable using these methods (Chan et al., 2011). Halgren, Chan, and colleagues have also used penetrating laminar depth electrodes to record multiunit activity in individual cortical layers during these tasks and have shown that the timing of responses in input and output layers suggests an early (~130 ms) first-pass selective response, followed by a later (~400 ms) selective response that is consistent with the N400 recorded at the scalp (Chan et al., 2011; Halgren et al., 2006). This suggests that higher order linguistic representations not only are spatially distributed but also arise from a complex temporal pattern of neural activity.

Together, these studies demonstrate the context-sensitive nature of evoked neural responses. Crucially, they demonstrate that both fine spatial resolution and temporal resolution are necessary to understand how cognitive representations influence and modulate lower level sensory and perceptual neural responses. Differences across frequencies in the neural signal also

encode important aspects of this modulation, which nicely complements work using noninvasive methods.

39.4 THE FUTURE OF INVASIVE METHODS IN LANGUAGE RESEARCH

We have argued that methodological advances in recording and analysis tools have allowed invasive neurophysiology to provide a window into the neural basis of speech and language that cannot be seen by other methods. The past several years have been particularly exciting because there has been a fusion of novel engineering approaches (machine learning and multivariate statistics) with linguistic and neuroscientific questions. In general, there have been two ways in which these fields have met. In the first, traditional experimental paradigms have been used with increasingly higher density neural recordings, which have in some cases provided new spatial information and often an entirely novel temporal dimension (Edwards et al., 2009, 2010; Molholm et al., 2013; Steinschneider et al., 2011; Travis et al., 2012). In the second approach, researchers have used data mining and machine learning techniques to understand how the activity observed in the paradigms from the first approach reflect the encoding and representation of stimulus and abstract information (Chan et al., 2013; Chang et al., 2010; Cogan et al., 2014; Mesgarani et al., 2014; Pasley et al., 2012; Zion Golumbic et al., 2013). Together, and in the context of noninvasive studies, these investigations are converging on the ultimate goal of neurolinguistics: to understand how neurons and neural networks generate the linguistic representations that are at the core of our daily experience.

Although the machine learning and data mining approaches have provided an unprecedented understanding of the underlying information representations in areas such as STG, there are many equally fundamental questions that remain that invasive recording methods may be well-suited to answer. A basic question for speech perception is how tuning and representations in A1 and STG are integrated over time to form more abstract word-level representations. Surprisingly, many of the studies cited neglect the temporal dimension of the data; it is common for input to linear classifiers to be an average over a large time window or even a single time point (Mesgarani et al., 2014). Although examining high-gamma band power inherently focuses on an aspect of the data involving fast time scales (e.g., acoustic onsets), there is a major question regarding how information is encoded over time in different brain regions.

One method for examining neural activity over time, which was originally developed for understanding the

dynamics of populations of single units (Churchland et al., 2012), involves characterizing the shared variability across space and plotting neural activity as trajectories through a “state-space” over time. In a recent study on the organization of articulatory representations in vSMC, principal components analysis was used to reduce the dimensionality across ECoG electrodes and showed that activity closely tracks the articulatory features of consonant-vowel syllables on a millisecond time scale (Bouchard, Mesgarani, Johnson, & Chang, 2013). Given that abstract representations such as lexical and semantic features are known to be more spatially distributed (Huth, Nishimoto, Vu, & Gallant, 2012) than lower level sensory features, it may be possible to use high-density neurophysiological recordings to understand how speech is transformed from primary sensory areas to distributed cortical networks. Overall, the field of neurolinguistics faces an exciting period with a multitude of experimental approaches that contribute unique and complementary information to our understanding of language.

Factors That Increase Processing Demands When Listening to Speech

Ingrid S. Johnsrude¹ and Jennifer M. Rodd²

¹Department of Psychology and Centre for Neuroscience Studies, Queen's University, Kingston, ON, Canada;

²Department of Experimental Psychology, University College London, London UK

For many individuals, speech listening usually feels effortless. However, whenever background noise is present, or when the person is hearing-impaired, perception of speech can be difficult and tiring (Ivarsson & Arlinger, 1994). It has become increasingly evident to applied hearing researchers that “listening effort” is an essential concept (McGarrigle et al., 2014) because it can explain behavior. For example, two hearing-impaired individuals may experience similar improvements in speech perception with an auditory prosthesis, but one may also experience increased listening effort and choose not to wear a listening device, whereas the other one who does not feel like he/she must “listen harder” wears it habitually. Although listening effort is an appealing and intuitive concept, it has not been well-elaborated in the cognitive literature. In particular, it has not been differentiated from nonspecific factors such as arousal, vigilance, motivation, or selective attention. We suggest that listening effort can be productively considered as the interaction of two factors—the processing demands, or challenges, imposed by the utterance and the listening situation and cognitive resources that an individual brings to the situation, that they can deploy to compensate for the demand. Different types of processing load draw on different resources in different cognitive domains. Listening effort is only manifest when the resources available to an individual are only barely adequate, or are inadequate, given the demand. For example, when utterance and listening conditions are straightforward and demands are low, effort is necessarily low for everyone. As processing load increases, effort will begin to increase sooner for people with more limited resources in the cognitive domains relevant for that type of load compared with

people with greater resources. Eventually, effort asymptotes, at which point the cognitive resources are no longer adequate for the conditions, and perception and comprehension suffer (Figure 40.1).

We focus on the different kinds of processing demands that arise for all listeners in different listening situations and discuss the kinds of perceptual and cognitive processes that may be required to meet these challenges. Individual differences in cognitive resources (such as memory, perceptual learning, processing speed, fluid intelligence, and control processes) that permit one person to cope more efficiently or more successfully than another with the challenges imposed by a listening situation (i.e., that allow them to cope with the processing demands) are outside the remit of this chapter.

The listening conditions of everyday life are highly variable. Sometimes speech is heard in quiet. More often, however, it is degraded or masked by other sounds. Such challenging situations increase processing demand (which we also call processing load) in three different ways. First, an increase in processing load can be driven by perceptual challenges. Processing load can increase, for example, when the stimulus is masked by interfering background noise or by speech from other talkers, or as a result of degradation of the stimulus caused by hearing loss.

Second, processing load depends strongly on the linguistic properties of the stimulus. For example, the processing load required to understand a sentence increases with the syntactic (i.e., grammatical) complexity (Gibson & Pearlmutter, 1998; Stewart & Wingfield, 2009), or when its meaning is difficult to compute due to the presence of homophones (Rodd, Davis, & Johnsrude, 2005; Rodd, Johnsrude, & Davis, 2012), or

FIGURE 40.1 Schematic depiction of the interaction between processing demand and cognitive resources and how they manifest in behavioral performance, effort, and brain activity (as measured by, e.g., fMRI). The three different kinds of processing demand reviewed in this chapter will recruit somewhat different cognitive resources, but the general principle is that, for those with more limited cognitive resources, effort begins to be required at a lower level of processing demand and may grow more quickly as demand grows compared with those with greater cognitive resources. Performance is high when processing demand is low and declines as cognitive resources become insufficient to cope with the demand (i.e., as effort reaches an asymptotic maximum). Brain activity in areas sensitive to a particular type of processing demand (e.g., perceptual demand) will be low when that demand is low (e.g., speech is produced clearly, against a quiet background) because cognitive resources are not recruited to cope with the demand. As demand increases (as stimulus quality degrades), effort and brain activity increase. As demand exceeds available cognitive resources, effort and brain activity reach asymptotic levels.

when the structure of the utterance places demands on memory (Lewis, Vasishth, & Van Dyke, 2006).

Finally, the overall processing load placed on the listener can increase because of the concurrent demands of another extrinsic task performed at the same time as speech is being processed. These dual-task situations are relatively common in everyday life: we often listen to speech while doing something else (e.g., driving; Wild, Yusuf, et al., 2012). We first review the ways in which processing load is measured, and then we consider each of these different types of processing loads in turn.

The processing load associated with any given listening situation is difficult to measure directly: what can be measured is behavior or performance. Speech perception (and, by inference, comprehension) is often measured using word-report tasks, in which listeners report all the words they can understand from an utterance. Performance on such tasks not only depends on signal quality but also depends on the cognitive resources the individual can use to compensate for declines in signal quality. In other words, performance on a word report task is a function both of the signal

quality and of the ability of the individual listener to overcome degradations in signal quality.

A particular problem in using behavioral measures of speech perception (like word-report scores) to measure processing load is that these often suffer from ceiling effects. Perfect or near-perfect performance (i.e., near 100% intelligibility) may result either from a listening situation that involves a low processing load (comprehension of clearly audible speech in quiet), with which cognitive resources can cope easily, or from a higher-load situation with greater recruitment of cognitive resources (see Figure 40.1). Methods used to measure the processing load associated with different listening situations therefore not only must be sensitive to listeners' overall performance on some measure of speech perception/comprehension, but also must be sensitive to the degree to which cognitive resources were taxed to achieve that level of performance. The degree to which cognitive resources are taxed has been, in the literature, operationally defined as listening effort. Effort is high if processing load is nonzero, and if the available cognitive resources are not easily or amply sufficient to cope with the processing load (Figure 40.1). Performance can be measured behaviorally; effort can be measured using either behavioral dual-task methods or physiological (including neuroimaging) methods. The constructs that interact to give rise to such measures (i.e., processing load, which is the topic of this chapter, and cognitive resources, which are not) cannot be measured directly.

Broadly speaking, there have been two approaches to the measurement of listening effort: (i) dual-task methods and (ii) methods that measure changes in physiological responses. Dual-task methods typically measure performance on a second (usually unrelated) task that is being performed at the same time as the speech is being presented. Reduced performance on this second task is assumed to reflect increased processing load of the first task (one involving speech perception/comprehension), resulting in a commensurate increase in listening effort. For example, researchers have shown that performance on a secondary task can change as a function either of the perceptual properties of the speech (e.g., the sensory quality; Gosselin & Gagné, 2011; Pals, Sarampalis, & Baskent, 2012) or of the linguistic properties of the speech (e.g., the presence of a semantic ambiguity; Rodd, Johnsrude, & Davis, 2010). Although dual-task approaches have been extensively used, these behavioral measures are, at best, an indirect test of effort required to process a speech stimulus. Furthermore, claims that dual-task effects are only observed when the two concurrent tasks overlap in the set of cognitive processes they recruit raise the possibility that such methods may be

differentially sensitive to different forms of listening effort (Rodd, Johnsrude, et al., 2010).

Physiological responses have also been used to provide a more direct index of effort. For example, some researchers have suggested that pupillometry (i.e., changes in pupil diameter) can provide an index of cognitive and listening effort (Kahneman & Beatty, 1966; Piquado, Isaacowitz, & Wingfield, 2010; Sevilla, Maldonado, & Shalóm, 2014; Zekveld & Kramer, 2014; Zekveld, Kramer, & Festen, 2011). This approach is limited by difficulties in understanding exactly *how* and *why* pupil diameter changes in response to changes in the task being performed. It is still not clear whether this measure indexes effort per se or instead reflects correlated factors such as task engagement (Franklin, Broadway, Mrazek, Smallwood, & Schooler, 2013), aspects of perception/comprehension (Naber & Nakayama, 2013), or arousal (Bradshaw, 1967; Brown, van Steenbergen, Kedar, & Nieuwenhuis, 2014).

Another physiological measure of effort is brain activity. Researchers typically assume that an increase in brain activity in a region (measured, e.g., using electroencephalography [EEG], magnetoencephalography [MEG], or functional magnetic resonance imaging [fMRI]) indexes the extent to which a particular stimulus has recruited that region (i.e., the “effort” being expended within that region) (Figure 40.1). As with all measures of effort, processing load and cognitive resources interact to produce brain activity. Imaging measures have two key advantages over other approaches to measuring effort. First, they can be used for a wide range of listening situations and are potentially sensitive to changes in listening effort across all stages of speech processing, from early perceptual processes (i.e., analysis of sound in primary auditory cortex [PAC]) to higher-level aspects of semantic and syntactic processing involving anterior and posterior temporal, frontal, and parietal regions. Second, imaging measures can be used in conditions in which a participant is not exclusively attending to the critical speech stimulus and therefore can be used to measure changes in processing that arise as a function of attentional modulation. Behavioral reports for unattended speech may be unreliable, and being asked to report something out of the focus of attention may inadvertently reorient attention back to that stimulus. Imaging provides an excellent way to measure processing and how it varies with attention because imaging data can be acquired both when a participant is attending to a stimulus and when he or she is distracted from it (Heinrich, Carlyon, Davis, & Johnsrude, 2011; Wild, Yusuf, et al., 2012). If one assumes that effort requires attention, then imaging can be used to compare relatively load-free stimulus-driven processing (Wild, Yusuf, et al., 2012), with the more effortful processing observed under full attention, when a processing load is present.

40.1 TYPES OF PROCESSING DEMAND

40.1.1 Perceptual Demands

Perceptual demands are imposed by a target signal that is not perfectly audible, such as hearing an announcement over loudspeakers in a busy train station. The audibility of speech can be compromised in many different ways, through degradation or distortion of the signal, and/or through the presence of concurrent interfering sounds. These different demands are probably met through different cognitive mechanisms. For example, a degraded signal requires that missing bits be “filled in,” whereas following a target in the presence of multiple competing sounds requires sound segregation processes and selective attention. In this section, we review the different types of perceptual demand and the cognitive mechanisms that may be required to compensate, as summarized in Table 40.1.

Taking the public announcement example, the speech signal itself is likely to be both degraded and distorted because of the limitations of most public-transport loudspeaker systems. (An audio signal is *degraded* if frequency components have been reduced or removed; it is *distorted* if components, not originally present, have been somehow introduced). Degradation places demands on processes that help to recover obliterated signal, whereas distortion introduces segregation demands—the listener must be able to perceptually distinguish the components of the original signal from the artefactual components of the distortion to recognize the signal. A common form of distortion is reverberation: the surfaces of indoor spaces, in which so much communication happens, reflect sound and the reflected sounds must be distinguished from the direct sound source for the sound to

TABLE 40.1 Different Types of Perceptual Demand and the Nature of the Cognitive Processes Required to Cope with Such Demands

Perceptual demand	Imposes a processing load on cognitive mechanisms required for
Target signal degradation, energetic masking of target	Perceptual closure, including linguistically guided perceptual closure Linguistically guided word-segmentation processes
Target signal distortion; and informational masking of target due to reverberation or competing, acoustically similar, sounds	Sound source segregation Selective attention Voice identity processing
Hearing impairment	All of the above

be understood. The presence of concurrent sounds (also introduced by the competing sounds, including concurrent speech, in that busy train station) requires listeners to recruit processes that serve to segregate the target signal from the background, to selectively attend to the target, and to recover obliterated signal (perceptual closure). Masking that physically interrupts or occludes a target signal so that it is effectively not transduced at the periphery is called *energetic masking*. When both target and masker are audible but are difficult to separate perceptually, *informational masking* occurs (Kidd, Mason, Richards, Gallun, & Durlach, 2007; Leek, Brown, & Dorman, 1991; Pollack, 1975).

Compensation for energetic masking (which is typically transient in the dynamic conditions of real-world communicative environments) requires that the occluded signal be “filled in” in some way. Accumulating evidence suggests that such perceptual closure comprises at least two, if not more, physiologically separable phenomena. First, if discrete frequencies are occluded for a brief period, then the brain can complete the partially masked sound so that it is heard as a complete whole (Carlyon, Deeks, Norris, & Butterfield, 2002; Ciocca & Bregman, 1987; Heinrich, Carlyon, Davis, & Johnsrude, 2008). For example, if a steady-state tone is interrupted by a gap filled with noise, the tone is “heard” to continue through the gap. Electrophysiological and MRI studies suggest that, in such cases, the illusion is complete at a relatively early stage of processing. Petkov and colleagues (Petkov, O'Connor, & Sutter, 2007) measured the responses of macaque A1 neurons to steady tones, to noise bursts, and to interrupted tones where the silent gap could optionally be filled by a noise. In this latter case, they found that the response of approximately half the neurons to the noise was more similar to that elicited by an uninterrupted tone than it was to that produced by an isolated noise burst. This suggests that the continuity illusion, at least for tones, is complete by the level of auditory cortex. Physiological investigations involving humans also suggest that continuity for tones is complete at relatively early stages of auditory processing and happens obligatorily in the absence of full attention (Heinrich et al., 2011; Micheyl et al., 2003).

The second type of perceptual closure also compensates for transient energetic masking but works to fill in missing speech sounds, or even missing words, on the basis of linguistic knowledge (Bashford, Riener, & Warren, 1992; Saija, Akyürek, Andringa, & Başkent, 2014; Shahin, Bishop, & Miller, 2009; Warren, 1970). For example, sounds that are distinguished by one phonetic feature such as /k/ and /g/ are acoustically similar and, if degraded, perhaps acoustically identical. Uncertainty about the identity of a phoneme (/k/ versus /g/) can be resolved through knowledge of

words: it will be heard as /k/ in the context *iss, and /g/ in the context *ift, because “kiss” and “gift” are words and “giss” and “kift” are not (Ganong, 1980). Such perceptual ambiguity can also increase processing load on higher-level linguistic processes because there are more candidate linguistic representations (“bark” versus “park” for example). This load can be met through effective use of syntactic and semantic context; many studies demonstrate that speech materials embedded in a meaningful context are easier to report than those without a constraining context (Davis, Ford, Kherif, & Johnsrude, 2011a; Dubno, Ahlstrom, & Horwitz, 2000; Kalikow, Stevens, & Elliott, 1977; Miller, Heise, & Lichten, 1951; Nittrouer & Boothroyd, 1990). Degradation would also stress processes involved in segmenting adjacent words because degradation means that word boundaries are less clearly demarcated. Thus, linguistically guided perceptual closure phenomena draw on prior knowledge at multiple levels: such linguistic priors would include knowledge of the words and morphology of a language and how words can be combined. These phenomena would also draw on word frequency effects, contextually contingent prior probabilities, and knowledge of the world.

Evidence from studies in which speech has been perceptually degraded (e.g., using noise vocoding; Shannon, Zeng, Kamath, Wygonski, & Ekelid, 1995) suggests that processes involving the use of prior knowledge to enhance speech comprehension (i.e., linguistically guided perceptual closure phenomena) rely on regions of the left inferior frontal gyrus (LIFG) and/or regions along the superior and middle temporal gyri (Davis, Ford, Kherif, & Johnsrude, 2011b; Davis & Johnsrude, 2003; Hervais-Adelman, Carlyon, Johnsrude, & Davis, 2012; Obleser & Kotz, 2010; Scott, Blank, Rosen, & Wise, 2000; Wild, Yusuf, et al., 2012), and possibly also on left angular gyrus (Golestani, Hervais-Adelman, Obleser, & Scott, 2013; Wild, Davis, & Johnsrude, 2012). Even though stimuli in these studies are carefully controlled and energetic masking introduces uncertainty at the acoustic level, the widespread patterns of activity in response are probably due to the fact that uncertainty propagates across linguistic levels—lexical, morphological, syntactic and semantic.

Informational masking is defined as any decline in perception or comprehension of a target stimulus (therefore “masking”) that cannot be attributed to energetic masking (Cooke, Garcia Lecumberri, & Barker, 2008; Kidd et al., 2007; Leek et al., 1991; Pollack, 1975). This includes everything from difficulty with segregation (i.e., due to perceptual similarity between target and masker) to attentional bias effects (due to the salience or “ignorability” of a target, or of a

masker due to familiarity or meaningfulness). If knowledge-based factors can produce a “release from masking” (i.e., better performance on a listening task), then the masking was, by definition, informational. However, informational masking should be distinguished from general inattentiveness (Durlach et al., 2003). There may be good reason to consider processing demands resulting from at least some types of informational masking as very different from those resulting from the perceptual demands of energetic masking (Cooke et al., 2008; Mattys, Barden, & Samuel, 2014; Mattys, Brooks, & Cooke, 2009; Mattys & Wiget, 2011). We discuss this idea in the section on *Concurrent task demands*.

Importantly, familiarity and expertise can reduce informational masking. In a recent study, Johnsrude et al. (2013) observed that listeners obtained a substantial release from (informational) masking when they heard their spouse’s voice in a two-voice mixture either when it was the target or when it was the masker, suggesting that familiar-voice information can facilitate segregation. Furthermore, although the ability to report novel-voice targets declined with age, there was no such decline for spouse-voice targets even though performance on spouse-voice targets was not at ceiling. The decline with age for novel targets could not be due to energetic masking (because this would apply equally to spouse-voice targets, which were acoustically perfectly matched, across participants, to the novel-voice targets) and thus must result from increased informational masking with age, which is reduced (or possibly eliminated) by familiar-voice information.

Perceptual demands imposed by degradation, distortion, and concurrent sounds are exacerbated by hearing impairment, including age-related hearing loss (presbycusis). Hearing impairment commonly involves both diminished sensitivity to sound (degrading the input signal) and diminished frequency acuity. Poorer frequency acuity means that acoustically similar sounds are less discriminable: the signal is degraded and harder to segregate from other sounds. Thus, hearing loss increases perceptual load and, like the other forms of perceptual load, hearing loss places greater demands on processes involved in perceptual closure, in selective attention, and in segregation (Gatehouse & Noble, 2004).

40.1.2 Linguistic Demands

Even in the case where all words are fully intelligible, the effort required to understand language can vary greatly. For example, cognitive models of sentence comprehension describe in detail the additional

processes that are required to comprehend a sentence that has a complex grammatical structure or that contains words with more than one possible meaning (Duffy, Kambe, & Rayner, 2001; Duffy, Morris, & Rayner, 1988; Frazier, 1987; MacDonald, Pearlmutter, & Seidenberg, 1994). These cognitive models have been developed largely on the basis of reading experiments, in which a relatively direct measure of the amount of processing that is required by different types of sentences can be obtained by measuring the time taken to read them. In contrast, it is more difficult to measure the processing demand imposed by particular types of spoken sentences, because the rate at which words arrive is typically controlled by the speaker (and not the listener).

One form of linguistic challenge that has been relatively well-studied using spoken as well as written language is lexical ambiguity, also known as semantic ambiguity, which arises when words with multiple meanings are included within a sentence. For example, to understand the phrase “the bark of the dog,” a listener must use the meaning of the word “dog” to work out that “bark” is probably referring to the noise made by that animal and not the outer covering of a tree. These forms of ambiguity are ubiquitous in language; at least 80% of the common words in a typical English dictionary have more than one definition (Rodd, Gaskell, & Marslen-Wilson, 2002), and most dictionaries list more than 40 different definitions for the word “run” (e.g., “an athlete runs a race,” “a river runs to the sea,” “a politician runs for office”). Each time one of these ambiguous words is encountered, the listener must select the appropriate meaning on the basis of its sentential context.

A dual-task experiment (Figure 40.2A) has revealed longer reaction times on an unrelated visual case-judgement task when participants are listening to high-ambiguity, compared with low-ambiguity, sentences (Rodd, Johnsrude, et al., 2010), indicating that high-ambiguity sentences are more effortful to understand. High-ambiguity sentences contained at least two ambiguous words (e.g., “There were *dates* and *pears* [homophonous with pairs] in the fruit bowl”) and were compared with well-matched low-ambiguity control sentences (e.g., “There was beer and cider on the kitchen shelf”; Rodd, Johnsrude, et al., 2010). A concurrent case-judgement task required participants to indicate, as quickly as possible with a key-press, whether a cue letter on the screen was presented in UPPER case or lower case. Interestingly, this ambiguity effect varies as a function of the sentence structure. In cases when the ambiguous word is preceded by disambiguating sentence context (e.g., “The hunter thought that the HARE/HAIR ...”), there is no observed cost of the case-judgement task, suggesting

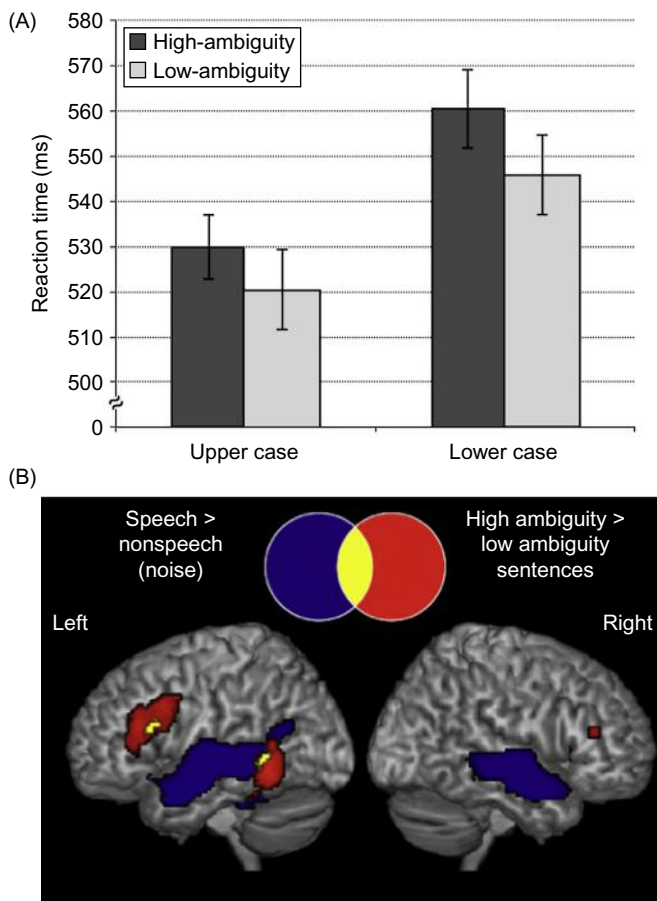

FIGURE 40.2 (A) Reaction times (in ms) for a case-judgment task presented while participants listened to high- and low-ambiguity sentences as a function of the case of the presented letter (UPPER case or lower case). Participants were asked to respond as quickly as possible when the letter cue was presented on the screen at the offset of the second homophone (or homologous word in the matched low-ambiguity sentence). At the end of each sentence, participants were also required to make a semantic relatedness judgment to a word presented on the screen. Case-judgment reaction times were significantly longer for high- compared with low-ambiguity sentences, suggesting that some cognitive process involved in resolving the meaning of the homophones in the high-ambiguity sentences is also involved in case-judgment. (B) Brain regions that are significantly more active for high-ambiguity sentences compared with low-ambiguity sentences in a group of normal young-adult right-handed participants are shown in red/yellow. These regions include the inferior frontal gyri bilaterally and the left inferior temporal gyrus. Brain regions that are significantly more active for all speech compared with unintelligible signal-correlated noise are shown in blue/yellow. These regions include the superior and middle temporal gyri bilaterally. Data from [Rodd et al. \(2005\)](#) with permission from the publisher.

that this process of selecting a contextually relevant word meaning on the basis of the information that is currently available is relatively undemanding. In contrast, when the disambiguating context is positioned *after* the ambiguous word (e.g., “The ecologist thought that the PLANT by the river should be closed down”),

there is a considerable increase in the time taken to make the case judgements ([Rodd, Johnsrude, et al., 2010](#)). The most likely explanation is that, for these sentences, listeners are frequently misinterpreting the ambiguous word by selecting the more frequent, but contextually inappropriate, meaning, and that the dual-task effect arises because of the increased processing load associated with the reinterpretation process that is triggered by the final word in the sentence.

Several neuroimaging studies using a range of different spoken-sentence materials confirm that comprehension of sentences that contain ambiguous words is more demanding than comprehension of sentences that do not. [Rodd et al. \(2005\)](#) compared high-ambiguity sentences with well-matched low-ambiguity sentences and reported a large cluster of LIFG activation with its peak within the pars opercularis, as well as a cluster in the posterior portion of the left inferior temporal gyrus (LITG) ([Figure 40.2B](#)). This is broadly consistent with the results of subsequent studies, which consistently find ambiguity-related activation in both posterior and anterior subdivisions of the LIFG ([Bekinschtein, Davis, Rodd, & Owen, 2011; Davis et al., 2007; Rodd et al., 2012; Rodd, Longe, Randall, & Tyler, 2010](#)). The precise location of the LITG activation has been more variable, with some studies finding no significant effect ([Rodd, Longe, et al., 2010](#)). Again, as with the dual-task studies, the ambiguity-related increases in BOLD signal have been shown to be largest when listeners must reinterpret a sentence that was initially misunderstood ([Rodd et al., 2012](#)), suggesting that this aspect of semantic processing is particularly demanding.

These two key brain regions (LIFG and posterior temporal lobe) have also been activated for a number of other linguistic manipulations. [Rodd, Longe, et al. \(2010\)](#) have shown that *syntactic* ambiguities (e.g., “VISITING RELATIVES is/are boring”) produce LIFG activation (compared with unambiguous sentences) in the same region as *semantic* ambiguities (within the same participants), as well as in posterior left middle temporal gyrus (MTG). [Tyler et al. \(2011\)](#) found similar effects of syntactic ambiguity that extended across both anterior and posterior LIFG, as well as smaller activations in homologous right frontal regions, posterior MTG, and parietal regions. Finally, similar frontal and posterior temporal regions have been shown to produce elevated activation for sentences that have a grammatical structure that is more difficult to process ([Mack, Meltzer-Asscher, Barbieri, & Thompson, 2013; Meltzer, McArdle, Schafer, & Braun, 2010; Peelle, McMillan, Moore, Grossman, & Wingfield, 2004; Shetreet & Friedmann, 2014](#)), although there is variability in the precise location of the posterior temporal lobe activations. In addition, studies have also found

that increased demands on syntactic processes are associated with activation in the *anterior* temporal lobe (Brennan et al., 2012; Obleser et al., 2011) and temporoparietal regions (Meyer et al., 2012).

Another linguistic challenge to comprehension is a relative lack of contextual constraint. For sentences that lack a strong determinative meaningful context (such as “Her good slope was done in carrot”), a region of LIFG appears more active when compared with sentences that have context (such as “Her new skirt was made of denim”) (Davis et al., 2011b). This increased activity is consistent with the idea that a lack of supportive context increases processing demands, possibly because weaker semantic constraint renders speech less predictable.

Although the precise cognitive roles of these different brain regions associated with higher-level aspects of speech comprehension remains unclear (Rodd et al., 2012), results are consistent with the view that the LIFG contributes to the integrative processes that are required to combine the meanings and syntactic properties of individual words into higher-level linguistic structures (Hagoort, 2005; Rodd et al., 2005; Willems & Hagoort, 2009). The structures of the LIFG may be required for cognitive control processes required to select and maintain task-relevant information while inhibiting information that is not currently required (Novick, Kan, Trueswell, & Thompson-Schill, 2009; Thompson-Schill, D’Esposito, Aguirre, & Farah, 1997).

Activation of posterior (and not anterior) aspects of the temporal lobe provide clear support for the view that these regions form part of a processing stream that is critical for accessing the meaning of spoken words (Hickok & Poeppel, 2007), although other authors have suggested that this region, like the LIFG, is associated with control processes that are necessary to select and maintain aspects of meaning that are currently relevant, rather than the stored representation of semantic/syntactic information (Noonan, Jefferies, Visser, & Lambon Ralph, 2013).

In summary, higher-level aspects of speech comprehension, such as selecting contextually appropriate word meanings and assigning appropriate syntactic roles, are largely associated with frontal and posterior temporal brain regions. Interestingly, these overlap with areas that are recruited to cope with the “lower level” perceptual demands reviewed earlier, suggesting that similar cognitive mechanisms are required to cope with different kinds of processing demand.

Overlapping domain-general processing resources are recruited in the face of both perceptual and cognitive demands, raising the possibility that competition for these resources may result in a “double whammy” effect: when both forms of processing resources are required, the listener is disproportionately disadvantaged. For example,

it is possible that when a listener needs to deploy additional resources to identify the sounds that are present in the speech stream, the resources that they have available to them for dealing with any semantic/syntactic demands may be reduced (and vice versa).

Because high-level cognitive processes operate on the output from lower-level perceptual processes, conditions in which the perceptual input is degraded may produce perceptual uncertainty that cascades to higher-level cognitive processes. For example, an “easy” sentence that, when presented with high perceptual clarity, would produce relatively low demand on semantic/syntactic processes might become more demanding at these higher cognitive levels when the input is degraded such that the listener is unsure (based on perceptual input alone) of the words that were actually present. As reviewed previously, demands on semantic/syntactic processes almost certainly increase as a function of the perceptual clarity of the input, even when semantic/syntactic properties are held constant.

In the face of perceptual degradation, higher-level cognitive resources make a key contribution to resolving perceptual ambiguity, such that information about the meaning, syntactic structure, or identity of a sentence (or a word) plays a key role in providing contextual cues that can be used to resolve perceptual ambiguities (Davis et al., 2011b; Sohoglu, Peelle, Carlyon, & Davis, 2012; Wild, Davis, et al., 2012). For example, Wild, Davis, et al. (2012) presented acoustically degraded speech that was preceded (200 ms) earlier by text primes that either matched each upcoming word or was incongruent. Preceding text primes enhanced the rated subjective clarity of heard speech, and activity within PAC was sensitive to this manipulation. A region-of-interest defined using cytoarchitectonic maps of PAC (Tahmasebi et al., 2009) revealed that activity was significantly higher for degraded speech preceded by matching compared with mismatching primes, and that this difference was significantly greater than the difference observed for matching and mismatching primes preceding either clear speech or unintelligible control sounds. Connectivity analyses suggested that sources of input to PAC are higher-order temporal, frontal, and motor regions, consistent with the extensive network of feedback connections in the auditory system (De la Mothe, Blumell, Kajikawa, & Hackett, 2006; Winer, 2006) that, in humans, may permit higher-level interpretations of speech to be tested against incoming auditory representations.

40.1.3 Concurrent Task Demands

A final type of processing load is that imposed by extrinsic tasks that are being performed while speech is heard. Although much research on speech

perception and comprehension is conducted under ideal conditions (undivided attention, in quiet environments, and with carefully recorded material), real-world speech perception often involves hearing speech while in the middle of other tasks that divert attention or impose perceptual or cognitive loads (Mattys et al., 2009). Such concurrent processing loads, if they render target speech less intelligible, qualify as “informational masking” according to the definition offered in the previous section on *Perceptual demands*. To what extent is speech that is heard under such conditions processed for information, and how is processing affected by the nature of the secondary task and by the acoustic quality of the speech signal?

The degree to which speech is processed when attention is elsewhere is a difficult question to address behaviorally because it is hard to measure the perception of a stimulus to which a participant is not attending. Wild, Yusuf, et al. (2012) used fMRI to compare processing of degraded (noise-vocoded) and clear speech under full attention and when distracted by

other tasks. In every trial, young listeners with normal hearing were directed to attend to one of three simultaneously presented stimuli: a sentence (at one of four acoustic clarity levels), an auditory distracter, or a visual distracter. When attending to the distracters, participants performed a target-monitoring task. A postscan recognition test showed that clear speech was processed even when not attended, but that attention greatly enhanced the processing of degraded speech. Speech-sensitive cortex could be fractionated according to how speech-evoked responses were modulated by attention, and these divisions appeared to map onto the hierarchical organization of the auditory system (Davis & Johnsrude, 2003; Hickok & Poeppel, 2007; Okada et al., 2010; Pelle, Johnsrude, & Davis, 2010). Critically, only in the region of the superior temporal sulcus (STS) and in frontal regions—regions corresponding to the highest stages of auditory processing—was the effect of speech clarity on BOLD activity influenced by attentional state (Figure 40.3). Frontal and temporal regions manifested this interaction

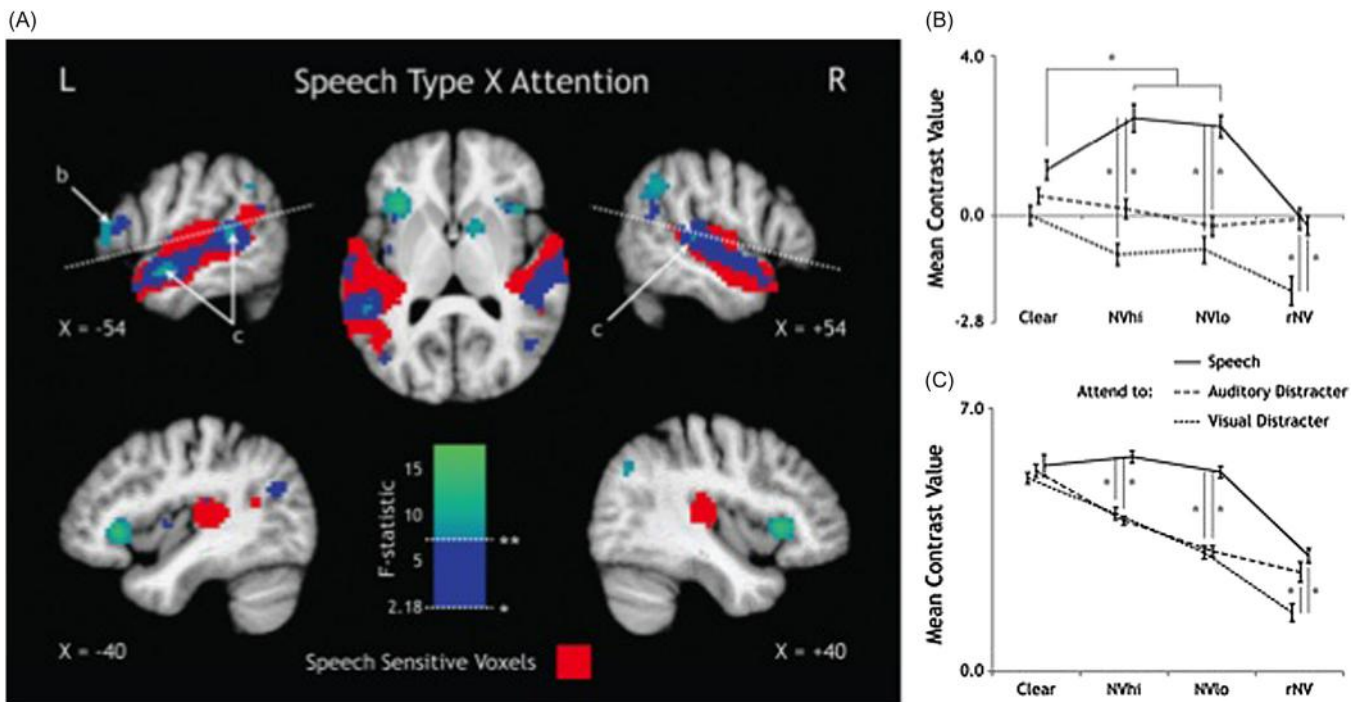

FIGURE 40.3 The interaction between Attention (three levels: attention to speech; attention to an auditory distracter, or attention to a visual distracter) and Speech Clarity (four levels: Clear Speech; 6-band noise vocoded speech [NVhi]; compressed 6-band noise vocoded speech [NVlo]; and spectrally rotated noise vocoded speech [rNV]). Materials were meaningful English sentences such as “His handwriting was very difficult to read.” Whereas both NVhi and NVlow are potentially intelligible (word-report scores for the materials in a pilot group of participants were 88% and 68% respectively), rNV is completely unintelligible. (A) The Speech Clarity by Attentional State interaction F-contrast is shown in blue. *Indicates the threshold at $p < 0.05$ uncorrected for multiple comparisons; **indicates family-wise correction for multiple comparisons. Voxels in red are sensitive to the different levels of Speech Clarity (i.e., demonstrate a significant main effect of speech type) but show no evidence for an interaction with Attention ($p < 0.05$, uncorrected). (B) Contrast values (i.e., estimated signal relative to baseline; arbitrary units) are plotted for LIFG and (C) an average of the STS peaks. Error bars represent the SEM suitable for repeated-measures data (Loftus & Masson, 1994). Vertical lines with asterisks indicate significant pairwise comparisons ($p < 0.05$, Bonferroni corrected for 12 comparisons). Figure taken from Wild, Yusuf, et al. (2012) with permission from the publisher.

in different ways. In the LIFG, when speech was attended, activity was greater for degraded than for clear speech. However, when the listeners attended elsewhere, LIFG activity did not depend on speech type (Figure 40.3B). Increased activity for attended degraded speech may reflect effortful processing that is required to enhance intelligibility or additional cognitive processes (such as those required for perceptual learning) that are engaged uniquely when a listener is attending to speech (Davis, Johnsrude, Hervais-Adelman, Taylor, & McGettigan, 2005; Eisner, McGettigan, Faulkner, Rosen, & Scott, 2010; Huyck & Johnsrude, 2012).

The pattern of activity around the STS was somewhat different; when speech was attended, degraded and clear speech produced similar amounts of activation, consistent with attention enhancing the intelligibility of degraded speech. When distracted, activity in the STS appeared to be driven by the speech quality of the stimulus (Figure 40.3C). Together, these results suggest that the LIFG only responds to degraded speech when listeners are attending to it, whereas the STS responds to speech intelligibility, regardless of attention or how that intelligibility is achieved.

A series of studies by Mattys and colleagues (Mattys, Barden, & Samuel, 2014; Mattys et al., 2009; Mattys & Wiget, 2011) explored how additional extrinsic cognitive load alters the processing of simultaneously presented spoken words. They observed that the mechanisms involved in processing speech under conditions of divided attention are not the same as those involved in processing speech in conditions of undivided attention. When listeners were required to perform a concurrent task that involved divided attention (Mattys et al., 2009), a memory load (Mattys et al., 2009), or a visual search task (Mattys & Wiget, 2011), they relied more on lexical semantic structure to aid segmentation of words and on lexical knowledge to identify phonemes, rather than on acoustic cues conveyed in fine phonetic detail. In fact, the “lexical drift”—this increased reliance on lexical knowledge when distracted—appears to be driven by the reduced acuity for acoustic cues to phoneme identity and word boundaries (Mattys et al., 2014). This may at first seem surprising. As load on central cognitive resources increases, listeners rely more, not less, on knowledge-guided factors (that presumably rely on the same central cognitive resources) for speech perception. Mattys and colleagues (2014) attribute this to a re-weighting of perceptual cues, such that acoustic cues to the identity of words and phonemes are weighted less than linguistic cues. Alternatively, a concurrent task may alter the rate at which acoustic information is sampled, causing some samples to be missed while attention is elsewhere. The results of these experiments, indicating

that concurrent tasks do not simply impair perception but rather alter it qualitatively by affecting perceptual decision criteria, highlight the importance of considering how different real-world situations might affect the effort required to understand speech.

40.2 SUMMARY

“Listening effort” is a unitary term that probably reflects several different challenges to speech comprehension met through a variety of cognitive mechanisms. Our position is that effort is due to an interaction between the perceptual, linguistic, or task challenges imposed by the situation and stimulus and the cognitive resources that the listener brings to bear. This framework allows us to separate different cognitive mechanisms that contribute to listening effort. Behavioral measures such as effort ratings, dual-task reaction time, and pupil dilation may not be able to differentiate among different kinds of processing demand because the measure is one-dimensional. In contrast, neuroimaging methods such as fMRI permit exploration of different kinds of processing demand because they may recruit different regions/networks.

Although this chapter has considered these demands separately, they are not independent. An increase in processing demand at a lower level of representation (e.g., perceptual) can affect processing at a higher level of representation (e.g., semantic/syntactic) in at least three ways: (i) by reducing the domain-general processing resources that are available; (ii) by increasing the ambiguity at later levels of representation; and (iii) by increasing the listeners’ reliance on these representations to resolve lower-level ambiguities. Increases in processing demands at a *higher* level of representation may also have consequences for *lower*-level processing through the extensive network of feedback connections documented in the auditory system. These complex interactions mean that processing demands cannot be fully understood by studying them in isolation.

Neural Mechanisms of Attention to Speech

Lee M. Miller

Center for Mind & Brain, and Department of Neurobiology, Physiology, & Behavior,
University of California, Davis, CA, USA

41.1 OVERVIEW AND HISTORY

Speech perception rarely occurs under pristine acoustic conditions. Background noises, competing talkers, and reverberations often corrupt speech signals and confuse the basic organization of our auditory world. In modern life this perceptual challenge is inescapable, pervading the home, workplace, social situations (e.g., restaurants), and modes of transit (cars, subways). Fortunately, our brains have a remarkable ability to filter out undesired sounds and attend to a single talker, dramatically improving our comprehension (Kidd, Arbogast, Mason, & Gallun, 2005).

In this chapter we address *selective attention* to speech, as distinguished from general arousal or vigilance that is not directed at specific locations, objects, or features. William James described the essential phenomenology of selective attention as “the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. . . It implies withdrawal from some things in order to deal effectively with others” (James, 1890). Mechanistically, this comprises two separable components: *control* and *selection*. Attentional control refers to the cognitive processes that coordinate and direct our attention to specific aspects of our world, for instance, to the high-pitch female talker on the left. In contrast, attentional selection describes the biasing or filtering operation by which one object is highlighted or processed further and the rest is ignored. Selection is therefore the effect that attentional control exerts on the representations of speech content (e.g., acoustic, phonetic, semantic, affective). In the metaphor of the spotlight (Posner, Snyder, & Davidson, 1980), attentional control points the spotlight and attentional selection is evident by its illumination.

The modern study of attention to speech began in 1953 with Colin Cherry’s behavioral work on speech

comprehension in the presence of other distracting talkers, a situation he termed the “cocktail party problem” (Cherry, 1953). His observations and the experimental paradigms he pioneered, such as dichotic listening (different messages to left and right ears) and shadowing (repeating aloud), attracted many investigators to the topic over the ensuing decades. Attention-to-speech therefore became a driving force behind general cognitive theories of attention through the 1950s and 1960s, when the “early versus late selection” debate arose (Broadbent, 1958; Deutsch & Deutsch, 1963; Treisman, 1960). In contrast to the cognitive theory, the neuroscience of attention to speech began much later. In part, this delay was methodological, awaiting the widespread use of noninvasive human electrophysiology in the 1970s (electroencephalography [EEG]) and the advent of neuroimaging in the 1980s and 1990s (positron emission tomography [PET] and functional magnetic resonance imaging [fMRI]). Additionally, much early neuroscientific work on audition and attention eschewed speech for simpler stimuli such as isolated pure tones or noise bursts (Miller et al., 1972). Simple, isolated stimuli offer substantial experimental benefit because they are easily parameterized, have consistent neural responses that are straightforward to analyze, and provide a ready comparison between humans and nonhuman neurophysiology where simple stimuli prevail. However, especially when presented in isolation, they cannot approximate a “cocktail party” environment where selective attention is so crucial. Moreover, simple stimuli lack speech’s rich spectro-temporal structure that may be indispensable to understand the mechanisms of attentional selection.

Consequently, the neuroscience of selective attention to speech—in the tradition of Cherry—began only in 1976, using traditional low-density (here, three

electrodes) EEG in humans (Hink & Hillyard, 1976), which showed increased neural response to speech in the attended ear with a latency of approximately 100 ms. In other words, attention can “select” a target speech stream by enhancing its neural processing at an early stage, a result that has been replicated many times since. We build on this basic idea, reviewing some of the evidence and conceptual advances that have brought us to our current understanding. Notably, recent years have witnessed a surge of interest and increased appreciation for realistic conditions with high perceptual load (Lavie, 2005), especially using continuous competing speech stimuli, degraded acoustics, and realistic spatial scenes. In the following sections we review the neural networks for attentional control, the levels of processing or representations that attention selects, and current neural theories about how mechanistically selective attention brings about such profound improvement in speech perception.

41.2 NEURAL NETWORKS FOR ATTENTIONAL CONTROL

Communicating in daily life requires that we direct the focus of our attention: maintain it on one talker in a noisy background, scan for a friend’s voice in a crowd, listen for a certain word, or switch between different talkers in a conversation. All these are aspects of attentional control, whose functional neuroanatomy provides a framework for understanding attention-to-speech generally. Although attentional control to speech has been studied less than attentional selection, many aspects of control are cross-modal or supramodal (Krumbholz, Nobis, Weatheritt, & Fink, 2009; Macaluso, 2010; Salmi, Rinne, Degerman, Salonen, & Alho, 2007; Shomstein & Yantis, 2004), so several key principles observed in other sensory systems apply to speech as well. One influential model holds that two independent neural networks exert attentional control (Corbetta & Shulman, 2002). An “endogenous” dorsal fronto-parietal network guides top-down or volitional attention. This network consistently includes intraparietal sulcus (IPS) or superior parietal lobule and the frontal eye fields (FEF). A second, “exogenous” ventral fronto-temporo-parietal control network is proposed to handle reflexive or bottom-up reorienting of attention, as when triggered by stimulus saliency and target detection. This ventral control network consistently includes lateral cortical areas such as the temporo-parietal junction (TPJ).

Adverse speech environments virtually always require top-down, volitional attention to particular talker locations, voice qualities, and speech content. Consistent with this requirement, “cocktail party”

paradigms often recruit the dorsal fronto-parietal “endogenous” attention network: particularly IPS and superior parietal lobule, and the superior precentral sulcus in the characteristic location of FEF. Clear evidence for this dorsal network is observed for cued attention (Krumbholz et al., 2009), including when listeners deploy the attention to a desired pitch or location of a talker before the speech occurs (Hill & Miller, 2009). Dorsal network involvement is also evident through suppression of alpha (~10 Hz) EEG power over the parietal lobe contralateral to the attended hemifield (Kerlin, Shahin, & Miller, 2010) and later in the fronto-parietal network after perception of degraded speech (Obleser & Weisz, 2012). Notice that in speech studies, such superior fronto-parietal regions including likely FEF appear to be involved when attending not only to space but also to speech features such as pitch, and they are even recruited when attending to speech with no spatial acoustic cues whatsoever (as well as visual distractor stimuli; Wild et al., 2012). This supports the model that a supramodal dorsal fronto-parietal network handles volitional attention to speech (Corbetta & Shulman, 2002), in contrast to alternate models that postulate, for instance, a dorsal-spatial versus ventral nonspatial specialization (Hill & Miller, 2009; Lee et al., 2012). That said, some studies report little if any fronto-parietal activation associated with attention to speech (Alho et al., 2006). Though the reasons are unclear, in some cases this may be due to low perceptual interference (high speech clarity) or ease of the behavioral task, both of which would reduce the need for attentional control.

Another area robustly involved in attention to speech is the inferior frontal gyrus (IFG), especially the dorsal part and in some cases specifically the inferior frontal junction (IFJ; posterior part of the inferior frontal sulcus where it meets the precentral sulcus). Early suggestions for an attentional role of IFG came not from neuroimaging studies on attention per se, but from those that happened to require attention to phonetic attributes of clean speech. For instance, Zatorre reviewed a number of reports that used phonetic monitoring and discrimination, all of which show activation in dorsal posterior Broca’s area (Zatorre, Meyer, Gjedde, & Evans, 1996). Although Broca’s area is a large region heterogeneous in its cytoarchitectonics, anatomical connectivity, and function (Amunts & Zilles, 2012; Rogalsky & Hickok, 2011), evidence suggests that in addition to phonetic and other linguistic processing, this consistency in dorsal IFG is due to sustained active monitoring (i.e., attentional control). Subsequent studies using selective attention to one of multiple concurrent speech sounds also found left lateralized dorsal-posterior IFG activity when selective attention was required (Hashimoto, Homae, Nakajima, Miyashita, & Sakai, 2000; Lipschutz, Kolinsky, Damhaut,

Wikler, & Goldman, 2002), or bilateral inferior frontal involvement only when acoustic-phonetic cues could not easily distinguish the two competing speech streams (Nakai, Kato, & Matsuo, 2005). Another study approximated the challenge of a cocktail party using degraded speech and clever manipulation to distinguish controlled attention: subjects were first presented with noises, unaware that they could be heard as speech, and then the subjects learned to listen to the noises as degraded words (Giraud et al., 2004). The results showed that effortful “auditory search” recruits left dorsal posterior IFG without reflecting comprehension directly. Wild et al. (2012) also reported effects in IFG with similarly degraded sentences, in this case effects of auditory attention broadly but with an interaction such that a portion of dorsal IFG was only active when degraded but *potentially comprehensible* speech was attended. This is similar to the aforementioned “auditory search” in that listeners use internal expectations of speech to parse it, effortfully, from noise. In a rather different paradigm, left dorsal IFG/IFJ was specifically related to attentional control as opposed to selection of a competing speech stream, because it was shown to be active while directing attention before the speech occurred (Hill & Miller, 2009). Finally, although it is not universally the case (Alho et al., 2003), a majority of speech paradigms show this activation to have a left-hemisphere bias, likely reflecting linguistic hemispheric dominance (Giraud et al., 2004; Hill & Miller, 2009).

Even when attending to nonspeech noise bursts, IFG is active when listening in silence before the stimulus occurs (but here leading to a right hemisphere activation; Voisin, Bidet-Caulet, Bertrand, & Fonlupt, 2006). Moreover, specifically the dorsal posterior part of IFG is involved in a wide array of challenging tasks—both auditory, such as sequencing speech or nonspeech sounds (Gelfand & Bookheimer, 2003), and nonauditory, from math to cognitive control to working memory (Fedorenko, Duncan, & Kanwisher, 2012). All of these are consistent with a domain-general function of (usually left) dorsal IFG in attentional control or perhaps more broadly cognitive control (Novick, Trueswell, & Thompson-Schill, 2005). Interestingly, rather than being squarely part of a ventral reflexive attention network, IFJ may play an integrative role in both goal-directed and stimulus-driven attention (Asplund, Todd, Snyder, & Marois, 2010). This would clearly be important in a “cocktail party” environment, where momentary attentional goals would be continually updated by the varying salience of corrupted speech attributes.

In addition to IFG, attention to speech may recruit the hypothesized posterior member of the ventral

“exogenous” control system—inferior parietal lobule and especially the TPJ—although here the evidence is not quite as consistent. Nevertheless, in the first neuroimaging study of concurrent *continuous* speech (as opposed to brief tokens), Alho et al. (2003) observed right lateralized TPJ activity regardless of whether subjects attended to the left or right ear. Similar activation is seen when attending to one of two concurrent streams of dichotic syllables (Lipschutz et al., 2002) and when switching and reorienting attention to one of two streams of spoken digits, whether simultaneously presented (Larson & Lee, 2012) or not (Krumbholz et al., 2009). Although bilateral TPJ involvement has been shown in a number of auditory attention studies (Huang, Belliveau, Tengshe, & Ahveninen, 2012), a right-hemisphere bias of a ventral attentional network is nevertheless consistent with visual attention and the phenomenon of hemispatial neglect (Corbetta & Shulman, 2011).

Thus, attentional control to speech relies on a supramodal, largely bilateral, dorsal fronto-parietal “volitional” network that directs attention to numerous speech attributes including but not limited to spatial location. Additionally, ventral prefrontal cortex (IFG) appears to be crucial for deploying attention flexibly to comprehend degraded or competing speech, whether it be attending to pitch or location, monitoring phonemes, or analyzing sound sequences. Like the dorsal network, left IFG appears to be supramodal in the sense that parts of it handle a wide array of attention-demanding perceptual and cognitive functions, both verbal and nonverbal. This agrees with the suggestion that the ventral frontal attention network, IFJ in particular, may be a kind of attentional nexus playing an integrative role in both goal-directed and stimulus-driven attention (Asplund et al., 2010; Huang et al., 2012). Finally, ventral posterior cortices consistent with a supramodal “orienting network,” usually TPJ and particularly in the right hemisphere, appear to be important for attentional control and switching to speech in certain paradigms. Overall, the evidence shows that attentional control to speech is domain-general, sharing principles and functional neuroanatomy with other modalities.

41.3 LEVELS OF ATTENTIONAL SELECTION

Once attentional control “points the spotlight,” its “illumination” then selects or modulates internal speech representations. Historically, since the time of Cherry, perception of competing speech has been central to the debate about attentional selection. Cherry and others observed that when attending to and

shadowing one of two competing speech streams, listeners may not notice even dramatic changes in the unattended stream, such as a switch from English to German or backward speech (Cherry, 1953; Wood & Cowan, 1995). Such evidence inspired the “early selection” theory, championed by Broadbent (1958), which held that processing of unattended speech is thoroughly blocked at an early sensory stage. Other investigators advocated “late selection”: that some speech information was still maintained through the entire sensory processing hierarchy, with attentional selection occurring just before entering working memory (Deutsch & Deutsch, 1963). Still others developed variants of these, with different stages of attenuation or filtering by attention (Treisman, 1960).

Today the debate is less heated, with most investigators recognizing that attention may act at different levels, and unattended speech may be processed to different depths, depending on the nature of the stimuli and task goals. The neural evidence shows that in some cases, attention can modulate the ascending pathway at the thalamus (Frith & Friston, 1996), brainstem including inferior colliculus (Galbraith & Arroyo, 1993; Rinne et al., 2008), or even the cochlea (Delano, Elgueda, Hamame, & Robles, 2007; Giraud et al., 1997). However, most evidence for attentional modulation of speech, based on latency and anatomical location, points to auditory cortex and higher-level speech-related cortex. The emerging pattern is that selective attention can modulate acoustic speech representations in primary or early nonprimary auditory cortical areas and at numerous higher levels, evidently depending on the task demands and on the degree of perceptual load or interference.

Our understanding of the neural selection of speech builds on and parallels a large body of research on auditory attention to nonspeech, especially simpler stimuli. Although this chapter does not aspire to thoroughly review auditory attention, a few notable studies provide some context. The earliest demonstration of auditory attentional selection occurred in cat auditory cortex, where Hubel observed cells that only responded when the animal paid attention to the stimulus (Hubel, Henson, Rupert, & Galambos, 1959). This appeared to be an early and strong form of gating or gain modulation due to auditory attentional selection, but little scientific work pursued the idea for many years. In humans, the “early versus late selection” debate was finally addressed with neural data using EEG; in a dichotic listening task, attention modulated the neural response with an enhanced negativity (at the top of the scalp) to tones in the attended ear at latencies 80–110 ms, corresponding to the auditory N1 wave (Hillyard, Hink, Schwent, & Picton, 1973). This observation has been replicated many times, and the

modulation has been shown in some circumstances to occur earlier, from 20 to 50 ms and from 80 to 130 ms (Woldorff et al., 1993). Thus, early studies demonstrated a gain modulation of neural responses to attended sounds at latencies consistent with low-level auditory cortex.

These principles appeared to hold for speech sounds as well, with the aforementioned Hink and Hillyard dichotic speech study (Hink & Hillyard, 1976) that showed a larger N1 to stimuli in the attended ear. Subsequent EEG work approximated Cherry’s shadowing paradigm, again reporting enhanced negativity to speech probe sounds and again co-temporal with the N1 wave (Woods, Hillyard, & Hansen, 1984). In a significant step toward ecologically valid “cocktail party” perception, Teder et al. first used continuous speech itself to elicit ERPs rather than independent probe sounds in the attended “channel,” finding increased negativity beginning at approximately 40 ms and peaking at 80–90 ms latency (Teder, Kujala, & Naatanen, 1993). This study also used free-field speakers rather than dichotic presentation and highlighted the potential importance of realistic spatial cues, which may influence comprehension more as the scene becomes complex (Yost, Dye, & Sheft, 1996).

Neuroanatomically, the timing of effects in the electromagnetic studies suggest attentional modulation of primary and early nonprimary auditory cortices (Godey, Schwartz, de Graaf, Chauvel, & Liegeois-Chauvel, 2001). This conjecture was supported by a number of neuroimaging studies that used attention to speech in the absence of competing sounds or degradation (Grady et al., 1997; Jancke, Mirzazade, & Shah, 1999), or with brief dichotic speech stimuli spaced out in time (Jancke, Buchanan, Lutz, & Shah, 2001). Many early imaging studies using concurrent speech reported attentional modulation of large areas of the superior temporal lobe and give mixed results or lacked the spatial specificity to determine whether the modulation extended to presumed primary or early secondary auditory cortex (Alho et al., 2003; Hashimoto et al., 2000; Hugdahl et al., 2000; Lipschutz et al., 2002; Nakai et al., 2005; O’Leary et al., 1996). As a group, these leave unanswered the question of “early selection” but provide powerful evidence for attentional modulation at multiple higher stages of processing.

Meanwhile, studies using nonspeech sounds with more precise mapping techniques demonstrated that even for isolated (nonconcurrent) sounds, attentional modulation tended to be weak or absent in primary auditory cortex and stronger in secondary and tertiary fields (Petkov et al., 2004; Woods et al., 2009). Recent reports using more ecological “cocktail party” speech tasks also tend to report superior temporal attentional modulations that selectively spare primary auditory

cortex but affect neighboring areas (Hill & Miller, 2009). On the basis of timing and source location, MEG demonstrated such modulations in planum temporale at approximately 100 ms latency but not earlier (Ding & Simon, 2012). This contrasts with attentional enhancements of response phase and coherence to nonspeech tonal stimuli, interpreted to occur in core or primary auditory cortex (Elhilali, Xiang, Shamma, & Simon, 2009). Another recent imaging study addressed selective attention to distorted speech in the presence of additional auditory and visual distractors, in other words, a very demanding and realistic task (Wild et al., 2012). Attentional modulation occurred throughout auditory cortex when subjects attended to audition as opposed to vision. However, attentional enhancement *specifically to distorted speech* occurred only in speech-sensitive anterior and posterior STS—high-level areas hierarchically distant from primary auditory cortex. In other words, much of auditory cortex showed some nonspecific modulation but only high-level speech processing benefitted from targeted, selective attentional enhancement.

Attentional selection of speech is thus remarkably flexible and can modulate processing at multiple levels of the cortical auditory and speech hierarchy, even during the same task. In all likelihood, this variable selection is as rapidly deployed and adaptive as observed in vision (Hopf et al., 2006). However, the specific modulation appears to be constrained by perceptual load or separability at the acoustic-phonetic level (Shinn-Cunningham, 2008). For sounds that differ on basic acoustic dimensions (or for sounds versus stimuli in another sensory modality), attention may be able to act earlier in the hierarchy. For competing speech that shares many physical characteristics or in cases of high perceptual load, attention may only be able to modulate higher-level, more abstract speech processing. This suggests that the levels of attentional selection are determined by both the processing level at which sensory representations can be readily distinguished and the amount of competition among those representations.

41.4 SPEECH REPRESENTATIONS THAT ATTENTION SELECTS

To fully understand the levels of attentional selection, we must also characterize the nature or content of speech representations that are actually selected. Here, manipulating task demands has been particularly informative, showing that selection works on a vast array of perceptually salient speech attributes depending on their momentary relevance. For this reason,

attention to speech has been used most often *not to study attention* but as a tool to identify brain areas devoted to components of speech-perceptual and linguistic processing. The advantage of using attention in such paradigms is that one can equate low-level stimulus attributes among conditions, changing only the task goal, and with it the attentional focus. These studies range from the well-established “what versus where” streams distinguishing speech identity from location processing (Ahveninen et al., 2006; Alain, Arnott, Hevenor, Graham, & Grady, 2001; Maeder et al., 2001), to recognizing voices versus comprehending them (Alho et al., 2006; von Kriegstein, Eger, Kleinschmidt, & Giraud, 2003), to performing syntactic and semantic operations (Rogalsky & Hickok, 2009). However, although they use attentional selection as a tool, most of these approaches are not intended to reproduce the ecological conditions (e.g., high perceptual load) that may be necessary to strongly engage and reveal the attentional system (Lavie, 2005).

When listeners are challenged to understand degraded or competing speech, one of the key neural representations that correlates with comprehension is a low-frequency response (approximately 2–16 Hz, and especially 4–8 Hz) likely evoked or entrained by the speech amplitude envelope (Ahissar et al., 2001; Ding & Simon, 2013; Giraud & Poeppel, 2012; Luo & Poeppel, 2007; Peelle & Davis, 2012) or other salient acoustic features time-varying at a syllabic rate (Ghitza, Giraud, & Poeppel, 2012; Obleser, Herrmann, & Henry, 2012). That is, the neural response has substantial power at the same frequencies that speech acoustic power fluctuates across syllables. And it is phase-locked in the sense that neural fluctuations in that frequency range follow the acoustic speech events with a consistent latency. This particular response has a latency of approximately 100 ms, appears to be strongly represented in early auditory cortices, and is modulated by attention (Ding & Simon, 2012; Kerlin et al., 2010; Power, Lalor, & Reilly, 2011; Zion Columbia et al., 2013). Recordings from the cortical surface in humans furthermore show that not only temporal envelope but also *spectro-temporal* envelope of the attended talker are preferentially modulated by attention, largely along the lateral superior temporal gyrus (STG) (Mesgarani & Chang, 2012). These observations are consistent with reports of nonhuman animals showing rapid, attention-dependent changes in spectro-temporal tuning of single cells and populations in auditory cortex (Fritz, Elhilali, & Shamma, 2007). As noted, other perceptually salient speech features such as pitch and spatial location are also clearly modulated by attention, but compared with spectro-temporal envelope the specific nature of these selected representations is relatively less apparent or less understood

beyond a well-documented contralateral bias for spatial hemifield (Alho et al., 2003).

The prominent role of dynamic speech attributes for attention and comprehension highlights the unique importance of time. Unlike in vision, *all* auditory stimuli—and particularly speech—are distinguished by their temporal evolution. Thus, speech perception may rely on attention to specific moments even more than in other perceptual domains (Coull & Nobre, 1998; Lange & Roder, 2006). Behaviorally, temporal expectancy or attention in time has a powerful influence on speech comprehension. For instance, knowing both an expected word and the moment of a critical phoneme, but not one or the other, allows focused attention to alter the perceptual continuity of speech (Samuel & Ressler, 1986), even when the attentional state generally has no effect on continuity (Heinrich, Carlyon, Davis, & Johnsrude, 2011). This suggests that attention-in-time to speech may require an internal representation or prediction (e.g., lexical or syntactic) on which it operates (Shahin, Bishop, & Miller, 2009). In adverse environments such as context-guided, temporal expectations would be the rule rather than the exception. EEG shows that specific attention in time results in an enhanced N1 response (~100 ms) around the time of word onsets (Astheimer & Sanders, 2008), similar to the enhanced N1 often observed for nontemporal attention (Hillyard et al., 1973). These results complement mounting evidence that context and predictions, whether strictly attentional in nature or not, improve the neural processing of speech (Oleser, Wise, Alex, Dresner, & Scott, 2007; Sohoglu, Peelle, Carlyon, & Davis, 2012).

Notice that most of our understanding about the neural basis of attentional selection for speech regards specific speech features or attributes (e.g., pitch, temporal envelope, spectral attributes; Tuomainen, Savela, Oleser, & Aaltonen, 2013). Perceptually, rather than experiencing a collection of individual features, we perceive talkers as coherent, unified *objects* or *streams*. An important theoretical question, then, has been whether attention acts on neural speech representations as objects or as individual features. And if it acts on individual features, does attention then automatically “spread” to other features shared by the object? Although the question is not yet settled, most evidence is consistent with an object-based mechanism of attention to speech (Alain & Arnott, 2000; Ihlefeld & Shinn-Cunningham, 2008; Shinn-Cunningham, 2008). More specifically it seems that, similar to vision (Kravitz & Behrmann, 2011), auditory-speech object formation causally precedes but potentially still interacts with attentional selection. A recent MEG study supports this idea, showing that when the intensity of competing talkers is separately varied, the neural

representation of attended speech adapts only to the intensity of that speaker and not to the background object even though they overlap spectro-temporally (Ding & Simon, 2012). These object representations, related to speech envelope and evident in the M100 response (~100 ms latency), were localized to planum temporale (i.e., in nonprimary auditory cortex). So even though we may attend to individual components of speech, naturalistic speech perception likely relies on bound object representations beginning early in the processing hierarchy.

41.5 NEURAL MECHANISMS AND TOP-DOWN/BOTTOM-UP INTERACTIONS

In the tradition of the “early versus late selection” debate, most inquiry into the neural bases of attention-to-speech has focused on neural timing and functional anatomy to determine the hierarchical level of speech processing where attention acts. Recent years, however, have brought an increased interest in the specific mechanisms by which attention modulates the speech representations. The historical, often implicit, concept of attentional selection has been that of a gain model: selection increases neural firing for the attended speech feature or object, and perhaps suppresses it for unattended ones. *Prima facie*, most empirical evidence is consistent with some type of gain modulation, including single-cell neurophysiology (beginning with Hubel’s “attention units”; Hubel et al., 1959) as well as the majority of data from neuroimaging and EEG/MEG. One should of course keep in mind that different approaches may be more sensitive to different mechanisms (e.g., noninvasive neuroimaging techniques such as PET or fMRI might be blind to many non-gain temporal mechanisms), whereas in EEG and MEG increased neural synchrony (without more activity overall) may be interpreted as a “gain” effect.

Nevertheless, recent studies using a variety of methods continue to support selectively greater activity for attended speech representations. In several EEG or MEG reports, gain modulation has been observed for the phase-locked, syllable-rate responses noted, reflecting increased neural following of the attended speech envelope (approximately 4–8 Hz; Ding & Simon, 2012; Kerlin et al., 2010). The envelope response to unattended speech may also be somewhat suppressed (Kerlin et al., 2010) as it is with music (Choi, Rajaram, Varghese, & Shinn-Cunningham, 2013). Moreover, the selection of spectro-temporal speech modulations observed in cortical surface recordings (Mesgarani & Chang, 2012) appears to reflect a gain effect. Interestingly, the amount of gain modulation in the time-varying speech response, effectively the strength

of attentional selection, is predicted by the strength of attentional control exerted. Specifically, gain in the speech representation correlates with the strength of *anticipatory* alpha power ($\sim 8\text{--}12$ Hz) suppression over the parietal lobe contralateral to attended speaker hundreds of milliseconds earlier (Kerlin et al., 2010). Greater alpha suppression throughout the superior fronto-parietal control network furthermore predicts intelligibility of degraded speech (Obleser & Weisz, 2012). Thus, consistent with the visual system, the engagement of the attentional control network and consequent suppression of alpha oscillations may reflect the lifting of inhibition, followed by increased gain in attended speech representations (Jensen & Mazaheri, 2010). However, the details of such a “gating by inhibition” for speech, including any potential relationships between speech envelope and alpha oscillation phase, need further study.

In addition to modulating the intensity of activity in certain neural populations, attentional selection may also rapidly alter the spectrotemporal tuning of auditory cortical cells and populations to match the target sound features. Using nonspeech stimuli, Fritz and colleagues have shown such effects in nonhuman animals over multiple time scales (Elhilali, Fritz, Chi, & Shamma, 2007; Fritz, Shamma, Elhilali, & Klein, 2003). Evidence that attention can narrow spectral tuning in auditory cortex has also been observed in humans with MEG/EEG and fMRI (Ahveninen et al., 2011). Yet another proposed mechanism broadly compatible with increased gain and tuning is that attention aligns intrinsic, ongoing neural oscillations with the temporal evolution of attended speech (Besle et al., 2011; Lakatos, Karmos, Mehta, Ulbert, & Schroeder, 2008; Lakatos et al., 2009; Schroeder & Lakatos, 2009; Zion Golumbic et al., 2013). This “selective entrainment hypothesis” holds that spontaneous low-frequency neural oscillations (e.g., 1–8 Hz) reflect fluctuations in neural excitability (Bastos et al., 2012) and, therefore, preferred moments for sensory processing. In other words, the brain has natural rhythms and, during different moments in the rhythmic cycles, neurons are more or less excitable. Attention, using temporal predictions about precisely when speech information should occur, would align these endogenous oscillations to be in phase with the evoked sensory response, thereby selecting and boosting the attended speech representation. The idea that attention alters the temporal alignment of neural responses has further support from a study using nonspeech sounds showing greater temporal coherence for an attended rhythm across a bilateral auditory network (Elhilali et al., 2009). Therefore, attention may act through several mechanisms that complement simple gain modulation or may lead to it via different means. Much work remains to

clarify both these additional possibilities and the behavioral circumstances in which they play a role.

41.6 INTERACTIONS BETWEEN ATTENTION, PERCEPTION, AND PREDICTION

As our mechanistic understanding of attention to speech grows, so does the recognition that attention may not simply modulate early sensory activity—boosting or shifting it but leaving the nature of the representations essentially intact. Rather, attention and similar mechanisms may interact with how our perceptual systems fundamentally parse and organize the world, a process known as auditory scene analysis (Bregman, 1990; McDermott, 2009; Shinn-Cunningham, 2008; Snyder, Gregg, Weintraub, & Alain, 2012). Most research on this topic has used nonspeech stimuli, but the principles may readily apply. For instance, it can take time, approximately 1 second, for our auditory systems to segregate or stream multiple objects in a complex scene. This “building up” of streaming may begin without attentional influence (Sussman, Horvath, Winkler, & Orr, 2007) but might require attention in some circumstances (Carlyon, Cusack, Foxton, & Robertson, 2001; Snyder, Alain, & Picton, 2006). These ideas are incorporated in a theory of auditory scene analysis that posits that the formation of auditory streams depends primarily on temporal coherence of neural responses to different object features (Shamma, Elhilali, & Micheyl, 2011). The theory furthermore holds that attention to one object feature is then *necessary* to bind the other temporally coherent features into a stream. All the other incoherent, unattended features are left unstreamed, as if you “wrap up all your garbage in the same bundle” (Bregman, 1990, p. 193). This is related to the idea, also shown in vision and cross-modally, that attention “spreads” to encompass the bound features of an object (Cusack, Deeks, Aikman, & Carlyon, 2004). However, this “temporal coherence” theory contradicts some evidence mentioned that attention acts on objects (Alain & Arnott, 2000; Shinn-Cunningham, 2008) and that object formation is largely pre-attentive or automatic (Bregman, 1990). Perhaps as with the levels of attentional selection, the degree to which attention interacts with basic object formation depends on the intrinsic competition or ambiguity among the sensory representations.

The notion that attention interacts fundamentally with speech processing is also consistent with a growing body of research on the perceptual role of context. We mentioned several instances where attention may guide sensory predictions or expectations (Astheimer & Sanders, 2008; Lakatos et al., 2008). Many more studies

beyond the scope of this chapter show that the auditory system maintains a continuous, adaptive representation of context at multiple levels. Some expectations are largely automatic and depend on stimulus statistics, as indexed by the well-known MMN EEG response when patterns are violated (Naatanen, Gaillard, & Mantysalo, 1978; Sussman, Ritter, & Vaughan, 1998). However, even this so-called automatic response can be modulated by attention (Nyman et al., 1990; Sussman, Winkler, Huottilainen, Ritter, & Naatanen, 2002; Woldorff, Hillyard, Gallen, Hampson, & Bloom, 1998). Others, still largely unconscious, will be more linguistic in nature (Clos et al., 2014) and rely more on long-term memory. These linguistic contextual cues profoundly influence how well speech is processed, particularly when it is degraded (Baumgaertner, Weiller, & Buchel, 2002; Oleser & Kotz, 2009; Pichora-Fuller, Schneider, & Daneman, 1995) and when accompanied by age-related hearing loss, where peripheral impairment has been shown to interact with numerous cognitive and attentional functions (Humes et al., 2012). Still other expectations will be conscious, as when anticipating a specific word. Admittedly, not all of these phenomena will use attention-like mechanisms to select the predicted speech content, but some evidently do (e.g., with attention-in-time to emphasize representations of word onsets) (Astheimer & Sanders, 2008).

One increasingly prominent perceptual theory known as “predictive coding” relies inherently on the interaction between sensory input and expectation or context. Bayesian in nature, it holds that predictions formulated at higher levels are fed back to early sensory cortices, which act as comparators between prediction and sensory input, with the ultimate goal of minimizing prediction error. Thus, early sensory activity feeding forward reflects an error signal or mismatch between expectation and reality. Because the acoustic and linguistic statistics of speech support such rich predictions, this theory is a promising model to characterize attention to speech as well. Several recent results lend some empirical support to predictive coding. For instance, in a concurrent EEG + MEG study, increased prior knowledge about speech increased activity in IFG but *decreased* activity in STG, in line with predictive coding (Sohoglu et al., 2012). The timing of these effects suggested that an initial feed-forward draft of the speech allows IFG to activate likely predictions that are then fed back to sensory cortex. In another study, MEG responses localized to STG were consistent with predictive coding when perceiving newly learned words that were similar to known (predictable) words (Gagnepain, Henson, & Davis, 2012). Further clues about predictive coding used audiovisual speech, suggesting that “top-down” predictions based on vision may be fed back via lower-frequency oscillations (14–15 Hz) and, coupled with

them, error signals propagated forward via high-frequency (60–80 Hz) activity (Arnal, Wyart, & Giraud, 2011). Typically “top-down” implies more abstract representations or rules originating at higher levels and flowing to lower levels of an anatomical or functional hierarchy, whereas bottom-up implies information, in this model an error signal, flowing up the hierarchy in the direction of an initial sensory volley. Such mechanistically different roles for different frequency bands agree with recent models of cortical information processing (Bastos et al., 2012; Wang, 2010). It also recalls a seminal nonhuman primate study of volitional versus stimulus-driven attentional control in vision, where volitional attention began in prefrontal cortex (FEF), exogenous attention initiated in the parietal lobe, and the coherence between them was greater in lower frequencies for volitional control and in higher frequencies for stimulus-driven attention (Buschman & Miller, 2007). Although results from different systems and paradigms should be taken with care, they are at least consistent with the notion that attention to speech could act within a predictive coding framework.

41.7 FUTURE DIRECTIONS

Our understanding of attention to speech has advanced considerably in the past half century, but many questions remain. Regarding basic functional neuroanatomy, for instance, how should attention to speech be reconciled with the influential dual-stream theory of speech perception (Hickok & Poeppel, 2007)? The dual stream model broadly conforms to a dorsal “where/how” pathway for sensorimotor transformation and perception-for-action and a ventral “what” pathway for identifying objects (Goodale & Milner, 1992; Hickok & Poeppel, 2007; O’Reilly, 2010; Scott, 2005). This is consistent with evidence from attentional selection, with multiple, flexible levels of modulation along the speech hierarchy. However, correspondence with the dual-stream model is less clear for the fronto-temporo-parietal attentional control network. For example, ventral areas for orienting attention overlap those thought to perform sensorimotor (acoustic-articulatory) integration and, particularly in Broca’s area, other linguistic perceptual functions. Perhaps the supramodal dorsal fronto-parietal attentional network controls volitional attention to speech as an acoustic *object in the world* (e.g., to its spatial location) or when using other attributes to segregate the object from others. In contrast, perhaps the inferior frontal attentional system controls volitional attention as well as stimulus-driven orienting to identifying attributes of speech (i.e., those that contribute directly to its intelligibility). Perhaps function is lateralized in the ventral attention network such that right

TPJ is devoted to exogenous attention while left TPJ handles acoustic-motor mapping. At present, we lack a framework that integrates these necessary but somewhat incompatible roles.

In terms of mechanisms, most investigators would agree that gain modulation plays a central role in attentional selection of speech. But other plausible mechanisms have not yet been thoroughly vetted. Are some effects that we attribute to gain instead due to increased synchrony or coherence in neural activity, or are they due to altered receptive field tuning in individual auditory cortical cells? Does attentional control selectively entrain endogenous fluctuations to be in phase with incoming speech, thereby boosting it at the expense of distractors? Does alpha activity act as “gating inhibition” and, when suppressed, dis-inhibit the attended speech representations? If so, then how would alpha fluctuations relate to the well-known syllabic rate sensory activity or to behavioral performance (Zoefel & Heil, 2013)? Such interactions between top-down control and sensory selection also lead naturally to the relation between attention and perceptual segregation of speech streams. Are speech objects formed independently of attention (and then selected by it), or is attention required—and, if so, under which circumstances and at what levels of processing? Is attention organized hierarchically for features and objects so that attention to any feature always spreads to other features of that speech stream? Does attention to speech operate as “predictive coding,” seeking to minimize the error between context-based expectations and reality? Far more empirical evidence is needed, but the proposal fits well with a growing appreciation that the brain often adheres to Bayesian principles (Bastos et al., 2012).

Still other possible attentional mechanisms have hardly been explored with speech, including several already demonstrated in the visual system. For instance, should we conceive of selective attention to speech as a form of biased competition (Desimone & Duncan, 1995; Shinn-Cunningham, 2008) and, if so, how should we think of the high-order “receptive field” within which different stimuli compete? As noted, at the single neuron and population level, we expect that attention might induce rapid adaptive receptive field changes in how auditory neurons respond to speech. But does it also decorrelate neural activity, which in visual cortex can explain behavioral performance more than gain modulation (Cohen & Maunsell, 2009)? Or does attention perform a kind of “normalizing” computation to yield a winner-take-all selected speech object in certain circumstances (Reynolds & Heeger, 2009)? Already we know that attentional control networks are neuroanatomically largely supramodal and so, too, could the underlying mechanisms of attention be universal.

As the abundance of open questions makes clear, great effort will be required to characterize the neural bases of attention to speech. But it also demonstrates how our understanding has become more informed, nuanced, and mechanistic over time. We are now at the threshold of characterizing how this profoundly important everyday ability works. After 60 years, we have returned to Cherry’s cocktail party.

Audiovisual Speech Integration: Neural Substrates and Behavior

Michael S. Beauchamp

Department of Neurosurgery and Core for Advanced MRI, Baylor College of Medicine, Houston, TX, USA

Speech is the most important form of human communication. Speech perception is multisensory, with both an auditory component (the talker's voice) and a visual component (the talker's face). When the auditory speech signal is compromised because of auditory noise or hearing loss, the visual speech signal gains in importance (Bernstein, Auer, & Takayanagi, 2004; Ross et al., 2007; Sumbly & Pollack, 1954). In the case of profound deafness, lip-reading by itself can be sufficient for speech perception (Suh, Lee, Kim, Chung, & Oh, 2009). Visual speech information is also beneficial in cases of partial hearing loss; older adults with hearing impairments identify visual-only speech *better* than older adults with normal hearing (Tye-Murray, Sommers, & Spehar, 2007).

42.1 NEUROARCHITECTURE OF AUDIOVISUAL SPEECH INTEGRATION

The most popular technique for examining human brain function is blood-oxygen level-dependent functional magnetic resonance imaging (BOLD fMRI) (Friston, 2009), and neurophysiological studies of multisensory speech are no exception (Beauchamp, Lee, Argall, & Martin, 2004; Blank & von Kriegstein, 2013; Lee & Noppeney, 2011; Miller & D'Esposito, 2005; Nath & Beauchamp, 2011; Noppeney, Josephs, Hocking, Price, & Friston, 2008; Okada, Venezia, Matchin, Saberi, & Hickok, 2013; Wilson, Molnar-Szakacs, & Iacoboni, 2008). The multisensory speech network in a typical subject is easily identifiable with fMRI and includes regions of occipital, temporal, parietal, and frontal cortex (Figure 42.1A: left and right hemisphere in one subject). The most consistent activations (found in every hemisphere in every subject,

example subject in Figure 42.1B) are in three regions: (i) visual cortex, especially lateral extrastriate motion-sensitive areas, including areas MT and MST; (ii) auditory cortex and auditory association areas on the superior temporal gyrus; and (iii) multisensory areas in the posterior superior temporal sulcus (STS) and adjacent superior temporal gyrus and middle temporal gyrus (pSTS/G).

A working hypothesis for the function of these areas is that extrastriate visual areas process the complex biological motion signals carried by the talker's facial motion and form a representation of visual speech. Auditory association areas process the complex auditory information necessary to form a representation of auditory speech sounds. These representations must abstract away from the physical stimulus properties to represent the key features of speech to be behaviorally useful; for instance, it is important to integrate auditory and visual speech from a talker even if we have never seen or heard them before. Multisensory areas in the STS then integrate the visual and auditory speech representations to decide the most likely speech percept produced by the talker. A critical feature of speech is that the amount of information carried by the auditory and visual modalities varies tremendously from moment to moment. According to Bayesian models of perception, ideal observers should weight each modality by its reliability (the inverse of its variance). For instance, in a conversation in a very loud room, the visual information is more reliable than the auditory information and should be given more weight; in a dark room, the auditory information is more reliable and should receive more weight. In a BOLD fMRI experiment, Nath and Beauchamp (2011) examined the neural mechanisms for this dynamic weighting of auditory and visual information. Auditory speech

FIGURE 42.1 The neural network for processing audiovisual speech measured with BOLD fMRI. (A) Lateral views of the partially inflated left hemisphere (top) and right hemisphere (bottom). Dark gray shows sulcal depths and light gray shows gyral crowns. Colored brain regions showed a significant increase in BOLD fMRI signal to audiovisual speech (recordings of meaningless syllables) compared with fixation baseline. All activations thresholded at $F > 5.0$, $P < 0.05$, corrected for false discovery rate. Color scale shows t -values for contrast of all syllables versus fixation. (B) Anatomical-functional regions of interest (ROIs) created from activation map in (A). The STS ROI (green) contains voxels responsive to both auditory and visual speech greater than baseline in the posterior STS. The auditory cortex ROI (blue) contains voxels responsive to auditory speech greater than baseline within Heschl's gyrus. The visual cortex ROI (red) contains voxels responsive to visual speech greater than baseline within extrastriate lateral occipitotemporal cortex. The IFG ROI (purple) contains voxels responsive to both auditory and visual speech greater than baseline within the opercular region of the inferior frontal gyrus and the inferior portion of the precentral sulcus.

information was degraded by adding masking noise, and visual speech information was degraded by blurring the stimulus (across experiments, different levels of degradation were used with similar results). To assess functional connectivity, the psychophysiological interaction (PPI) method was used. Functional connections between STS and auditory association areas and lateral extrastriate visual cortical areas were observed, but not between STS and primary auditory or primary visual cortex.

As shown in [Figure 42.2](#), increased functional connectivity between the STS and auditory association cortex was observed when the auditory modality was more reliable, and increased functional connectivity between the STS and extrastriate visual cortex was observed when the visual modality was more reliable, even when the reliability changed rapidly during rapid event-related presentation of successive words. This finding suggests that changes in STS functional connectivity may be an important neural mechanism underlying the perception of noisy speech. Changes in functional connectivity may also be important for audiovisual learning ([Driver & Noesselt, 2008](#); [Powers, Hevey, & Wallace, 2012](#)).

FIGURE 42.2 fMRI functional connectivity within the audiovisual speech network. (A) Auditory-reliable speech: undegraded auditory speech (loudspeaker icon) with degraded visual speech (single video frame shown). (B) Visual-reliable speech: undegraded visual speech with degraded auditory speech. (C) Functional connectivity during auditory-reliable speech in a representative subject. The green region on the cortical surface model shows the location of the pSTS/G ROI; the blue region shows the location of the auditory cortex ROI; and the red region shows the location of the lateral extrastriate visual cortex ROI. The top number is the path coefficient between pSTS/G and auditory cortex. The bottom number is the path coefficient between the pSTS/G and visual cortex. (D) Functional connectivity during visual-reliable speech (same subject and color scheme as in C).

fMRI studies have provided a wealth of information about audiovisual speech perception, but they are constrained by the limitations of the BOLD signal. Most critically, BOLD is an indirect measure of neural function that relies on slow changes in the cerebral vasculature. The BOLD response to a stimulus consisting of a single syllable (duration ~ 0.5 s) extends for 15 s; most fMRI studies have a temporal resolution of only 2 s. This temporal resolution is thousands of times slower than the underlying neural information processing (duration of a sodium-based action potential < 1 ms). Because speech is itself a rapidly changing signal, and because the speech information must be processed rapidly by the brain to be behaviorally useful, fMRI is far too slow for direct observation of the underlying neural events.

In contrast, studies that use electrical and magnetic measurements can directly measure neural activity with high temporal precision. In the first approach, event-related potentials are recorded. Transient responses to audiovisual syllables display peaks between 100 and 200 ms after stimulus onset ([Bernstein, Auer, Wagner, & Ponton, 2008](#)). In a second approach, induced oscillations are recorded. These have the advantage of allowing for the examination of sustained neuronal activity that is not phase-locked to the stimulus and can extend for several hundred milliseconds after stimulus onset ([Schepers, Schneider, Hipp, Engel, & Senkowski, 2013](#)).

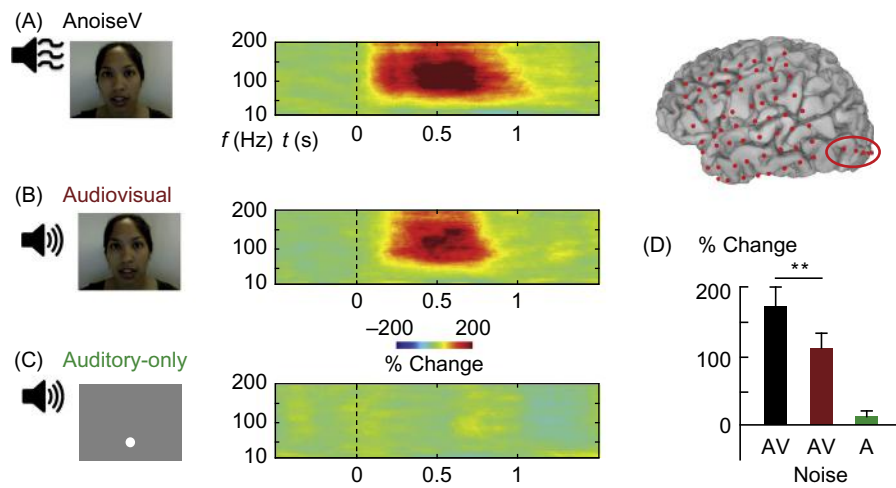

FIGURE 42.3 Electrocortigraphy of visual cortex responses to audiovisual speech. (A) A patient being treated for intractable epilepsy was implanted with subdural electrodes (red dots on cortical surface model, right). Brain activity was recorded from electrodes over visual cortex (red dots inside ellipse) as the subject was presented with noisy audiovisual speech (visual speech with auditory white noise, AnoiseV). A time-frequency analysis was used to determine the neural response at different frequencies (y -axis) at each time (x -axis) after stimulus onset (dashed vertical line). Color scale indicates amplitude of change from pre-stimulus baseline. (B) Time-frequency response of visual cortex to audiovisual speech (undegraded visual and auditory). (C) Response to auditory-only speech. (D) Amplitude of high-frequency responses to each stimulus condition averaged across the entire course of the response. **Significant difference between AnoiseV and AV speech, $P = 0.0016$.

EEG and MEG have provided important insights into the neural basis of multisensory speech perception. Another technique known as electrocortigraphy has two important advantages (Allison, Puce, Spencer, & McCarthy, 1999). First, electrocortigraphy offers superior spatial resolution: activity recorded from each approximately 1-mm electrode on the cortical surface is generated by neurons in close proximity to the electrode. In contrast, EEG and MEG suffer from the inverse problem: for any distribution of electrical or magnetic fields measured outside the head, there are an infinite number of patterns of brain electrical activity that could have resulted in the observed fields. Practically speaking, this limits the spatial resolution, making it difficult to untangle the location of sources that are in close proximity, as are the areas in the audiovisual speech network. Second, electrocortigraphy signals have much greater signal-to-noise than EEG/MEG, especially for high-frequency responses, because the electrode is much closer to the source, eliminating filtering by the cerebrospinal fluid and skull that lies between the cortex and the EEG/MEG sensors. High-frequency activity is ubiquitous in the human brain (Canolty et al., 2006; Crone, Miglioretti, Gordon, & Lesser, 1998; Schepers, Hipp, Schneider, Roder, & Engel, 2012) and is thought to be an excellent population-level measure of neuronal activity correlated with single-neuron spiking (for a recent review see Lachaux, Axmacher, Mormann, Halgren, & Crone, 2012; Logothetis, Kayser, & Oeltermann, 2007; Nir et al., 2007; Ray & Maunsell, 2011).

Most electrocortigraphy studies of speech perception have investigated auditory-only speech, either in a single brain area, such as auditory cortex (Chang et al., 2010), or in a more distributed network (Canolty et al., 2007; Pei et al., 2011; Towle et al., 2008). We collected electrocortigraphy data while subjects were presented with clear and noisy auditory and visual speech. Our hypothesis was that multisensory interactions between auditory and visual speech processing should be most pronounced when the visual speech information is most important, such as when noisy auditory speech information is present. We tested this hypothesis by examining the responses to visual speech in visual cortex.

In the noisy audiovisual and audiovisual speech conditions (Figure 42.3A and B), the subject viewed a video of a talker speaking a word. This is a powerful visual stimulus that evoked a strong response in visual electrodes. As is commonly reported for responses to visual stimuli, the response differed by frequency. For low frequencies (<20 Hz) there was a decrease in power relative to pre-stimulus baseline (blue colors at bottom of plot). For high frequencies (>40 Hz) there was a large increase in power relative to pre-stimulus baseline (yellow and red colors at middle of each plot). These high-frequency responses are thought to reflect spiking activity in neurons underlying the electrode and therefore served as our primary measure of interest. As is expected for visual cortex, there was a negligible response to stimuli without a visual component (auditory-only speech, Figure 42.3C). Responses to noisy audiovisual speech (video of a speaker accompanied by

auditory white noise) were stronger than the responses to AV speech (Figure 42.3D).

This supports a simple model in which the goal of the cortical speech network is to extract meaning from AV speech as quickly and efficiently as possible. When the auditory component of the speech input is sufficient to extract meaning, the visual response is not needed and therefore not enhanced. When the auditory stimulus does not contain sufficient information to extract meaning (as is the case for visual-only speech or visual speech with auditory white noise), the visual response is needed to extract meaning and activity in visual cortex is upregulated.

42.2 BEHAVIORAL APPROACHES FOR STUDYING AUDIOVISUAL SPEECH INTEGRATION

There are a number of behavioral approaches to studying the contributions of the auditory and visual

modalities to audiovisual speech perception. In the most straightforward method, noisy auditory speech is accompanied by clear visual speech, such as a video of a talker saying the words that match the auditory signal (Figure 42.4A). The information available from viewing the face of the talker improves the ability to understand speech. This improvement is equivalent to an approximately 10-dB increase in signal-to-noise ratio; at increased levels of auditory noise, this can correspond to a dramatic improvement in the number of words understood (Ross, Saint-Amour, Leavitt, Javitt, & Foxe, 2007b).

At a neural level, we might imagine that there are different pools of neurons that represent representations of different auditory and visual speech representations. When presented with a noisy auditory phoneme, many pools representing many different auditory phonological representations are weakly active, with no single pool reaching an activity level sufficient to form a perceptual decision, assuming a Bayesian evidence accumulation model (Beck et al., 2008). When visual information is added, pools of neurons representing the

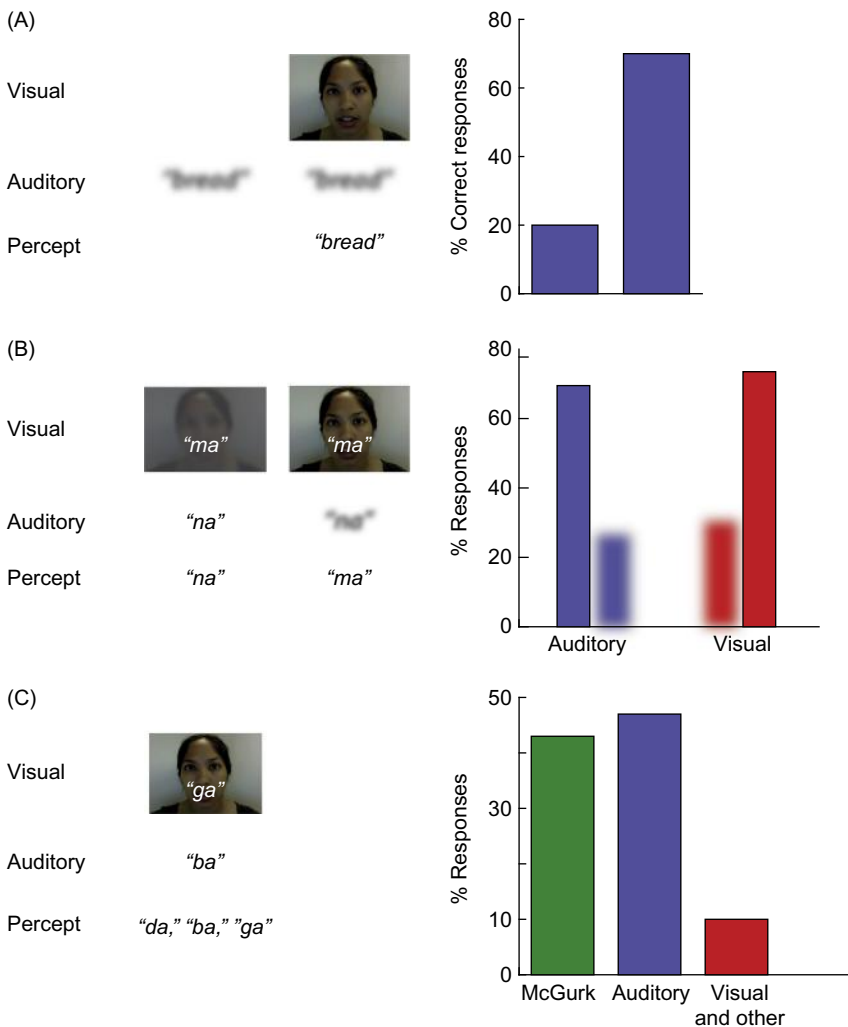

FIGURE 42.4 Behavioral responses to incongruent audiovisual speech. (A) Noisy auditory speech with and without congruent visual speech. If a degraded auditory word (e.g., bread; auditory filtering indicated by blurriness of printed word) is presented, then the subject only rarely is able to correctly identify it (left bar in plot). If the same degraded auditory word is accompanied by a video of a talker speaking the word, then the subject is usually able to identify it (right bar in plot). Data replotted from Ross, Saint-Amour, Leavitt, Javitt, and Foxe (2007a) with permission from the publisher. (B) Incongruent audiovisual speech consisting of a visual /ma/ and an auditory /na/ (or vice versa). If the visual component of speech is degraded by blurring (left column), then subjects report a percept corresponding to the auditory component of the stimulus (indicated in plot by solid blue bar and complementary blurry red bar). If the auditory component of speech is degraded by filtering (right column), then subjects report a percept corresponding to the visual component of the stimulus (indicated in plot by blurry blue bar and complementary solid red bar). (C) Incongruent audiovisual speech consisting of a visual /ga/ and an auditory /ba/ (or a visual /pa/ and an auditory /ka/). In 43% of trials (green bar in plot) subjects reported a McGurk fusion percept of /da/ (or /ta/), corresponding to neither the auditory nor the visual components of the stimulus.

visual speech information respond strongly. Combining the information available in the visual and auditory-responsive pools of neurons allows a perceptual decision to be reached.

In a more complex approach, auditory speech and visual speech are presented together, but the modalities are incongruent; the auditory modality signals one syllable at the same time as the visual modality signals a different one (Figure 42.4B). The advantage of this approach is that it pits the auditory and visual modalities against each other, allowing an evaluation of their relative contributions to perception. If the reported percept matches the auditory modality, then we infer that the auditory modality was most important; if the reported percept matched the visual modality, then we infer that the visual modality was most important. For instance, if a visual /ma/ is paired with an auditory /na/ that is heavily degraded, subjects will often report perceiving /ma/, implying that they used the visual information more than the auditory information in forming their decision (Nath & Beauchamp, 2011). However, it is not possible to directly quantify the contribution of each modality to each response as it is with other perceptual decisions. For continuous variables, such as location, the percept of an incongruent audiovisual stimulus (e.g., beep in one location and flash in a different location) can vary anywhere between the location of the two unisensory stimuli. A report of a percept at a location exactly midway between the locations of the two stimuli indicates that both modalities contributed equally to the percept, with locations closer to one or the other of the two stimuli indicating more influence of that modality. However, speech perception is categorical—any given speech sound is perceived as a particular phoneme, and subjects in general do not make intermediate responses. Therefore, it is only possible to state that one modality or the other was dominant. Subjects are often aware that the auditory and visual modalities are incongruent, but this does not change their conscious percept of a single syllable.

At a neural level, we could imagine that adding auditory noise weakens the response of the pool of neurons representing the auditory speech representation. At high levels of auditory noise, the response of the neurons representing the incongruent visual speech representation is stronger than the response of the neurons representing the auditory speech, and thus the reported percept corresponds to the visual speech representation.

A third approach to studying multisensory integration in speech also involves the presentation of incongruent audiovisual syllables (Figure 42.4C). For most incongruent audiovisual syllables, subjects perceive either the auditory component of the stimulus or the visual component. However, for a few incongruent audiovisual syllables, subjects perceive a third syllable

that corresponds to neither the auditory nor the visual component of the stimulus. Two of these unusual incongruent syllables, first discovered serendipitously by McGurk and MacDonald (1976), consist of an auditory /ba/ paired with a visual /ga/ (perceived as /da/) and an auditory /pa/ paired with a visual /ka/ (perceived as /ta/). These illusory percepts have come to be known as the McGurk effect.

The McGurk effect is widely used in research for at least two reasons. First, because the percept corresponds to neither the auditory nor the visual component of the stimulus, the McGurk effect provides strong evidence that speech perception is multisensory. Second, the McGurk effect offers a quick and simple way to measure multisensory integration. A single trial in which the subject perceives the illusion demonstrates that the subject is integrating auditory and visual information. In contrast, measuring audiovisual integration with other approaches requires many trials at different levels of auditory noise, which is time-consuming for normal volunteers and may be impossible for clinical groups such as elderly subjects or children.

42.3 INTERSUBJECT VARIABILITY

The McGurk effect has also been used as a sensitive assay of individual differences in audiovisual integration. Although it is generally appreciated that the ability to see and hear varies across the population (hence the need for eye glasses and hearing aids), difference in central perceptual abilities are less well-appreciated. Healthy young subjects were tested with auditory-only stimuli and congruent audiovisual stimuli and identified them without errors. However, when presented with McGurk stimuli, there were dramatic differences between individuals. Across 14 different McGurk stimuli (recorded by many different speakers), some subjects never reported the illusion, whereas some subjects reported the illusory percept on every trial of every stimulus (Figure 42.5A). However, for most subjects, the illusion was not “all or nothing.” Most subjects reported the illusion for some stimuli but not others, and, even for multiple presentations of the same stimulus, a subject might report the illusion on some trials but not others.

To better understand this variability, we created a simple model with three sets of parameters. One parameter described the strength of each stimulus (across subjects, how often this stimulus elicited an illusory percept). Another parameter described each subject’s individual threshold for reporting the illusion (any stimulus perceived to lie above this threshold would evoke the illusion). A third parameter described the sensory noise in each subject’s measurement of a

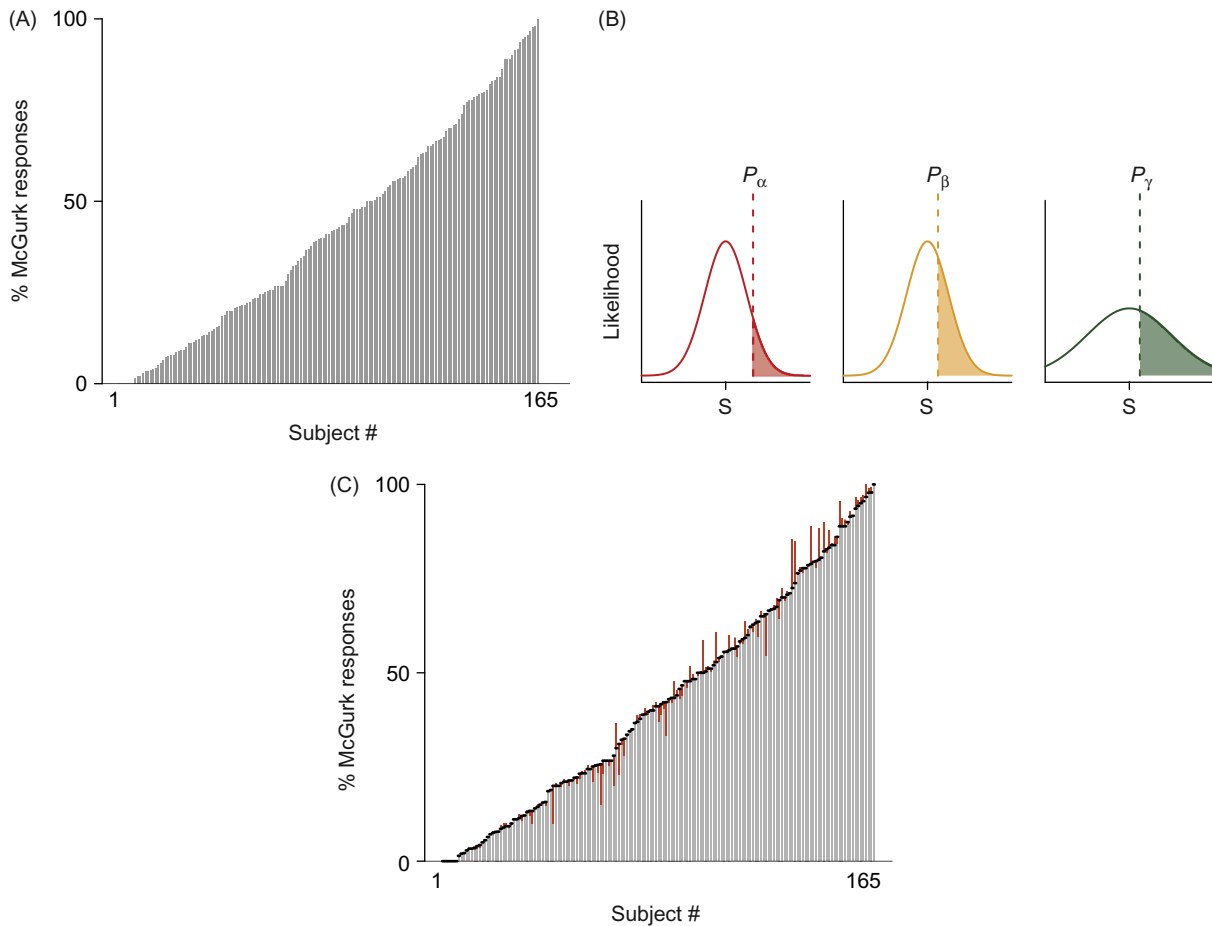

FIGURE 42.5 Intersubject variability in the McGurk effect. (A) Each bar represents a single subject ($n = 165$). The height of each bar corresponds to the proportion of McGurk fusion responses (e.g., percept of /da/ when presented with visual /ga/ and auditory /ba/) out of all responses when the subject was presented with 10 repetitions of up to 14 different McGurk stimuli. Subjects are ordered by rate of McGurk fusion responses. (B) A model of McGurk perception in which each stimulus is fit with a given strength (tick mark labeled S on x-axis) and each subject is fit with a given threshold (vertical dashed line). In each trial, the strength of the stimulus is measured by the subject with a process that includes sensory noise (width of Gaussian curve corresponds to amount of sensory noise). This leads to a distribution of measured strengths across trials. In those trials in which the measured strength exceeds threshold, the McGurk effect is perceived by the subject (shaded regions). The left plot shows a subject with low susceptibility (P_α): the subject threshold is greater than the stimulus strength, leading to few trials on which the illusion is perceived (small red shaded area). A second subject (P_β , middle plot) has the same sensory noise as P_α (width of yellow curve same as width of red curve) but a lower threshold (dashed yellow line to the left of dashed red line along x-axis), leading to increased perception of the McGurk effect (yellow shaded region) for the identical stimulus. A third subject (P_γ , right plot) has greater sensory noise (width of green curve greater) but the same threshold as P_β , leading to increased perception of the McGurk effect (green shaded region). (C) The model is fit to the behavioral data from each subject shown in (A). Each black point shows the behavioral data (mean proportion of fusion responses across all stimuli). Each gray bar shows the model prediction for that subject. Each red bar shows the prediction error for that subject.

stimulus's strength. In any given trial, the subject does not perceive the actual strength of the stimulus, only the subject's noisy internal representation of it. The sensory noise term describes how much variability is added to the (true, external) stimulus strength when creating this internal representation. The sensory noise term is critical to account for the observation that the exact same stimulus can evoke different reports on different trials. If subjects perceived the true stimulus strength, then for any given stimulus they should either always report the illusion (if the stimulus strength falls above their threshold) or never report it

(if the stimulus strength falls below their threshold). Because subjects instead perceive a corrupted version of stimulus strength, in some trials, the perceived strength lies above the subject's fusion threshold, and the illusion is reported. In other trials, the perceived strength lies below the subject's fusion threshold and the illusion is not reported. Using these simple sets of parameters (two for each subject and one for each stimulus), we can accurately reproduce the pattern of observed reports of the illusion. Even more importantly, the model can predict responses to stimuli that subjects have never before seen.

42.4 NEURAL SUBSTRATES OF THE MCGURK EFFECT

Different individuals with normal hearing and vision report very different percepts when presented with the same McGurk stimulus. The source of this variability must lie within the central nervous system. To examine the neural underpinnings of this behavioral variability, we conducted three parallel BOLD fMRI studies in young adults (Nath & Beauchamp, 2012), children (Nath, Fava, & Beauchamp, 2011), and older adults. Subjects were divided into those who only weakly perceived the

McGurk effect and subjects who more strongly perceived it in a behavioral pre-test performed outside the scanner (Figure 42.6A). Then, the STS was identified using an independent set of fMRI data that used different stimuli (audiovisual words) to eliminate bias in voxel selection (Simmons, Bellgowan, & Martin, 2007).

After the STS was identified, responses in the STS to individual McGurk syllables were measured. Only passive viewing of the syllables was used; subjects did not make a behavioral response during MR scanning. Even though the physical stimulus presented to the two groups was identical, subjects who strongly

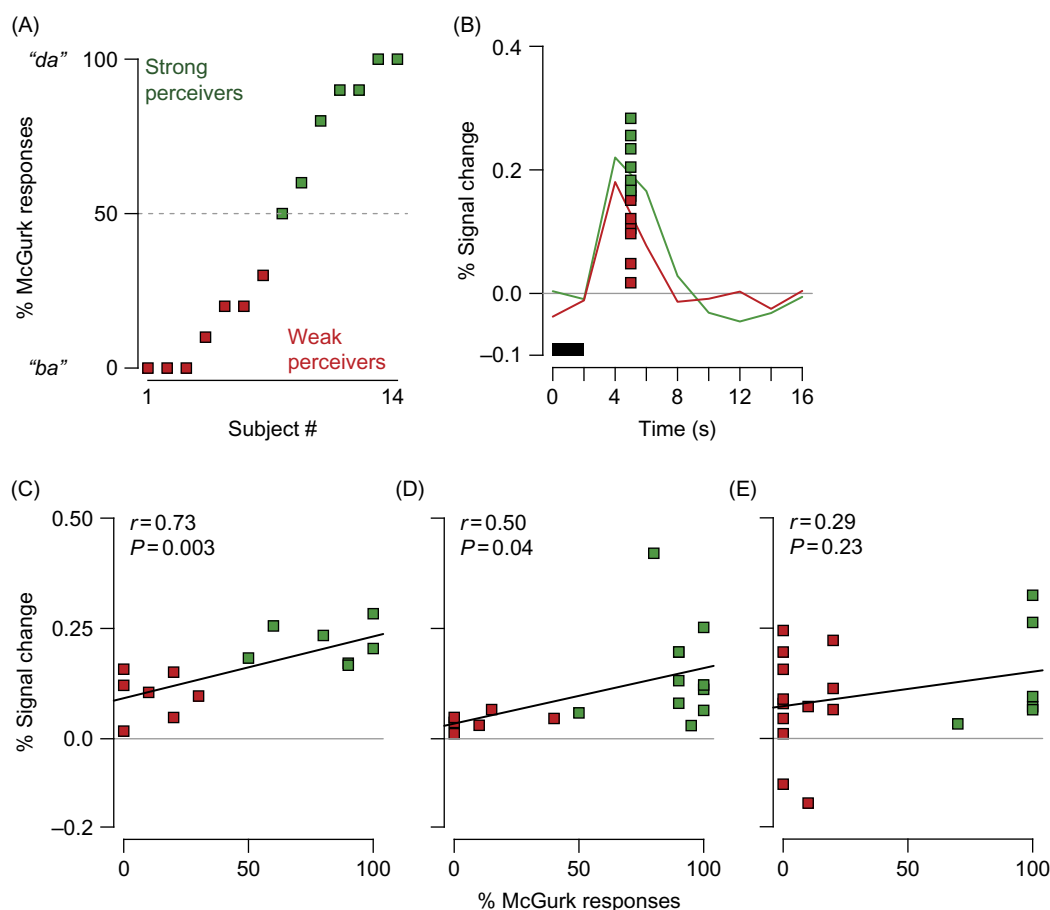

FIGURE 42.6 Intersubject variability in neural responses to the McGurk effect. (A) Young adult subjects ($n = 14$) were ordered by proportion of McGurk fusion responses and divided into strong perceivers of the McGurk effect (green squares, proportion of McGurk fusion responses ≥ 0.50) and weak perceivers of the McGurk effect (red squares, proportion of McGurk fusion responses < 0.50). (B) The STS was localized in each young adult subject using independent stimuli (auditory and visual words). Then, the BOLD fMRI response to single McGurk syllables (black bar) was measured in the STS ROI. The average BOLD response across all strong perceivers (green curve) and across all weak perceivers (red curve) is shown. Each square shows the peak response of a single subject who strongly perceived the effect (green square) or weakly perceived it (red square). (C) Each young adult subject's McGurk fusion rate (x -axis) was correlated with the BOLD fMRI signal change in the STS ROI (y -axis). Error bars show the intersubject variability in the fMRI response across trials for each subject (green squares are strong perceivers, red squares are weak perceivers). (D) Children aged 5–12 years were tested using a similar protocol (the STS was localized with independent localizer; subjects were divided into strong and weak perceivers based on their behavioral responses to the McGurk effect; the fMRI signal in the STS ROI was plotted against the proportion of fusion responses; error bars show within-subject variability). (E) Older adult subjects aged 5–12 years were tested using a similar protocol (the STS was localized with independent localizer; subjects were divided into strong and weak perceivers based on their behavioral responses to the McGurk effect; the fMRI signal in the STS ROI was plotted against the proportion of fusion responses).

perceived the McGurk effect had greater BOLD responses to McGurk stimuli. There was a positive correlation between how often they perceived the illusion and the amplitude of the BOLD fMRI response of the STS. No other brain regions showed such a correlation.

A possible explanation for this finding is that neurons in the STS perform the computations necessary to integrate the auditory and visual components of the stimulus and create the McGurk illusion. If these neurons are not active, then the illusory percept is not created. It is important to emphasize that this does not indicate anything defective about audiovisual integration in subjects who do or do not perceive the McGurk illusion. In fact, the STS in both groups responded identically to congruent audiovisual syllables. Rather, subjects may be differentially sensitive to the incongruent nature of the McGurk stimuli. If subjects infer that the auditory and visual components of the stimulus are likely to have originated from different speakers, then the optimal solution is to respond with only one component of the stimulus (typically the auditory component, because the auditory modality is usually more reliable for speech perception). If subjects infer that the auditory and visual components of the stimulus are more likely to have originated from the same speaker, then the optimal solution is to fuse the components and respond with the illusory percept, because this percept is most consistent with both the auditory and visual components. This process of Bayesian causal inference may account for audiovisual speech perception under conditions in which the synchrony between the auditory and visual modalities varies (Magnotti, Ma, & Beauchamp, 2013).

In children aged 5 to 12 years, the correlation between STS responses and McGurk susceptibility was weaker than in adults but still significant (Figure 42.6B). In addition to the STS, the fusiform face area (FFA) on the ventral surface of the temporal lobe was also correlated with McGurk susceptibility.

In older adults aged 53 to 75 years, the correlation between STS responses and McGurk susceptibility was not significant. One possible explanation for the difference is that older adults had significantly greater intra-subject variability than younger adults. Each subject viewed the same McGurk stimuli multiple times, allowing for an estimate both of the mean BOLD fMRI response (used to correlate with the McGurk susceptibility for that individual) and the variability of the BOLD fMRI response. This variability was much larger in older adults, possibly obscuring a true correlation between the mean response and susceptibility. A second possible explanation is that most of the older subjects did not perceive the illusion. Because the number of weak and strong perceivers was unbalanced, this reduced the power available to detect differences between them. In the younger adult study, this imbalance was avoided

by pre-screening the subjects so that equal numbers of strong and weak perceivers were included.

The observed positive correlation between left STS activity and perception of the McGurk effect (and no significant correlation in any other brain region) is provocative, but it does not demonstrate that activity in the STS is necessary for the illusion. To demonstrate this, we interfered with activity in the STS using transcranial magnetic stimulation (TMS).

The STS is found in every human brain, but there is substantial variability in its anatomical configuration, as well as in the anatomical location of the functionally defined subregion within the STS that responds to auditory and visual speech (although it is often found at the bend where the STS turns upward into posterior lobe). Most TMS studies stimulate the brain based on skull landmarks (e.g., 2 cm lateral to the occipital pole) or on functional landmarks (e.g., 2 cm anterior to motor cortex). However, the STS is not easily localized with either of these techniques. Therefore, we used fMRI to identify the multisensory region of the STS in each subject (Beauchamp, Nath, & Pasalar, 2010). Then, frameless stereotaxic registration was used to position the fMRI coil over the STS. Single pulses of TMS (<1 ms duration) were delivered as subjects viewed McGurk and control stimuli (Figure 42.7). Subjects were pre-screened so that only those who strongly perceived the illusion were tested. Without TMS, the McGurk percept was reported on nearly every trial. However, when TMS was delivered to the STS, the illusion was reported in only approximately half of trials. Perception of other auditory or visual stimuli was not affected. Stimulating cortex outside the STS did not produce any change in the illusion, demonstrating that it was a specific result of STS stimulation and not related to the auditory click produced by the TMS coil or the scalp tactile stimulation induced by the pulse. The “virtual lesions” introduced with TMS interfered with McGurk only in a temporal window just before and after onset of the auditory stimulus (Figure 42.7C), similar to the window in which electrocorticographic activity is observed. The impairment in perception of the McGurk effect caused by TMS stimulation of the STS lasted for <1 s. Across multiple trials of TMS, there were no appreciable changes: TMS interfered with McGurk perception as effectively at the end of the experiment as it did at the beginning. However, permanent damage to the STS might engage cortical mechanisms for plasticity.

To examine this possibility, we tested a patient, SJ, who experienced a stroke that ablated the entirety of her left posterior STS (Figure 42.8); her right hemisphere was unaffected (Baum, Martin, Hamilton, & Beauchamp, 2012). She was severely impaired immediately after the brain injury but underwent extensive

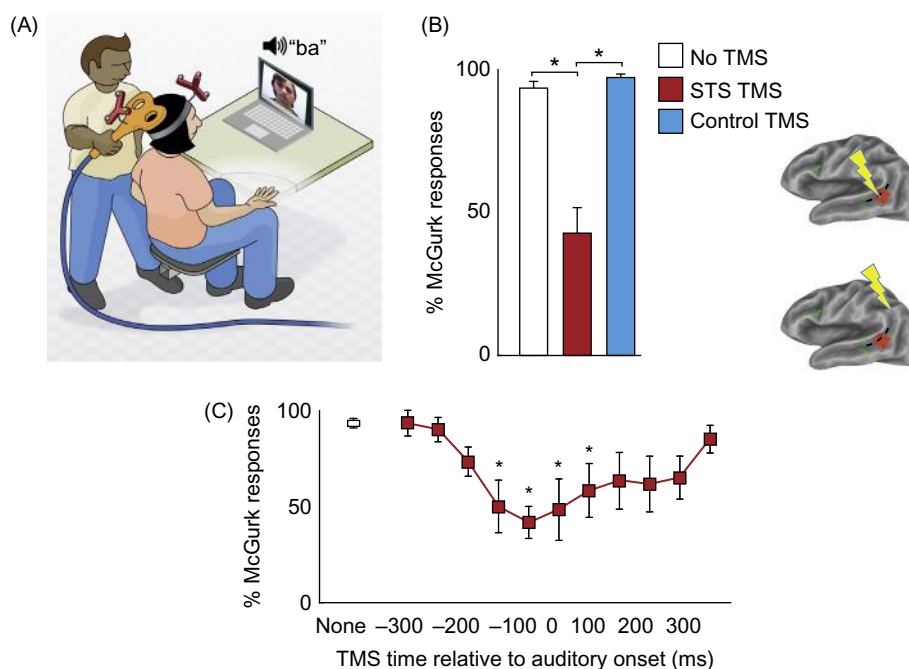

FIGURE 42.7 Disruption of the McGurk Effect with TMS. (A) A TMS coil was used to stimulate the STS or a control location as subjects viewed a McGurk stimulus and reported their percept. fMRI was used to identify target regions in each subject and frameless stereotaxy was used to position the TMS coil over the identified target. A single pulse of TMS was applied in each trial. (B) Behavioral responses to McGurk stimuli with no TMS, with STS TMS, and with control TMS. The lightning bolt icon positioned over the inflated cortical surface model and fMRI activation map of a sample subject shows the location of the applied TMS. Figure adapted from [Beauchamp et al. \(2010\)](#) with permission from the publisher. (C) The time at which the single pulse of TMS was delivered was varied. With no TMS, the McGurk effect was always perceived. Maximal interference with the McGurk effect was observed when the TMS was delivered at times near the onset of the auditory stimulus. *Significant reduction in McGurk perception, $P < 0.05$.

daily rehabilitation in the 5 years after her stroke. After recovery, she reported good ability to understand speech but reported that it was very effortful. At testing, her ability to understand auditory syllables was similar to that of age-matched controls. Surprisingly, she also reported experiencing the McGurk illusion. Because her left STS was ablated, we performed a BOLD fMRI study to try and understand the brain circuits active when she was presented with audiovisual speech. No activity was observed in her left STS, but her right STS was highly active when she was presented with speech, including words, congruent syllables, and McGurk syllables. The volume of cortex active in her right STS exceeded that of any age-matched control. This suggests a scenario in which the right STS reorganized to perform the multisensory integration performed in the left STS by normal individuals. This, in turn, suggests substantial plasticity in the circuit for perceiving audiovisual speech. A promising direction for future research is exploring the training parameters that are most effective at modifying the multisensory speech perception network.

Another important direction for future research is a better understanding of how the auditory cortex, visual cortex, and STS interact with other brain areas important

for speech perception. A subcortical structure, the superior and inferior colliculus ([Wallace, Wilkinson, & Stein, 1996](#)), is a brainstem hub for integrating auditory and visual information. Although the role of the colliculus in audiovisual speech perception is unknown, a lesion study suggested that damage to subcortical structures can impair audiovisual speech perception ([Chamoun, Takashima, & Yoshor, 2014](#)). Within the cortex, Broca's area is critical for linguistic processing ([Nagy, Greenlee, & Kovacs, 2012](#); [Sahin, Pinker, Cash, Schomer, & Halgren, 2009](#)) and may play a role in audiovisual integration and speech comprehension, especially for noisy speech ([Abrams et al., 2012](#); [Noppeney, Ostwald, & Werner, 2010](#); but see [Hickok, Costanzo, Capasso, & Miceli, 2011](#)). A common finding is activity in Broca's area for producing (or repeating), but not perceiving, words ([Towle et al., 2008](#)). Another important brain area to consider is the FFA, which plays an important role in face processing ([Engell & McCarthy, 2010](#); [Grill-Spector & Malach, 2004](#)) and has also been implicated in the processing of voices ([von Kriegstein, Kleinschmidt, & Giraud, 2006](#)). Recent evidence from probabilistic tractography suggests that there exist anatomical connections between FFA and STS ([Blank, Anwender, & von Kriegstein, 2011](#)). High-resolution fMRI and

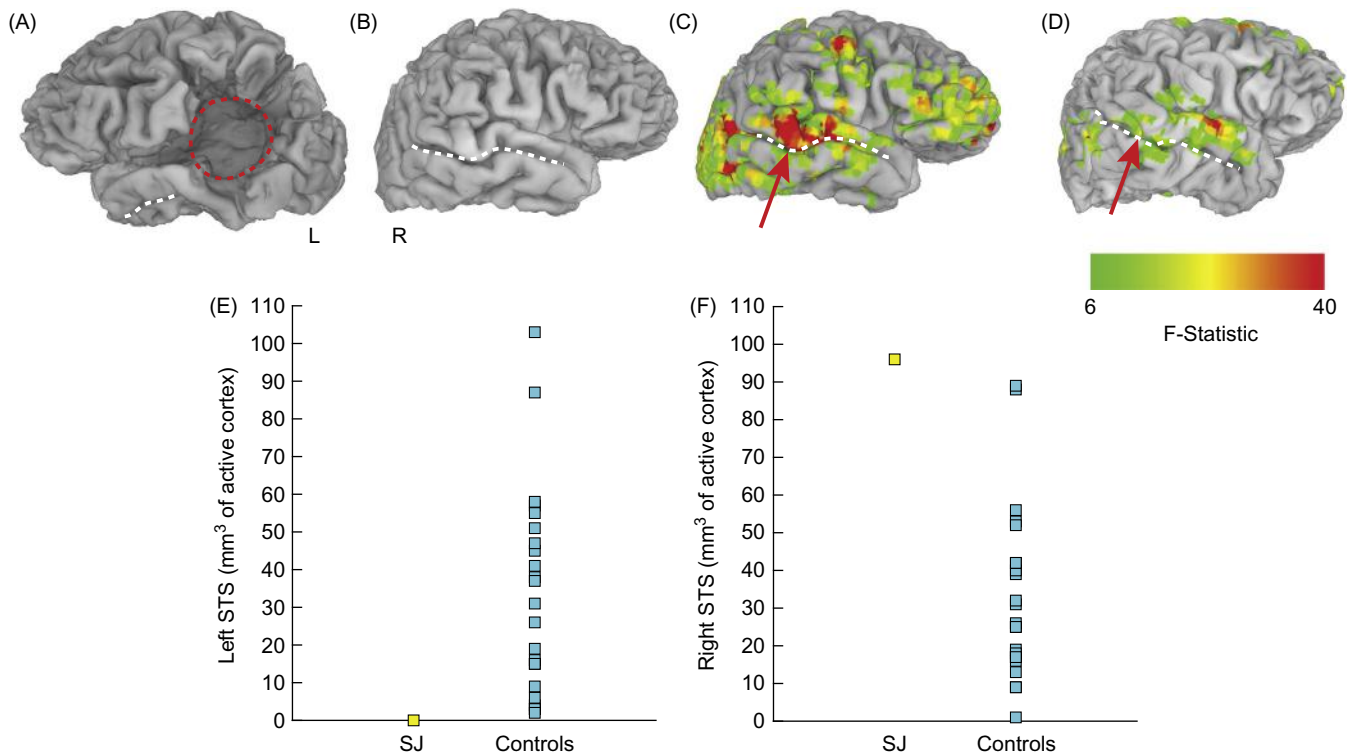

FIGURE 42.8 Plasticity of the neural substrates of audiovisual speech perception after brain injury. (A) Cortical surface model created from a T1-weighted MRI of patient SJ 5 years after stroke showing extensive lesion to left posterior STS (red circle). Dashed white line shows the location of STS; only the most anterior portion is spared. Adapted from Baum et al. (2012) with permission from the publisher. (B) Cortical surface model of right hemisphere of patient SJ showing undamaged STS (dashed white line). (C) Cortical surface model of right hemisphere of SJ showing BOLD fMRI activity in response to audiovisual speech. Color scale shows significance of activation. Red arrow highlights extensive activity in posterior STS. (D) BOLD fMRI responses to audiovisual speech in the right hemisphere of a healthy age-matched control. Red arrow highlights paucity of activity in posterior STS (same color scale for (C) and (D)). (E) Volume of cortex in left posterior STS responsive to audiovisual speech in patient SJ (yellow square) and 23 healthy age-matched controls (blue squares). (F) Volume of cortex in right posterior STS responsive to audiovisual speech in patient SJ (yellow square) and 23 healthy age-matched controls (blue squares).

electrocorticography may also make it possible to record responses from small pools of neurons that respond to auditory or visual speech (Chang et al., 2010), allowing a detailed understanding of the neural circuits underlying audiovisual speech perception.

43.1 INTRODUCTION

In this chapter, we provide an overview of the literature on the neurobiology of statistical information processing that is relevant for studies of language processing. We intend this chapter for those interested in understanding how the coding of statistics between sublexical (nonsemantic) speech elements may impact language acquisition and online speech processing. For this reason, we focus particularly on studies speaking to the sublexical level (syllables), but we also address the processing of statistics within auditory nonspeech stimuli.

As detailed in this chapter, there is increasing evidence that the human brain implements computations that allow it to understand the environment by extracting and analyzing its regularities to derive meaning, simplify the representation of inputs via categorization or compression, and predict upcoming events. The auditory environment is particularly complex, presenting humans with a seemingly infinite combination of sounds with an immensely rich spectral diversity, originating from a wide variety of sources. Among these sounds are speech sounds, that is, syllables and phonemes. Speech sounds occur within rapid and continuous streams that must be parsed into their constituent units for meaning to be extracted. Speech streams are sequentially organized based on complex language-specific (i.e., phonotactic) constraints. These constraints, whose delineation is the focus of linguistic approaches (e.g., Optimality theory; see McCarthy, 2001), are manifested, at the surface level, in language-specific *statistics*. One such statistic is “transition probability” (TP), which

refers to the conditional probability of transitioning from one syllable to the immediately successive one, $P(\text{syllable2} \mid \text{syllable1})$. Importantly, syllables with high TPs tend to form words, whereas those with lower TPs mark word boundaries. Because, unlike written language, the speech stream does not contain invariant cues marking word boundaries (Cole & Jakimik, 1980; Lehiste & Shockey, 1972), access to statistical information, in particular TP, is considered critical for learning how to segment continuous speech into syllables and words, especially during early childhood when word boundaries are still unknown. There is a large behavioral literature detailing the statistical abilities of infants and children, but also adults, all of whom are sensitive to TP in speech (Newport & Aslin, 2004; Pelucchi, Hay, & Saffran, 2009a, 2009b; Pena, Bonatti, Nespor, & Mehler, 2002; Saffran, Aslin, & Newport, 1996; Saffran, Johnson, Aslin, & Newport, 1999) as well as in nonspeech auditory and visual stimuli (Fiser & Aslin, 2001, 2002; Kirkham, Slemmer, & Johnson, 2002; Saffran et al., 1999; Saffran, Pollak, Seibel, & Shkolnik, 2007).

Importantly, statistics within the auditory domain support more than just language acquisition. In early and late adulthood, statistical information can be used for predicting upcoming syllables and words or for disambiguating partly heard words, especially in contexts in which the speech signal is degraded, such as in noisy environments and for people with hearing loss. It is well-known that during speech comprehension the speech system seeks to identify the target lexical item as quickly as possible (Gaskell & Marslen-Wilson, 1997). While processing the auditory input, the

cohort of lexical items that form possible lexical continuations becomes accessible, and the lexical item is identified as soon as the “uniqueness point” is reached, that is, the point at which only one continuation is possible and at which it can be discriminated from similar words in the “mental lexicon.”¹ This process is further sensitive to the statistical distribution of potential complements: the uncertainty of possible word continuations (the potential cohort) near the recognition point, as quantified by the cohort’s entropy, is negatively correlated with word identification, suggesting that the set of potential complements is made accessible during the word comprehension itself (Wurm, Ernestus, Schreude, & Baayen, 2006). Given that interpretations are sought prior to word completion, a probabilistic model of potential completions can optimize recognition by differentially activating more probable completions. Recent work supports the premise that such predictions are made prior to reaching the uniqueness point (Gagnepain, Henson, & Davis, 2012). Beyond accounting for online processing, it has been shown that adults with better capacities for representing input statistics have more efficient language processing capacities, suggesting a tight link between the two mechanisms (Conway, Bauernschmidt, Huang, & Pisoni, 2010; Misyak & Christiansen, 2012).

The studies we review here focus on the neurobiology of statistical information processing. These studies draw on three research traditions: information theory, artificial grammar learning (AGL), and perceptual learning. Therefore, they use different terminologies. Studies grounded in information theory differentiate “regular” from “irregular” or “random” inputs. Here, regular inputs are generated by a process with some level of constraints (e.g., a first- or second-order Markov process²) in which the transitions between tokens is not uniform in the ordered condition but is uniform in the random condition. For instance, given a grammar of N tokens, in the random condition transition probabilities between tokens will be $1/N$ uniformly for all token-pair transitions, whereas the regular conditions will increase the probability of some transitions and decrease the probability of others. Studies using AGL paradigms, which are grounded in formal learning theories, often refer to the generating process as a transition network and examine responses to sequences that could or could not be generated by the learned grammar. Many of the grammars used in

the AGL literature are of the simplest type (regular grammars) that can be represented via a Markov process. The third body of literature, grounded in perceptual learning, uses manipulations in which random token-sequences are contrasted with sequences in which some tokens are always concatenated in a fixed order to form “words.” It is important to note that both the random and word-forming conditions can be described by a first-order Markov process: the random condition has a uniform distribution of transitions whereas the word-forming condition contains several cells with a 100% TP. We further note that these latter studies are different from those grounded in AGL or information theory in that once the “words” are decoded, learners benefit from numerous points in the sequence that completely lack uncertainty (particularly when each word begins with a unique syllable). To illustrate, if words are four syllables long, then after the words have been learned, identifying a word-initial syllable will uniquely determine the next three syllables for the listener. That is, including “words” introduces a measure of determinism that is not present in other studies of statistical processing, and there is evidence that this results in chunking of the words into single units, with less attention given to those syllables in the sequence that are predictable with absolute certainty (Astheimer & Sanders, 2011; Buiatti, Pena, & Dehaene-Lambertz, 2009).

We also emphasize that the findings we review in this chapter derive from studies examining the acquisition or representation of statistical constraints, a field that only partly overlaps with studies of grammar acquisition and representation or rule learning. The study of transition-probability statistics takes as its model inputs that are generated by regular grammars, that is, grammars that can be described via finite state automata (also referred to as finite state systems or Markov processes), that are defined solely by an alphabet, states, and transitions. Finite state systems can model simple grammars, but not grammars that require a memory stack (e.g., $A^n B^n$ grammars). Studies that examine the representation of more complex grammars such as these, which necessitate memory stores, hierarchical representations, recursion, or that use of symbolisms such as phrase structures or unification-based constraints, are outside the scope of this review and may utilize different neural systems (see Fitch & Friederici, 2012, for recent neurobiological studies

¹The mental lexicon is a concept used in linguistics and in psycholinguistics to refer to a speaker’s lexical representations.

²Markov chains are stochastic processes that can be parameterized by estimating TP between discrete states in a system. In first-order Markov chains, each subsequent state depends only on the immediately preceding one. In second-order Markov chains, the next state depends on two or more preceding states.

comparing regular versus context free grammars and for representative experimental work; Bahlmann, Schubotz, & Friederici, 2008; Folia, Forkstam, Ingvar, Hagoort, & Petersson, 2011). Work on formal rule learning and evaluation of stimuli against rules is also outside the scope of the current chapter.

Importantly, whereas much of the data in the studies we discuss are interpreted in terms of the learning of statistical relations (transition probabilities) or use of systems that represent statistics, these interpretations often ignore the relation between processes associated with the coding of statistics and those related to chunking of tokens. There is a strong relation between sequence statistics, the process of chunking sequences, and the resulting segmentation of the input into a “mental alphabet” consisting of distinct units (Perruchet & Pacton, 2006). Computationally, if two or more tokens always appear jointly, it would be most optimal to chunk (represent) them as a single unit for the purpose of any statistical computation. Depending on interpretive traditions, some of the studies reviewed in this chapter address differences in brain activity for regular and random sequences, not in terms of statistical learning of relations between items, but in terms of chunking. It has been shown that chunking-based accounts can explain many of the findings in the statistical learning literature and whether the same systems mediate chunking and statistical learning is an ongoing issue (see Perruchet & Pacton, 2006 for an important discussion). Thus, from a neurobiological perspective, it is still difficult to determine whether sensitivity to statistical regularities is dependent on chunking-related processes or on processes more specifically related to statistical learning, such as the updating of associative information and the construction of predictions.

The structure of the rest of the chapter is as follows. Section 2 identifies and discusses the brain regions most commonly involved in processing statistical information. Section 2.1 focuses on the cortical regions, and section 2.2 focuses on the subcortical ones. Finally, section 2.3 discusses the connectivity between the cortical and subcortical structures involved in statistical information processing. We conclude by discussing the potential usefulness of statistical information processing in the context of auditory, language, and system neurosciences.

43.2 BRAIN SYSTEMS INVOLVED IN STATISTICAL INFORMATION PROCESSING

Not much is known about the anatomy and functional organization of the brain systems that process and use statistical information in the speech signal.

From a neurobiological perspective, different systems might be involved in the representation and use of such statistical information. Some might represent associative links between speech elements (e.g., the distribution of all elements that follow what is currently perceived), whereas some may mediate more general auditory-attention processes that enable the use of statistical information. For instance, hearing the syllable “que” [kwε/] can invoke a representation of a range of possible complements such as “est” or “estion.” Processing of acoustic signals uses active “look-ahead” mechanisms that aim to identify target words given minimally sufficient acoustic information prior to the moment when a word has been presented in its entirety (Gaskell & Marslen-Wilson, 1997). This representation, which can be formally represented via a cumulative distribution of possible following syllables could be instantiated on the fly. The deployment of neural systems to construct and utilize these distributions may further depend on the “diagnosticity” of the auditory cue (i.e., the degree to which it constrains future inputs). Whereas a syllable such as /kwε/ is highly diagnostic because it can be followed by relatively few continuations, a syllable such as “bi” [baɪ/] allows numerous ones (bite, bilateral, bicycle) in which case making predictions may be counterproductive and, instead, paying greater attention to bottom-up input (i.e., to the acoustic details themselves) may be more optimal. When the number of potential complements is large, systems associated with modulation of auditory attention likely play a role to favor bottom-up processing.

As discussed in sections 2.1 and 2.2, neuroimaging research has begun to uncover a complex and distributed system, including both cortical and subcortical components, which is important for processing auditory statistical information either by directly supporting statistical mechanisms, or by controlling more general mechanisms such as auditory segmentation, auditory attention, and working memory. The functional organization and specific contributions of the different components of this distributed system, however, remain largely unknown. A range of experimental paradigms has been used to study this question, which included either speech or nonspeech stimuli (such as pure tones), or sometimes both, presented in either auditory or visual modalities. Passive listening tasks have been used to focus on automatic and perhaps more naturally occurring processes, whereas other tasks have targeted deliberate/executive processes, including various forms of learning and pattern recognition paradigms. This range of experimental paradigms may explain the diverse network of regions that have been associated with statistical information processing, which includes part of temporal and

frontal parietal lobes and subcortical structures. That said, in the present chapter we do not review research focusing on decision-making about future outcomes.

43.2.1 Cortical Systems Underlying Statistical Processing of Linguistic Inputs

At the cortical level, perhaps not surprisingly, sensitivity to statistical information in auditory input streams has been found mainly in the supratemporal plane (STP) of healthy adults, including the auditory cortices. This is generally consistent with the idea that representation of statistics in different modalities relies on separate circuits rather than on a general system for coding statistics (Bastos et al., 2012). However, several studies have also implicated the left inferior frontal gyrus (IFG), a region that may play a more domain-general role in this process.

43.2.1.1 Involvement of Temporal Regions

Several studies examining statistical information processing in auditory nonspeech streams, usually using pure-tone streams, have identified temporal and temporal-parietal regions whose activation is modulated by the statistical properties of the input signal. In a magnetoencephalographic (MEG) study (Furl et al., 2011), sensitivity to statistical information, quantified as transition probabilities (second-order Markov chains of tones comprising five possible pitches), was found in the right temporal-parietal junction, including the most posterior part of the STP. Using functional magnetic resonance imaging (fMRI), we found sensitivity to perceived changes in statistical regularity in auditory sequences of pure tones in a region of the left superior temporal gyrus (STG) as well as in several other regions, including the bilateral medial frontal gyrus (Tobia, Iacovella, Davis, & Hasson, 2012). Using near-infrared spectroscopy (NIRS), Abta and Okanoya (2008) examined the processing of tone sequences containing “tone-words” and random sequences. Prior to the experiment, participants were presented with the tone-words during a 10-minute training phase. During the experiment, participants were asked to try to recognize the word tones they had learned during the training phase, a task that requires continuous segmentation of the input and evaluation against the learned words. The results showed increased activation in both left STG and left IFG. Although the authors argued *against* the STG as being involved in statistical information processing, suggesting instead that the observed task-related modulation reflects auditory selective attention, the finding of greater activation in this area adds to a literature suggesting that STG is indeed involved in statistical

information processing. Comparing auditory melodies to unstructured sequences of tones comparable in terms of pitch and rhythm revealed stronger fMRI signal in bilateral IFG and anterior and posterior STG, including the planum temporale (PT) (Minati et al., 2008). Interestingly, the PT has been shown to respond to the presentation of unexpected silences in auditory sequences of complex sounds (modulated scanner noise), further suggesting that it is sensitive to the structure of sound sequences (Mustovic et al., 2003). In sum, neuroimaging studies, including MEG, fMRI, and NIRS studies, focusing on the processing of auditory sequences robustly find activation along the supratemporal cortex, particularly at the level of the posterior STG and PT, that is modulated by the internal statistical structure of nonspeech auditory sequences.

Neuroimaging studies that have used speech instead of nonspeech stimuli lead to conclusions that are consistent with those found in nonspeech studies. Using fMRI, McNealy, Mazziotta, and Dapretto (2006) examined brain activity of healthy adults during passive listening to: (i) syllable streams from an artificial language containing statistical regularities; (ii) streams containing statistical regularities and speech cues (stressed syllables); and (iii) streams containing no statistical regularities and no speech cues. The comparison of streams containing regularities with those that did not revealed activity in the left posterior STG. Importantly, activity in this region was found to increase over time for the streams containing statistical regularities but not for the random streams. This finding is particularly important for understanding the potential role of the posterior STG in statistical processing. If the posterior STG were involved in the updating of statistical representations (i.e., statistical updating *per se*), then this process of updating probabilities should not differ in its dynamics for regular versus random series. In contrast, if it were implicated in segmentation of words from the stream, then it would show more activation for regular series, as was found by the authors. A subset of the participants in McNealy et al. study also completed a word discrimination task in which words, part-words, and nonwords taken from the speech streams were presented to the participants who were given no explicit task. Results show activity in the left posterior IFG and left middle frontal gyrus (MFG) for words compared with nonwords and part-words, altogether suggesting that posterior frontal regions are involved in word recognition once these words are learned, whereas statistical information and segmentation processes may be accomplished within the STP. This experimental paradigm was reapplied with a group of 10-year-old children; results show essentially the same BOLD activation pattern (McNealy, Mazziotta, & Dapretto, 2010).

In a related fMRI study (Karuza et al., 2013), participants were also exposed to an artificial language and tested on their ability to recognize words (three-syllable combinations with high transitional probabilities) and part-words that occurred during the exposure streams (learning). Exposure streams included forward and backward speech streams. Greater activation was found in the left STG, right posterior middle temporal gyrus (MTG), and right STG when comparing the forward speech stream with the backward speech control condition. Relating each participant's change in learning across postexposure test phases to changes in neural activity during the forward as compared with the backward exposure phase revealed activation in the left IFG pars triangularis and a small portion of the left IFG pars opercularis. Together with the findings of McNealy et al. (2006), this suggests that when statistical dependencies are found in speech stream, "chunks" of colinear elements are coded as single items ("words") in a representation accessible to left inferior frontal regions. That is, these regions may be specifically involved in word learning or word recognition, whereas more general auditory statistical information processing mechanisms involve the STP.

In our own fMRI work (Tremblay, Baroni, & Hasson, 2012), we used a slightly different approach to study statistical information processing in speech and nonspeech auditory sequences. We exposed participants to meaningless sequences of native syllables and spectrally complex natural nonspeech sounds (bird chirps) that varied in terms of their statistical structure, which was determined by their transition-probability matrices (participants monitored a visual stimulus in an incidental task). The auditory sequences ranged from random to highly structured in three steps: predictable sequences were associated with strong transition constraints between elements in a way that allowed making a strong prediction about the next element, whereas mid-level or random sequences were associated with weaker or no transition constraints. In contrast to prior work, we used a detailed anatomical ROI approach and focused on the STP, which we partitioned into 13 subregions in each hemisphere. Our results emphasize the importance of the posterior STP in the automatic processing of statistical information for both speech and nonspeech sequences. Several areas in the left STP were sensitive to statistical regularities in both speech and nonspeech inputs, including the PT, posterior STG, and primary auditory cortex in the medial transverse temporal gyrus (TTG). The bilateral lateral TTG and transverse temporal sulcus (TTS) were sensitive to statistical regularities in both speech and nonspeech, but patterns of activation were distinct with earlier activation for speech than nonspeech, suggesting easier segmentation for familiar than unfamiliar sounds. These findings for

TTG are also in agreement with work showing sensitivity to regularities in that region using direct recordings in rats (Yaron, Hershenhoren, & Nelken, 2012). Recent data from our group (Deschamps, Hasson, & Tremblay, submitted) shows that the cortical thickness of left anterior STG correlates with the ability to perceive statistical structure in speech sequences. An additional exploratory whole-brain analysis revealed significant correlations in the superior parietal lobule (SPL) and intraparietal sulcus (IPS), regions more typically associated with attentional processes. These data suggest that the ability to process statistical information depends on auditory-specialized cortical networks in STP, as well as a network of cortical regions supporting executive functions.

43.2.1.2 Involvement of Left IFG

As indicated, the left IFG appears to play a role in the segmentation of word or word-like structures in an auditory stream. It is an outstanding question whether the left IFG mediates a modality-general function. In a nonspeech study, Petersson, Folia, and Hagoort (2012) introduced participants to written (visual) sequences generated by a seven-item artificial grammar. In a subsequent fMRI session, these participants were asked to determine whether sequences presented to them were grammatical. The authors found greater activation for accurate nongrammatical versus grammatical judgments in left IFG, suggesting that these regions generally evaluate the well-formedness of inputs by examining whether they are licensed given the grammar learned, even outside language contexts. However, other fMRI work (Nastase, Iacovella, & Hasson, 2014) argues that the left IFG may mediate low-level auditory statistical processing rather than a modality-independent process. The Nastase et al. study showed that activity in left IFG was sensitive to regular versus random series of pure-tone series, but it was not sensitive to regularity when the tokens were substituted with simple visual objects. One possibility is that participants in the Petersson et al. study represented the visual stimuli using a verbal code in preparation for the task required of them. In contrast, the short sequences, passive perception context, and rapid presentation rate used by Nastase et al. do not favor that strategy, which may explain the discrepant findings.

In sum, a review of the literature indicates that the posterior STP, particularly at the level of the PT and posterior STG, as well as the left IFG, are the cortical structures most frequently implicated in the processing of statistical information in the auditory domain. Further studies are needed, however, to delineate the specific role(s) of each region as well as the manner in which information flows between these different regions.

43.2.2 Subcortical Systems Underlying Statistical Information Processing

43.2.2.1 Involvement of Basal Ganglia in Statistical Learning

Relying mainly on neuroimaging and neurophysiology studies, we now consider the potential role of the basal ganglia (BG) in mediating statistically informed aspects of phonemic and syllable-level processing. The BG is involved in several cortico-striatal loops, including limbic, associative, and motor loops, each originating and terminating in distinct cortical areas, and connecting via different parts of the BG (Alexander, DeLong, & Strick, 1986). The basal motor loop connects primary and nonprimary motor areas including the supplementary motor area (SMA) to the posterior striatum, particularly the putamen, the external and internal pallidum, the subthalamic nucleus, and ventrolateral thalamic nuclei. This loop has been associated with the acquisition, storage, and execution of motor patterns and sequence learning (Graybiel, 1998). Functionally, it has been suggested that the BG is involved in the coding of context (Saint-Cyr, 2003) and in the generation of sequenced outputs via rule application (Lieberman, 2001). Neuropsychological, anatomical, and behavioral evidence for these notions are not discussed here; they have been discussed extensively elsewhere, particularly in relation to populations with BG dysfunction (see Alm, 2004 for dysfunctions related to stuttering; see Saint-Cyr, 2003 for a review of BG dysfunctions such as Parkinson's and Huntington's diseases).

The potential role of BG in representing statistical constraints among short nonsemantic units has been examined in several studies. An early neuroimaging study (Lieberman, Chang, Chiao, Bookheimer, & Knowlton, 2004) provides a convincing demonstration of this point. In this study, participants were presented with letter strings constructed from an artificial grammar as part of a training stage; then, in a test stage, they were tested on novel grammatical and nongrammatical letter strings. Orthogonally to the grammaticality manipulation, the authors constructed test items that either strongly or weakly overlapped with the training items in "chunk strength," which is a measure not relating to the grammaticality of the string, but rather to the frequency in which the "alphabet" of the grammar tended to occur conjointly (co-occurrence frequency). In this way, the authors could separate regions implicated in retention of grammar rules from those involved in retention of chunks of letters. When chunk strength was low, offering little superficial overlap with the training items, the caudate nucleus was sensitive to grammaticality, showing more activity for grammatical items. Examination of the correlates of

chunk strength revealed hippocampal and putamen activation, with hippocampal activation interpreted as being related to retrieval of training items.

The putamen has been linked to the coding of regularity in the study of McNealy et al. (2006) discussed in the previous section. That study reported stronger activity in the putamen during presentation of random syllable strings than during presentation of artificial languages. Furthermore, activation in the region was stronger for unstressed language-like streams than for stressed language-like streams (in the latter, word-strings were easier to disambiguate). Thus, the putamen showed a gradient of activation with the least activity during the condition in which words were easiest to segment. Interpreting such relatively focal regional effects in the context of more general approach to understanding BG-thalamic loops is an important goal for future work. The BG is internally connected via inhibitory connections so that increased activity in the striatum can inhibit or excite the pallidum and, via different pathways, result in either increased or decreased activity in thalamus. Future work with high temporal and spatial resolution (e.g., time-resolved fMRI or MEG) may identify such interactions. In any case, the involvement of BG in grammar learning is supported by work (De Diego-Balaguer et al., 2008) showing that individuals diagnosed with Huntington's disease, which affects the striatum (i.e., the caudate and the putamen), show deficits in word and morph-syntactic learning, with the former necessitating veridical memory for three-syllable combinations and the latter necessitating the extraction of morphological regularities (e.g., artificial words ending in "mi" always begin with "pa").

A role for the BG in representing statistical relationships between input elements, or their prediction, is also supported by research on auditory processing. For example, Leaver, Van Lare, Zielinski, Halpern, and Rauschecker (2009) linked the BG to auditory sequencing, a process that is closely related to the processing of statistical information, given that statistics information can only be computed and processed if the independent units in a signal have been properly segmented. In that study, participants were scanned while anticipating a familiar or unfamiliar melody. While silently anticipating a familiar melody, SMA, pre-SMA, left BG (globus pallidus/putamen), and several other regions showed more activity than when anticipating a recently learned melody, suggesting a role in auditory prediction. However, for the BG, this pattern was stronger during the early stages of familiarization with the "familiar" melody than in later stages, suggesting that the involvement of BG is related to the learning process itself ("learning stimulus associations," *ibid.*, p. 2482) rather than prediction.

Whether the BG mediates pattern learning or use of statistical information for prediction is more directly addressed by recent work on beat perception, stimulus anticipation, and music perception (Grahn & Rowe, 2013). In that study, the authors presented participants with auditory streams consisting of regular beats that either changed or were the same as the beat patterns in streams presented immediately before. Results showed that the putamen was most strongly active in the condition where the current pattern was the same as the previous one, and showed the least activity when the current pattern was new and did not bear a relation to the prior one. Mid-levels of activity were found for changes in speed. On the basis of these findings, the authors proposed that “the basal ganglia’s response profile suggests a role in beat prediction not beat finding” (Grahn & Rowe, 2013, p. 913). Geiser, Notter, and Gabrieli (2012) also linked the putamen to processing of auditory regularities by demonstrating that it shows more activity in the context of regular (versus irregular) beat patterns (the opposite pattern found by McNealy et al., 2006) and, furthermore, across individuals, greater activity in the putamen was negatively correlated with activity in auditory cortex. We note that the studies of Grahn and Rowe and that of Geiser et al. address predictions given temporal regularities rather than regularities of content; establishing the relation between these two kinds of phenomena, in the domain of language, is a topic for future work.

It is still unclear whether activity in BG reflects the coding of regularity, predictive processes, or evaluation of input against predictions. Seger et al. (2013) found that the caudate head and body (though not the putamen) were sensitive to the degree of mismatch in musical progression of a chord series, suggesting that the caudate is involved in evaluation of predictions, whereas the putamen is involved in constructing predictions. However, even this interpretation of putamen activity necessitates further work, as Langners et al. (2011) have shown that the putamen shows higher activity when more specific versus less specific predictions are violated (see also Haruno & Kawato, 2006).

Furthermore, it is also unclear whether temporal or content-based predictions mediated by BG, such as those reviewed in the aforementioned studies, extend to the lexical level. Interestingly, some work suggests that the role of BG in the construction or evaluation of predictions is limited to the sublexical level. Wahl et al. (2008) examined responses to semantic or syntactic violations in spoken sentences. Deep brain recordings monitored activity in the thalamus and BG. Results showed that BG were not sensitive to either type of violation, leading the authors to propose that “syntactic and semantic language analysis is primarily realized within cortico-thalamic networks, whereas a

cohesive BG network is not involved in these essential operations of language analysis” (p. 697). It is therefore possible that the BG mediates statistical learning, but only when learning applies to sublexical units (phonemic, syllabic, morphemic) rather than to word or clause-level phenomenon.

43.2.2.2 Debates on the Functional Role of Basal Ganglia

It is important to consider the empirical findings reviewed here in the context of the continuous discussion on the role of BG in language comprehension. Whether the BG’s computations during language comprehension are intrinsically linguistic and related to grammatical computations or, alternatively, associated with more general functions is currently being debated. Arguing for the linguistic-computation view, Ullman (2001) has suggested that the BG subserves aspects of mental grammar and that it allows learning of grammars in various domains, including syntax, morphology, and even phonology. Given that grammar learning reflects, at minimum, extraction of regularities or invariants, this would entail sophisticated mechanisms for extracting regularities that can include phrase-structure rules, lexical-level constraints, or rules governing long-distance movements between constituents. This viewpoint has received empirical support from work (Nemeth et al., 2011) showing that in dual-task conditions where one task involves statistically driven motor sequence learning, a parallel sentence comprehension task diminishes learning, whereas mathematical or word-monitoring parallel tasks do not. In contrast, Crosson and colleagues have argued that the BG is not involved in primary language functions, but rather increases signal to noise during action selection. Thus, during speech comprehension, the region may be implicated in increasing the coding precision (activation sharpening) of those phonemes most appropriate in a given context (Ford et al., 2013, p. 6). Understanding the role of BG in statistical contexts containing both auditory and nonauditory language content is important for differentiating these different theoretical frameworks.

43.3 CONNECTIONAL ANATOMY OF THE STATISTICAL NETWORK

Our review suggests that the caudal part of STP, including the posterior STG and PT extending to TTG, as well as the striatum, and possibly the IFG (pars opercularis, triangularis), form the core regions involved in processing statistical information. However, whether these regions form a functional network for segmenting auditory inputs or processing embedded

statistical information remains unclear, because no studies thus far have attempted to examine the connectivity patterns associated with processing auditory statistics. We briefly outline reasons for supposing these three areas (IFG, posterior-middle temporal cortex, BG) have the potential for integrative processing of statistics in the auditory stream.

The idea of some degree of anatomical connectivity between the human IFG and posterior temporal areas has a long history, but it is not without controversy (see [Dick, Bernal, & Tremblay, 2013](#); [Dick & Tremblay, 2012](#) for reviews on the subject and references therein for data in support of and against the presence of such connectivity). There is, however, evidence for functional connectivity between these regions ([Hampson et al., 2006](#)).

The other question of interest concerns the connectivity of the striatum with posterior STP and/or IFG. Although there is extended structural connectivity (monosynaptic) between the cortex and the striatum, evidence of anatomical connectivity between the IFG and the striatum, as well as between STP and the striatum, is scarce. [Schmahmann and Pandya \(2006\)](#), using an anterograde tract-tracer technique in the macaque monkey, reported some projections from the posterior STG to the caudate nucleus. In humans, a recent diffusion MRI study conducted on 13 healthy adults suggest that the temporal cortex (including posterior segment) projects to the posterior part of the caudate nucleus ([Kotz, Anwander, Axer, & Knosche, 2013](#)), consistent with the macaque evidence. Documentation of structural connectivity between the IFG and the striatum is scarce. A recent DTI study conducted on a relatively small sample ($N = 10$) and focusing on the IFG reported that both the opercular and triangular convolutions of the IFG connect with the rostral putamen ([Ford et al., 2013](#)).

Another way of assessing connectivity between regions is to examine their functional connectivity, that is, the tendency (in the statistical sense) of different regions to be active synchronously, which does not necessarily imply direct (monosynaptic) connectivity. The functional connectivity literature, however, provides a slightly less consistent account. A detailed study of the functional connectivity of the human striatum conducted on a large sample ($N = 1000$; [Choi, Yeo, & Buckner, 2012](#)) reported only weak connectivity between the posterior STP and the striatum and between the IFG and the striatum. Using dynamic causal modeling (DCM) during a phonological (rhyming judgment) task, [Booth et al. \(Booth, Wood, Lu, Houk, & Bitan, 2007\)](#) reported functional connectivity between the putamen and left IFG as well as between the putamen and the lateral temporal cortex (including both superior and middle temporal areas). Another

study, using resting-state connectivity, documented functional connectivity between the putamen and posterior STP ([Di Martino et al., 2008](#)).

In sum, there is some evidence of functional connectivity but very limited evidence of anatomical connectivity between the IFG and posterior STP and the striatum. Additional research is needed to further current understanding of how these areas, which appear to form the core of a statistical information processing network, interact either directly or indirectly to extract and process that information.

43.4 RELATED WORK AND FURTHER AFIELD

There are a number of research lines that appear related to the processing of statistical information but address substantially different issues. The first defines statistical relations between inputs not in terms of formal properties such as transition probabilities, but in terms of the degree of physical (metric) changes in (sound) frequency space that occur between tones in more and less ordered sequences. In that literature, regularity is quantified via the serial autocorrelation of tones in the pitch sequence ([Overath et al., 2007](#); [Patel & Balaban, 2000](#)) so that regularity is higher when low frequencies dominate or sample entropy is lower. These studies have implicated auditory cortical regions in regularities, but it is important to note that the term “regularity” is used differently and that the explanations for such effects could have a purely physiological basis; when “statistical regularity” is related to the magnitude of transitions in frequency space, the explanation for these effects could be due to low-level repetition suppression effects *per se* driven by the tuning curves of auditory neurons.

There is also a body of work examining neural responses to varying levels of uncertainty, but in which uncertainty originates from the degree of uniformity of the distribution from which the tokens are sampled (captured by Shannon’s entropy of the variable generating the input), rather than to the strength of transition probabilities. Particularly relevant are studies that did not require directing attention to stimulus statistics ([Harrison, Duggins, & Friston, 2006](#); [Strange, Duggins, Penny, Dolan, & Friston, 2005](#); [Tobia, Iacovella, & Hasson, 2012](#)). The studies of [Strange et al. \(2005\)](#) and [Harrison et al. \(2006\)](#) used visual stimuli and linked the hippocampus to coding series uncertainty (quantified via Shannon’s entropy). However, one study using passive listening to auditory stimuli ([Tobia, Iacovella, & Hasson, 2012](#)) has identified perisylvian regions including both inferior parietal and lateral temporal cortex as sensitive to the

relative frequency distribution of auditory tokens without hippocampal involvement (see Tobia, Iacovella, & Hasson, 2012 for a discussion of the role of the hippocampus in statistical learning).

Another important and unresolved issue concerns the domain specificity of the neural processes involved in learning and representation of statistical information. Our own work (Nastase et al., 2014) suggests that rapid learning of sequence statistics within auditory or visual streams is largely mediated by separate neural systems, with little overlap and without hippocampal involvement. Others (Bubic, von Cramon, & Schubotz, 2011) have shown that violations of regularity-induced predictions evoke activities in different systems depending on whether the regularity is temporal-, location-, or feature-based, suggesting a domain-specific basis for the construction or evaluation of predictions. However, several studies (Cristescu, Devlin, & Nobre, 2006; Egner et al., 2008) suggest that there are domain-general systems that mediate predictions of items' perceptual features, location, and semantic features.

43.5 CONCLUSION AND FUTURE WORK

The study of the neurobiological substrates underlying the representation and use of statistical information is in its initial stages. Although statistical information may be crucial to language acquisition and online speech processing, experimental work has just begun identifying the neural mechanisms mediating these processes as well as their functional importance. Several core areas identified in this experimental work are regions of the STP and lateral temporal cortex that appear to be sensitive to the degree of statistical regularity in an input and potentially initial word segmentation and left IFG regions that play a role in word recognition but that may not be involved in the coding of statistics *per se*. The BG appears to have a role in online temporal predictions and anticipation, with a particularly important role for the putamen, a core part of the cortico-basal motor loop. Finally, although there is some evidence for functional and structural connectivity between IFG, STP, and BG, future work is needed to examine the relation between statistical processing mechanisms and the strength of functional and structural connectivity within this network.

The Neurobiology of Lexical Access

Matthew H. Davis

Medical Research Council, Cognition and Brain Sciences Unit, Cambridge, UK

44.1 INTRODUCTION

By comparison with other animals, humans use an exceptionally large inventory of communicative sounds (i.e., words). Infants learn to recognize their first words in the first year of life (Kuhl, 2004; Werker & Tees, 1999), and from approximately 18 months of age they add words to their vocabulary at an astonishing rate, learning perhaps as many as 10 new words per day (McMurray, 2007). Estimates of the number of words known by a typical adult who is a native English speaker vary from 25,000 to 75,000, but they clearly depend on the degree of lexical redundancy assumed (Altmann, 1997).¹ The resulting lexicon of familiar words is key to effective communication. The neurobiological foundations of lexical knowledge are correspondingly central to understanding the human faculty of language.

Knowing a word involves several distinct forms of knowledge. Critically, a listener must know the specific sequence of speech sounds that comprise a word, and these word forms must be linked to representations of word meaning, syntactic properties, and orthographic form. The focus of the present chapter is to provide the neural basis of lexical access for spoken words. We consider three functional challenges in guiding our specification of the neurobiological foundations of lexical access. Together, these help us to account for the remarkable speed, robustness, and flexibility of human spoken word recognition.

44.2 THREE CHALLENGES FOR LEXICAL ACCESS IN SPEECH

A typical spoken word in connected speech lasts less than half a second, during which time we must recognize one specific word from the thousands that we know. Words are fleeting and transient, speech sounds unfold rapidly in time, and we cannot listen again to earlier speech sounds (unlike regressive eye movements in reading) to compensate for uncertain information heard at the start of the current spoken word (e.g., in distinguishing between *speaker* and *beaker*; Allopenna, Magnuson, & Tanenhaus, 1998). In connected speech there may be even longer delays before the arrival of critical information. For example, listeners may use subsequent words to resolve perceptual ambiguity when short words also match the start of longer words (Davis, Marslen-Wilson, & Gaskell, 2002), or to correctly interpret word-final coarticulation (Gaskell & Marslen-Wilson, 2001).

The first of our three challenges arises because spoken words unfold so rapidly, and yet the neurobiological system that supports spoken word recognition must use information that is spread out in time. Lexical access requires an internal memory that retains a record of prior speech to guide perception of current speech sounds or words (the TRACE in McClelland & Elman, 1986, or recurrent context units in Gaskell & Marslen-Wilson, 1997). In Section 44.3.2 of this chapter, we link this internal memory to a processing hierarchy in anterior regions of the superior

¹It can be unclear, for example, whether inflections (“drives,” “driving”) and derivations (“driver”) are counted as additional known words despite being predictably given knowledge of the stem (“drive”). Consideration of morphological relationships in the lexicon is of great importance but is beyond the scope of the present chapter, which concerns the recognition of monomorphemic words (see Chapter 13; Marslen-Wilson & Tyler, 2007).

and middle temporal gyrus (STG/MTG). Neurons in more anterior regions integrate information over progressively longer time periods (i.e., have longer temporal receptive fields) to support spoken word identification and recognition of longer prosodic elements.

A second challenge in recognizing spoken words is to identify a single spoken word despite noise and variability in the form of speech sounds. Human spoken word recognition is robust to the range of speakers that we converse with, each with characteristic fundamental and formant frequencies (Smith, Patterson, Turner, Kawahara, & Irino, 2005), speech rates (Summerfield, 1981), or accents (Clarke & Garrett, 2004). This chapter proposes that a key process during identification (particularly for degraded spoken words) is that listeners retrieve the speaker's intended articulatory gestures (or equivalently) and determine how they would say the words that they hear. This computational goal is supported by the sensorimotor or dorsal processing pathway in the temporoparietal junction (TPJ). This dorsal pathway is known to link the words that we hear to motor representations used in speaking (Hickok & Poeppel, 2000; Scott & Johnsrude, 2003). However, the claim that this pathway contributes to speech perception remains controversial.

In accessing the meaning of spoken words, a third computational requirement is that we deal flexibly with the lexical and semantic ambiguity that is ubiquitous in spoken language (Piantadosi, Tily, & Gibson, 2012; Rodd, Gaskell, & Marslen-Wilson, 2002). Ambiguity occurs because spoken language fails to distinguish words that differ orthographically (e.g., *knight/night*) and/or semantically (e.g., *bark*) or due to the flexible meanings of polysemous words (e.g., *run*; Rodd et al., 2002). In such cases, additional neural processes are recruited to support retrieval of multiple meanings and for the selection of the contextually appropriate meaning. Functional imaging links these processes to posterior inferior temporal regions (Rodd, Davis, & Johnsrude, 2005; Rodd, Johnsrude, & Davis, 2012) that contribute to accessing the meaning of spoken words.

44.3 MAPPING LEXICAL COMPUTATIONS ONTO NEUROBIOLOGY

A key method for isolating the brain regions that make distinct contributions to lexical access for spoken words comes from studies contrasting hemodynamic responses to familiar words to unfamiliar word-like pseudowords. This contrast has been assessed in a number of published functional imaging studies. We review these studies by summarizing a meta-analysis of 11 published PET and fMRI studies including data from 184 healthy adult participants (Davis & Gaskell, 2009).

These studies report significant differential responses to spoken words and pseudowords with substantial inter-study agreement in the location and direction of neural response differences between words and pseudowords, as shown in Figure 44.1.

However, a significant challenge in interpreting the results of the Davis and Gaskell (2009) meta-analysis is that differential responses are observed in both directions: additional responses for words compared with pseudowords are observed in anterior, posterior, and inferior regions of the lateral temporal lobe and for pseudowords greater than words in peri-auditory regions of the STG. These bidirectional findings are not indicative of unreliable findings in functional imaging—the activation likelihood estimation method confirms that both response differences are statistically significant when corrected for multiple comparisons. Furthermore, bidirectional response differences were

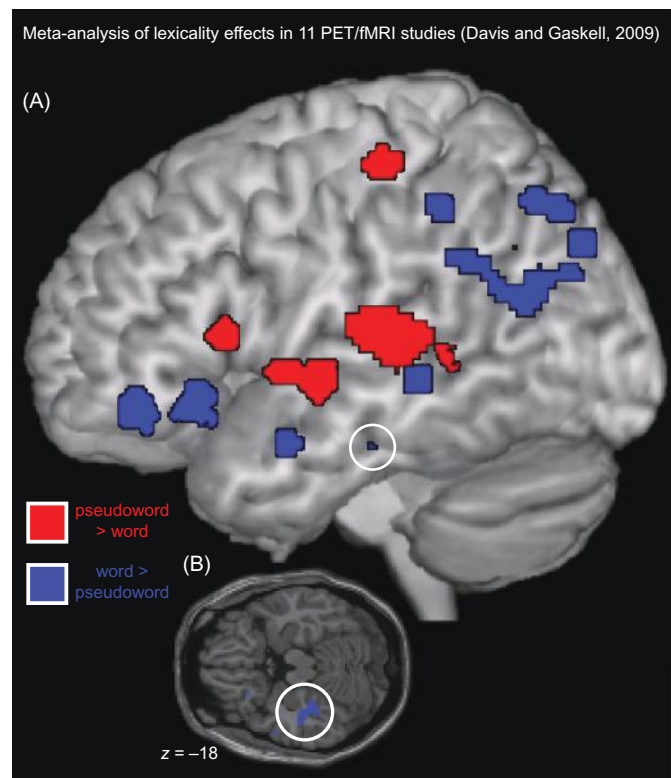

FIGURE 44.1 Results of an Activation Likelihood Estimation (ALE) meta-analysis of 11 functional imaging studies comparing neural responses to spoken words and pseudowords (from Davis & Gaskell, 2009). (A) ALE maps are thresholded at $P < 0.05$ FDR corrected with only clusters larger than 100 mm^3 displayed rendered onto a canonical brain. Greater activation for pseudowords compared with words (red) is seen primarily in peri-auditory regions of the STG. Additional activation for words compared with pseudowords (blue) is seen in anterior, posterior, and inferior regions of the lateral temporal lobe and adjacent parietal regions. Inset (B) shows a single axial slice at $z = -18$ to more clearly illustrate word activation in inferior temporal regions (circled).

observed in 4 of the 11 single studies when considered individually. Hence, before we can draw conclusions concerning the neurobiological systems supporting lexical access, we must first consider how these two directions of neural difference arise from brain regions supporting the recognition of spoken words.

The standard, subtractive assumption for functional imaging studies suggests that lexical processing should be localized to brain regions that respond to familiar words more than to pseudowords. However, when a similar subtraction is used to isolate stages of language processing (e.g., syntactic or semantic computations), potentially contradictory findings are observed. Many studies report additional activation for syntactically or semantically anomalous compared with well-formed sentences in regions that contribute to higher-level sentence comprehension (see [Davis & Rodd, 2011](#), for discussion). These findings suggest that unsuccessful lexical processing could provide additional activation compared with successful recognition, and that the reverse contrast of pseudowords versus words would also highlight lexical processes. These conflicting assumptions suggest that explicit linking assumptions are required to mediate between computational and neural explanations when interpreting word versus pseudoword differences.

A recent review article on visual word recognition ([Taylor, Rastle, & Davis, 2013](#)) proposed two linking principles by which cognitive models can inform interpretation of differential activity in functional imaging studies. First, neural engagement can lead to additional responses for stimuli that are represented in a specific brain region compared with stimuli that are not (explaining standard cognitive subtractions). However, if both classes of stimuli are represented in a specific brain region, then differential processing effort leads to an increased neural response for items with less familiar representations because they are more difficult to process (explaining increased responses to anomalous sentences). In combination, these two principles combine to produce an inverted U-shape linking function depicted in [Figure 44.2](#). The [Taylor et al. \(2013\)](#) article offers further background and simulations to justify these linking principles.

Predictions due to differential neural engagement are easily applied to localist models of spoken word recognition such as TRACE ([McClelland & Elman, 1986](#)) or NAM ([Luce & Pisoni, 1998](#)). These models propose a lexicon of localist nodes that represent words but not pseudowords. Thus, engagement of lexical representations would predict additional activation for words versus pseudowords. Based on these models, then, we must explain why multiple brain regions (at least three in the left temporal lobe alone) show this profile in the [Davis and Gaskell \(2009\)](#)

FIGURE 44.2 Illustration of an inverted U-shape function proposed to relate the goodness of fit between the current speech input and neural representations and the observed BOLD response measured with functional MRI (following [Taylor et al., 2013](#)). This inverted U function arises due to a large increase in BOLD response for stimuli that engage a specific neural system (engagement) and a reduced neural response for stimuli that are processed more easily (effort). For example, a system representing phonetic form (such as the STG) will produce a minimal response to nonspeech stimuli (no engagement), a large response to pseudowords (engaged with maximal processing effort), and an intermediate response for highly familiar words (engaged with minimal effort). Conversely, a brain region representing the meaning of familiar words (such as the ITG) will respond minimally to pseudowords and maximally to low-familiarity or ambiguous words, and will produce a reduced response to words that are high-familiarity, primed, or that can be processed with reduced effort. A similar inverted U-shape profile is described by [Price and Devlin \(2011\)](#) motivated by predictive coding principles.

meta-analysis. Furthermore, although additional activation for words is straightforward, localist models struggle to explain the reverse observation in the STG. Feedforward accounts of spoken word recognition (such as Shortlist; [Norris, 1994](#)) provide no mechanism by which lexical knowledge can modulate activity in prelexical processes. Even interactive models such as TRACE propose top-down excitatory connections, which seem likely to increase rather than decrease responses to familiar words compared with pseudowords.

Conversely, models that include distributed representations of the lexical form (such as the Distributed Cohort Model of [Gaskell & Marslen-Wilson, 1997](#), hereafter DCM) assume that representations of the phonetic form are common to words and pseudowords. In these distributed models, neural responses associated with sublexical processing would be increased for pseudowords relative to words because increased familiarity for words leads to reduced processing effort. Therefore, these models have a ready explanation for increased activation for pseudowords in the STG. The following section assesses a further prediction made by the DCM that additional responses for pseudowords should overlap with brain regions in which neural

activity differs for classes of words (e.g., high versus low neighborhood items) that require more or less processing effort for recognition.

44.3.1 Processing Effort and STG Responses to Familiar and Unfamiliar Words

A range of functional imaging studies has localized processing effort during the recognition of spoken words to regions of the STG that respond more strongly to pseudowords than to words. For example, [Gagnepain et al. \(2008\)](#) contrasted neural responses to degraded spoken words and pseudowords, half of which were primed in a study phase prior to participants entering the scanner. They report neural interactions between lexicality and priming in bilateral regions of the STG; additional responses for pseudowords clearly overlap with regions showing repetition suppression for spoken words. Other studies have similarly localized immediate repetition suppression for spoken words to peri-auditory regions of the STG ([Cohen, Jobert, LeBihan, & Dehaene, 2004](#); [Kouider, de Gardelle, Dehaene, Dupoux, & Pallier, 2010](#)). Studies using semantic priming with spoken words also localize reduced neural responses for primed words to regions of the STG that respond more to pseudowords ([Kotz, Cappa, von Cramon, & Friederici, 2002](#); [Rissman, Eliassen, & Blumstein, 2003](#); [Wible et al., 2006](#)). Finally, reduced activity for spoken words with phonological forms that are more easily recognized (due to having fewer lexical competitors) localizes to the same regions of the STG. This finding has been reported for comparisons of words with smaller and larger phonological neighborhoods ([Okada & Hickok, 2006](#)), for words without versus with onset-embedded competitors (such as *claim*, which contains the word *clay*; [Bozic, Tyler, Ives, Randall, & Marslen-Wilson, 2010](#)), and for pseudowords that diverge earlier from existing words and are thus more phonologically distinct from real words ([Zhuang, Tyler, Randall, Stamatakis, & Marslen-Wilson, 2014](#)). Additional processing effort in recognition of spoken words explain additional responses to pseudowords in the STG and all these observations of differential responses during recognition of familiar words.

Despite this compelling correspondence between neural data and computational predictions, we must still explain additional responses to real words compared with pseudowords in several left² temporal regions: anterior STG/MTG, anterior fusiform, and

posterior MTG, and inferior temporal gyrus (ITG). Outside the temporal lobe, additional responses to real words are also observed in the TPJ (including supramarginal gyrus [SMG] and adjacent regions of posterior STG) and the ventral and anterior portions of the inferior frontal gyrus (IFG orbitalis). For these temporal lobe regions, we invoke the first linking principle described by [Taylor et al. \(2013\)](#) and propose that these activations reflect neural representations that are uniquely engaged for familiar words. However, although it might appear self-evident that these responses delineate the neural basis for lexical processing, we must still explain why several different neural systems show an elevated response to familiar words. This redundancy is not anticipated by typical cognitive models that propose a unitary lexical system or domain-specific lexicons for reading, listening, and speaking. However, these three systems might serve to address the three computational challenges involved in spoken word recognition. We assess this proposal by considering other imaging contrasts that also activate each of these temporal lobe regions.

44.3.2 Anterior Temporal Lobe Contributions to Integrating Speech Over Time

The first system to consider is the anterior temporal region that responds more strongly to spoken words than to pseudowords ([Davis & Gaskell, 2009](#)). This ventral processing pathway for spoken language comprehension has been described in detail by Scott and colleagues ([Rauschecker & Scott, 2009](#); [Scott & Johnsrude, 2003](#)). They designate the anterior STG/MTG as an auditory association area by analogy with homologous regions in the auditory system of macaque monkeys ([Scott & Johnsrude, 2003](#)). It seems reasonable to assume that associative knowledge is similarly critical for the recognition of familiar spoken words. However, other authors (notably [Hickok & Poeppel, 2007](#)) have cast doubt on these claims, instead proposing that anterior regions of the temporal lobe support combinatorial processing of sentences.

Consistent with the claim that anterior temporal regions contribute to combinatorial processing, functional imaging studies using spoken sentences are more likely to report activation of anterior temporal regions than studies using single words or syllables (see a meta-analysis by [DeWitt & Rauschecker, 2012](#)). Among the contrasts that show reliable anterior temporal activity are comparisons of more and less

²In summarizing this meta-analysis, we focus on responses in the left hemisphere; however, many of the differential responses reported are similarly observed in homologous regions of the left hemisphere. Some authors—most notably [Bozic et al. \(2010\)](#)—have argued that lexical access processes are supported by the temporal lobe bilaterally. However, the extended lexical network (including associated frontal regions) appears to be largely left-lateralized.

intelligible sentences (Scott, Blank, Rosen, & Wise, 2000). Those studies that compare responses to different acoustic forms of intelligible speech confirm that more anterior regions of the STG and MTG respond to intelligible speech in an acoustically invariant manner, consistent with higher-level linguistic processes (Davis & Johnsrude, 2003; Evans et al., 2014; but see Okada et al., 2010). Studies that manipulate sentence coherence and speech intelligibility report an interaction between these factors in anterior regions of the MTG (Davis, Ford, Kherif, & Johnsrude, 2011) with delayed responses in more anterior MTG regions, consistent with temporal integration. Similar findings are apparent in analysis of the phase of the BOLD responses to sentences in anterior STG regions (Dehaene-Lambertz et al., 2006), or in studies using dynamic causal modeling (Leff et al., 2008). For clearly spoken materials, studies contrasting sentences versus word lists consistently show anterior STG activation (Mazoyer et al., 1993) with additional activation in overlapping regions due to the presence of either sentential prosody or syntactic structure (Humphries, Binder, Medler, & Liebenthal, 2006). Another fMRI study shows activity in anterior temporal regions during narrative comprehension is correlated over subjects and perturbed by reordering larger units in progressively more anterior regions (Lerner, Honey, Silbert, & Hasson, 2011).

These functional imaging findings point to a hierarchy of temporal receptive fields in more anterior regions of the superior and middle temporal gyri. More anterior regions respond preferentially during sentence comprehension, particularly for connected speech containing familiar lexical items and supra-lexical elements (e.g., prosodically well-formed phrases). Within this temporal hierarchy, then, additional responses to familiar words would be expected at the relevant level of temporal structure (the 300- to 500-ms duration of typical spoken words in connected speech). Such regions serve as an internal memory for prior speech to guide perception of current speech sounds and words (TRACE in McClelland & Elman, 1986, or recurrent context units in Gaskell & Marslen-Wilson, 1997). Interestingly, a similarly anterior temporal system has been proposed as the neural basis of auditory echoic memory for speech in short-term memory experiments (Buchsbbaum, Olsen, Koch, & Berman, 2005). We argue that this is a critical part of the lexical system and retains a representation of recently heard spoken words.

44.3.3 Temporoparietal Regions Link Auditory and Motor Representations of Spoken Words

The second neural system that responds more to familiar words than to pseudowords is the TPJ.

This is the largest cluster highlighted in the Davis and Gaskell (2009) meta-analysis and extends over a number of cortical areas, including posterior portions of the STG (classically, Wernicke's area), and adjacent parietal regions in the supramarginal and angular gyri. This anatomy broadly corresponds to the temporoparietal portion of the dorsal processing pathway, which is the main point of agreement between dual-pathway accounts by Scott (Rauschecker & Scott, 2009; Scott & Johnsrude, 2003), and Hickok and Poeppel (2007). Both have proposed that this temporoparietal pathway forms an auditory-motor interface, mapping heard speech onto the premotor and motor representations used to control speech production. However, whereas others have emphasized nonlexical contributions of the dorsal stream (e.g., in supporting nonword repetition; Hickok, Buchsbbaum, Humphries, & Muftuler, 2003), this chapter follows Gow (2012) in proposing this as a "dorsal lexicon" critical for mapping heard words onto motor representations involved in producing these words aloud. We further propose that this system supports processes that contribute to the recognition of degraded or acoustically ambiguous spoken words and that guide perceptual learning.

The clearest evidence that TPJ regions contribute to lexical processing is the observation of increased responses to spoken words versus pseudowords (Davis & Gaskell, 2009). This cannot be explained by additional processing effort or task difficulty (which would typically be greater for pseudowords), but instead it suggests neural representations that are specifically engaged by spoken words. Further, evidence for lexical representations in the TPJ is that exactly the same region is activated for words versus pseudowords in visual word recognition (Taylor et al., 2013) and in short-term memory tasks with written and spoken words (Buchsbbaum et al., 2005). This is in contrast to the anterior temporal system, which is seldom activated in studies using single written words (although activation is observed for written sentences and narratives; Spitsyna, Warren, Scott, Turkheimer, & Wise, 2006).

The cross-modal convergence of lexicality effects for spoken and written words in TPJ is compatible with two distinct functional proposals discussed by Taylor et al. (2013): (i) TPJ contributes to semantic processing (Binder, Desai, Graves, & Conant, 2009) or (ii) TPJ supports a multimodal phonological lexicon shared between speech and print (the sensorimotor account proposed by Hickok & Poeppel, 2007). Functional imaging evidence is more consistent with the second of these proposals because purely phonological manipulations lead to differential TPJ activation. For example, repetition suppression effects for pseudowords and isolated syllables localize to posterior STG and adjacent parietal regions such as the SMG

(Jacquemot, Pallier, LeBihan, Dehaene, & Dupoux, 2003). The SMG has been associated with phonological change responses for sine-wave stimuli perceived as speech, but not equivalent nonspeech (Dehaene-Lambertz et al., 2005). Furthermore, changes before and after training with sine-wave speech are correlated with individual differences in the strength of categorical responses in the SMG (Desai, Liebenthal, Waldron, & Binder, 2008).

Studies that manipulate the difficulty of lexical processing provide further evidence that phonological processes in the TPJ contribute to lexical access in speech perception and speech production. For instance, additional neural responses in posterior superior temporal regions are seen during perception and production of words with greater phonological complexity (due to more consonant clusters; Tremblay & Small, 2011). Similarly, words with higher neighborhood density (i.e., that have more similar sounding competitors) require greater phonological specificity for identification and are associated with increased activation of the SMG (Prabhakaran, Blumstein, Myers, Hutchison, & Britton, 2006) during speech perception and similarly in the SMG during speech production (Peramunage, Blumstein, Myers, Goldrick, & Baese-Berk, 2011). These results are distinct from the findings reviewed in Section 44.3.2 because mid-STG activity is associated with the difficulty of lexical access during spoken word recognition (Bozic et al., 2010; Okada & Hickok, 2006), but not during speech production. However, there are inconsistencies in lexical difficulty effects observed in spoken word recognition (see Vaden, Piquado, & Hickok, 2011). These may be resolved by using computationally informed measures of processing difficulty (such as prediction error) combined with time-locked measures of neural activity (MEG or EEG; see Gagnepain, Henson, & Davis, 2012).

How, then, do these TPJ regions—and the dorsal auditory-motor pathway more broadly—contribute to the comprehension of spoken words? The introduction to this chapter highlighted the problems faced by listeners who must understand words despite variation in their acoustic form (due to different speakers, accents, acoustic degradation, etc.). For a listener attempting to repeat back single words, many different acoustic forms should lead to the same motor response (assuming that words are correctly perceived). In the context of a repetition task, then, the computational goal of the auditory-motor pathway should be to take variable or degraded speech as an input, to abstract

from this acoustic or phonetic variability, and to extract the correct motor commands or articulatory gestures that the listener should use to repeat the speech that was heard. Although normalization for variability in visual processing is traditionally assumed to be part of the ventral visual processing stream (Ungerleider & Mishkin, 1982), speech is different from vision because we not only hear speech but also produce it.³ For verbal communication to be successful, listeners must be able to produce sounds that lead to essentially the same phonological percept as the speech that they hear (Lieberman & Whalen, 2000). That is, listeners in a repetition task should be able to retrieve the same articulatory gestures as those produced by the person speaking. In this way, the goal of the auditory-motor pathway during repetition (though perhaps not the goal of the perceptual system as a whole or during all tasks) embodies a key proposal of the motor theory of speech perception that the similarity of heard and spoken necessitates a direct mapping between sensory and motor representations of speech (Lieberman & Whalen, 2000; Chapter 15, but see Chapter 16).

Accessing the intended articulatory gesture for a heard spoken word is thus one key outcome in the perceptual identification of degraded speech (Davis & Johnsrude, 2007). Evidence for activation of articulatory representations comes from imaging studies showing increased inferior frontal and motor recruitment during perception of degraded speech compared with clear speech (Adank & Devlin, 2010; Davis & Johnsrude, 2003), even if the current task does not require access to articulatory representations (Hervais-Adelman, Carlyon, Johnsrude, & Davis, 2012). Recent fMRI studies using multivoxel pattern analysis methods show that (particularly for degraded or ambiguous syllables) frontal and motor regions represent the phonological content of heard speech (Du, Buchsbaum, Grady, & Alain, 2014), although this study included overt phoneme categorization tasks. Venezia, Saberi, Chubb, and Hickok (2012) showed that activity in these frontal and motor regions is correlated with response bias in phoneme decision tasks and, hence, argue that frontal regions are involved in response selection but do not contribute to perception *per se* (Binder, Liebenthal, Possing, Medler, & Ward, 2004). However, other multivoxel pattern analysis studies have shown that inferior frontal (Lee, Turkeltaub, Granger, & Raizada, 2012) and motor areas (Evans & Davis, submitted) encode the perceptual content of speech even when no response is

³One exception is that skilled artists can generate images (e.g., using a pencil on paper) that reproduce essential aspects of their subjective visual experience. However, this ordinarily requires substantial training and many (including this author) never achieve even limited proficiency at this. Note that the same is not true for speech. One of the earliest foundations for spoken language is the ability to reproduce (with the voice) the auditory patterns that one hears (i.e., verbal repetition).

required to indicate this perceptual content. We take these findings as evidence against the view that frontal and motor responses are only involved in response selection. At the same time, we acknowledge that there is less functional imaging evidence for motor responses to clear speech or in tasks focused on natural comprehension (see [Scott, McGettigan, & Eisner, 2009](#) for a review). We have previously shown that frontal activation is both specific to degraded speech and linked to attentive perception because it is absent during distraction ([Wild et al., 2012](#)). Similarly, it is only in challenging listening situations—such as when the speech signal is perturbed by noise ([Meister, Wilson, Deblieck, Wu, & Jacoboni, 2007](#)) or made perceptually ambiguous ([Möttönen & Watkins, 2009](#))—that TMS disruption of motor regions leads to perceptual impairments (though, again, [Venezia et al., 2012](#) have argued against this).

One possible contribution of the dorsal auditory-motor pathway to speech perception that is consistent with the evidence reviewed is to support perceptual learning or adaptation. Perceptual learning is apparent in a range of circumstances in which listeners hear spoken words that are artificially degraded (by noise-vocoding, [Hervais-Adelman, Davis, Johnsrude, & Carlyon, 2008](#); or by sine-wave synthesis, [Remez et al., 2011](#)). For both these forms of artificial distortion, prior exposure enhances perception of trained and untrained words ([Dahan & Mead, 2010](#); [Hervais-Adelman, Davis, Johnsrude, Taylor, & Carlyon, 2011](#)). For vocoded speech, perceptual learning is enhanced by prior knowledge of speech content ([Hervais-Adelman et al., 2008](#)) and feedback from lexical representations ([Davis, Johnsrude, Hervais-Adelman, Taylor, & McGettigan, 2005](#)) or visual speech ([Wayne & Johnsrude, 2012](#)). Evidence to tie perceptual learning to the dorsal auditory-motor pathway is that lexical feedback is equally successful in enhancing perceptual learning when it is supplied in written or spoken form ([Davis et al., 2005](#)). Thus, perceptual learning is plausibly linked to convergence of written and spoken lexical representations in TPJ regions. However, existing functional imaging evidence has inconsistently highlighted frontal ([Eisner, McGettigan, Faulkner, Rosen, & Scott, 2010](#)), motor ([Hervais-Adelman et al., 2012](#)), and thalamus ([Erb, Henry, Eisner, & Obleser, 2013](#)) as supporting perceptual learning. A recent tDCS study provides further evidence for inferior frontal contributions to perceptual learning ([Sehm et al., 2013](#)).

A link between lexical knowledge and frontal/TPJ activity is also apparent for a second perceptual learning paradigm first reported by [Norris, McQueen, and Cutler \(2003\)](#). In this paradigm, phonetic category boundaries are systematically altered after exposure to ambiguous segments (e.g., a segment intermediate between /f/ and /s/) in the context of disambiguating

familiar words (“peace” or “beef”), but not in pseudo-words (“dreace” or “dreef”; [Norris et al., 2003](#)). Regarding degraded speech, perceptual learning generalizes to untrained words consistent with a prelexical locus for learning ([McQueen, Cutler, & Norris, 2006](#)). Functional imaging evidence links perceptual learning to auditory-motor pathways because ambiguous segments in contexts that support learning activate posterior temporal and adjacent parietal regions ([Myers & Blumstein, 2008](#)) in addition to the inferior frontal regions activated for nonlexical segment disambiguation ([Blumstein, Myers, & Rissman, 2005](#)). MEG data suggests top-down causal influences from SMG to posterior STG regions during perception of Ganong stimuli ([Gow, Segawa, Ahlfors, & Lin, 2008](#)) similar to those that induce perceptual learning. Functional imaging during periods of audio-visually induced phoneme category boundary changes has also been shown to be associated with activation of inferior frontal and parietal regions (angular gyrus; [Kilian-Hütten, Vroomen, & Formisano, 2011](#)).

Another situation in which perceptual learning enhances comprehension is when listeners hear an unfamiliar or artificial accent ([Clarke & Garrett, 2004](#)). As previously described for vocoded speech, parallel presentation of a written transcription supports perceptual learning of accented speech (e.g., movie subtitles; [Mitterer & McQueen, 2009](#)). Furthermore, requiring listeners to imitate the novel accent (i.e., engaging audio-motor pathways) also enhances learning ([Adank, Hagoort, & Bekkering, 2010](#)). Functional imaging evidence to link perceptual learning of accented speech to TPJ regions comes from the observation that posterior STG is activated during perception of accented speech relative to speech in noise of equivalent intelligibility ([Adank, Davis, & Hagoort, 2012](#)) and that accent repetition leads to suppression of activity in posterior STG and SMG ([Adank, Noordzij, & Hagoort, 2012](#)). These results suggest a role for auditory-motor representations during accent perception that parallels the involvement of this same system in other forms of lexically driven perceptual learning. Thus, evidence from three different forms of perceptual adaptation is consistent with auditory-motor mappings for familiar words in the dorsal auditory pathway being key to the accurate perceptions of the degraded or variable speech that are part of the everyday experience of spoken words for listeners.

44.3.4 Posterior Middle and Inferior Temporal Regions Map Spoken Words onto Meaning

The ultimate goal of listeners hearing spoken words is surely to access the meaning that the speaker

intended. Determining the anatomical and functional organizations of neural systems that support access to meaning from spoken words and distinguishing this process from semantic representation *per se* has proved challenging. For a time it was unclear whether any single neural system supports semantic memory: recent reviews on semantic processing of language stimuli argued for the involvement of multiple cortical areas. For example, a functional imaging meta-analysis of semantic processing of spoken and written words (Binder et al., 2009) highlighted a semantic system that encompasses most of the lateral temporal lobe and inferior parietal lobe, including both the anterior and posterior pathways reviewed previously. This is perhaps because Binder included the contrast of spoken and written words versus pseudowords as a means of identifying semantic regions. This may highlight neural systems involved in processing the form of familiar words as well as their meaning. Other semantic contrasts assessed by Binder et al. (2009) involve comparing semantic and phonological tasks or more/less meaningful utterances. These comparisons may be less sensitive to form-based processes, although they may instead highlight brain regions that are sensitive to effects of task or comprehension difficulty (see Davis & Rodd, 2011 for discussion).

A more focal localization of semantic processing is suggested by meta-analyses that contrast the neural representation of different types of semantic information also reported by Binder et al. (2009). Binder and colleagues showed activation during semantic processing of words referring to actions in posterior portions of the MTG. However, inferior temporal and fusiform regions are activated in tasks that require access to perceptual attributes of the referents of spoken or written words (e.g., in responding to words with concrete meanings). These findings may explain some of the other regions activated for word versus pseudoword contrasts in Davis and Gaskell (2009) and Taylor et al. (2013): many of the studies reported use of tasks that involve access to word meaning (e.g., lexical decision; Plaut, 1997) and use of words with object and action associations. Thus, activation of posterior middle and inferior temporal regions for familiar words compared with pseudowords might reflect responses to perceptual or action semantic attributes.

The semantic feature specificity reported by Binder et al. (2009) is consistent with a distributed, embodied view of semantic processing in which some forms of conceptual information (visual appearance, associated actions, etc.) are grounded in sensory and motor cortices (see Martin, 2007; Chapter 62 for reviews). Although these data rule out purely symbolic accounts of semantic cognition, strong and weak embodied theories remain to be distinguished (Meteyard, Cuadrado,

Bahrani, & Vigliocco, 2012). One key question concerns whether embodied semantic representations are accessed directly from relevant perceptual representations (e.g., from superior temporal regions, in the case of spoken words; Martin, 2007) or whether semantic representations are accessed via an amodal semantic hub localized in the ventral anterior temporal lobe (Chapter 61; Patterson, Nestor, & Rogers, 2007).

Considerable evidence from neuroimaging suggests that these anterior temporal regions are activated during semantic processing (Visser, Jefferies, & Lambon Ralph, 2009), particularly in studies that overcome the susceptibility artifacts that lead to loss of signal in conventional fMRI acquisitions (Devlin et al., 2000; Visser & Lambon Ralph, 2011). Evidence for anterior temporal lobe contributions to semantic processing also comes from neuropsychological deficits in individuals with focal neurodegeneration of ventral temporal regions (specifically, semantic dementia; see Patterson et al., 2007) and from semantic impairments observed after rTMS to similar regions (Pobric, Jefferies, & Ralph, 2007). However, one striking aspect of all these observations is that the semantic contribution observed is domain general—impacting all modalities of input (written and spoken language, pictures, etc.) and multiple output modalities (naming, drawing, familiarity judgment—Patterson et al., 2007). Thus, this semantic hub may be responsible for binding together (and maintaining the links between) distributed representations that themselves code for the form and meaning of spoken words. In other work, we have proposed that the semantic hub may play a mnemonic function in acquiring and maintaining lexical representations (perhaps due to projections to medial temporal regions) rather than a purely linguistic function (Davis & Gaskell, 2009).

In contrast, more posterior portions of the MTG and ITG are more specifically associated with semantic processing of spoken words (Gow, 2012; Lau, Phillips, & Poeppel, 2008) and may explain the observation of increased activation for spoken words compared with pseudowords in the Davis and Gaskell (2009) meta-analysis. Evidence from imaging studies using semantic priming manipulations also show reductions in neural activity in the same posterior temporal regions for spoken word pairs that are semantically related (Rissman et al., 2003; Wible et al., 2006). Other manipulations of the ease of meaning access—such as variations in word frequency—also modulate activity in these regions (e.g., reduced activity for higher-frequency words in Hauk, Davis, Kherif, & Pulvermüller, 2008). This inverted U-shape response—neural engagement for words compared with pseudowords and a decreased response to words that are less-effortfully processed—corresponds closely with

expectations for a region involved in accessing semantic representations given the inverted U-shape in Figure 44.2. These findings provide further evidence that neural processes involved in accessing word meaning localize to posterior inferior temporal regions.

Another semantic challenge that activates posterior middle and inferior temporal regions during comprehension of spoken language is seen in studies exploring neural responses to lexical-semantic ambiguities in connected speech. High-ambiguity sentences (such as “there were *dates* and *pears* in the fruit bowl”) require additional semantic processes to activate multiple possible meanings of ambiguous words (e.g., *dates/pears*) and select appropriate meanings in context. By comparison with matched, low-ambiguity sentences (“there was beer and cider on the kitchen shelf”), comprehension of these sentences produces additional activation in posterior middle and inferior temporal gyri and adjacent fusiform regions (Rodd et al., 2005) as well as in inferior frontal regions. Similar combinations of inferior frontal and posterior temporal responses have been obtained for sentences in which lexical ambiguities lead to syntactic as well as semantic selection (Rodd, Longe, Randall, & Tyler, 2010) and for sentences in which the timing of the initial ambiguity and subsequent disambiguation is varied (Rodd, Johnsrude, & Davis, 2012).

Neuropsychological data from brain-injured patients also suggest impaired spoken word comprehension following lesions to posterior portions of the MTG and ITG following stroke (Bates et al., 2003; Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004) and in some, but not all, studies of neurodegenerative conditions such as semantic dementia (Peelle et al., 2008). Further evidence to link posterior activation to successful semantic processing comes from activation during graded anesthetic sedation that disrupts comprehension. Propofol sedation attenuates activation in posterior temporal regions (Davis et al., 2007) in a semantic ambiguity paradigm. Yet, posterior ITG activation remains reliable for partially sedated participants who are able to make accurate semantic judgments on spoken words (Adapa, Davis, Stamatakis, Absalom, & Menon, 2014). Such findings further implicate posterior inferior regions of the temporal lobe in accessing semantic representations of heard words (consistent with the proposal made by Hickok & Poeppel, 2007).

44.4 FUNCTIONAL SEGREGATION AND CONVERGENCE IN LEXICAL PROCESSING

This chapter has presented the functional organization of three temporal lobe pathways that contribute to lexical access for spoken words. A sketch of the

anatomical and functional organization of this tripartite model is shown in Figure 44.3. This account suggests considerable functional segregation, with three distinct pathways contributing to recognition and comprehension of spoken words.

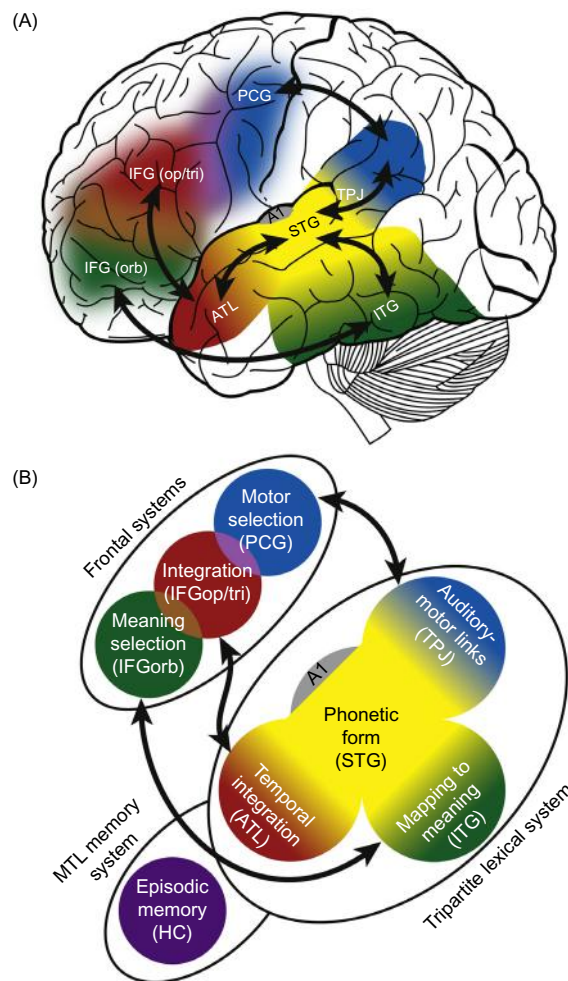

FIGURE 44.3 Tripartite Lexical System. Anatomical (A) and functional (B) organizations of the Tripartite Lexical System and associated frontal and medial temporal systems. The sounds of spoken words are coded in primary regions (A1, gray) before processing of phonetic forms in the STG (yellow). Representations of speech sounds in the STG are combined with three other systems during lexical processing: (i) they are temporally integrated with hierarchical representations of prior segmental and lexical context in anterior regions of the STG/MTG (yellow–red, ATL); (ii) they are mapped onto articulatory representations via auditory-motor links in the TPJ (yellow–blue); and (iii) they are mapped onto meaning representations in posterior and inferior portions of the temporal lobe (yellow–green, ITG). Associated frontal systems show a graded form of the same specialization based on convergent connectivity: precentral gyrus (PCG; blue), inferior frontal gyrus opercularis/triangularis (IFGop/tri; red), and inferior frontal gyrus orbitalis (IFGorb; green). Convergent connectivity among the three parts of the lexical system is apparent in two other systems: re-entrant connections to the STG (in A) and in MTL/HC regions (purple in B, not shown in A) that code episodic representations of words and associated contextual information during lexical learning.

One challenge for this tripartite account is to specify how particular tasks or behavioral goals are achieved. This is particularly true for listening situations that challenge one or more processing streams (e.g., degraded speech sounds, ambiguous word). Listeners hearing an unexpected word in a sentence must determine whether this is the result of mishearing the current word, erroneous segmental or lexical predictions, an unfamiliar accent, ambiguity in word meaning, or some other error. Each of these causes of misidentification brings specific computational challenges or repair operations associated with one or more processing pathway.

One common observation across a range of different experimental situations that involve effortful listening to speech is that inferior frontal, insula, and motor regions show additional activation compared with easy or effortless comprehension conditions (see Chapter 40). Anatomical evidence would suggest that these prefrontal regions receive convergent projections from the three posterior pathways (Scott & Johnsrude, 2003) and, in turn, provide re-entrant connections back to posterior regions. A key function of frontal connections may be to support learning processes that guide interpretation of noisy or ambiguous speech input (Davis & Johnsrude, 2007). However, frontal mechanisms can also support other processes that contribute to lexical access—such as competitive selection of single lexical items (Bozic et al., 2010; Prabhakaran et al., 2006), maintenance of recognized words in working memory (Rodd et al., 2012), combining multiple words to infer sentence level meaning (Hagoort, 2005; Chapter 28), and others. These and other higher-level processes will be actively engaged during effortful comprehension of speech (see Chapter 40; Guediche, Blumstein, Fiez, Holt, & Peelle, 2014).

Another form of functional convergence that may be critical for successful recognition of spoken words are top-down projections from frontal and lateral temporal regions back to earlier auditory and peri-auditory regions. Direct evidence for top-down connections has been difficult to obtain from fMRI data (Davis et al., 2011; Guediche, Salvata, & Blumstein, 2013). However, evidence from MEG/EEG (Arnal, Wyart, & Giraud, 2011; Sohoglu, Peelle, Carlyon, & Davis, 2012) is more clearly consistent with the top-down mechanism as proposed in predictive coding theories (Rao & Ballard, 1999). One such proposal is that spoken word recognition is achieved by comparing lexically informed predictions for upcoming segments with incoming speech sounds (Gagnepain et al., 2012). Prediction errors are propagated forward from early auditory regions and provide a bottom-up signal to support or reject previously activated lexical candidates. This predictive coding view is supported by evidence that phonological mismatch responses in EEG studies are time-locked to deviating or absent segments in

expected spoken words (Bendixen, Scharinger, Strauß, & Obleser, 2014; Desroches, Newman, & Joanisse, 2009). Furthermore, MEG responses to spoken words and pseudowords in the STG and changes due to learning and consolidation study are uniquely explained by computational simulations in which word recognition is achieved using prediction error signals (Gagnepain et al., 2012).

A final form of convergence involves projections from lateral to medial temporal lobe (MTL) regions including the hippocampus (HC) (Davis & Gaskell, 2009). Connections to the MTL are proposed to play a key role in initial learning of phonological forms (Davis, Di Betta, Macdonald, & Gaskell, 2009) or form-meaning links (Breitenstein et al., 2005). MTL regions are commonly co-activated with lateral temporal regions (such as the STG) when recognizing recently learned spoken words (Takashima, Bakker, van Hell, Janzen, & McQueen, 2014), and the STG shows enhanced coupling with the hippocampus during memory encoding for spoken words (Gagnepain et al., 2011). Involvement of the MTL in initial acquisition of novel spoken words is consistent with complementary learning system theories of lexical learning (Davis & Gaskell, 2009). One proposal of the CLS theory is that overnight sleep after learning plays a key role in consolidating neocortical representations of newly acquired words. This has support from overnight changes in cortical responses to novel words (Davis et al., 2009; Gagnepain et al., 2012; Takashima et al., 2014) and correlations between sleep-spindles measured during postlearning slow-wave sleep and individual differences in lexical integration of novel words (Tamminen, Payne, Stickgold, Wamsley, & Gaskell, 2010). One question that remains, however, is whether these MTL regions have functional overlap with, or are distinct from, the anterior temporal semantic hub proposed to bind the form and meaning of familiar spoken words (Patterson et al., 2007).

44.5 CONCLUSION

This chapter has presented a tripartite account of the brain regions that support lexical processing of spoken words. The functional goals of three temporal lobe systems have been introduced in the context of key computational challenges associated with spoken word recognition. First, listeners must integrate current speech sounds with previously heard speech in recognizing words. This motivates a hierarchy of representations that temporally integrate speech signals over time localized to anterior regions of the STG. A second challenge is that for listeners to repeat degraded words correctly requires that they recover the speakers' intended articulatory gestures. The tripartite account localizes this process to auditory-motor links mediated by TPJ regions and proposes that these

links play a key role in supporting robust identification and perceptual learning of degraded spoken words. The third challenge relates to extracting meaning from spoken words, which is proposed to be supported by cortical areas in posterior ITG and surrounding regions (MTG and fusiform). Despite the three-way functional segregation that is at the heart of this tripartite account, this chapter also acknowledges that reliable recognition of familiar words, optimally efficient processing of incoming speech, and learning of novel spoken words all depend on combining information between these processing pathways. This is achieved through convergent connectivity within the lateral temporal lobe, in frontal or medial temporal regions, and through top-down predictions mapped back to peri-auditory regions of the STG. A key goal for future research must be to specify these convergent mechanisms in more detail and derive precise computational proposals for how the tripartite lexical system supports the everyday demands of human speech comprehension.

Language is a system that allows an interlocutor to effectively and efficiently create mental states in a communication partner. Words and phrases are memory cues that are often embedded in sentences and larger language units that provide directions for combining those cues into complex, structured mental representations. At its heart, therefore, language comprehension involves a temporally extended process of accessing and updating semantic memory, the brain's repository of general experience and implicit and explicit knowledge. Semantic memory consists of stored experiences that can be accessed without making reference to specific details of the episodic context from which those experiences were derived. It includes information about people (and their faces, voices, and biographies), objects (attributes, functions), places, words (features, meanings, and combinatorial statistics), and general world knowledge of all types (facts, events, social norms, beliefs, etc.). Semantic access, then, is a protracted process whereby information in semantic memory comes to be activated via links to an internal or external stimulus. The specific nature and structure of semantic memory remains a topic of debate. In particular, there is disagreement about the extent to which semantics is abstract/symbolic in nature versus directly built from perceptual stimulations, amodal versus modality-specific, spatially organized according to features versus discrete categories, and so forth (for a variety of views see, e.g., Barsalou, 2008; Binder & Desai, 2011; Mahon & Caramazza, 2008; Martin, 2007; Patterson, Nestor, & Rogers, 2007). However, there is a general consensus on some aspects of semantic memory,

and these pose important challenges for understanding the neural and cognitive mechanisms involved in semantic access.

First, a highly distributed (albeit not exactly the same) brain network is engaged in association with semantic memory access. This network comprises a variety of heteromodal areas, including much of the temporal lobe and inferior parietal cortex, coupled with higher-order sensory and motor processing areas and control structures in the left prefrontal lobe (e.g., review in Binder & Desai, 2011). Understanding how representations and processes in such an extensive set of brain areas are coordinated to mediate semantic access would seem to call for a fundamentally different framework for thinking about the relationship between cognitive functions and the brain than has been typical in much of the cognitive neuroscience literature to date, wherein a common approach to pinpointing the neurobiological roots of a particular cognitive process is to locate that process in a particular brain region or small network of areas. For semantic memory, however, spatial localization in isolation is unarguably an inadequate anchor for function, if not also representation. Instead, the process (and not moment) of semantic access requires the dynamic creation of a functional circuit, with *time* as a critical component (see, e.g., Federmeier & Laszlo, 2009).

Second, access to semantic memory manifests a jarring juxtaposition of consistency and flexibility. Semantic access must be sufficiently stable that the mental states elicited by physically different stimuli

(e.g., hearing the word “brain” and seeing a picture of a brain) as well as by the same type of stimulus encountered at different times and in different contexts are all recognizable as (linking to) the “same” concept. Such stability is necessary for learning and generalization and also critically enables human communication. Moreover, for any given instance of semantic access, only a subset of all the information linked to a particular concept is likely to be relevant, and, correspondingly, the exact configuration of conceptual features accessed for a given input (word, picture, etc.) is highly context-sensitive. In fact, although in the laboratory semantic access has often been examined for isolated stimuli (a single face, object, or word), in everyday life, and especially in the context of language comprehension, semantic access for any given stimulus occurs in a rich context, including information that has come in (and will continue to come in) over time.

Time and timing thus play a critical role in semantic access (indeed, in most cognitive processes and their neural mechanisms!). In this chapter, we therefore examine the time course of semantic access across two temporal scales: first, that associated with accessing long-term memory from an individual stimulus and, second, the scale associated with building meaning across multiple inputs in a stimulus stream (e.g., an unfolding sentence or discourse).

45.1 PART 1: THE TIMECOURSE OF SEMANTIC ACCESS OUT OF CONTEXT

Access to semantic memory is not exclusive to language stimuli. Linking perceptual inputs to meaning is arguably one of the brain’s most fundamental tasks, because this allows more flexible, well-tuned, and complex responses to stimuli. Meaning is accessed from all modalities and from many sundry representation types: environmental sounds; somatosensory stimuli; visual objects, faces, and scenes; tastes and smells; and nonlinguistic symbolic systems (such as numbers); as well as spoken, written, and signed language stimuli. However, each of these stimulus types present different challenges for semantic access. Comparisons across modality/representation type have played a critical role in investigations of the *structure* of semantic memory (see, e.g., discussion in [Federmeier & Kutas, 2001](#)), offering important insights into the factors that govern how semantic information is stored and organized. Surprisingly, however, the literature looking at the *process* of semantic access from different types of inputs (faces, objects, printed words, spoken words, etc.) have not been similarity integrated. Such comparisons afford an understanding of the extent to which the timing—and, by inference, the

mechanism—of semantic access does or does not differ as a function of factors such as input modality, perceptual expertise (greater for faces and written or spoken words than objects and environmental sounds), developmental trajectory (earlier for faces and objects than written words), evolutionary precedence (earlier for nonlinguistic than linguistic inputs overall; earlier for auditory than for visual words), and iconicity (more for faces and objects than words), among others.

Moreover, debates about the timecourse of semantic access from linguistic stimuli (e.g., [Laszlo & Federmeier, 2014](#); [Rayner & Clifton, 2009](#)) can be importantly informed by knowledge about the timecourse of access from nonlinguistic ones. For example, the ability to rapidly analyze a face stimulus and link it with biographical and emotion-related information is clearly a critical social skill with implications for an organism’s health and survival. Accessing memory from faces is also a phylogenetically and ontologically earlier ability than is accessing memory from words (especially printed words). The timecourse of semantic access from faces can thus provide an important point of reference for understanding semantic access from words, serving as a possible upper limit on the speed with which perceptual stimuli can be linked with information in long-term memory. Therefore, we review the timecourse of semantic processing, as revealed by event-related brain potentials (ERPs), for faces and visual objects, visual and auditory words, and numbers.

45.1.1 Face and Object Processing

A large body of literature has used techniques with high temporal resolution, especially ERPs, to track the timecourse of face and object processing, from extracting basic features, isolating the figure from the ground, identifying whole complex structures, to ultimately accessing meaning. The timecourse thus obtained is particularly well-attested because, unlike for language stimuli, it can be validated through work in nonhuman animals using more invasive techniques. Recordings in monkeys have revealed onset latencies of about 100 ms for face-selective neurons in the inferior temporal cortex ([Kiani, Esteky, & Tanaka, 2005](#)), and intracranial recordings in humans (who have bigger brains, meaning generally longer neural response latencies) first find face-specific responses beginning at approximately 160 ms in posterior fusiform gyrus ([Halgren, Baudena, Heit, Clarke, & Marinkovic, 1994](#)). This accords well with the timecourse inferred from scalp-recorded ERPs, for which the first reliable categorization of visual stimuli is seen in amplitude modulations on the N1 component, part of the normal evoked response to all visual onsets, offsets, or

changes (see Di Russo, Martínez, Sereno, Pitzalis, & Hillyard, 2002 for a description of onset latencies and hypothesized localizations of early visual components). This neural response begins at approximately 130 ms after stimulus onset and peaks between 150 and 170 ms. In the object and face recognition literatures, the N1 is often referred to as the “N170,” with (what is likely) the positive end of this dipole seen over central electrode sites and referred to as the Vertex Positive Potential or the P150 (see Jeffreys, 1989).

The N170/P150 to images containing objects reliably differs from those to nonsense images generated by phase-scrambling their intact counterparts (while maintaining low-level cues including spatial frequency; Schendan & Lucia, 2010). In this same time window, visual stimuli with which people have special expertise, such as faces (Bentin, Allison, Puce, Perez, & McCarthy, 1996) and word-like strings (Schendan, Ganis, & Kutas, 1998), elicit enhanced responses compared with responses to objects. Critically, N170/P150 amplitude modulations do not simply track the presence of particular visual features, but seem to reflect the *detection* of a particular type of stimulus. For example, studies using Mooney images—which, when presented in one orientation (rightside up) are generally perceived as faces but, presented upside-down, are not—have shown that N170 enhancements occur only when a visual stimulus is perceived as a face (George, Jemel, Fiori, Chaby, & Renault, 2005). However, faces need not have typical or even coherent structure to elicit enhanced N170s, which have been seen even when faces are upside-down or cut in half, or when facial features are scrambled or even missing (e.g., Bentin et al., 1996). Similarly, P150 enhancements to word-like strings are obtained even when the elements comprising the string are unfamiliar (“pseudofonts”; Schendan et al., 1998), and P150 sensitivity to repetition is independent of the familiarity or meaningfulness of the eliciting stimuli (Voss, Schendan, & Paller, 2010). The initial categorization of a stimulus as “object-like,” “face-like,” or “word-like” at a basic level thus seems to begin in the time window of the N170/P150 potential.

Responses in the late part of the N170 time window (160–190 ms) and on the subsequent P2 component have been tied to perceptual grouping and structural encoding processes, which create a structured representation of an object or face and enable, for example, the matching of different instantiations and viewpoints of the same form. Studies using fragmented line drawings have shown repetition effects on the posterior P2 for globally similar forms (e.g., drawings of the same object) despite differences in lower-level features (e.g., local contours) (Schendan & Kutas, 2007a, 2007b). Critically, P2 reductions in this design only occur when images on both first and second presentations

are fragmented or incomplete (not when images are intact)—in other words, presumably only when both presentations pose a challenge to perceptual grouping processes. P2 amplitudes are also larger for phase-scrambled than for intact images, likely reflecting grouping difficulties for images without perceivable objects (Schendan & Lucia, 2010).

Structural encoding of faces has further been associated with an ERP response known as the N250r. The N250r is a negative-going potential seen between about 230 and 300 ms over (right) inferior temporal electrode sites (thought to have a neural generator in the fusiform gyrus; Schweinberger, Pickering, Jentsch, Burton, & Kaufmann, 2002) and is selectively enhanced to immediate repetitions of faces (compared with nonface objects). These repetition effects are transient and do not persist beyond more than a few intervening stimuli (Schweinberger, Pickering, Burton, & Kaufmann, 2002). Repetition effects for intact objects appear a little later on a component known as the frontal N300 (sometimes N350). This potential is thought to reflect global object processing after perceptual grouping has occurred and independent of local features (Schendan & Kutas, 2007a); it has been linked to occipitotemporal generators, including the object-selective lateral occipital cortex (Schendan & Kutas, 2002, 2003).

Critically, these components observed in the first 300 ms of processing have been argued to precede access to long-term semantic memory. The N170/P150 does not differentiate between unfamiliar and familiar or famous faces (Bentin & Deouell, 2000; Eimer, 2000) or between familiar objects and unfamiliar pseudo-objects (Schendan et al., 1998). The N250r is reduced for novel faces compared with those that are perceptually familiar (Begleiter, Porjesz, & Wang, 1995; Schweinberger, Pfützte, & Sommer, 1995). It has been linked to the creation of a transient, individuated facial representation as a necessary precursor to recognition and semantic access, and prior experience creating that structural representation seems to facilitate the creation process. The N250r, however, is unaffected by the degree to which a face has any learned associations (Paller, Gonsalves, Grabowecky, Bozic, & Yamada, 2000). The N300 has similarly been linked to the creation of higher-level object representations. Repetition effects on the N300 are reduced if the object in the two presentations differs in viewpoint (Schendan & Kutas, 2003) and the component is larger for unusual views of objects than for canonical ones and for unidentified as opposed to identified objects (Schendan & Kutas, 2002, 2003; Schendan & Lucia, 2010).

Effects of semantic variables are first consistently reported on an ERP component known as the N400. The N400 is a negative-going response seen to all potentially meaningful stimuli, including faces, objects,

scenes, environmental sounds, and auditory and visual words, among others. It begins at approximately 250 to 300 ms and peaks just before 400 ms in healthy young adults. The scalp-recorded N400 seems to arise from a highly distributed network of brain areas, with important sources in the medial and anterior temporal lobes, but also reflects activity in higher-level perceptual areas, the superior temporal lobe, and dorsolateral frontal regions (Halgren et al., 1994, 2002; Lau, Phillips, & Poeppel, 2008; Tse et al., 2007). The widespread nature of these neural sources is consistent with the well-attested functional link between the N400 and semantic memory: the amplitude (but, strikingly, not the timing) of this potential is highly sensitive to a wide range of factors related to the ease of semantic access (for review, see Kutas & Federmeier, 2011).

In the face processing literature, the first effects of delayed repetition—that is, repetition effects that clearly involve long-term memory—present as N400 amplitude reductions (e.g., Joyce & Kutas, 2005). The N400 window also encompasses the first reliable differentiation of unfamiliar faces from those that are familiar and associated with biographical information, such as faces that have been learned along with names (Paller et al., 2000) or famous faces (Bentin & Deouell, 2000), and first reliable effects of semantic association, such as between a face and a name (Huddy, Schweinberger, Jentsch, & Burton, 2003). Similarly, in the literature on object/picture processing, semantic effects of a variety of kinds all consistently manifest within the N400 time window. This includes, but is not limited to, semantic priming effects between pictures and effects from words onto pictures, in which semantically primed pictures elicit smaller N400s, as well as congruity effects for a pictured object in a sentence, in a visual scene, in a picture story, or in a video, wherein congruous objects elicit reduced N400s compared to incongruous or unexpected ones (e.g., Federmeier & Kutas, 2001; Ganis & Kutas, 2003; Ganis, Kutas, & Sereno, 1996; Holcomb & McPherson, 1994; Sitnikova, Kuperberg, & Holcomb, 2003; West & Holcomb, 2002). Additional evidence that conceptual processing of objects occurs during the N400 time window comes from a study using novel, meaningless “squiggles,” which each participant rated for meaningfulness. Only squiggles rated high in meaningfulness showed a repetition effect between 300 and 500 ms after stimulus onset (Voss et al., 2010). Because ratings were idiosyncratic, the same visual forms were assigned to the low and high meaningful categories across participants; thus, the repetition effect could not have been driven by perceptual features, but rather reflects the conceptual representations and associated semantic information evinced by the stimuli for each participant.

In summary, the majority of studies examining the timecourse of processing for nonlinguistic visual

stimuli suggest that it takes about 150 ms for the brain to be able to extract sufficient information to reliably categorize a stimulus at a basic level (as an object, string, or face) and an additional 150 ms to exercise perceptual grouping processes and to create a (transient) structured representation of an individual object or face. Beginning at approximately 300 ms, this representation makes links to associated information in semantic memory.

45.1.2 Visual Word and Number Processing

With the timecourse of semantic access from nonlinguistic stimuli as a basis for comparison, we next examine ERP data regarding the processing timecourse for written words and numeric symbols. As already discussed, early differentiation of word-like stimuli (strings) from nonword-like stimuli appears in the range of 150 ms. Potentials in this timeframe (the N/P150 component; see review by Grainger & Holcomb, 2009) are sensitive to the repetition of single letters and words in a manner that is independent of size but sensitive to both font (Chauncey, Holcomb, & Grainger, 2008) and letter case (Petit, Midgley, Holcomb, & Grainger, 2006). This repetition effect is eliminated by changes in the position of the words by a shift of even a single letter, suggesting that at this point in processing representations are still retinotopic (Dufau, Grainger, & Holcomb, 2008). This aligns well with what is known about the rate of information flow through visual cortex, where single unit recordings in higher visual areas with complex receptive fields (e.g., V4) tend to show activation peaks between 100 and 200 ms after stimulus onset (e.g., Luck, Chelazzi, Hillyard, & Desimone, 1997).

The N/P150 is followed by a negativity peaking at approximately 250 ms, known as the N250 (Holcomb & Grainger, 2006). Like the similarly named potential to faces, the N250 is most robustly characterized in the context of repetition (in this case, primarily masked repetition). The N250 to letter strings, whether familiar (words) or unfamiliar (pseudowords), is larger (more negative) for unrepeated than for repeated items and has a widespread distribution maximal over (left) midline anterior sites. (*Note:* face processing studies often use an average reference, whereas word processing studies generally use an average mastoid reference, making comparisons of waveform morphology and scalp topography difficult; using an average reference, Pickering and Schweinberger reported an N250r to names, which is similar in form to the face N250r but is more prominent over left rather than right posterior electrode sites.) The N250 is sensitive to the degree of orthographic overlap between visually presented primes and targets but is not sensitive to font changes

or positional shifts (Chauncey et al., 2008; Dufau et al., 2008; Grainger, Kiyonaga, & Holcomb, 2006; see also Pickering & Schweinberger, 2003). The N250 response is not domain general, because it is not seen for spoken words or pictures or in cross-modal priming onto visual words (Kiyonaga, Grainger, Midgley, & Holcomb, 2007; Pickering & Schweinberger, 2003). Like the face N250r, the N250 to words is transient. Studies varying the time interval between prime and target have observed the N250 with stimulus-onset asynchronies of 60 and 180 ms, but not 300 ms or longer (Holcomb & Grainger, 2007). Grainger and Holcomb (2009) suggest that the neural activity indexed by the N250 arises from the processing of sublexical orthographic representations important for building whole word representations from letters.

Following the N250 is a positivity, known as the P325, that manifests larger repetition effects for words than for pseudowords. These effects are obtained only when prime and target are identical, whereas strings with partial overlap produce graded responses on the N250. Thus, the P325, unlike components before it, seems to be sensitive to whole item identity and familiarity (see Friedrich, Kotz, Friederici, & Gunter, 2004; King & Kutas, 1998; Pylkkänen, Stringfellow, & Marantz, 2002 for other reports of word-level effects in this time window). This also seems to be a time window during which phonological information is being associated with written words, as Grainger et al. (2006) report pseudohomophone priming effects (e.g., “bacon” primed by “bakon” more than “bafon”) on the P325. Holcomb and Grainger (2006) thus link the P325 to processes at the whole word—but not yet semantic—level. Semantic processing effects are then seen in the form of amplitude changes on the N400, which, as for faces and objects, peaks just before 400 ms.

This timecourse, established primarily using component-based analyses on average data and captured in a language processing architecture known as the Bimodal Interactive Activation Model (see review in Grainger & Holcomb, 2009) has also been validated using a multiple regression approach on single-item ERP data, including responses to words, pseudowords, familiar acronyms, and illegal letter strings collected from a large set of participants (Laszlo & Federmeier, 2014). This regression approach revealed effects of bigram frequency and other orthographic variables (orthographic neighborhood size and frequency) beginning at approximately 130 ms (in the range of the N/P150) and continuing throughout most of the first half-second of processing. Whole word frequency began to have an independent effect on the ERP waveform beginning at approximately 270 ms (i.e., in the late N250/early P325 timewindow). In contrast, semantic variables (number of lexical associates, concreteness,

imageability, number of senses, and noun–verb ambiguity) did not begin to influence the waveform until after 300 ms in the N400 time window.

The impact of a wide range of semantic variables on N400 amplitudes to visual words is well-attested (see Kutas & Federmeier, 2011, for a review). In particular, the N400 is sensitive to immediate and long-term repetitions (e.g., Laszlo & Federmeier, 2007) and to semantic priming of all types: association-based, graded by association strength (e.g., Kandhadai & Federmeier, 2010), and category-based, graded by typicality (e.g., Federmeier, Kutas, & Schul, 2010). The N400 is also sensitive to the semantic fit between a word and its phrasal, sentential, or discourse context, based on the structure of semantic memory (e.g., Federmeier & Kutas, 1999b), event knowledge (Metusalem et al., 2012), and world knowledge (Hagoort, Hald, Bastiaansen, & Petersson, 2004). Repetition, priming, and contextual fit all decrease N400 amplitude while leaving latency relatively unchanged. As Federmeier and Laszlo (2009) reviewed, the N400 has all of the properties one would expect of a neural marker of access to semantic memory (see also Lau et al., 2008).

Despite readers having relatively less experience with numerals than with other visual forms, the extraction of meaning from numbers appears to proceed with little to no differences compared with that from faces, objects, and visual words. For example, when alphanumeric symbols are rendered predictable by contextual cues (e.g., “20” when preceded by the simple arithmetical formula of “ 5×4 ”), correct answers elicit smaller (facilitated) N400s relative to incorrect answers (Niedeggen & Rösler, 1999; Niedeggen, Rösler, & Jost, 1999).

Analogous findings across the face, object, visual word, and number processing literatures thus reveal a reliable timecourse of processes leading to the access of semantic information, despite the fact that these stimulus types are associated with different degrees of expertise, engender different processing challenges, and have been linked to partially distinct neural pathways. Processing of these stimuli all culminate in a similar response during the same time window: the N400. The consistency in when and how semantic information comes to be linked with a perceptual stimulus becomes even more striking when the processing timecourse for these meaningful visual stimuli is compared with that for auditory words and other meaningful sounds.

45.1.3 Auditory Word Processing

Whereas “the time locking of neural activity in the visual pathway is poor, its timing is sluggish, and its ability to follow fast transitions is limited”

(Pratt, 2012), the auditory system is fast and exquisitely sensitive to timing. Nevertheless, semantic access seems to proceed with a remarkably similar timecourse in the two modalities.

One of the earliest language-related, albeit not language-specific, effects is an enhancement of the amplitude of the auditory N100 component, which peaks at approximately 100 ms and is part of the normal evoked response to acoustic onsets, offsets, and deviations. Although not acoustic onsets, word onsets in continuous speech elicit larger N100s than matched, non-onset sounds (Sanders & Neville, 2003). This effect seems to reflect increased temporally directed selective attention to less predictable information in an auditory stream (Astheimer & Sanders, 2011).

Paralleling the timecourse of orthographic processing for written words, phonological—but not yet semantic—processing of spoken words has been associated with ERP amplitude modulations between 250 and 300 ms. The Phonological Mapping Negativity (PMN) has been attributed to the detection of a mismatch between expected and realized phonological information, such as when an incoming phoneme violates a context-based or task-induced auditory/phonological expectation (e.g., Connolly & Phillips, 1994; Desroches, Newman, & Joanisse, 2009; Newman & Connolly, 2009). For example, in a task wherein participants were given an input to transform (e.g., “talk” or “hat”) and a target transformation of the initial phoneme (e.g., “m”), PMNs were larger when the onset phoneme of the probe stimulus mismatched the resulting expectation (e.g., for “melk” or “mat”). Importantly, PMN effects are obtained for both words and pseudowords (e.g., Newman & Connolly, 2009). The PMN has therefore been proposed to reflect phonological mapping processes that precede semantic access.

Effects associated with word level processing have been reported beginning at approximately 300 ms. Using a cross-modal word fragment priming task, Friedrich and colleagues (Friedrich, Kotz, Friederici, & Alter, 2004; Friedrich, Kotz, Friederici, & Gunter, 2004; Friedrich, Schild, & Röder, 2009) found larger positivities peaking at approximately 350 ms (P350) over left frontal electrode sites for words that mismatched (versus matched) the visual fragment prime. Partially mismatching targets elicited an intermediate response. The authors interpret their results as reflecting activation of abstract word forms. Effects of word repetition and word frequency have also been reported in this time window in studies using MEG (the M350; Pylkkänen & Marantz, 2003) and have been linked to sources in the left superior temporal lobe (Pylkkänen et al., 2002).

P/M350 modulations are coincident in time with (but are of opposite polarity from) effects of repetition, frequency, and phonological priming on the N400.

The N400 time window is also when effects of semantic manipulations of many kinds (semantic priming, context effects, etc.) are first observed for auditory words (see review in Kutas & Federmeier, 2011). As with the visual modality, the N400 elicited by auditory stimuli is not specific to linguistically relevant inputs (syllables or words), because meaningful nonlinguistic environmental sounds also elicit N400s and N400 effects (Van Petten & Rheinfelder, 1995).

45.1.4 Summary

Comparisons of N400 responses to spoken and written words or for linguistic and nonlinguistic stimuli (e.g., pictures and visual words; auditory words and environmental sounds) assessed for the same stimuli and/or under the same task conditions (e.g., Federmeier & Kutas, 1999b, 2001; Federmeier, McLennan, De Ochoa, & Kutas, 2002; Ganis et al., 1996; Holcomb & Neville, 1990; Van Petten & Rheinfelder, 1995) reveal striking similarities: similar peak latencies, similar response characteristics (amplitude reductions—but not latency shifts—to repeated, primed, or contextually more predictable items), and similar patterns of sensitivity to many factors that are taken to affect semantic access. Remarkably, then, different neural pathways with different functional and anatomical constraints ultimately culminate in a similar brain response, with consistent and stable timing. Federmeier and Laszlo (2009) argued that the collective N400 literature highlights the importance of time as a mechanism for linking incoming stimuli (of all types and in all modalities) to distributed information in long-term semantic memory. Although there are brain areas that are likely to be common across specific instances of the N400, neither the neural process nor the cognitive function the N400 indexes is localized. Instead, semantic access arises from a dynamically configured neural circuit, for which time and timing are critical and which implements a shared function, even in the absence of a spatial anchor. The dynamic nature of the mechanism affords it the necessary speed and flexibility to accrue information from stimuli over time and thereby construct complex messages, which, in turn, shape the processing of subsequent meaningful stimuli.

45.2 PART 2: CONTEXT AND THE TIMECOURSE OF SEMANTIC ACCESS

Making sense clearly requires a stable (if transient) linking between perceived sensory input and information in long-term memory (i.e., semantic access), and, as we have described, the timing of semantic access so

defined is relatively reliable, occurring between approximately 300 and 500 ms, whether words are encountered in isolation or embedded in a sentence and/or a larger discourse. However, this reliability belies the fact that the availability of context information allows word-related information to be activated—via prediction—before the word is actually encountered, and, to the extent that it is, processing (identification, access, integration) of that word's "word form" and the perceptual and semantic information linked to it are eased. The past decade of ERP research attests to the pervasive presence of predictive processing with graded facilitation at multiple levels (semantic, morphosyntactic, phonological, and orthographic) during natural language comprehension, at least in young adult readers and listeners (DeLong, Urbach, & Kutas, 2005; Federmeier & Kutas, 1999b; Van Berkum, Brown, Zwitterlood, Kooijman, & Hagoort, 2005; Wicha, Moreno, & Kutas, 2004).

As previously noted, N400 amplitude modulations provide a sensitive measure of the state of activation of the probing item in semantic memory and of the various factors that influence that state. As such, N400 data have proven especially useful in determining the extent to which there are predictive processes at play during routine language comprehension. Through clever designs, several researchers have found evidence of graded contextually driven facilitation of semantic, morphosyntactic, phonological, and orthographic features of likely upcoming words or pictures (DeLong et al., 2005; Federmeier & Kutas, 1999b; Laszlo & Federmeier, 2009; Van Berkum et al., 2005; Wicha, Bates, Moreno, & Kutas, 2003).

Federmeier and Kutas (1999b), for example, examined the ERPs to sentence final words as young adults read two sentences for comprehension; final words were moderately to highly expected members of a particular category, unexpected members of the same category, or unexpected members of a different category. N400 amplitudes were reduced for the unexpected endings that shared features with the expected endings relative to those that did not. The fact that this pattern of N400 effects came primarily from the strongly (versus weakly) constraining sentence frames, wherein the unexpected categorically related items were highly implausible if not downright anomalous, evidenced that processing of the accruing context preactivated semantic features of likely upcoming words and related ones. The interpretation of this effect as demonstrating that prediction plays an important role in normal language comprehension was bolstered by the fact that the pattern replicated for natural speech for young adult comprehenders (Federmeier et al., 2002). However, this study also showed that prediction is not the only mechanism for context-based facilitation. Although healthy older adults showed clear effects of contextual congruency on the N400, they did not show

the pattern indicative of predictive processing. The tendency for (most) older adults to rely more heavily on stimulus-driven rather than predictive processing comprehension mechanisms has been seen in a number of studies (see review by Wlotko, Lee, & Federmeier, 2010).

The availability of different mechanisms by which context can shape language comprehension is also attested by studies of hemispheric differences. For example, a (young adult) visual half-field version of the Federmeier and Kutas study, with the sentence final words randomly lateralized to the left or right visual field (LVF/RVF), revealed asymmetric patterns of context use during online sentence processing (Federmeier & Kutas, 1999a). The left hemisphere (based on RVF initiated processing) seems to use context to preactivate information and compare the actual input with the prediction, whereas the right hemisphere (based on LVF initiated processing) seems to adopt a more passive (what we have called "integrative") strategy that does not involve prediction (for a review, see Federmeier, 2007). Notably, the local scale timing of semantic effects retains its typical stable form in the two hemispheres, with context effects manifesting between about 300 and 500 ms, in the form of N400 amplitude reductions. This further emphasizes our point that semantic access is not a unitary or localized process, but rather is a temporally constrained one. However, at the larger scale, the effective timecourse of availability of information is different in the two hemispheres, creating an emergent mechanism by which the brain can both benefit from the use of context information to constrain processing via predictions while still maintaining a more veridical representation of the actual bottom-up stimulus stream to allow for recovery when predictions are incomplete or misleading.

The Federmeier and Kutas studies provide evidence that semantic feature information, essential for semantic categorization, can be predicted (i.e., activated in advance) during sentence comprehension (but see Van Petten & Luka, 2012, for a proposed distinction between expectation of semantic features and prediction of word forms). A growing body of evidence further attests to the ability of the language comprehension system to predict a wide range of information, including morpho-syntactic, phonological, and orthographic features of upcoming words. Investigations of gender-marked languages, such as Spanish (Wicha, Bates, et al., 2003; Wicha, Moreno, & Kutas, 2003; Wicha et al., 2004) and Dutch (Otten, Nieuwland, & Van Berkum, 2007; Van Berkum et al., 2005), have reported ERP differences to articles (Wicha, Moreno, et al., 2003; Wicha et al., 2004) or adjectives (Otten et al., 2007) depending on whether they agree in gender with the predicted (but not yet presented) noun that they modify. DeLong et al. (2005) found similar results by exploiting the A/AN alternation in English, which varies with the onset phonology of the upcoming

word (beginning with a consonant versus vowel sound, respectively); N400 amplitudes to the article closely tracked the predictability of the not yet presented noun.

Clearly, then, sentence contextual information can lead to expectancies for specific words. Moreover, Laszlo and Federmeier (2009) demonstrated that information brought online by prediction is specific enough to affect processing based on orthography: nonsensical orthographic neighbors of expected sentence endings had smaller N400s than nonsensical non-neighbors, regardless of whether the item was a word, a meaningless pseudoword, or an orthographically illegal string of letters. Critically, this means that prediction affects the availability of specific orthographic features of likely upcoming items and begins to influence the bottom-up processing of inputs before what might be thought of as “word recognition,” manifesting through clear downstream consequences on N400 amplitude and reflecting the mapping of the stimulus form to its meaning.

As these N400 findings demonstrate, processing of contextual information (or experience or task goals) can allow predictions to be made about specific stimulus features; consequently, any perceptual information accrued about incoming stimuli—available before the stimulus can be linked with semantic memory—should provide early indicators about what the stimulus is likely to be. In these cases, then, relatively early effects of predictive processes are evident in modulations of sensory ERP components that precede the N400. For example, a number of ERP investigations have also observed semantic context-driven modulation of the amplitude of a frontally maximal sensory-evoked P2 potential (180–250 ms) that has been linked to higher-order visual processing, including perceptual analysis and the allocation of visuo-spatial attention (e.g., Luck & Hillyard, 1994). Words in highly constraining sentence contexts have been found to elicit enhanced P2s, presumably because contextually driven expectations for a particular form affords the focusing of attentional resources. Federmeier and colleagues have attributed this P2 effect to predictive mechanisms in the left hemisphere, based on findings of selective enhancement of P2 amplitudes to words in highly (as opposed to weakly) constraining contexts when those words were presented to the RVF/LH but not when presented to the LVF/RH (Federmeier & Kutas, 2002; Federmeier, Mai, & Kutas, 2005; Huang, Lee, & Federmeier, 2010; Kandhadai & Federmeier, 2010; Wlotko & Federmeier, 2007).

Predictive processing mechanisms are also reflected on even earlier components under the right conditions. For example, when the sentence final words in the Federmeier and Kutas experiments were replaced by line drawings, either unfamiliar or rendered familiar via pre-exposure, the N400 was qualitatively similar in

its sensitivity to both contextual fit and category-based semantic feature overlap with the predicted item (Federmeier & Kutas, 2001). Critically, the results also revealed that context also interacted with perceptual predictability, affecting both perceptual and semantic processing. When perceptual features of expected pictures were predictable based on pre-exposure, as manifest in smaller early sensory components (anterior N1, posterior P1, and P2) linked to visual processing and the allocation of visuospatial attention, contextual constraint did not provide any additional facilitation (i.e., no effect on visual components or N400 amplitude). By contrast, when pictures were unfamiliar and thus less perceptually predictable, more constraining contexts allowed better predictions for perceptual features of expected pictures, easing perceptual processing (as seen on the anterior N1 and P2) and creating downstream benefits for semantic access (N400).

Evidence for the prediction of visual word form properties has come from studies of the so-called early Left Anterior Negativity (eLAN), originally characterized as a response to word category violations (Friederici & Kotz, 2003). Having noticed that eLANs were observed almost exclusively in sentences wherein a specific word category was highly predictable, Lau, Stroud, Plesch, and Phillips (2006) proposed an alternative account on which it is the violation of expectations for word forms derived from syntactic regularities, rather than the word category violation as such, that is critical for eLAN elicitation. Dikker and colleagues likewise argued that the eLAN or the early negativity (EN, renamed to acknowledge the more broad bilateral distribution of this class of negativities across the scalp) is a response to the presence of unexpected sensory information in the context of a predicted word and/or word category. Dikker, Rabagliati, and Pykkänen (2009) tested their hypothesis by comparing word category violations that contained an unexpected morpheme or were missing an expected morpheme. They observed an M100 (the presumed magnetic counterpart of the eLAN/EN) to the unexpected morpheme but not to the absence of an expected one (e.g., *The discovery was REPORT). Definitive interpretation of the latter finding, however, is confounded by the word category ambiguity of the critical word—it could be experienced as a noun (word category violation) or a verb (agreement violation). In a follow-up study, Dikker, Rabagliati, Farmer, and Pykkänen (2010) further tested their hypothesis by comparing responses to two types of nouns following an adverb that led to an expectation for an upcoming verb instead. Members of one class of nouns had the phonotactics of typical nouns (*The beautifully SOFA), whereas those of the other had phonotactics equally consistent with nouns or verbs (*The

beautifully WINDOW). An EN, with a left occipital source, was elicited only by the unexpected noun that clearly violated the phonotactics of the expected category (verb). Whether or not these negativities are all the same, it does appear that the language system is sensitive to expectations based on syntactic constraints and violations thereof, which are seen in ERP modulations within the first 200 ms after word onset and clearly can have downstream repercussions for semantic processing.

The language comprehension system thus takes advantage of context information to make predictions about features of likely upcoming stimuli, and, in turn, those predictions shape attention and affect how and how easily a stimulus is perceived and then linked to aspects of meaning in the course of interpretation. Perhaps surprisingly, context-based facilitation does not seem to speed the timecourse with which contact is established between perception and long-term semantic memory. However, at least in some cases, indications that an incoming stimulus matches or mismatches predictions at a perceptual level can provide early cues about whether that stimulus is likely to have particular semantic features as well—and the brain does a remarkable job of making use of this information in the service of preparing rapid responses (e.g., to initiate/inhibit a saccade or other motor response). Thus, although context may not actually speed semantic access as such, it can shift the apparent timecourse of semantic processing, as is revealed in brain responses and unfolds in behavior.

45.3 CONCLUSIONS

Information of all types dynamically accrues via context and experience, allowing comprehenders to construct meaning from past and present inputs and to anticipate future ones as a function of their likelihood in the ongoing context. The process of semantic access—and an extended process it is—takes time because it requires the brain to establish a stable and reliable, yet ultimately idiosyncratic, neural linking between the perceptual form constructed from an incoming stimulus and distributed, stored representations of relevant prior experience. Moreover, meaningful stimuli typically accrue rapidly, and the brain must then collate and integrate the information it collects from, for example, a continuous auditory signal or a sequence of saccades over text or a scene. Constructing meaning is thus arguably one of the most challenging tasks the brain must perform. However, it is also what the brain evolved to do, and to do quickly and well enough, even under less than ideal circumstances. Semantic constraints may not speed aspects of brain processing (e.g., N400 latency) as they do offline reaction times, but they can (re)direct

attentional focus and shape current activation states to facilitate sensory and mapping processes for the future—allowing the brain to effectively bypass its own temporal constraints.

46.1 INTRODUCTION

Left ventrolateral prefrontal cortex (VLPFC) has attracted much attention in cognitive neuroscience, not only for its involvement in numerous cognitive operations but also for its historical significance as one of the first brain regions to be formally linked to a specific function. In the mid 19th century, Pierre Paul Broca called this area (later to be called “Broca’s area”) the locus for production of articulate language and the seat of motor speech (Broca, 1861, 1865).

Although modern theories of language production (i.e., the dual stream model) have revived the notion that this area might be involved in motor production by proposing its involvement in storing articulatory representations, phonetic encoding, and retrieving or generating the articulatory codes (Hickok & Poeppel, 2004, 2007), much more has come to light about VLPFC in the past few decades. These new findings do not negate the possible role of this region in motor production, but rather call for an expansion of its role in the processing of language and perhaps even in nonlinguistic tasks. For instance, VLPFC has been implicated in semantic processing (Buckner et al., 1995; Demb et al., 1995; Démonet et al., 1992; Fiez, 1997; Kapur et al., 1994; Martin, Haxby, Lalonde, Wiggs, & Ungerleider, 1995; McCarthy, Blamire, Rothman, Gruetter, & Shulman, 1993; Petersen, Fox, Snyder, & Raichle, 1990; Raichle et al., 1994), phonological/phonetic processing, especially when phonological segmentation and sequencing is required (Démonet et al., 1992; Démonet, Price, Wise, & Frackowiak, 1994; Fiez et al., 1995; Newman, Twieg, & Carpenter, 2001; Paulesu, Frith, & Frackowiak, 1993;

Price et al., 1994; Shaywitz et al., 1995; Zatorre, Evans, Meyer, & Gjedde, 1992), phoneme-to-grapheme conversational processes (Fiebach, Friederici, Müller, & Von Cramon, 2002), syntactic processing (Ben-Shachar, Hendler, Kahn, Ben-Bashat, & Grodzinsky, 2003; Embick, Marantz, Miyashita, O’Neil, & Sakai, 2000; Grodzinsky, 2000), and domain-general processes such as temporal sequencing regardless of the specific stimulus type (Gelfand & Bookheimer, 2003). Also, the term “working memory” appears frequently in the VLPFC literature (Awh et al., 1996; Paulesu et al., 1993).

Moreover, within each domain there is more than one view. For example, even among researchers who agree on VLPFC’s involvement in semantic processing, there has been disagreement about whether it is involved in semantic retrieval (Demb et al., 1995; Démonet et al., 1992; Martin et al., 1995), conflict resolution (Thompson-Schill, D’Esposito, Aguirre, & Farah, 1997), or controlled semantic processing (Wagner, Paré-Blagoev, Clark, & Poldrack, 2001). Similarly, there have been debates among proponents of VLPFC’s role in syntactic processing, some of whom had a strong hypothesis for the region’s involvement in a specific syntactic operation (Grodzinsky, 2000; Musso et al., 2003) whereas others argued for multiple syntactic functions being mediated by the region (Friederici, Meyer, & von Cramon, 2000). The discussion of all these functions is obviously beyond the scope of this chapter. Therefore, we focus on the role of VLPFC in semantic processing, especially in the context of language. In most of what we discuss, the nature of the tasks addresses semantic-lexical mapping; however,

some of the concepts could apply to semantic processing without lexical retrieval.

Because it is our goal to discuss not only single-word but also sentence-level processing, it is inevitable to discuss syntactic theories of VLPFC as well. We review evidence from language comprehension and production studies and, whenever possible, present converging evidence from multiple sources (neuroimaging studies, patient studies, and transcranial magnetic stimulation (TMS) studies) to build a complete picture of the circumstances that lead to VLPFC recruitment and operations that are crucially dependent on this region. The chapter begins with an overview of the anatomy of VLPFC, followed by two main sections, discussing the debates on the region's role in (semantic) the processing of single words and (semantic–syntactic) the processing of sentences. We close by offering a unifying account that best summarizes the body of evidence in the earlier sections, with some future questions to consider.

The terms Broca's area, left inferior frontal gyrus (LIFG), left inferior prefrontal cortex (LIPC), and VLPFC have sometimes been used interchangeably. It is generally accepted that Brodmann area (BA) 44 and BA 45 (corresponding roughly to pars opercularis and pars triangularis) are the cytoarchitectonic correlates of Broca's region (Aboitiz & García, 1997; Uylings, Malofeeva, Bogolepova, Amunts, & Zilles, 1999; Figure 46.1),

FIGURE 46.1 Anatomy of the VLPFC. Figure adapted from Petrides and Pandya (2002). Reproduced with permission from Michael Petrides and Wiley-Blackwell publishing.

although there are finer subdivisions in these areas as well, with the dorsal part of BA45 (BA45B in Figure 46.1) resembling BA44 more closely than its ventral part (BA45A in Figure 46.1; Amunts et al., 2004). VLPFC also includes BA47 (pars orbitalis), the ventral cortical area inferior and anterior to the horizontal ramus of the lateral fissure. Most of the findings in this chapter concern BA44 and/or BA45.

46.2 VLPFC IN SINGLE-WORD PROCESSING

Although classic psycholinguistic studies primarily conceived of VLPFC as involved in either motor processing (following Broca's suggestion) or syntactic processing, memory researchers had an altogether different idea. In PET and fMRI studies, VLPFC activation has been consistently found in a variety of tasks requiring semantic processing. Among these are living/nonliving classification (Demb et al., 1995; Gabrieli et al., 1996; Kapur et al., 1994), feature-based similarity judgment (Thompson-Schill et al., 1997; Whitney, Kirk, O'Sullivan, Ralph, & Jefferies, 2011), global similarity judgment (Thompson-Schill et al., 1997; Wagner et al., 2001), and category-based verbal fluency (Basho, Palmer, Rubio, Wulfeck, & Müller, 2007; Birn et al., 2010; Gurd et al., 2002; Paulesu et al., 1997). VLPFC activation in a wide variety of tasks requiring semantic access points strongly to its role in some aspect of semantic processing. Initially, this was hypothesized to be semantic retrieval (Demb et al., 1995; Martin et al., 1995). Starting in the late 1990s, a series of experiments pointed out the region's particular sensitivity to the *control demands* of semantic retrieval as opposed to retrieval *per se*.

The first in this series was the study by Thompson-Schill et al. (1997) in which, through three experiments, the authors showed that activation of VLPFC was much more prominent in conditions with high-selection demands. Two of these experiments concerned single-word comprehension. In the first task, subjects had to judge whether a word matched a picture either in its identity (e.g., the word CAR matching the picture of a car; low selection) or in a feature belonging to it (e.g., the word EXPENSIVE matching the picture of a car; high selection). In the second task, subjects had to judge the similarity of a probe word to a number of alternatives. In the low-selection condition, judgment was to be based on global similarity (e.g., TICK–FLEA/WELL), whereas in the high-selection condition, selection based on a specific feature—and ignoring other attributes—was necessary for making the correct choice (e.g., TOOTH–BONE/TONGUE). The third experiment was a production task. Subjects had to generate verbs in

response to nouns that induced either low competition (e.g., SCISSORS, which strongly evokes the verb CUT) or high competition (e.g., CAT, which could be associated with a number of verbs, like MEOW, PLAY, EAT, etc.) between response alternatives. In the same group of subjects, in all three tasks an overlapping area of VLPFC was found to respond more to conditions that placed higher demands on selection. Wagner et al. (2001) extended these findings by showing that it was possible to manipulate control demands even within the global similarity judgment task. Increased VLPFC activation was found when global similarity was probed for low-association items (e.g., CANDLE-HALO) compared with high-association items (e.g., CANDLE-FLAME).

Although the pattern of activation in these neuroimaging studies was suggestive of a role for VLPFC in semantic control, it remained to be seen if such control depended crucially on this prefrontal region. It was Thompson-Schill et al. (1998) who showed that patients with lesions encompassing VLPFC had trouble with the verb generation task described, but only when the noun was not strongly associated with a unique verb. They further showed that the percentage of damage to BA 44 (but not overall lesion volume or damage to dorsolateral prefrontal regions) was a significant predictor of errors in the trials with high-selection demand.

These early studies convincingly demonstrated that the picture was incompatible with VLPFC's role in pure semantic retrieval but pointed to a role in enforcing top-down control when stimulus-response associations were weak (Miller & Cohen, 2001; Norman & Shallice, 1986). Following Desimone and Duncan (1995), it was proposed that when bottom-up association is not strong enough to pick a clear "winner" among the alternatives, competition must be resolved by top-down control to bias selection toward a single representation, and VLPFC was a likely candidate for implementing this bias (Kan & Thompson-Schill, 2004; Miller & Cohen, 2001; Wagner et al., 2001). Since that time, this idea has been tested using various tasks and paradigms; some of which that are related to word processing are reviewed later.

46.2.1 Deciphering Words with Multiple Meanings

Every tongue contains words that carry more than one meaning, and efficient processing of language requires that speakers and listeners would be able to handle this ambiguity by flexibly retrieving the relevant meaning and suppressing the irrelevant meaning in different contexts. As such, these types of words provide a good opportunity for investigating which brain region is involved in biasing selection. Bedny, McGill, and Thompson-Schill (2008) had participants

judge the relatedness of word pairs, with some subsequent pairs containing ambiguous words (e.g., SUMMER-FAN → CEILING-FAN [same meaning]; ADMIRER-FAN → CEILING-FAN [different meaning]). Whereas posterior temporal cortex proved to be sensitive to semantic overlap regardless of ambiguity, VLPFC activity depended on the amount of semantic ambiguity.

This finding is mirrored by VLPFC patients' difficulty in efficiently selecting the appropriate meaning of ambiguous words. Bedny, Hulbert, and Thompson-Schill (2007) chose three groups of participants, patients with VLPFC damage, patients with frontal damage sparing VLPFC, and matched controls, and asked them to determine the lexicality of the third word in a triplet of words, with the second word being either a homonym or a polysemous word. Both homonyms and polysemous words have more than one meaning, although these meanings are unrelated in the case of homonyms (e.g., ceiling FAN, vs. football FAN) and related in the case of polysemous words (e.g., live CHICKEN, vs. food CHICKEN). In the triplet, the first and the third words were related to either the same meaning of the second word (e.g., BACK, PACK, BAG; consistent condition) or a different meaning (WOLF, PACK, BAG; inconsistent condition). Unlike controls and patients with non-VLPFC frontal lobe lesions, VLPFC patients' performance did not show a reliable difference between the consistent and inconsistent conditions. These patients did, however, show priming in the consistent condition compared with an unrelated baseline. This finding suggests that, in all likelihood, both meanings of the words were activated, and the activation of the context-relevant meaning benefited performance. However, the context-irrelevant meaning was not properly suppressed. This is consistent with the distinction we made earlier between semantic retrieval versus biasing competition; only the latter of which seems to depend critically on VLPFC.

Event-related potentials (ERP) findings are consistent with the results of Bedny et al. (2007). Swaab, Brown, and Hagoort (1998) presented participants with sentences that primed either the dominant or the subordinate meaning of a homonym, or was unrelated to the target (e.g., target word: RIVER; consistent prime: "The man planted a tree on the bank"; inconsistent prime: "The man made a phone call to the bank," and unrelated prime: "The boy petted the dog on the head"). The target word (RIVER) was always related to the subordinate meaning of the homonym (BANK) and followed the sentence with either a short (100 ms) or a long (1,250 ms) ISI. N400 (as a measure of violation of semantic expectancy) was measured in response to the target word. The logic was that proper priming of the meaning should decrease the amplitude of N400 in the

consistent, but not in the inconsistent, condition. Healthy controls showed this pattern. Broca's patients, the majority of whom had prefrontal lesions, however, showed evidence of reduced N400 under *both* conditions for the short ISI, meaning that context had not successfully abolished the irrelevant meaning. In the longer ISI, some of the patients no longer exhibited this abnormal pattern, implying that given enough processing time, suppression of the irrelevant meaning was slowly achieved, perhaps through a complementary/compensatory network. More recently, [Vuong and Martin \(2011\)](#) supported this position by showing that a patient with damage that included VLPFC damage was considerably slower than two patients with non-VLPFC lesions in using context to bias toward the subordinate meaning of an ambiguous word. However, when tested using balanced ambiguous words, this patient, similar to the other two patients and healthy controls, was unimpaired in using context to resolve ambiguity.

46.2.2 Verbal Fluency

Verbal fluency tasks are among the oldest neuropsychological tasks for assessing the integrity of memory and language. There are two categories of verbal fluency tasks. In the *semantic* verbal fluency task a semantic cue is provided, based on which the individual must search for as many words as possible in a short duration of time (e.g., "Name all the animals you can."). In the *phonological* variant, the cue is phonological (e.g., "Name all the words you can that start with B."). Given the very different nature of the search in these two tasks, it is not surprising that semantic and phonological verbal fluency tasks rely, at least in part, on different cognitive architectures. For example, [Martin, Wiggs, Lalonde, and Mack \(1994\)](#) found that the semantic verbal fluency task is subject to interference from object recognition, whereas phonological verbal fluency task performance is sensitive to motor sequence tasks. Likewise, each variant of the task induces preferential activation in a certain frontal region ([Birn et al., 2010](#)). However, despite their unique elements, both tasks have been shown to activate VLPFC, although there is disagreement on whether they activate the same or different subpopulation of neurons in this region ([Frith, Friston, Liddle, & Frackowiak, 1991](#); [Mummery, Patterson, Hodges, & Wise, 1996](#); [Paulesu et al., 1997](#)).

The verbal fluency task provides a unique opportunity to study two cognitive operations within the verbal fluency task. At any given point during this task it is possible to continue retrieving names from the same subcategory as the previous item or to switch to a new subcategory. For example, when prompted to name as many animals as you can, you may cue yourself by starting with the subcategory of farm animals. The

ability to retrieve many names in one subcategory is called *Clustering*. Even when you have good clustering abilities, at some point you will run out of names of farm animals, and to maximize your output you must switch to a new subcategory, for example, wild animal. The ability to switch from one subcategory to another is called *Switching*. It has been proposed that clustering reflects the intactness of semantic knowledge, whereas switching reflects the biasing ability. In tandem with this proposition, damage to the temporal cortex typically causes clustering deficits and damage to the left prefrontal cortex is associated with switching deficits ([Chertkow & Bub, 1990](#); [Troyer, Moscovitch, & Winocur, 1997](#)). In two experiments, [Hirshorn and Thompson-Schill \(2006\)](#) showed that it was the switching aspects of the task that elicited VLPFC activation. In Experiment 1, subjects were told either to switch on every trial or to freely produce words given a category cue. In Experiment 2, they were given instructions for free category-based name generation while pushing a button but were asked to push a different button whenever they switched to a new category. In both cases, VLPFC activation was linked directly to switching.

On the lesion side, lesions in the frontal cortex have long been known to cause impairments in performing verbal fluency tasks ([Baldo & Shimamura, 1998](#); [Janowsky, Shimamura, Kritchevsky, & Squire, 1989](#); [Owen, Downes, Sahakian, Polkey, & Robbins, 1990](#); [Perret, 1974](#); [Robinson, Shallice, Bozzali, & Cipolotti, 2012](#); [Stuss et al., 1998](#); [Troyer, Moscovitch, Winocur, Alexander, & Stuss, 1998](#)), and some have specifically pinned the effect down to the VLPFC ([Novick, Kan, Trueswell, & Thompson-Schill, 2009](#)).

46.2.3 Picture Naming and the Need for Control

This discussion raises the question of where the boundary is for the need for top-down control. Does naming pictures, for example, require top-down control? This question is particularly important because picture naming is the single most important neuropsychological test in localizing deficits in lexical retrieval. Furthermore, in many cases a patient's response pattern in picture naming allows for predictions to be made about their other production abilities, such as word repetition ([Nozari & Dell, 2013](#); [Nozari, Kittredge, Dell, & Schwartz, 2010](#)). But is picture naming measuring lexical-semantic retrieval or controlled selection? The reports are mixed. Although some have found activation of VLPFC in picture naming ([Murtha, Chertkow, Beauregard, Dixon, & Evans, 1996](#); [Murtha, Chertkow, Beauregard, & Evans, 1999](#)), some have not ([Etard et al., 2000](#)). We briefly discuss two factors, name agreement and context, that speak directly to the

control aspect of picture naming, and help reconcile these seemingly disparate findings. [Novick et al. \(2009; Experiment 2\)](#) showed that a patient with VLPFC lesion was significantly impaired in naming pictures with low name agreement (e.g., COUCH/SOFA) compared with controls and patients with frontal lesions sparing VLPFC. However, the same patient showed no marked deficits in naming pictures with high name agreement. Given what has been discussed earlier in this chapter, the explanation for this finding should be clear. When bottom-up cues are not strong enough to unequivocally select a unique representation, VLPFC is needed to implement top-down control and help with selection.

But even when the picture itself is associated with a unique label, the context in which the name is to be retrieved can modulate retrieval demands. When pictures are named in the context of same-category items (e.g., DOG, HORSE, LION), they are named more slowly in the neurologically intact adults ([Belke, Meyer, & Damian, 2005; Damian, Vigliocco, & Levelt, 2001; Kroll & Stewart, 1994](#)) and with more errors in aphasic patients with left frontal lesions ([McCarthy & Kartsounis, 2000; Schnur, Schwartz, Brecher, & Hodgson, 2006](#)). These tasks control for pure lexical retrieval because picture naming in a semantically heterogeneous context (e.g., DOG, TRUCK, APPLE) is also assessed and acts as a baseline for comparison. While the exact mechanisms of this *semantic blocking effect* are disputed ([Howard, Nickels, Coltheart, & Cole-Virtue, 2006; Oppenheim, Dell, & Schwartz, 2010](#)), there is consensus that competition is higher in the semantically homogenous context, and both neuroimaging and lesion studies link the effect to VLPFC ([Schnur et al., 2009](#)). Incidentally, the [Murtha et al. \(1996, 1999\)](#) picture naming study administered only a homogenous block of animals to subjects to name, whereas [Etard et al. \(2000\)](#) used a heterogeneous block. Given the well-established semantic blocking effect, it is not surprising that picture naming designs that strongly tap into the effect activate VLPFC. In summary, picture naming seems to require top-down support from VLPFC primarily under conditions of high competition.

46.2.4 TMS Studies

So far, we have shown that neuroimaging and patient studies converge on the biasing role of VLPFC in semantic/lexical retrieval. We end this section by providing a brief review of the TMS studies related to this issue. [Devlin, Matthews, and Rushworth \(2003; Experiment 2\)](#) presented subjects with single words and asked them to make a natural/man-made judgment for each word. In a control perceptual task, subjects judged whether the horizontal line above the word was shorter than the

word. They showed that TMS to the anterior portion of VLPFC interfered with the semantic, but not the perceptual, decision. This finding, along with higher activation of anterior VLPFC in making semantic versus phonological judgments ([Devlin et al., 2003; Experiment 1](#)), was taken as evidence for this region's contribution to making semantic judgments. [Gough, Nobre, and Devlin \(2005\)](#) provided additional support for this finding by showing that TMS over the anterior VLPFC caused a selective impairment in a semantic (synonym judgment) as opposed to a phonological (homophone judgment) task, whereas the opposite pattern was found when posterior VLPFC was stimulated (see also [Wig, Grafton, Demos, & Kelley, 2005](#)) for a demonstration of eliminatory priming as a function of encoding under TMS).

The direct involvement of VLPFC in biasing semantic selection was also demonstrated in a number of recent TMS studies. [Hindy, Hamilton, Houghtling, Coslett, and Thompson-Schill \(2009\)](#) used TMS and computer-mouse tracking to examine the role of VLPFC in semantic processing. In each trial, two words appeared on the screen, one of which was better matched to a probe word that appeared with some delay, and participants had to move the mouse toward the correct response. Either the probe was strongly associated with the response (e.g., KING-HOOK; probe = QUEEN) or this association was weak (e.g., CARDS-HOOK; probe = QUEEN). Repetitive TMS was delivered soon after the onset of the first two words and before the appearance of the probe item. The results showed greater deviation of mouse movement trajectories toward the incorrect response when the association was weak, compatible with the hypothesized role of VLPFC in biasing competition toward the correct meaning (however, the effect was not found when the congruency between the stimuli and the probe item was manipulated). Importantly, when the delay between the response and target words was removed (and TMS was delivered afterwards), the effect disappeared. [Hindy et al. \(2009\)](#) suggested that the disappearance of the effect with this timing manipulation implies that the contextually appropriate association is formed, and conflict is already resolved before receiving TMS. In a conceptually similar study, [Whitney et al. \(2011\)](#) used a design similar to that of [Wagner et al. \(2001\)](#), in which subjects had to select a word that had either a strong (e.g., PEPPER) or a weak (e.g., GRAIN) association with the probe word (SALT). Although performance in the strong-association condition was unaffected by TMS over VLPFC, stimulation disrupted performance in the low-association condition. Similar to the results of [Devlin et al. \(2003\)](#), a control (nonsemantic) judgment task was insensitive to TMS effects in this area (see also [Whitney, Kirk, O'Sullivan, Ralph, & Jefferies, 2012](#)).

To summarize, we reviewed evidence for the possible role of VLPFC in comprehension and production of single words and showed that while this region does have an involvement in semantic/lexical retrieval, this involvement appears to be specific to situations in which there is a need for biasing competition through top-down control.

46.3 VLPFC IN SENTENCE PROCESSING

Although the role of VLPFC was being investigated in semantic processing mostly by memory researchers, many linguists and psycholinguists were attempting to understand the role that VLPFC played in processing syntax. The initial motivation for the various syntactic hypotheses might have stemmed from the clinical profile of Broca's aphasia (Grodzinsky, 2000), an impairment that is characterized by agrammatical speech without marked semantic difficulties. There was a major problem with this inference. Damage to Broca's area is neither sufficient nor necessary for generating symptoms constituting Broca's aphasia. Damage restricted to Broca's area leads only to a transient mutism with spontaneous recovery (Levine & Mohr, 1979; Mohr et al., 1978). However, Broca's aphasics' lesions often extend beyond BA 44 and BA 45 to involve some parts of BA 6, BA 8, BA 9, BA 10, and BA 46, as well as the underlying white matter and basal ganglia (Damasio, 1992; Dronkers, Plaisant, Iba-Zizen, & Cabanis, 2007).

However, regardless of whether the profile of Broca's aphasia is informative about the role of Broca's area, a large number of neuroimaging studies have also implicated VLPFC in "syntactic processing" (see Kaan & Swaab, 2002, for an excellent review). Here, we use the general framework used by Kaan and Swaab (2002) to review the evidence for a syntactic role of VLPFC.

46.3.1 Syntactic Complexity

The first group of studies constitutes experiments comparing syntactically simple versus syntactically complex sentences using a variety of manipulations (Caplan, Alpert, & Waters, 1998, 1999; Cooke et al., 2002; Dapretto & Bookheimer, 1999; Fiebach, Schlesewsky, & Friederici, 2001; Inui et al., 1998; Keller, Carpenter, & Just, 2001; Michael, Keller, Carpenter, & Just, 2001; Stowe et al., 1998; Stromswold, Caplan, Alpert, & Rauch, 1996). For example, Caplan et al. (1999) had subjects judge the plausibility of cleft object and cleft subject sentences (e.g., "It was the actress that the award thrilled" vs. "It was the award that thrilled the actress") and found increased VLPFC activation when subjects processed the cleft object sentences. Although these two

sentences are close in meaning in the sense that they both convey that the actress was thrilled by the award, they are different in their syntactic forms, making VLPFC a suspect in processing syntactic complexity. However, Cooke et al. (2002) failed to find increased VLPFC activation in object-relative clauses with short antecedent gaps (e.g., "The flower girl who Andy punched in the arm was 5 years old"), but they did find it when the gap was long (e.g., "The messy boy who Janet, the very popular hairdresser, grabbed was extremely hairy."). In line with this, Fiebach et al. (2001) showed that when the case marker disambiguated the thematic roles in sentences containing relative clauses (as is the case in German), it was only the long-distance dependencies that induced VLPFC activation. This led to the proposal that VLPFC mediates *syntactic working memory*. However, it is unclear how the finding of Caplan et al. (1999) would fit into this account.

Moreover, Chen, West, Waters, and Caplan (2006) showed that when length and syntactic structure were kept constant, higher activation of VLPFC was found when the subject of the relative clause was inanimate (e.g., "The golfer that the lightning struck survived the incident") compared with when it was animate (e.g., "The wood that the man chopped heated the cabin."). Neither syntactic ambiguity nor syntactic working memory can be blamed for this difference. Corroborating the antisyntactic evidence were findings of Keller et al. (2001), who showed that syntactically complex sentence with object-relative clauses (e.g., "The boy who the doctor visited had contracted pneumonia") actually elicited *less* activity in VLPFC compared with syntactically simple sentences that contained a temporarily ambiguous word (e.g., "The desert trains [= noun] usually are late"; "The desert trains [= verb] its inhabitants to conserve their resources"). An innovative study in this genre was conducted by Dapretto and Bookheimer (1999), who claimed that their design allowed for teasing apart semantic from syntactic processing. They asked subjects to make same/different judgments for sentences such as "The bridge is west of the airport" paired with what the authors considered either a semantically different sentence (e.g., "The bridge is west of the river") or a syntactically different sentence ("West of the bridge is the airport"). VLPFC was selectively implicated for the syntactically different sentences. However, the syntactically different sentences also perform different meanings ("The bridge is west of the airport" does not mean that "West of the bridge is the airport"). It is therefore unlikely that this design can single-out syntactic processing.

One of the most famous syntactic accounts of VLPFC, based on syntactic complexity, is its role in syntactic (or *transformational*) movements (Grodzinsky, 1995, 2000). This account proposes that when faced with a sentence

like “Which man did the woman like?”, the parser would create a placeholder (trace) to the right-hand side of the verb to simulate an active sentence structure: “[Which man] did the woman like {trace}?”. By establishing a common index between the trace and its antecedent (which man), the parser recognizes the antecedent as the theme of the verb “like.” Following this proposal, Grodzinsky (2000) claimed that in Broca’s aphasia, all traces of movements are deleted and, primarily based on this assumption, concluded that Broca’s area handles exclusively intrasentential dependency relations. Grodzinsky’s theory has received criticism not only for equating Broca’s aphasia with Broca’s area, an issue that we touched on earlier in this chapter but also because of its oversight in explaining the full picture of Broca’s aphasia that it targets (see Grodzinsky, 2000 for full commentaries). For one thing, there are Broca’s patients who perform better than chance in comprehension of certain transformationally derived passives (Balogh & Grodzinsky, 1996; Druks & Marshall, 1995; Hickok & Avrutin, 1995; Saddy, 1995). The most serious criticism for the theory, though, is the finding that the deficits in such patients is not limited to processing sentences with syntactic structures requiring transitional movements. Agrammatic patients can have problems with active sentences, too, as long as the semantic roles are reversible. Schwartz, Saffran, and Marin (1980), among others, have reported such deficits when semantic symmetry is possible around a verb (e.g., “The dancer applauds the clown”) or around a spatial preposition (e.g., “The square is above the circle”).

To summarize, VLPFC is recruited for processing of certain syntactic complexities, but its activation does not seem to be either necessary for or limited to all syntactically complex sentences. It is worth mentioning that the activation of VLPFC in difficult sentences has been attributed to subvocal rehearsal, which presumably helps with parsing (Paulesu et al., 1993; Smith & Jonides, 1999). To test this hypothesis specifically, Caplan, Alpert, Waters, and Olivieri (2000) investigated VLPFC activation in subject-relative and object-relative sentences under concurrent articulation conditions (which seriously reduce the chance of subvocal rehearsal) and showed that the differential activation of VLPFC for object-relative sentences survived this manipulation. It is therefore unlikely that this explanation sufficiently justifies the nature of VLPFC’s involvement in these cases.

46.3.2 Anomalous Sentences

Another category of studies aiming at semantic–syntactic comparison of VLPFC involves presenting anomalous sentences. Many such studies have failed to show a syntax-specific role for this cortical region

(Indefrey, Hagoort, Herzog, Seitz, & Brown, 2001; Kuperberg et al., 2000; Newman, Pancheva, Ozawa, Neville, & Ullman, 2001; Ni et al., 2000; Nichelli et al., 1995; cf., Embick et al., 2000). In some cases VLPFC was not recruited when detecting syntactic anomalies such as “Trees can grew,” and in some other cases detection of syntactic and semantic anomalies was not dissociable. Also, the choice of baseline should be taken into account when interpreting claims about the exclusivity of VLPFC’s processing to syntax. For example, Moro et al. (2001) showed VLPFC’s selective activation during detection of syntactic anomalies, but the baseline for comparison was detection of phonotactic and orthographic anomalies. To attribute greater VLPFC activation in detecting syntactic over, for example, phonotactic anomalies, one must assume that the cognitive processes required for detecting these two types of violation are the same, except for the materials. This is very unlikely to be the case because spotting syntactic errors, for example, noun–verb agreement errors, requires keeping track of earlier parts of the utterance, whereas phonotactic violations can be detected without any memory of what has been stated earlier. In fact, there is now ample evidence that semantic and pragmatic violations do recruit VLPFC (Hagoort, Hald, Bastiaansen, & Petersson, 2004; Kiehl, Laurens, & Liddle, 2002; Kuperberg, Holcomb, et al., 2003; Kuperberg, Sitnikova, Caplan, & Holcomb, 2003; Newman et al., 2001; Ni et al., 2000; see also Marini & Urgesi, 2012 for a TMS study). Baumgaertner, Weiller, and Büchel (2002) took this one step further by showing that unexpected sentence endings, even if they do not qualify as violations, elicit activation in VLPFC.

46.3.3 Other Semantic–Syntactic Comparisons

Another category of studies speaking to a semantic–syntactic differentiation in the role of VLPFC compared either word lists to sentences or meaningful sentences to jabberwocky and syntactic prose. Kaan and Swaab (2002) point out that the studies in this category that have failed to identify VLPFC (Kuperberg et al., 2000; Mazoyer et al., 1993; Stowe et al., 1998; 1999) outnumber the studies that have reported a positive effect (Bottini et al., 1994) and point to task-specific demands for recruiting VLPFC in the latter cluster.

46.3.4 Ambiguity

Although there is simply too much evidence to deny the involvement of VLPFC in some aspect of semantic processing, it is also clear that there are some syntactic structures that elicit VLPFC activation more than others, as pointed out in the *syntactic complexity* section. Here, we separately review a subset of these

studies, focusing on garden path sentences (temporarily ambiguous sentences that initially lead to an incorrect interpretation), because they have been particularly useful in reconciling the semantic–syntactic debate over the role of VLPFC. We mentioned the Keller et al. (2001) study showing VLPFC activation when subjects encountered sentences containing ambiguous words like TRAIN. Minimizing the differences between surface forms of sentences, Mason, Just, Keller, and Carpenter (2003) used a similar logic by using ambiguous words like WARNED in the following sentences and observed the following activation pattern in VLPFC: $a > b > c$.

- a. *The experienced soldiers warned about the dangers conducted the midnight raid. (ambiguous verb, subordinate form)*
- b. *The experienced soldiers warned about the dangers before the midnight raid. (ambiguous verb, dominant form)*
- c. *The experienced soldiers spoke about the dangers before the midnight raid. (unambiguous verb)*

When there was a single possible interpretation of the verb (i.e., spoke = past tense, active), VLPFC's role in parsing was minimal. When there were alternative meanings to be considered, VLPFC activation increased to bias toward one of the two interpretations (i.e., warned = past tense, active or passive). The maximum involvement of VLPFC was observed when the correct interpretation required biasing toward the subordinate meaning of an ambiguous verb (i.e., warned = passive; see Garnsey, Pearlmutter, & Myers, 1997, for a discussion of verb bias).

A few years after the Mason et al. study, January, Trueswell, and Thompson-Schill (2009) presented the first clear demonstration for the involvement of the same cortical region in processing both syntactic and nonsyntactic high-conflict tasks. These authors demonstrated within-subject overlap in neural substrates of processing garden path sentences and the word Stroop task, localizing both effects to VLPFC. Studies of patients with VLPFC lesions confirm that they have problems recovering from the wrong interpretation of sentences that initially induce a bias toward the incorrect meaning (Novick et al., 2009; Novick, Trueswell, & Thompson-Schill, 2005). The same patients show selective impairment in suppressing interference in a memory task (Novick et al., 2009; see also Hamilton & Martin, 2005).

But does VLPFC respond to the ambiguous word itself, or to the need for revision (i.e., the disambiguating information)? Fiebach, Schlesewsky, Lohmann, Von Cramon, and Friederici (2005) found greater VLPFC activation when disambiguating information came later, as opposed to earlier, in the sentence. This is expected if VLPFC starts the biasing process at the moment the parser encounters an ambiguity and

continues to update the bias as more cues accumulate. If the initial commitment to a meaning is incorrect, then the later the disambiguating information comes in, the farther the bias in the incorrect direction, the more work needed to shift the competition in favor of the alternative meaning, and, hence, the greater activation in the delayed disambiguation condition. Compatible with this interpretation, Rodd, Johnsrude, and Davis (2012) manipulated the relative timing of the ambiguous word and the disambiguating information and showed VLPFC activation by the ambiguous word and by the subsequent disambiguating information. In contrast, left inferior temporal gyrus responded only to the disambiguating information.

The evidence strongly suggests that when there is need for biasing interpretation toward one of the two meanings, VLPFC is activated, especially if the favored meaning turns out to be incorrect. If this is really the role of this region, then the bias need not be induced by syntax; semantics also should be able to create the incorrect bias. Recently, Thothathiri, Kim, Trueswell, and Thompson-Schill (2012) demonstrated that this is true. By keeping the verb constant in an unambiguous syntactic structure and changing the content nouns around the verb, they evaluated parsing of three types of sentences (a–c in the following sentences). The pattern of VLPFC activation was as follows: $a > b > c$.

- a. *The journalist was interviewed by the undergraduate. (violation of the usual role of journalist)*
- b. *The patient was interviewed by the attractive man. (neutral roles)*
- c. *The celebrity was interviewed by a reporter. (congruent with the usual role of reporter)*

Although there is no ambiguity in these sentences, violation of the usual semantic roles recruits VLPFC proportionally to the degree of violation. Similarly, Saffran, Schwartz, and Linebarger (1998) reported that patients with agrammatic aphasia exhibited high error rates even with syntactically simple sentences when semantic information contradicted the correct thematic role assignment (e.g., “The deer shot the hunter”), but the exact site of lesion was not specified for the patients in this study.

46.4 SUMMARY

46.4.1 Against a Rigid Semantic–Syntactic Distinction in VLPFC

Our goal for organizing this chapter into two sections was to better classify studies pertaining to the role of VLPFC in single-word versus sentence processing. In so doing, we also captured the spirit of a

fundamental debate over the role of VLPFC, namely the semantic–syntactic debate. In the first section, we discussed an abundance of evidence from neuroimaging, TMS, and lesion studies converging on the role of VLPFC in biasing competition during semantic/lexical selection in the absence of any syntax-like structure. In the second section, we discussed studies that directly pitted semantic processing against syntactic processing in VLPFC and showed that the evidence for a pure syntactic account is sparse.

Our contention is that drawing a hard line between semantic and syntactic processing in understanding the role of VLPFC in language processing is not very useful. By this assertion, we do not mean to deny that semantic and syntactic aspects of language processing are distinct and can be teased apart, but that given the empirical evidence, this distinction does not seem critical to VLPFC operations. ERP studies have shown that both syntactic violations (e.g., “at breakfast the boys would eat...”) and certain semantic violations in the absence of syntactic violations (“at breakfast the eggs would eat...”) evoke a positivity called P600 (Kuperberg, 2007; Kuperberg, Caplan, Sitnikova, Eddy, & Holcomb, 2006; Kuperberg, Holcomb, et al., 2003; Kuperberg, Sitnikova, et al., 2003). Interestingly, even though these two sentence types are different from violations of world knowledge, such as “The Dutch trains are white...” (Hagoort et al., 2004), or expected events “...at breakfast the boys would plant...,” which elicit N400 instead, all of these violations activate VLPFC (Kuperberg, Sitnikova, & Lakshmanan, 2008).

What is the cognitive explanation for this? Modern theories of language comprehension (MacDonald, Pearlmutter, & Seidenberg, 1994) propose that on encountering a sentence, multiple sources of information (syntactic, semantic, pragmatic, etc.) are triggered and collaborate to derive the meaning. Activation of information in each domain is probabilistic and frequency-dependent, and convergence of information from these multiple domains leads to proper comprehension of a sentence. Because the ultimate goal is to arrive at a coherent meaning supported by all cues, any type of information, if it creates a bias toward an interpretation that clashes with other types of information, leads to conflict, and this conflict requires top-down control to be resolved. The source of initial incorrect bias could be syntactic (e.g., in the case of less frequent object-relative clauses without strong semantic cues), semantic (e.g., when the world knowledge is incongruent with the thematic roles, like celebrities photographing paparazzi), or perhaps other (e.g., pragmatic and prosodic). Regardless, on encountering potential for multiple interpretations, VLPFC is activated to use the existing information to create the bias and continues to do so until conflict is minimized.

If VLPFC fails, due to lesion or temporary deactivation via TMS, then top-down control is significantly reduced and processing would follow bottom-up cues, giving rise to the difficulty that VLPFC patients have with sentences, the correct interpretation of which requires overriding a strong semantic–syntactic cue. Complementary to this picture are cases where bottom-up cues are limited. Although a sentence bombards the comprehension system with multiple external cues, production is much more internally driven. Thus, the speaker must use top-down control to successfully initiate (and to fluently continue) the generation of concept/linguistic materials, except for cases when a strong bottom-up cue is presented (e.g., a picture of an object with a unique label), eliminating the need for top-down biasing.

46.4.2 A New “Broca’s” Aphasia

Earlier in this chapter we alluded to the fact that Broca’s aphasia does not necessarily correspond to pathology in Broca’s area. In this section, we present other clinical profiles of aphasia that have stronger ties to VLPFC lesions. First, we discuss the revival of an old profile described by Alexander Luria, called “dynamic aphasia” (Luria, 1970, 1973; Luria & Tsvetkova, 1968), which has been directly linked to VLPFC damage. Next, we discuss a syndrome called Semantic Aphasia (SA), also seen in VLPFC patients, although certain temporoparietal regions can induce similar symptoms. Our goal is not to argue that these two are distinct syndromes. In fact, it is quite likely that the patients reported under these two labels have similar clinical deficits; however, to date they have been studied and discussed under different literature.

A typical dynamic aphasic profile is portrayed by a patient described by Robinson, Blair, and Cipolotti (1998). This patient had a frontal meningioma that impinged on BA 45 and presented with no impairment in simple picture naming, word repetition, comprehension, or reading, but who did have markedly decreased spontaneous or propositional speech. In multiple experiments, the authors showed that the patient was unimpaired in generating words or phrases given a strong cue that limited the possible responses, and also was severely impaired under conditions where the cue was not strongly associated with a unique response (see Robinson, Shallice, & Cipolotti, 2005, for a similar report). It is worth mentioning that the patient reported in Robinson et al. (1998) had a lesion that also impacted the dorsolateral PFC (DLPFC). Alexander (2006) has also considered lesions of DLPFC to be relevant to symptoms of dynamic aphasia. To investigate exactly which aspect of the impairment in dynamic aphasia was linked to the VLPFC, Robinson,

Shallice, Bozzali, and Ciolotti (2010) extended their case study to a group study. In this new study, patients with VLPFC damage were compared with patients with frontal lesions sparing VLPFC and patients with posterior lesions. Compared with the other two groups, VLPFC patients showed selective impairment in sentence generation tasks only when stimuli activated multiple conceptual propositions that competed with each other for selection. For example, VLPFC patients were impaired in generating sentences from high-frequency words, but not from low-frequency words and proper nouns, because the latter two are more constraining in their associations. In contrast, when the lesion spared VLPFC (i.e., non-VLPFC and the left temporal groups), the patients did not show sensitivity to the number of possible propositions.

Impairment in this experimental task was shown to be predictive of the clinical problem. VLPFC patients' scores in the high-frequency minus low-frequency and in the high-frequency minus proper noun conditions showed a reliable correlation with their spontaneous speech rate. In keeping with this, Blank, Scott, Murphy, Warburton, and Wise (2002) found that BA 44 showed greater activation under conditions of propositional compared with nonpropositional speech (i.e., counting and overlearned nursery rhymes). However, it must be pointed out that based on these findings, Robinson et al. (2010) concluded that VLPFC has a fundamental role in selection for conceptual propositions, as opposed to selection during lexical retrieval. Given the evidence reviewed in earlier sections, we are skeptical about the exclusivity of the role of VLPFC to conceptual biasing. For instance, under this account, it is unclear why VLPFC lesions would cause impairment in naming a picture COUCH/SOFA when the "concept" is right in front of the patient. However, we concur that profile of dynamic aphasia is compatible with the perspective taken in this chapter on the role of VLPFC.

Another clinical syndrome that has been recently linked to VLPFC is SA (Jefferies & Ralph, 2006), a deficit that is meant to be contrasted with Semantic Dementia (SD). SD, which generally results from bilateral damage (often of the atrophic type) to anterior temporal lobes, affects conceptual knowledge in verbal and nonverbal domains across different sensory modalities (Bozeat, Lambon Ralph, Patterson, Garrard, & Hodges, 2000; Coccia, Bartolini, Luzzi, Provinciali, & Lambon Ralph, 2004; Luzzi et al., 2007). Thus, the hallmark of SD is that failure to activate a concept is stable across tasks and processing modalities (Bozeat et al., 2000; Jefferies & Ralph, 2006). TMS studies on healthy controls corroborate this assertion (Pobric, Jefferies, & Ralph, 2007; Ralph, Pobric, & Jefferies, 2009). In contrast to SD, SA patients have intact

conceptual knowledge, but controlling that knowledge has become dysregulated. These patients usually have poststroke lesions in the VLPFC, although it has been reported that lesions in inferior parietal cortex (i.e., BA 39/40) and posterior temporal (especially temporoparietal junction) can create similar symptoms, suggesting that semantic control is achieved through a distributed network (Whitney et al., 2012). Importantly, SA patients differ from SD patients in their inconsistent performance on the same items when the control demands of the task change, and their picture naming performance shows great sensitivity to constraining or distracting cues.

Deficits of SA patients closely mirror what we discussed as VLPFC's function. For example, Noonan, Jefferies, Corbett, and Ralph (2010) performed four experiments in a group of SA patients, three of which are in line with the studies previously discussed in this chapter. In Experiment 1, participants had to judge which of three alternatives was closest in meaning to a probe item. The semantic distance between the probe item (CHIPMUNK) and the target was manipulated to be low (e.g., SQUIRREL) in half of the trials and high (e.g., BEE) in the other half, whereas the two distractors were kept the same (and unrelated to both the probe and the target). In Experiment 2, they examined synonym and antonym judgments when the associative strength between the probe (e.g., HAPPY/NEAT) and one of the distractors was either stronger or weaker than the association between the probe and the target (e.g., HAPPY-SAD [distractor] > HAPPY-CHEERFUL [target]; NEAT-MESSY [distractor] < NEAT-TIDY [target]). Consistent with the past findings, SA patients showed selective impairment when the correct response required biasing towards the weak association. In Experiment 4, participants were asked to select which of four words was related in meaning to a probe word presented at the top of the page. In half of the trials, the target referred to the dominant meaning of the probe word (FIRE → HOT). In the remaining trials, the target word was related to the subordinate meaning of the probe word (FIRE → RIFLE) while distractors remained the same. Three cue conditions preceded these trials: no cues, correct cues (e.g., "I lit a fire" → HOT), or miscues (e.g., "Fire at will" → HOT). SA patients showed great difficulty activating the less frequent meaning, and this was the condition that specifically benefitted from cueing.

On the production side, the cue/miscue paradigm has been used to probe the sensitivity of SA patients to constraining and distracting information. Jefferies, Patterson, and Ralph (2008) showed that phonological onset cues (e.g., /k/) when naming pictures (e.g., a cup) were very useful in helping SA patients overcome their difficulty in suppressing competing

names (e.g., tea). Noonan et al. (2010; Experiment 3) showed that the opposite manipulation in the cuing paradigm of Jeffries et al. (2008) does yield the opposite effect. Miscuing the picture name (e.g., /t/ for the picture of a cup) impaired the SA patients' ability to name the pictures correctly and elicited additional semantic errors.

It is noteworthy that semantic control deficits in SA patients are not restricted to the verbal domain. Corbett, Jefferies, Ehsan, and Ralph (2009) compared object use in SD and SA patients and found that SD, but not SA, patients' performance was sensitive to item frequency and was consistent irrespective of task demands. Straightforward object use demonstration, for example, was relatively intact in SA patients in comparison with much poorer performance on an executively demanding, mechanical-puzzles task (see also Corbett, Jefferies, & Ralph, 2009).

46.5 CONCLUDING REMARKS AND FUTURE AVENUES

Although left temporal cortex is consistently implicated in storing long-term representations of knowledge (Binder, Desai, Graves, & Conant, 2009; Indefrey & Levelt, 2004; Vigneau et al., 2006), VLPFC seems to mediate processes necessary for controlling the use of this knowledge. We reviewed evidence from multiple sources in single-word and sentence production and comprehension consistent with a crucial role of this region in implementing top-down biasing at the semantic/lexical level. It is important to point out that this is not restricted to the language domain. VLPFC's involvement has been shown in selecting the target among nontarget items in target detection tasks, even when items are complex symbols without known lexical labels (Hampshire, Duncan, & Owen, 2007). More generally, VLPFC has been proposed as a critical part of a system involved in processing hierarchical structure of goal-directed behavior (Koechlin & Jubault, 2006).

Although we have made considerable progress in understanding the role of VLPFC in processing language, much remains to be explored. We close by posing four main questions that we consider to be excellent avenues for promoting our understanding of the role of VLPFC in language:

1. How many stages are there in (controlled) lexicosemantic retrieval, and which stage/stages requires VLPFC? Badre and Wagner (2007) proposed that VLPFC implements semantic control in two steps. Step 1 constitutes controlled access to stored representations when bottom-up input is not enough. Step 2 operates postretrieval and is thought to bias competition among representations that have been activated during Step 1. A similar idea has been expressed by Thompson-Schill and Botvinick (2006) using a Bayesian framework. According to Badre and Wagner (2007), both steps recruit VLPFC, albeit different parts of it (BA 47 and BA 45, respectively; Whitney et al., 2012). The exact computations by which this is achieved are not clear.
2. Are subdivisions of VLPFC specialized based on different materials or different processes? An example of a material-based parcellation in the context of language is the semantic-phonological distinction, born out of the differential sensitivity of the posterior parts of VLPFC to phonological, and the anterior parts to semantic processing (Devlin et al., 2003; Gold, Balota, Kirchhoff, & Buckner, 2005; Gough et al., 2005; Poldrack & Wagner, 2004). Studies of statistical mapping between speech errors and lesion sites using Voxel-based Lesion-Symptom Mapping also link damage to the posterior aspects of VLPFC to phonological errors (Schwartz, Faseyitan, Kim, & Coslett, 2012) and its anterior aspects to semantic errors (Schwartz, Kimberg, Walker, Faseyitan, & Brecher, 2009). Similarly, using a version of the technique that maps lesions to parameters in a computational model of language production, Dell, Schwartz, Nozari, Faseyitan, and Branch Coslett (2013) showed that lesions in the more posterior parts of VLPFC correspond to the phonological parameter of the model, whereas lesions in the more anterior parts of VLPFC are associated with semantic errors.
3. Do the same regions in the prefrontal cortex that support domain-general mechanisms also support language processing? Although some have argued for domain-generality (January et al., 2009), some have contested this view (Fedorenko, Behr, & The semantic-phonological distinction, however, does not negate a process-based organization. Semantic and phonological processing may differ not only in the materials they use but also in the operations performed on those materials. One dominant process-based view is that of a rostrocaudal functional gradient of abstraction, with more anterior regions processing more abstract information (Badre, 2008; Badre & D'Esposito, 2009). This view has found support in the dorsolateral prefrontal cortex (Badre & D'Esposito, 2007; Koechlin & Jubault, 2006; Koechlin, Ody, & Kouneiher, 2003) and, more recently, also in the VLPFC (Race, Shanker, & Wagner, 2009). It remains to be seen if such a view is sufficient for explaining the separation of semantic and phonological processing in VLPFC.

- Kanwisher, 2011) and some have proposed a middle ground, identifying both language-specific and domain-general regions in the PFC (Sakai & Passingham, 2002). A recent study tested whether the rostrocaudal gradient of abstraction is sensitive to the nature of the representations (spatial versus verbal). Bahlmann, Blumenfeld, and D'Esposito (2014) found an indistinguishable pattern of activity for the two stimulus types along this rostrocaudal axis. However, a task-sensitive topographic segregation was also found in the dorsolateral axis, such that processing of spatial information was localized to more dorsal areas, whereas processing of verbal information activated more ventral regions.
4. What other regions are in the control network that VLPFC is part of, and what role do they play? As pointed out, semantic control deficits of the SA type can also arise from lesions to posterior temporal or inferior parietal lobes. These two areas are heavily connected to the prefrontal cortex via arcuate and longitudinal fasciculi (Parker et al., 2005) and have both been previously implicated in tasks requiring controlled semantic access (Badre, Poldrack, Paré-Blagoev, Insler, & Wagner, 2005; Gennari, MacDonald, Postle, & Seidenberg, 2007; Lee & Dapretto, 2006; Rodd, Davis, & Johnsrude, 2005; Thompson-Schill et al., 1997; Wagner et al., 2001; Whitney et al., 2012; Zempleni, Renken, Hoeks, Hoogduin, & Stowe, 2007). It remains to be demonstrated how labor is divided in this frontotemporoparietal network that supports semantic and lexical retrieval.

The Role of the Anterior Temporal Lobe in Sentence Processing

Corianne Rogalsky

Department of Speech and Hearing Science, Arizona State University, Tempe, AZ, USA

There are numerous computations necessary for successful sentence comprehension; phonological, semantic, syntactic, and combinatorial processes are all critical. This chapter focuses on the syntactic and combinatorial operations involved in sentence comprehension. The neuroanatomy supporting these processes, and perhaps even the definitions of these terms, are hotly debated (Grodzinsky & Santi, 2008; Hickok & Poeppel, 2004, 2007; Rogalsky & Hickok, 2011; Scott, Blank, Rosen, & Wise, 2000). Although Broca's area has long been the focus of these debates, the anterior temporal lobe (ATL) has emerged as a strong candidate for supporting sentence-level computations because there is strong evidence that the ATL is sensitive to the presence of sentence structure (Brennan et al., 2012; Humphries, Binder, Medler, & Liebenthal, 2006; Humphries, Love, Swinney, & Hickok, 2005; Humphries, Willard, Buchsbaum, & Hickok, 2001; Mazoyer et al., 1993; Rogalsky & Hickok, 2009; Rogalsky, Rong, Saberi, & Hickok, 2011). Two hypotheses regarding the ATL's responsiveness to sentence structure are: (i) the ATL supports basic syntactic operations or (ii) the ATL supports combinatorial semantic operations. In this chapter, we examine the evidence in support of both of these hypotheses. First, we discuss the historical framework and evidence for the ATL being sensitive to sentence structure.

47.1 WHAT ABOUT BROCA'S AREA?

Broca's area has traditionally been the focus of sentence-level investigations, particularly regarding syntactic processes (Bradley, Garrett, & Zurif, 1980; Caramazza & Zurif, 1976; Grodzinsky, 2000). This view originates from neuropsychological findings

involving individuals with Broca's aphasia who often produce syntactically simple constructions and exhibit agrammatic production (i.e., speech that lacks function words and inflections) (Gleason, Goodglass, Green, Ackerman, & Hyde, 1975; Goodglass, 1968, 1976; Goodglass & Berko, 1960). Those with Broca's aphasia also demonstrate sentence comprehension deficits that similarly appear to implicate syntactic processes because comprehension failures are common for semantically reversible sentences that do not follow canonical word order (which in English is subject-verb-object; e.g., "It was the boy that the girl kissed") (Bradley et al., 1980; Caramazza & Zurif, 1976). However, there is also evidence that those with Broca's aphasia do have access to syntactic knowledge to some degree. For example, those with Broca's aphasia are able to make grammaticality judgments of sentences that they cannot completely comprehend (Linebarger, Schwartz, & Saffran, 1983; Wulfeck, 1988). It is also important to note that those with Broca's aphasia do not always have damage to Broca's area (Dronkers, Shapiro, Redfern, & Knight, 1992), and damage to Broca's area is not sufficient for Broca's aphasia (Mohr, 1976; Mohr et al., 1978). This lack of correspondence further complicates the claims that Broca's area plays a fundamental role in syntactic processing.

Functional imaging studies implicate Broca's area in aspects of syntactic processing, particularly in the comprehension of complex syntactic structures, such as noncanonical compared with canonical structures (Caplan, Alpert, & Waters, 1998, 1999; Dapretto & Bookheimer, 1999; Just, Carpenter, Keller, Eddy, & Thulborn, 1996; Stromswold, Caplan, Alpert, & Rauch, 1996). However, other functional imaging studies have found that activation in Broca's area does not track

with the presence or absence of syntactic information (Humphries et al., 2001, 2005, 2006; Mazoyer et al., 1993; Rogalsky et al., 2011; Stowe et al., 1998), suggesting that Broca's area plays a restricted role in sentence processing rather than a fundamental role in structure building or combinatorial processes. This has led researchers interested in syntactic processing to explore the response properties of other brain areas, including the ATL.

47.2 WHERE IS THE ATL?

The term "anterior temporal lobe" in this chapter is used to refer to cortex anterior to Heschl's gyrus in the lateral temporal lobe. The ATL regions implicated in sentence comprehension are in both the superior temporal gyrus and the middle temporal gyrus primarily, including in the superior temporal sulcus (e.g., the green areas in Figure 47.1). The approximate Brodmann areas corresponding to these functionally defined ATL regions include anterior BA 21 and BA 22 and posterior

BA 38 (Brodmann, 1909; Wong & Gallate, 2012). It is worth noting that these ATL regions extend more posteriorly than the temporal pole (approximately BA 38), which has been proposed to be a multimodal hub supporting processes such as semantic memory, abstract conceptualizations, object concepts, personal narratives, and social concepts (Bonner & Price, 2013; Olson, McCoy, Klobusicky, & Ross, 2013; Simmons & Martin, 2009; Wong & Gallate, 2012).

47.3 DOMAIN-GENERAL SEMANTICS

Across the field of cognitive neuroscience, the term "anterior temporal lobe" is perhaps most associated with semantic memory (Simmons & Martin, 2009). Semantic dementia (SD), related to atrophy originating in the temporal pole(s), is associated with domain-general semantic deficits seen in naming, categorizing, and discriminating objects (Hodges, Patterson, Oxbury, & Funnell, 1992; Hodges et al., 1999; Mummery et al., 2000). Semantic deficits are also

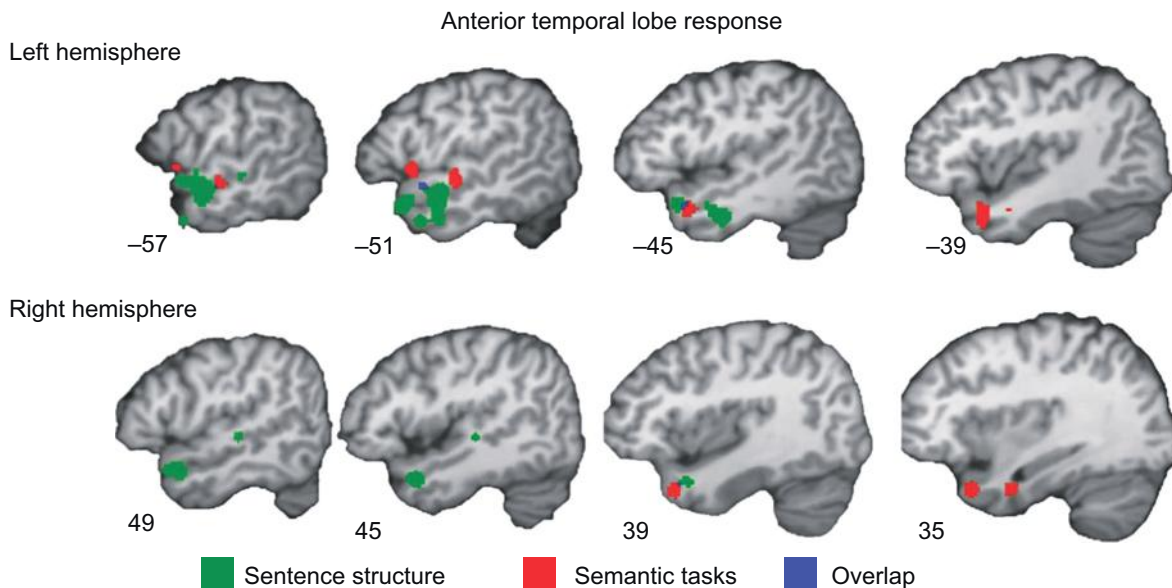

FIGURE 47.1 Meta-analysis of neuroimaging studies implicating the ATL in sentence structure and semantic processing. Activation likelihood estimations (ALEs; Eickhoff et al., 2009; Turkeltaub et al., 2012) derived from 17 studies reporting ATL activation to sentence structure (green), and 18 studies reporting ATL activation during single-word or object semantic tasks (red) (totaling 569 subjects and 157 peak coordinates); $p < 0.05$, false discovery rate (FDR)-corrected. The overlap between the sentence and semantic ALEs is shown in blue. The semantic task studies are those described in the review by Wong and Gallate (2012) of ATL function that reported peak activation coordinates (Wong & Gallate's Table 1, labeled as domain-general and nondomain general semantic functions) and in articles referencing or referenced by these studies. The sentence structure studies were identified by a PubMed.gov search using the terms "fMRI" or positron emission tomography ("PET") or "neuroimaging" and "sentence," and then by including all studies reporting ATL coordinates in response to sentences compared to stimuli without sentence structure (e.g., word lists). In addition, a dataset of Rogalsky et al. (submitted) was included. Four representative slices for each hemisphere are shown (left to right = lateral to medial). Only coordinates in the temporal lobes anterior to the posterior boundary of Heschl's gyrus were included. Included studies are denoted in the references by "*" for sentence structure and "*" for semantic tasks. This figure is not intended to portray an exhaustive meta-analysis of ATL function, but rather the paucity of overlap between the significant sentence structure and semantic activation estimates suggests that the ATL's response to sentence structure cannot be accounted for by semantic processing alone.

reported in temporal lobe epilepsy patients who have undergone anterior temporal lobectomies (Drane et al., 2009; Ellis, Young, & Critchley, 1989). Functional imaging data suggest that the ATL is engaged by a variety of lexical and semantic tasks, including categorization, naming, lexical decisions, and semantic knowledge decisions (Bright, Moss, & Tyler, 2004; Devlin et al., 2002; Ellis, Burani, Izura, Bromiley, & Venneri, 2006; Kellenbach, Hovius, & Patterson, 2005; Noppeney & Price, 2002; Peelen & Caramazza, 2012). The ATL is also more activated by content versus function words, and more by concrete versus abstract words (Diaz & McCarthy, 2009; Kiehl et al., 1999). The “semantic hub” hypothesis has recently been modified to include the idea that the ATL is not amodal, but rather there are modality-specific subregions (Olson et al., 2013; Skipper, Ross, & Olson, 2011). Nevertheless, as is discussed and as can be seen in Figure 47.1, these “semantic” ATL regions are physically dissociated from the ATL’s activation during sentence comprehension. A meta-analysis of neuroimaging data by Visser, Jeffries, and Lambon Ralph (2010) also indicates that the activations in the ATL, across a variety of tasks, for auditory sentences are more dorsal and lateral than the ATL responses to pictures.

47.4 THE ATL RESPONDS TO SENTENCE STRUCTURE

Functional imaging first implicated the ATL in sentence processing. The Mazoyer et al. (1993) positron emission tomography (PET) study found that the ATL, and not Broca’s area, reliably activated to sentence structure. Mazoyer et al. presented several types of speech stimuli to participants: sentences in the participant’s native language; sentences in an unfamiliar language; pseudoword sentences (sentences in which the content words were replaced with nonwords); semantically anomalous sentences; and word lists. The three stimuli types containing syntactic information (native language sentences, pseudoword sentences, and semantically anomalous sentences) reliably activated the ATL, whereas the remaining stimuli did not. Several subsequent neuroimaging studies also found the ATL to track sentence structure; sentences and pseudoword sentences reliably activate the bilateral ATL significantly more than scrambled sentences, semantically related and unrelated word lists, spectrally rotated speech, and environmental sounds sequences (Friederici, Kotz, Scott, & Obleser, 2010; Humphries et al., 2001, 2005, 2006; Rogalsky & Hickok, 2009; Rogalsky et al., 2011; Spitsyna, Warren, Scott, Turkheimer, & Wise, 2006; Xu, Kemeny, Park, Frattali, & Braun, 2005). The ATL’s response to

sentence structure is independent of input modality; both listening to and reading sentences elicit greater responses in the ATL than word lists in each modality, respectively (Bemis & Pytkkanen, 2013a; Jobard, Vigneau, Mazoyer, & Tzourio-Mazoyer, 2007; Stowe et al., 1998; Vandenberghe, Nobre, & Price, 2002).

Lesion evidence also indicates that the ATL is engaged in sentence-level processing. ATL lesions are associated with sentence comprehension deficits for all but the simplest of sentence structures (Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004). Damage to the left ATL has also been implicated in complex syntactic processing deficits. Specific impairment of noncanonical sentence comprehension was associated with left ATL damage, whereas the comprehension of canonically structured sentences implicated a large temporoparietallocipital network (Magnusdottir et al., 2013). It is noteworthy that there are very few lesion studies specifically addressing ATL function. This may, in part, be due to the rarity of lesions from stroke in the ATL. Typically, ATL damage from stroke coincides with overall large left hemisphere damage and strokes restricted to the ATL are rare (Holland & Lambon Ralph, 2010).

In summary, the ATL responds to sentence structure. But is the ATL responding to sentence structure *per se* or hierarchical structure more generally? The ATL does respond significantly more to sentences than environmental sound sequences portraying the same event (Humphries et al., 2001), suggesting that the ATL is not responding to auditory sound sequences *per se*. However, a question still remains regarding whether the ATL is responding to speech-specific hierarchical structures or if it is involved in hierarchical processing more generally. One way to test these possibilities is with music. Melodies, like sentences, can be complex acoustic stimuli, with hierarchical structure, tone, and rhythm, requiring combinatorial representations (Lerdahl & Jackendoff, 1983; Patel, 2007). There are also behavioral findings of interactions between structured speech and music processes, suggesting that they may share neural resources (Fedorenko, Patel, Casanato, Winawer, & Gibson, 2009; Patel, 2003). Regarding the specificity of the ATL’s response to sentence structure, one PET study does report that ATL activity is modulated by structural complexity of the melodies presented (Griffiths, Buchel, Frackowiak, & Patterson, 1998). However, the only work, to our knowledge, to directly compare sentences and melodies has found that the ATL responds significantly more to the sentences than melodies, and that the ATL does not significantly activate for melodies compared with rest (Rogalsky et al., 2011). This suggests that it is not structural processing *per se* that is driving the ATL response to sentences.

47.5 SYNTAX

Now, we turn to the question of *why* the ATL is responsive to sentence structure: is the ATL's response to sentences driven by compositional semantic properties (i.e., integrating lexical semantic information to extract sentence meaning) or more basic syntactic (i.e., parsing) processes? There is evidence for both hypotheses and, in fact, there is evidence to suggest that both processes may be preferentially engaging subregions of the ATL (Rogalsky & Hickok, 2009; Vandenberghe et al., 2002). In this section, we discuss the evidence for a syntactic account of the ATL's role in sentence processing. The three main lines of evidence that support the syntactic account are: (i) the ATL is activated by sentences lacking lexical semantic content; (ii) the ATL is more responsive to syntactic errors than semantic errors; and (iii) different grammatical constructions elicit different activation patterns in the ATL. These three points are described in more detail here.

As described in the previous section, the ATL shows a greater response to sentences compared with scrambled sentences and word lists, suggesting that the ATL is involved in sentence processing beyond lexical-semantics. However, this finding does not rule out the possibility that the ATL is involved in sentence-level semantic processes, commonly referred to as combinatorial semantics (Fodor, 1995; Partee, 1995; Vandenberghe et al., 2002). Perhaps the strongest argument against this possibility, and for the hypothesis that syntactic information drives ATL activation, is how the ATL responds to pseudoword sentences (sentences in which the content words have been replaced by phonologically plausible nonwords). For example, "The klib were frimming in swak," or "A klinder ghasted the nederopit." The ATL consistently and robustly activates to pseudoword sentences compared with scrambled pseudowords and pseudoword lists, suggesting that the ATL's response to sentence structure is not necessarily driven by semantic information, but rather it is in response to the syntactic structure, which is preserved in pseudoword sentences (Humphries et al., 2006; Rogalsky et al., 2011). However, it could be argued that semantic combinatorial processes are driving this effect. Perhaps combinatorial analyses are still being attempted for these pseudoword sentences despite the lack of semantic content because typically the presence of syntactic structure correctly predicts the need to build a sentence-level semantic representation, thereby engaging the ATL.

Evidence that the ATL is responding to syntactic information also comes from error detection paradigms; sentences containing syntactic errors elicit more of a response in the ATL than correct sentences or

those containing semantic errors (Friederici, Ruschemeyer, Hahne, & Fiebach, 2003; Herrmann, Maess, Hahne, Schroger, & Friederici, 2011; Herrmann, Obleser, Kalberlah, Haynes, & Friederici, 2012). Syntactic errors include case, number, or gender disagreement, whereas semantic errors typically involve thematic role incompatibility or semantic anomalies. For example, an event-related potential study found that syntactic (but not semantic) errors elicit an early left anterior negativity, which is proposed to be associated with anterior superior temporal and inferior frontal regions (Friederici & Kotz, 2003). fMRI data also implicate the ATL in syntactic error detection; compared with correct sentences, syntactic errors activated a network of regions including the ATL, whereas semantic errors did not activate the ATL (Friederici et al., 2003; Herrmann et al., 2012).

Further evidence for the ATL supporting syntactic processing is that under some conditions, ATL regions respond differently to different grammatical constructions, even when semantic content and complexity are controlled (Allen, Pereira, Botvinick, & Goldberg, 2012; Hammer, Jansma, Tempelmann, & Munte, 2011; Newman, Supalla, Hauser, Newport, & Bavelier, 2010). For example, the Allen et al. fMRI study found differing patterns of activation in the ATL for the English dative construction (e.g., Mark gave the gift to Felix) versus the English ditransitive (e.g., Mark gave Felix the gift). The pattern of activation in the left ATL (in conjunction with inferior frontal areas) was different for these two grammatical constructions despite containing essentially the same semantic content, thereby suggesting that the syntactic structure is driving the patterns of activation.

One piece of evidence complicating the syntactic account of the ATL's role in sentence comprehension comes from work with SD patients. SD patients have progressive atrophy originating in the ATLs and present with progressive, selective deficits for lexical semantic knowledge (Wilson, Galantucci, Tartaglia, & Gorno-Tempini, 2012). Several studies report that SD patients do not exhibit syntactic deficits once lexical semantic deficits are accounted for (Gorno-Tempini et al., 2004; Hodges et al., 1992; Warrington, 1975; Wilson et al., 2011). However, Wilson et al. (2014) found SD patients to have impaired performance on a sentence comprehension task with minimal lexical semantic demands, and to have different levels of activation than controls in their atrophied ATLs for the sentence task compared with rest. This result is complicated by the SD patients also having posterior temporal atrophy in regions activated in controls during the sentence task, but this study suggests that the link between SD and lack of syntactic deficits is not as straightforward as previous behavioral studies would suggest.

As discussed previously, the ATL is activated more for sentences than for a variety of control conditions (e.g., word lists, scrambled sentences, and acoustically matched auditory stimuli). One may then wonder whether the kinds of sentence comprehension manipulations that implicate Broca's area also implicate the ATL (e.g., noncanonical versus canonical syntactic constructions). In fact, these types of "syntactic complexity" comparisons that consistently implicate inferior frontal regions do not activate ATL regions (Ben-Shachar, Hendler, Kahn, Ben-Bashat, & Grodzinsky, 2003; Ben-Shachar, Palti, & Grodzinsky, 2004; Caplan et al., 1998; Rogalsky & Hickok, 2011; Rogalsky, Matchin, & Hickok, 2008; Stromswold et al., 1996; see Santi & Grodzinsky, 2012 for one notable exception). The ATL's lack of sensitivity to different syntactic constructions could be interpreted as evidence against the ATL's involvement in syntactic processing. However, given the ATL's robust response to sentence structure in general, it is more likely that the ATL is supporting syntactic processes in both the canonical and noncanonical sentences, and that additional resources (such as in the inferior frontal lobe) are being recruited for the more difficult constructions (Brennan et al., 2012; Fiebach, Schlesewsky, Lohmann, von Cramon, & Friederici, 2005; Rogalsky & Hickok, 2011).

47.6 COMBINATORIAL SEMANTICS

The ATL and temporal pole broadly speaking are clearly involved in building semantic representations across modalities and for a variety of stimuli, as findings from SD and neuroimaging studies (Figure 47.1) attest. Accordingly, semantic processing at the sentence level has been suggested as a possible role of the ATL in sentence comprehension (Wilson et al., 2014; Wong & Gallate, 2012). Indeed, one could argue that many of the observations that have linked ATL activity to syntactic structure are attributable to combinatorial processes, for example, the difference in activation between sentences and word lists.

There are several pieces of evidence to suggest that the ATL's response to sentence structure is due to its involvement in combinatorial semantics (i.e., combining the meanings of the words in a sentence into a cohesive, meaningful unit) (Pallier, Devauchelle, & Dehaene, 2011; Vandenberghe et al., 2002; but for a notable exception, see Humphries et al., 2006). The evidence supporting this claim mostly comes from the fact that manipulating various semantic features of sentences modulates ATL activity. Semantic anomalies (e.g., "the excited students rode the *trampoline* to school") consistently modulate ATL activity, suggesting that the unexpected word is making the formation

of a global meaning more difficult to construct and thereby increasing activity in the ATL (Dapretto & Bookheimer, 1999; Ferstl, Rinck, & von Cramon, 2005; Vandenberghe et al., 2002). Even correct sentences in a semantic anomaly detection task drive ATL activation more than correct sentences in a syntactic error detection task, indicating that ATL regions are involved in building the sentence-level semantic representations necessary to complete the semantic anomaly detection task (Rogalsky & Hickok, 2009).

A variety of other paradigms besides semantic anomalies also implicate the ATL in combinatorial semantic processes in sentence comprehension. Idioms activate the ATL significantly more than literal sentences (Lauro, Tettamanti, Cappa, & Papagno, 2008), and narratives elicit greater activation in the ATL than sentences (Xu et al., 2005). ATL activity has also been found to increase as a function of combinatorial semantic load; ATL activity increases as the constituent size within word streams increases (Pallier et al., 2011). This effect was not found for pseudoword streams, suggesting that the ATL is responding to the presence of lexical semantic information but not the syntactic structure *per se*. Similarly, adaptation paradigms produce effects in the ATL for sentences with different syntactic structures but the same semantic content (Devauchelle, Oppenheim, Rizzi, Dehaene, & Pallier, 2009), and ATL activity is evoked more by minimal phrases (e.g., "blue car") than comparable word lists (e.g., "car, blue") (Bemis & Pytkkanen, 2011, 2013a, 2013b).

47.7 PROSODY

Another component of the ATL's contribution to sentence comprehension may be prosody. Variations in prosody and sentence structure are highly correlated in natural environments (Herrmann, Maess, & Friederici, 2011); the human brain has an expectation that speech will contain both syntactic and acoustic/prosodic information that will be informative regarding the overall meaning and tone of the speech stimulus (Frazier, Carlson, & Clifton, 2006; Herrmann, Maess, & Friederici, 2011; Shattuck-Hufnagel & Turk, 1996; Weintraub, Mesulam, & Kramer, 1981). One complication of the studies demonstrating that the ATL is sensitive to sentence structure and/or combinatorial semantics is that many of the auditory stimuli used were spoken by talkers using sentence-like prosody and compared with word lists or other baseline conditions lacking sentence-like prosody (e.g., word lists with list-like prosody; Humphries et al., 2001; Meyer, Steinhauer, Alter, Friederici, & von Cramon, 2004; Rogalsky & Hickok, 2009; Spitsyna et al., 2006). One

attempt to control for prosody was a study that applied “list prosody” to sentences and compared activation to lists of words with list prosody (Humphries et al., 2005). Sentences still activated portions of the ATL more robustly, but it is possible that the prosodic chimera sentences created a prosodic anomaly response that drove the activation. So, is prosody, not structure, driving ATL involvement?

Both functional imaging and lesion studies of prosody clearly implicate the ATLs (Adolphs, Damasio, & Tranel, 2002; Johnstone, van Reekum, Oakes, & Davidson, 2006; Phillips et al., 1998). The right ATL is implicated in perceiving a variety of emotional prosodic manipulations (Gorelick & Ross, 1987; Heilman, Scholes, & Watson, 1975; Hoekert, Bais, Kahn, & Aleman, 2008; Phillips et al., 1998), for example, angry, sad, or anxious tones of voice versus neutral tone (Hoekert et al., 2008). The left ATL has not been implicated in emotional prosody, but it does have subregions that are responsive to normal sentence prosody. The Humphries et al. (2005) fMRI study presented subjects with sentences, scrambled sentences, and lists of content words. All three stimulus types were presented in two ways, with sentence prosody and then also with flat list prosody. A left ATL subregion showed a main effect for syntactic structure, but both left and right ATL subregions exhibited main effects for sentence prosody (i.e., was activated by sentence prosody even for the scrambled and list stimuli). These findings may reflect the ATL’s involvement in prosody, but it is also possible that the ATL is responding because of its role in processing socio-emotional content in general (Olson et al., 2013; Wong & Gallate, 2012). The ATL and temporal pole are responsive to a variety of social and emotional parameters (Burnett & Blakemore, 2009; Reiman et al., 1997; Shin et al., 2000; Zahn et al., 2007), so it may be that the ATL is engaged by sentences, at least in part, to process the socio-emotional information that prosody provides as one component of a sentence-level representation.

47.8 THE ATL IS PART OF A LARGE LANGUAGE NETWORK

This chapter focused on how the ATL is sensitive to the various elements of sentence comprehension. However, it is critical to understand that these elements (syntactic structure, prosody, combinatorial semantics, lexical-semantics) engage large frontal–temporal–parietal networks, of which the ATL is one component (Hickok & Poeppel, 2000, 2004, 2007). Notably, posterior temporal regions are also sensitive to syntactic structure and sentence-level semantic information (Griffiths, Marslen-Wilson, Stamatakis, &

Tyler, 2013; Humphries et al., 2006; Wilson et al., 2014). Broca’s area, as discussed, is recruited during sentence comprehension in high-load, difficult situations. The point of this chapter is not to identify the ATL as the “site” of sentence processing, but rather the point is to discuss how the ATL is sensitive to sentence-level structure and semantics, and how the ATL may be contributing to sentence comprehension as part of a large network.

47.9 SUMMARY

The ATL is not a homogenous region with only one specific function. Overall, the functionally diverse ATL is involved in integrating information to form meaningful representations from all modalities (Visser et al., 2010; Wong & Gallate, 2012). The reliable activation of ATL subregions to syntactic structure suggests that portions of the ATL are particularly tuned to form representations from a speech signal. Although it is difficult to pinpoint the exact computations that the ATL is providing for sentence comprehension, it is clear that the ATL is engaged during the comprehension of sentences and is sensitive to syntactic, combinatorial semantic, and prosodic information. The ATL is one part of a large frontotemporoparietal network engaged in sentence comprehension.

Acknowledgments

The author thanks Colin Humphries and Greg Hickok for their help in developing this chapter, and Alvaro Diaz for his assistance in generating the figure.

Neural Systems Underlying the Processing of Complex Sentences

Lars Meyer and Angela D. Friederici

Department of Neuropsychology, Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

48.1 INTRODUCTION

The functional neuroanatomy of sentence processing is a major and, at the same time, one of the most enduring topics of the cognitive neuropsychology of speech and language processing. The present chapter serves three purposes. First, we define the cognitive processes necessitated by the processing of the two sentence types most extensively studied by neuroimaging research: noncanonical and embedded sentences. To this end, we review extensive behavioral evidence for the involved cognitive processes. In the second step, we perform a meta-analysis on all neuroimaging studies that directly contrasted either canonical with noncanonical or nonembedded with embedded sentences, identifying the brain regions that most likely activate during the processing of noncanonical and embedded sentences. Based on our meta-analysis, we explain why the functional neuroanatomy of complex sentence processing involves two core areas: the left inferior frontal cortex and the left middle and superior posterior temporal gyri. Finally, based on the resemblance in brain activations for noncanonical and embedded sentences in our meta-analysis, we discuss a possible common definition of the processing difficulty associated with complex sentences.

48.2 WHY ARE WORD-ORDER DEVIATIONS DIFFICULT TO PROCESS?

The increased processing difficulty of sentences with word orders deviating from the canonical order is a classical finding in psycholinguistics and neurolinguistics across languages—such as Chinese (Hsiao & Gibson, 2003), Dutch (Frazier, 1987), English (King &

Just, 1991), Finnish (Hyönä & Hujanen, 1997), French (Holmes & O'Regan, 1981), German (Friederici, Fiebach, Schlesewsky, Bornkessel, & von Cramon, 2006), Hindi (Vasishth & Lewis, 2006), Hungarian (MacWhinney & Pléh, 1988), Japanese (Mazuka, Itoh, & Kondo, 2002), and Kaqchikel (Ohta, Koizumi, & Sakai, 2014). Theoretical linguistics has long derived the increased difficulty of word-order deviations from their increased level of hierarchy and the according necessity to reorder a noncanonical order of object and subject into a canonical order of subject and object for the integration with their verb (Bever, 1970; Chomsky, 1955; Fodor, 1978; see Figure 48.1).

Psycholinguistic research inspired by this theoretical account has accumulated strong evidence that reordering can be translated into real-time processing reflections. Seminal work found that grammaticality judgment slows not only for object-initial sentences but also when transitive verbs are not followed by a prepositional phrase instead of their object, suggesting that objects are expected at a fixed position (Clifton, Frazier, & Connine, 1984; Holmes, 1987). In line with this interpretation, Trueswell, Tanenhaus, and Kello (1993) observed that in English, postverbal nouns are preferentially interpreted as objects—even if they are the subjects of a subsequent sentence. Complementary evidence is provided by cross-modal priming work. Tanenhaus, Carlson, and Seidenberg (1985) presented words that rhymed with an object that occurred early in the sentence at the canonical object position of an English sentence. Processing of the rhyming words was facilitated compared with control words, suggesting that the remote object had been retrieved at the canonical object position—a finding that was replicated numerous times (for review, see Nicol, Fodor, & Swinney, 1994). Evidence that such priming effects are

FIGURE 48.1 Simplified examples of (A) a canonical and (B) a noncanonical German subordinate clause. While the order of the subject (red) preceding the object (green) is the canonical order in German sentences, the order of the object (green) preceding the subject (red) is the noncanonical order in German sentences. Note also that the noncanonical sentence involves an additional level of hierarchy relative to the canonical sentence, and that the dependency between the object and its verb in the noncanonical structure crosses the subject (indicated by the arrow). Both sentences have the same meaning, translating to *that the man likes the boy*.

restricted to subject positions for subjects and to object positions for objects was presented by [Osterhout and Swinney \(1993\)](#). Besides the cross-modal priming studies, the evidence for fixed positions of subject and object is extended by syntactic interference studies. The work by [Van Dyke \(2007\)](#) used sentences with additional nouns whose syntactic features overlapped with those of a subject that occurred early in the sentence and needed integration with its verb late in the sentence. The results showed that processing at the verb's canonical subject position was exacerbated by feature overlap.

As a recurrent motif, an alternative explanation to the reordering mechanism is put forward time and again (for a recent instance, see [Rogalsky & Hickok, 2010](#)). This explanation is based on the fact that English noncanonical sentences are not only noncanonical but also place the object further away from its object position than the subject from its subject position. The time interval between subject or object and verb impedes processing ([Behaghel, 1932](#); [Frazier, Clifton, & Randall, 1983](#); [Yngwe, 1960](#)). This is most likely because of the decay of the subject or object in working memory prior to verb encounter ([Cowper, 1976](#); [Lewis, Vasishth, & Van Dyke, 2006](#)) and collaterally induced working memory storage and rehearsal demands. Still, while some of the English results may thus be ambiguous between a reordering and a working memory explanation, this is not the case for all languages that show noncanonicity effects. In German, recent work has compared canonical and noncanonical orders, keeping the time interval between either subject or object and their verb constant, finding that noncanonicity still impedes processing over canonicity ([Friederici et al., 2006](#); [Meyer, Obleser, Anwander, & Friederici, 2012](#)). In summary, the available evidence supports the notion that sentences with noncanonical orders are difficult to process because they necessitate reordering into the canonical order.

48.3 WHY ARE EMBEDDED SENTENCES DIFFICULT TO PROCESS?

When a subordinate clause is embedded into a superordinate clause, the resulting sentence has a hierarchical structure, and its processing becomes difficult ([Figure 48.2](#)). Such effects have been reported for Dutch ([Bach, Brown, & Marslen-Wilson, 1986](#); [Kaan & Vasić, 2004](#)), English ([Miller & Isard, 1964](#)), German ([Bach et al., 1986](#)), Hindi ([Vasishth, 2003](#)), Japanese ([Babyonyshev & Gibson, 1999](#)), and Russian ([Fedorenko, Babyonyshev, & Gibson, 2004](#)). The associated difficulty can have drastic consequences. When one of the three required verbs of a double-embedded sentence is experimentally removed, participants do not even realize the absence ([Gibson & Thomas, 1999](#); [Gimenes, Rigalleau, & Gaonach, 2009](#)).

One of the main cognitive challenges associated with the processing of embedded sentences lies in their hierarchy of multiple parallel syntactic dependencies between multiple subjects and objects and their respective verbs ([Bever, 1974](#); [Gibson, 1998](#); [Makuuchi, Bahlmann, Anwander, & Friederici, 2009](#)). Processing of an embedded sentence temporarily requires the parallel storage of two or more subjects or objects until their verbs occur. Although embedded sentences whose multiple subjects or objects are highly distinct along syntactic lines are processed relatively easily, recent work has reported that an overlap of syntactic features between the multiple subjects or objects increases processing difficulty, likely as a result of memory interference ([Badecker & Kuminiak, 2007](#); [Gibson, 1998](#); [Glaser, Martin, Van Dyke, Hamilton, & Tan, 2013](#); [Gordon, Hendrick, & Johnson, 2001](#); [Lewis, 1996](#); [Van Dyke & McElree, 2006](#)). Initial behavioral evidence for this explanation has been found in Japanese. [Babyonyshev and Gibson \(1999\)](#) presented embedded sentences in which the form of the case markings of three subjects matched and contrasted

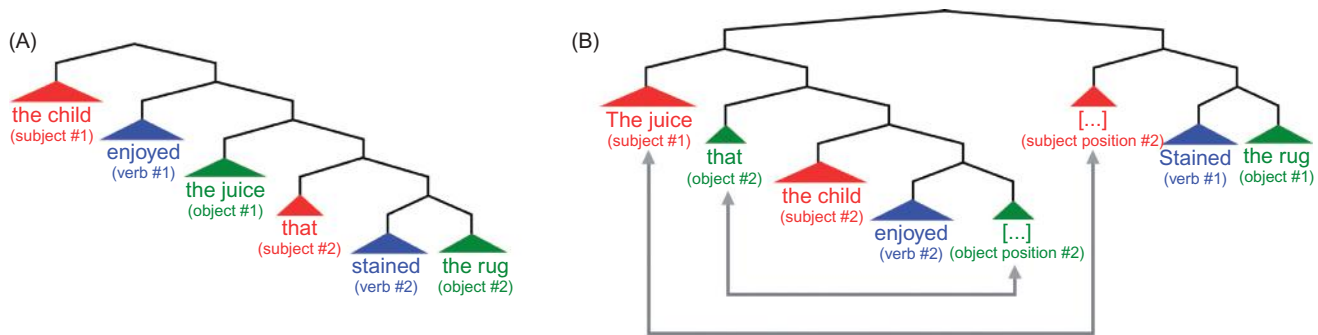

FIGURE 48.2 Simplified examples of (A) a nonembedded and (B) an embedded English sentence. In the nonembedded sentence, all subjects (red) and objects (green) are in their canonical positions and can be linked to their verbs (blue) directly, whereas in the embedded sentence, both the subject (red) of the superordinate clause and the object (green) of the subordinate clause form a dependency with their respective canonical positions (indicated by the arrows). Note that the embedded sentence is hierarchically more complex, and that the dependency between the superordinate-clause subject and its canonical position spans the subject and object of the subordinate clause. Both sentences have the same meaning. Adapted from *Caplan et al., 2000*, with permission from the publisher.

these with embedded sentences in which only two subjects' case markings matched. The result was that the sentences with three matching subjects were more difficult to process, pointing to interference-induced processing difficulty. Similar evidence has been found in Russian. *Fedorenko et al. (2004)* used embedded sentences in which the case marking of two objects either matched or did not match, finding that sentences with matching objects increased processing demands. In summary, there is good behavioral evidence that the difficulty of embeddings results from their hierarchical nature and the involvement of multiple dependencies between multiple subjects or objects and their respective multiple verbs.

48.4 WHICH BRAIN REGIONS ARE INVOLVED IN PROCESSING COMPLEX SENTENCES?

The functional neuroanatomy of noncanonicity and embedding has been extensively investigated by neuroimaging research. For this review, we conducted an activation likelihood estimation (ALE) meta-analysis on the left-hemispheric peak activation coordinates from all published studies that tested for a main effect of either noncanonicity or embedding, did not report an interaction with other experimental factors, and did report Talairach (*Talairach & Tournoux, 1988*) or Montreal Neurological Institute (MNI) coordinates (*Table 48.1* and *Figure 48.3A*). We first converted all non-MNI coordinates into MNI space (*Brett, Johnsrude, & Owen, 2002*). The ALE analysis then generated a smoothed brain map from each study's peak coordinate map, applying an individual smoothing kernel whose full width at half maximum was

calculated from each study's sample size (*Eickhoff et al., 2009*). The overlap of the individual study maps results in a voxel-wise ALE value (*Turkeltaub, Eden, Jones, & Zeffiro, 2002; Turkeltaub et al., 2012*), which is then tested against the null distribution ($P < 0.001$). The resulting whole-brain significance map is corrected for multiple comparisons using a cluster statistic (*Eickhoff, Bzdok, Laird, Kurth, & Fox, 2012*), which we ran at 1,000 permutations and a conservative cluster-level threshold of $P < 0.001$. The result of the ALE procedure (*Table 48.2* and *Figure 48.3B*) showed a striking likelihood for noncanonicity and embedding to activate two core regions: Brodmann area (BA) 44 of the left inferior frontal gyrus (IFG), MNI peak coordinates at maximum $X = -52$, $Y = 10$, $Z = 16$; and, less consistently reported across studies, BA 22 of the middle and superior temporal gyri (MTG/STG), MNI peak coordinates at maximum $X = -54$, $Y = -52$, $Z = -4$ (*Figure 48.3* and *Table 48.2*).

Representative of the coordinate overlap in BA 44 among studies are seven functional magnetic resonance imaging (fMRI) studies from languages that allow for testing the factor syntactic complexity while maximally controlling for confounding working memory storage and rehearsal demands—that is, keeping the temporal interval between either the subject or the object and their verb constant across experimental conditions. These are languages as diverse as German (*Friederici et al., 2006; Meyer et al., 2012; Obleser, Meyer, & Friederici, 2011; Röder, Stock, Neville, Bien, & Rösler, 2002*), Hebrew (*Ben-Shachar, Hendler, Kahn, Ben-Bashat, & Grodzinsky, 2003*), and Japanese (*Kim et al., 2009; Kinno, Kawamura, Shioda, & Sakai, 2008*). First, despite the linguistic heterogeneity of these languages, all these studies used either a factorial or a parametric design comparing sentences involving

canonical and noncanonical orders of subject and objects. Note also that all of these studies rigorously controlled their experimental paradigms for the confounding influence of working memory storage and rehearsal demands, which is crucial because BA 44 activity has been observed for working memory tasks outside of the sentence processing domain as well (Gerton et al., 2004; Paulesu, Frith, & Frackowiak, 1993). Conflicting working memory demands may render ambiguous some of the results of prior noncanonicity studies conducted in English (Ben-Shachar, Palti, & Grodzinsky, 2004; Just, Carpenter, Keller, Eddy, & Thulborn, 1996; Rogalsky, Matchin, & Hickok, 2008), where noncanonicity induced a collateral increase in working memory storage and rehearsal demands. However, the credibility of the results from the non-confounded paradigms is increased by a line of clinical

research that has demonstrated that reordering abilities can be impaired independently of verbal working memory as tested by standard working memory tests (Caplan & Waters, 1999; Martin & Romani, 1994). Although collateral working memory demands cannot be fully ruled out as a confound in the three imaging studies that compared embedded and nonembedded sentences (Caplan, Alpert, Waters, & Olivieri, 2000; Makuuchi et al., 2009; Santi & Grodzinsky, 2010), an explanation of the observed IFG activations by working memory demands is unlikely. First, the study by Rogalsky et al. (2008) on English crossed a canonicity manipulation with an overt rehearsal task, but it did not find activation in BA 44 under concurrent articulation to selectively increase during the processing of noncanonical sentences. Rather, BA 44 activation for both canonical and noncanonical sentences increased

under concurrent articulation, suggesting that sentence comprehension may interfere with a concurrent articulation task in a canonicity-insensitive manner. Second, the recent study by Ohta et al. (2014) on Kaqchikel reports BA 44 activity to increase during the processing of noncanonical sentences even when these exhibit a lower working memory storage and rehearsal demand than their canonical counterparts. We could not include the study by Ohta et al. (2014) in our ALE analysis because no activation coordinates were reported; only anatomical labels were reported.

Is this strong position on the involvement of BA 44 in the processing of noncanonicity and embedding warranted by causal, that is, clinical, evidence? A strong relationship between stroke lesions involving BA 44 and processing deficits on noncanonical sentences has been proposed (Grodzinsky, 2001), but stroke lesions are relatively large, associated comprehension patterns are diverse, and a number of methodological concerns about the studies have been raised (Bastiaanse & van Zonneveld, 2006). However, voxel-based lesion-symptom mapping work with glioma patients, lesion patients, and nonfluent primary progressive aphasics reported a processing decline on noncanonical sentences after damage to the left IFG. Two studies involving Japanese glioma patients by Kinno et al. (2009), Kinno, Ohta, Muragaki, Maruyama, and Sakai (2014) indicated that glioma in BA 44, but also in superior regions, predicts decreased performance on noncanonical sentences. In line with this, a study involving Icelandic stroke patients by Magnúsdóttir et al. (2013) indicates that damage to the IFG, among other left-hemispheric regions, is significantly associated with decreased performance on noncanonical sentences. Additionally, in recent work involving nonfluent primary progressive aphasics, Wilson et al. (2010) further reduced the localization variance, reporting both tissue degeneration in the left posterior IFG and a focal lack of activation increase in this region for noncanonical sentences (for review, see Leyton et al., 2011). Thus, the patient data do support the primary role of BA 44 in the processing of noncanonicity and embedding.

In addition to BA 44, the present ALE analysis isolated the MTG/STG as a second region to most likely activate during the processing of noncanonicity and embedding (Bahlmann, Rodriguez-Fornells, Rotte, & Munte, 2007; Ben-Shachar et al., 2003, 2004; Bornkessel, Zysset, Friederici, von Cramon, & Schlesewsky, 2005; Constable et al., 2004; Dapretto & Bookheimer, 1999; Friederici et al., 2006; Kinno et al., 2008; Michael, Keller, Carpenter, & Just, 2001; Newman, Ikuta, & Burns, 2010; Obleser et al., 2011; Santi & Grodzinsky, 2010). According to a meta-study by Vigneau et al. (2006), the MTG/STG is involved in semantic integration across linguistic tasks. In the case of noncanonicity

and embedding, increasing brain activity in a semantic integration region may result from increasing demands for sentence-level semantic information, most likely in accessing verb–argument structure representations (Friederici, Rueschemeyer, Hahne, & Fiebach, 2003). This interpretation is plausible considering a study by Shetreet, Palti, Friedmann, and Hadar (2007), who assessed the brain activation associated with increasing numbers of possible verb–argument structures in which a verb could be involved. The results show that the number of possible verb–argument structures associated with a verb parametrically increases activity in the MTG/STG region, in close proximity to the MTG/STG ALE maximum in the current meta-analysis. Our comparably agnostic position regarding the involvement of the MTG/STG with respect to the primary mechanisms involved in the processing of noncanonicity and embedding is in line with the studies enrolled in our meta-analysis. Although all studies report at least one inferior frontal activation, not all studies report posterior temporal activations.

48.5 WHAT DO WORD-ORDER DEVIATIONS AND EMBEDDING HAVE IN COMMON?

Our meta-analysis suggests that the processing difficulty associated with the processing of noncanonicity and embedding rely on a similar brain substrate. But what is the similarity between the involved cognitive processes? First, the difficulty associated with noncanonicity lies in a mismatch between the incoming order of object and the underlying canonical order of the subject and object positions at their verb. The resolution of this mismatch requires an assumed process that we defined as reordering. This process, independent of working memory storage and rehearsal, needs to ensure that subject and object of a verb are retrieved in the canonical order once the verb is reached. Second, the difficulty associated with embedded sentences lies in the multiple dependencies between multiple subjects and objects and their multiple verbs. This requires a process independent of working memory storage and rehearsal to keep items distinct, enabling the retrieval of each item only at their appropriate canonical position in relation to their appropriate verb.

Word-order deviations and embeddings are similar along two isomorphic lines. Both sentence types involve a syntactic structure that is more complex than the structure of their canonical or nonembedded counterparts—in formal terms—and both noncanonical and embedded sentences involve an additional level of hierarchy in the syntactic tree. However, both sentence types involve the temporary storage of at least a first

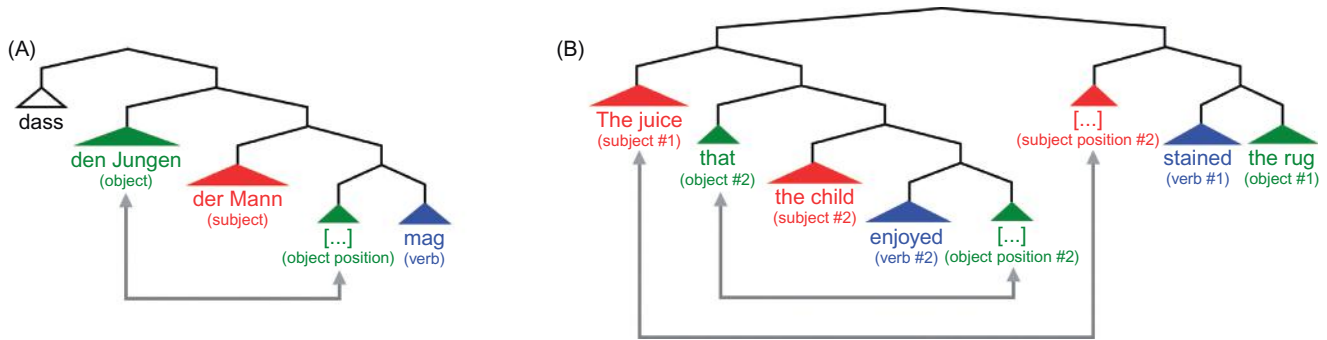

FIGURE 48.4 Comparison of the sentence structures associated with (A) a German noncanonical subordinate clause and (B) an English embedded sentence. The remote positioning of the object in the noncanonical sentence and the remote positioning of the superordinate subject and subordinate object in the embedded sentence result in an additional level of hierarchy (see Figure 48.1 and 48.2 and compare the number of nodes/triangles for sentence types (A) and (B), respectively) and a dependency that crosses at least either a second subject or object (consult Figure 48.1 and 48.2 and compare the number of arrows for sentence types (A) and (B), respectively).

noun phrase (subject or object) across at least a second noun phrase (subject or object) that may interfere—in functional terms—and noncanonical and embedded sentences necessitate the avoidance of an erroneous premature subject or object retrieval (Figure 48.4).

We consider that the establishment of syntactic hierarchy and the possible interference of elements in working memory may contribute to the processing difficulty of noncanonical and embedded sentences. This interpretation is in line with both classical assumptions of syntactic theory (Chomsky, 1955), more recent proposals of psycholinguistic sentence-processing research (Gibson et al., 2013; Lewis, 1996), and a recent fMRI study by Glaser et al. (2013) that reported BA 44 in the IFG activates more strongly for the processing of embeddings whose relative-clause subject interfered with the matrix-clause subject as compared with non-interfering embeddings. Thus, the available neurobiological literature suggests that the main function of BA 44 during sentence processing is to establish the hierarchical dependencies between subjects and objects and their verbs. There is now initial evidence for the neural basis of the second processing aspect, that is, the distinctive temporary storage and retrieval of possibly interfering subjects and objects from working memory; the interference account needs further neurolinguistic substantiation.

48.6 SUMMARY

The current chapter has outlined the cognitive processes involved in the processing of noncanonical and embedded sentences, for which cross-linguistic psycholinguistic research has reported increased processing difficulty relative to their canonical or nonembedded counterparts, respectively. Likely, the increased processing difficulty of noncanonicity results

from the need to reorder the noncanonical order of object and subject into the canonical order of subject and object at the verb; the increased processing difficulty of embedding results from its hierarchical nature and the need to distinctly track multiple dependencies between multiple subjects or objects and their respective multiple verbs. Our ALE meta-analysis provides strong evidence that both processes rely on a left-hemispheric brain substrate consisting of BA 44 in the IFG and the MTG/STG. Because only inferior frontal regions are found to be active in all studies, including in our meta-analysis, we suggest that BA 44 is primarily involved in the processing of noncanonicity and embedding. From our literature review and our meta-analysis, we synthesized the common underlying mechanism of BA 44 in complex sentence processing to lie in the tracking of the multiple hierarchical dependencies between subjects and objects and their verbs, avoiding their interference to ensure that subjects and objects are only retrieved from working memory at their appropriate positions.

49.1 PRELIMINARIES: CHALLENGES TO A NEUROBIOLOGICAL PERSPECTIVE ON THE TIMECOURSE OF SENTENCE PROCESSING

Timecourse information has long held a special significance for researchers interested in the cognitive architecture of language processing. At the level of sentence processing in particular, insights about timing have played a central role in shaping the defining debates of the field, such as the question of how different information sources are utilized during the comprehension of a sentence. In this respect, modular models maintain that distinct linguistic information sources are processed in succession, typically with at least some aspects of syntactic processing thought to take place first and in an informationally encapsulated manner (Frazier, 1987; Frazier & Clifton, 1996; Rayner, Carlson, & Frazier, 1983). Other information sources (semantics, plausibility, context, etc.) are not utilized until a later point during processing. In contrast, (strongly) interactive models posit that there is no priority for one particular information source over others and, thereby, that all available sources of information interact from the earliest stages of processing (MacDonald, Pearlmutter, & Seidenberg, 1994; Trueswell & Tanenhaus, 1994). Clearly, an evaluation of these competing architectural concepts requires detailed timecourse measures.

A problem arises, however, when we attempt to translate this classic cognitive view into a neurobiologically plausible perspective. In particular, what are the relevant units and mechanisms to consider when

describing the timecourse of the neurobiology of sentence processing? The heritage of cognitive models has typically led us to pose this question in a particular way: we tend to think of the relevant units as being part of linguistic subdomains such as phonology, syntax, and semantics, and of the relevant mechanisms as being tied to cognitive metaphors such as the notion of a mental lexicon (e.g., “lexical access,” “prelexical,” or “postlexical” processing). However, the utility of such concepts for the neurobiology of language is considerably less clear. Consider the intuitively appealing and cognitively plausible mental lexicon metaphor as an example. It is generally accepted that conceptual information is represented in the brain in a distributed fashion (e.g., Patterson, Nestor, & Rogers, 2007, for a review). Thus, the notion of a lexical “entry” that can be activated and accessed cannot be translated straightforwardly into neurobiological terms. Moreover, the mechanisms suggested by terms such as “lexical access” are unrevealing with respect to the question of how the human brain actually implements the processing of information thought to be encoded in a lexical entry. In their recent review of the N400 event-related brain potential (ERP) component in language processing, Kutas and Federmeier (2011) also conclude that the notion of a mental lexicon and the mechanisms suggested by it (such as prelexical or postlexical processing) are empirically inadequate for explaining the existing range of N400 results. In addition, the dissociation between the cognitive view and a neurobiological perspective is underscored by the discrepancy between timecourse estimates obtained using

ERPs as opposed to eye movements during reading (see Bornkessel & Schlesewsky, 2006; Rayner & Clifton, 2009; Sereno & Rayner, 2003; and Sections 49.3.1 and 49.4 in this chapter). In summary, advances in understanding the neurobiology of language will likely require a new, neurobiologically plausible conception of the timecourse of sentence processing.

The remainder of this chapter is organized as follows. In Section 49.2, we discuss some neurobiological considerations with respect to timecourse before turning to the major current perspectives on the timecourse of sentence processing in the brain in Section 49.3. Section 49.4 then attempts to relate these approaches to behavioral timecourse measures obtained using eye-tracking during natural reading. Finally, Section 49.5 offers some conclusions and also discusses open questions for future research.

49.2 NEUROBIOLOGICAL CONSIDERATIONS

So far, we have suggested that it is not trivial to map traditional cognitive perspectives on the timecourse of sentence processing directly onto the neurobiology of language. In this section, we briefly discuss some neurobiological considerations related to timecourse information.

With respect to the nature of the “units” or “domains” of processing, it is important to keep in mind that most neuroscientists do not consider the purpose of the human brain to lie in the construction of elaborate cognitive representations. Rather, there is a relatively broad consensus that the brain implements perception–action cycles (Fuster, 1997) and, hence, that “the purpose of the human brain is to use sensory representations to determine future actions” (Wolpert, Doya, & Kawato, 2003, p. 593). Ultimately, a neurobiologically plausible perspective on language (including sentence) processing should be compatible with these insights. Perhaps somewhat reassuringly, however, a commonality between these neurobiological considerations and the classic cognitive perspective lies in the notion of hierarchical organization as the basis for stable complex systems (Simon, 1962).

In terms of neurobiological organization, neither the strictly serial and encapsulated perspective of modular models nor the “everything is connected to everything”

perspective of strongly interactive models (often with connectionist implementations) is neurobiologically plausible. Rather, perception–action cycles in vision and audition (including the processing of speech and language) involve information transfer along multiple streams, with a hierarchical organization within streams (Rauschecker & Scott, 2009; see also Bornkessel-Schlesewsky & Schlesewsky, 2013 for discussion). Hierarchical processing implies properties of both serial and parallel organization. Ultimately, however, connectivity is considerably more complicated. First, because streams of information processing are inherently bidirectional, anatomical feedback connections must be considered in addition to feedforward connections.¹ Second, hierarchical organization does not imply “serial” connectivity in the sense that a level n of the hierarchy is only connected to levels $n + 1$ and $n - 1$. Rather, long-range (feedforward and feedback) connections can “skip” individual levels of the hierarchy (for possible implications, see Bar, 2003). Implications of these considerations for associated timecourse scenarios include the following: (i) information processing proceeds in a cascaded manner incorporating both serial and parallel aspects (consequence of hierarchical organization); and (ii) the interpretation of observable effects must take into account that processing comprises more than a feedforward sweep, with feedback connections and top-down modulations also playing an essential role (consequence of bidirectional and long-range connectivity).

A further complication arises from the methods currently available to study the timecourse of language processing in the brain. Electroencephalography (EEG) and magnetoencephalography (MEG) have long been the methods of choice for this purpose but, despite their exquisite temporal resolution, provide rather macroscopic measures of brain activity. Functional magnetic resonance imaging (fMRI), by contrast, does not offer the temporal resolution required for the question under consideration. Electrocorticography (ECoG) (i.e., the recording of electrophysiological activity directly from the cortex using subdural electrodes) (see Chang et al., 2010, for a recent application to language) is a highly promising approach because it offers both high temporal and high spatial resolution. However, ECoG studies can only be performed with patients and the electrode grids used typically only offer limited coverage because electrode placement is determined by clinical motivations.

¹Feedback and feedforward connections may further be asymmetrical (i.e., connectivity between regions A and B may be bidirectional but connectivity between regions A and C may not). For a detailed demonstration of this property for visual processing streams, see recent work by Kravitz and colleagues (Kravitz, Saleem, Baker, & Mishkin, 2011; Kravitz, Saleem, Baker, Ungerleider, & Mishkin, 2013).

These difficulties, which currently provide significant challenges to a neurobiological perspective on the timecourse of language processing, apply to all aspects of language. They are, however, aggravated further by the particular demands of sentence processing, which necessarily involves more complex units² than, for example, sound or word processing and a more complex interplay of different information sources.

In view of all of these considerations, it is virtually impossible to provide a comprehensive picture of the timecourse of sentence processing from a truly neurobiological perspective at this point. However, there exist a number of approaches that have set out to tackle these challenges from a variety of perspectives. In what follows, we aim to provide an overview of the different (types of) approaches that have been put forward and their respective claims about the timecourse of sentence processing in the brain.

49.3 DIFFERING PERSPECTIVES ON THE TIMECOURSE OF SENTENCE PROCESSING IN THE BRAIN

As is already the case in the cognitive domain, the timecourse of sentence processing in the brain has been debated intensely and it is not yet possible to outline a consensus view. Accordingly, we discuss a variety of different perspectives primarily based on ERP data because this remains the most widely used method by far for the examination of timecourse questions from a neurobiological perspective.

49.3.1 Component Mapping/Absolute Timing

Originally, ERP-based research into the timecourse of sentence processing closely mirrored the cognitive perspective that had been developed on the basis of behavioral results. Thus, ERP components such as the N400 and P600 were viewed as correlates of linguistic domains (semantic and syntactic processing, respectively), and the relative timing of these components as well as their interaction or mutual independence were thus thought to shed light on the organization of the language architecture (e.g., Friederici, Pfeifer, & Hahne, 1993; Hagoort, Brown, & Osterhout, 1999; Osterhout & Nicol, 1999, among many others).

This perspective forms part of two highly influential models of sentence processing in the brain, Friederici's

Neurocognitive Model of Auditory Sentence Processing (Friederici, 1995, 1999, 2002, 2009, 2011) and Hagoort's *Memory, Unification, and Control (MUC) Model* (Hagoort, 2003, 2005, 2013). In the spirit of the classic modularity versus interactivity debate, the Neurocognitive Model posits that different information sources are processed in several successive processing stages that are organized serially, whereas the MUC model advocates an interactive processing architecture. In each case, evidence for the respective view was provided by an assessment of ERP component timing. According to Friederici (see Friederici, 2011, for a recent review), acoustic–phonetic processing is followed by an initial stage of local syntactic structure building (150–250 ms, indexed by the early left anterior negativity [ELAN]). In a second processing stage, semantic and morphosyntactic relations are processed independently but in parallel, as evidenced by the N400 and the left anterior negativity (LAN), respectively. Finally, these separate information processing streams are integrated with one another in stage 3 of processing (correlating with the P600), which also comprises processes of reanalysis and/or repair if necessary. In this view, crucial evidence for the seriality of processing stems from the observation that a disruption of early syntactic processing (i.e., a word category violation that engenders an ELAN, example 1a) can “block” semantic processing (example 1b) because a double (both word category and semantic) violation (example 1c) engenders an ELAN-P600 pattern with no additional N400 (Friederici, 2002; Hahne & Friederici, 2002).

- (1) Examples of the syntactic, semantic, and double violations used by Friederici and colleagues to infer a staged processing timecourse (examples and ERP responses from Hahne & Friederici, 2002)
 - a. Syntactic (word category) violation (ELAN-P600 response in comparison with 1d)
 - *Das Eis wurde im gegessen
 - the ice cream was in-the eaten
 - b. Semantic violation (N400 response in comparison with 1d)
 - Der Vulkan wurde gegessen
 - the volcano was eaten
 - c. Double violation (ELAN-P600 response in comparison with 1d)
 - *Das Türschloss wurde im gegessen
 - the door lock was in-the eaten
 - d. Control condition
 - Das Brot wurde gegessen
 - the bread was eaten

²In view of the problem of distributed representations (see the discussion of the mental lexicon in Section 49.1), it is currently not at all clear how anatomical considerations such as hierarchical organization actually map onto the kinds of cognitively inspired units that (at least currently) appear to be unavoidable in the characterization of sentence processing (e.g., words, morphemes).

In contrast, while also subscribing to the view that the N400 and LAN/P600 are related to semantic and syntactic aspects of processing, respectively, the MUC model assumes that there is no priority for any one information source over another during sentence interpretation. Rather, the relative timing of when a particular information source is used depends on its availability in the input signal (Hagoort, 2008). In addition, the model posits a “one-step” interpretation process in which all available information sources interact directly irrespective of whether they are sentence-internal, sentence-external (e.g., discourse context), or even external to language (e.g., co-speech gestures, identity of the speaker) (Hagoort & van Berkum, 2007). It thus rejects any notion of stages during the comprehension process, including word recognition; there is no separate stage of “lexical access” that needs to precede integration into the current sentence (Hagoort, 2008). Evidence for timing based on availability stems, for example, from a study by Van Den Brink and Hagoort (2004) that used logic similar to that employed by Hahne and Friederici (2002) but changed the temporal availability of the syntactic and semantic information sources by incorporating the semantic violation into the word stem and the word category violation into the suffix. In contrast to Friederici and colleagues, they observed an N400 relative to word onset and an early anterior negativity relative to the category violation point (CVP), thus leading them to reject the stages posited in Friederici’s model.

- (2) Examples of the stimuli used by Van Den Brink and Hagoort (2004) to infer that the relative timing of syntactic and semantic processing depends on temporal availability within the acoustic signal
- a. Double violation (N400 followed by an ELAN relative to the CVP in comparison with 2b)
 - *Het vrouwtje veegde de vloer met een oude kliederde gemaakt van twijgen
The woman swept the floor with an old messed made of twigs
 - b. Control condition
 - Het vrouwtje veegde de vloer met een oude bezem gemaakt van twijgen
The woman swept the floor with an old broom made of twigs

The second crucial assumption of the MUC model (one-step interpretation) is supported by results showing that sentence-internal and sentence-external information all modulate the N400 component, with no evidence for a different timecourse depending on the source of the information (see Hagoort & van Berkum, 2007 for a detailed review of the relevant studies).

As in the cognitive domain, the debate between modular and interactive neurocognitive models of sentence processing remains unresolved even after several decades of work on this subject. Furthermore, continuing progress in the field has revealed challenges to some of the basic assumptions underlying the component mapping approach:

- (a) *Absolute timing*: Several observations have called into question the assumption that ERP component latencies provide absolute estimates of timing information. The first stems from measures of eye movements during reading, which, as briefly noted, sometimes provide different timing estimates to ERPs. This is perhaps most readily apparent with regard to the N400 component, which typically shows an onset latency of a little more than 200 ms in young adults (Kutas & Iragui, 1998 report an average onset latency of 236 ms for adults in their 20s) and is highly stable in terms of its timing (Federmeier & Laszlo, 2009). The N400 is reliably modulated by word frequency (at least for words occurring early on in a sentence; Van Petten & Kutas, 1990), a factor which is also known to affect the duration of the first fixation on a word during reading (Inhoff & Rayner, 1986). Because fixations last approximately 200–250 ms on average for English (Rayner, 1998), and because saccade programming is thought to require approximately 150–175 ms (Rayner, Slowiaczek, Clifton, & Bertera, 1983), word frequency appears to influence eye movements at a point in time that precedes the onset of the N400 (Rayner & Clifton, 2009; Sereno & Rayner, 2003; for discussion, see Bornkessel & Schlesewsky, 2006). This suggests that latencies of components such as the N400 and P600 may not be reliable indicators of when a particular information source first becomes available or when it is first utilized during sentence processing.

A second and related observation stems from the ERP domain itself. If components such as the N400 do not provide absolute timing information, perhaps markers of this information should be sought earlier in the ERP record. There have been a number of reports of language-related ERP effects “before the N400” (Dien, 2009). These include word frequency-based modulations of the N100 (Sereno, Rayner, & Posner, 1998) and modulations of the mismatch negativity (MMN), which peaks between approximately

100 and 250 ms poststimulus onset, by morphosyntactic violations presented as part of an oddball design (Hasting, Kotz, & Friederici, 2007). Recent MEG studies have also provided converging evidence for early effects by demonstrating a dissociation of brain responses to words and pseudowords from as early as 50 ms (MacGregor, Pulvermuller, van Casteren, & Shtyrov, 2012) or a modulation of the visual M100 by syntactic (Dikker, Rabagliati, & Pylkkänen, 2009) and lexical-semantic violations (Dikker & Pylkkänen, 2011) in highly predictive contexts. It is possible that findings such as these should be taken to indicate that ERPs and event-related magnetic fields (ERFs) *do* provide absolute timing information once early components—rather than “late” components such as the N400—are taken into account. We return to this perspective in Section 3.2.

- (b) *1:1 component mapping*: Although highly appealing, the notion that language-related ERP components can be used as diagnostic indicators of particular linguistic or cognitive domains, such as the N400 as a correlate of lexical-semantic processing or declarative memory contributions to language (Ullman, 2001) versus the LAN/P600 as correlates of morphosyntactic processing or procedural memory, is now challenged by a continually increasing number of findings. The occurrence of monophasic P600 effects for certain types of semantic violations—particularly violations that a plausible sentence would obtain if thematic role assignments to arguments were reversed (example 3)—has been discussed intensely in the literature on the electrophysiology of language over the past decade (e.g., Hoeks, Stowe, & Doedens, 2004; Kim & Osterhout, 2005; Kolk, Chwilla, van Herten, & Oor, 2003; Kuperberg, Sitnikova, Caplan, & Holcomb, 2003, among many others; see Bornkessel-Schlesewsky & Schlesewsky, 2008; Brouwer, Fitz, & Hoeks, 2012; van de Meerendonk, Kolk, Chwilla, & Vissers, 2009, for reviews; for an account of “semantic P600” effects that subscribes to a traditional functional interpretation of language-related ERP components, see Kim & Osterhout, 2005). In addition, many studies using “traditional” semantic violations in the style of Kutas and Hillyard’s famous “He spread the warm bread with *socks*” (Kutas & Hillyard, 1980) have observed N400s followed by P600 effects, and P600 effects have also been observed in response to other types of

incongruencies such as orthographic violations (Münte, Heinze, Matzke, Wieringa, & Johannes, 1998; Vissers, Chwilla, & Kolk, 2006), thus leading several groups to suggest more general interpretations of the P600 (e.g., as a correlate of “conflict monitoring”; Kolk et al., 2003; van de Meerendonk et al., 2009) or an instance of the domain-general P300 (Bornkessel-Schlesewsky et al., 2011; Coulson, King, & Kutas, 1998; Gunter, Stowe, & Mulder, 1997; Sassenhagen, Schlesewsky, & Bornkessel-Schlesewsky, 2014).

- (3) Semantic reversal anomaly (from Kim & Osterhout, 2005)

The hearty meals were *devouring*. . .

Although less well-known than semantic P600s, syntax-related or morphosyntax-related N400 effects have also been reported in a range of studies, such as for case violations (Choudhary, Schlesewsky, Roehm, & Bornkessel-Schlesewsky, 2009; Frisch & Schlesewsky, 2001; Mueller, Hahne, Fujii, & Friederici, 2005), gender incongruencies (Wicha, Moreno, & Kutas, 2004), object case ambiguities (Hopf, Bayer, Bader, & Meng, 1998), and word order variations (Bornkessel, McElree, Schlesewsky, & Friederici, 2004; Haupt, Schlesewsky, Roehm, Friederici, & Bornkessel-Schlesewsky, 2008). In summary, all of these results suggest that ERP components do not reflect a clear-cut functional divide between linguistic subdomains and that somewhat more general explanations may be required.

- (c) *Data interpretability*: A final problem concerns the ability of ERP or ERF data to conclusively arbitrate between competing models. Consider the ELAN/N400 debate, which we discussed in relation to examples (1) and (2). As is apparent from the discussion, these results have been interpreted differently by proponents of alternative models rather than helping to conclusively settle the modularity versus interactivity debate with respect to the neurocognition of language.

In view of these conflicting interpretations, some of us have previously proposed that the data may require a third type of explanation that shares characteristics with both a modular and an interactive view (Bornkessel-Schlesewsky & Schlesewsky, 2008, 2009). From this perspective, the processing architecture is organized in a hierarchical and cascaded manner (McClelland, 1979): whereas there are hierarchically organized processing “stages”, processing stage n need not be completed when processing stage $n + 1$ begins, thus allowing for a certain degree of parallelism.

Applied to the ELAN/N400 discussion, this proposal assumes that although word category processing does take hierarchical precedence vis à vis semantic processing, this does not mean that semantic processing cannot be initiated until unambiguous word category information is encountered. Rather, because the critical word in sentence example (2a) occurs in a sentence context that is highly predictive of a noun (a determiner + adjective sequence) and the initial several hundred milliseconds of the acoustic signal from word onset are compatible with this prediction, information for a “noun” analysis quickly accrues and processing can proceed. Accordingly, the semantic incongruity leads to an N400 just as would be expected if there were no additional word category violation. In contrast, when the word category violation is encountered several hundred milliseconds later, it nevertheless elicits an anterior negativity. An account along these lines thus explains the asymmetry between the ERP patterns for examples (1) and (2): when the word category violation precedes a semantic violation in the input signal, the ELAN “blocks” the N400, but not vice versa (i.e., an N400 for a semantic incongruity that temporally precedes a word category violation does not block an ELAN). Note also in this context, however, that the experimental paradigms that have traditionally been used to elicit ELAN effects have recently been criticized on a number of grounds (Steinhauer & Drury, 2012). Thus, some of the claims based on the ELAN literature may eventually require reevaluation.

Perhaps most importantly, irrespective of whether one is willing to accept the cascaded view as a viable alternative, these considerations at least highlight the need to take into account issues such as prediction and the interaction between top-down and bottom-up information sources when attempting to account for the timecourse of sentence processing in the brain. These concepts play an important role in the accounts discussed in the following sections.

49.3.2 Absolute Timing Revisited: Virtual Parallelism and an Early Cascade

As already discussed in some detail in the preceding section, there is considerable evidence to suggest that the latency of classic language-related ERP components such as the N400, LAN, and P600 does not provide an adequate estimate of absolute timecourse information. Within the neurocognitive domain, this perspective has been advocated for some time by Pulvermüller and colleagues, drawing primarily on experimental paradigms using the MMN. The MMN typically occurs in response to deviant stimuli in odd-ball paradigms, such as stimuli that occur infrequently

within sequences of high probability “standards.” The processes underlying the MMN are thought to be pre-attentive because it can be elicited even when participants are attending to something other than the critical stimuli (see Kujala, Tervaniemi, & Schröger, 2007 for a review of the MMN). Traditionally, MMN effects are elicited using relatively simple stimuli (e.g., sequences of tones) and their occurrence is explained in terms of sensory memory: the sequence of standard stimuli is assumed to comprise a sensory memory trace and MMN results when a (deviant) stimulus produces a mismatch with this memory representation (Näätänen, Paavilainen, Alho, Reinikainen, & Sams, 1989).

Pulvermüller and colleagues have extended this line of research to considerably more complex stimuli, including minimal phrases such as “we come” or, as a violation condition, “we comes” (Pulvermüller & Shtyrov, 2003; Shtyrov & Pulvermüller, 2002). In comparison with the same word presented out of context (i.e., “comes” preceded by a nonlinguistic noise mimicking the spectral envelope of the word “we”), the ungrammatical string elicited a larger MMN than the grammatical string between 100 and 150 ms after the acoustic divergence point between the two strings. MMN effects related to morphosyntactic information have also been reported for German using both subject–verb agreement violations and word category violations (Hasting et al., 2007). Semantic effects in MMN paradigms have also been observed (Menning et al., 2005; Shtyrov & Pulvermüller, 2007).

On the basis of these results and other findings on the processing of single written words, Pulvermüller and colleagues argue for early “near simultaneity,” with initial processing of different linguistic information sources (phonological, lexical, syntactic, and semantic information) taking place before 200 ms after stimulus onset and in an almost simultaneous but nevertheless cascaded fashion. The single word processing studies contributing to this argument contrasted various parameters (e.g., word frequency, word length, phonological/orthographic typicality, word category [considered a syntactic factor], semantic categories, and affective parameters) and all have in common that they observed effects that occurred considerably earlier than the classic language-related ERP components (see Pulvermüller, Shtyrov, & Hauk, 2009 for review and references to the individual studies). Pulvermüller and colleagues suggest that these very early effects may have been missed in many studies because they are focal and transient, thus requiring very tightly controlled stimuli and appropriately narrow time windows. In their account, the classic language-related ERP effects such as N400, LAN, and P600 reflect either a second stage of information processing or some type of “postprocessing” that is not specified further. The

early effects, in contrast, that are thought to reflect the initial processing of the relevant information sources are viewed as resulting from the activation of different cortical circuits depending on the exact type of information being processed. Although these circuits are activated with similar latencies (i.e., nearly instantaneously), thus accounting for the near simultaneity of the differing information sources, their internal conduction delays are assumed to differ, thus accounting for the “fine-grained activation delays in the millisecond range” (Pulvermüller et al., 2009, p. 89).

One problem that arises in this respect is that it is not clear whether the effects observed under these circumstances (i.e., single word presentation, MMN paradigms) generalize to more typical sentence processing settings. With respect to the single word paradigms, it is well-known, for example, that word frequency effects interact with sentence context in EEG studies (Van Petten & Kutas, 1990) and that word category effects vary depending on whether words are presented in isolation or in sentence context (Vigliocco, Vinson, Druks, Barber, & Cappa, 2011). Thus, although the observation of ERP modulations “before the N400” in response to various information sources is clearly an important finding that needs to be pursued further, it is not yet clear what conclusions should be drawn from such findings for the timecourse of sentence processing in the brain (for some initial reports of early semantic context effects, see Penolazzi, Hauk, & Pulvermüller, 2007; Sereno, Brewer, & O’Donnell, 2003; Tse et al., 2007).

Evidence from MMN paradigms is also sometimes viewed as problematic because of the highly repetitive nature of the stimuli and the lack of lexical variation (i.e., an experiment may consist simply of a large number of repetitions of the two stimuli “he walks” and “he walk,” with one the standard and one the deviant). However, because syntactic or semantic violation deviants are always contrasted against grammatical deviants in these paradigms, the linguistic properties of the stimuli obviously play at least some role in engendering the larger MMN response to incongruous stimuli. Perhaps the first word in a minimal phrase such as “he walks” creates certain expectations with regard to possible continuations that are commensurate with the prior experience of the language processing system.

The involvement of predictive processes in MMN paradigms in language processing is supported by at least two observations. First, context influences MMN magnitude, as shown by larger MMN responses when a deviant syllable or phoneme occurs in the context of a real word as opposed to a pseudoword (see Pulvermüller et al., 2009). Second, as argued by Friston and colleagues (Friston, 2005; Garrido, Kilner, Stephan, & Friston, 2009), the MMN response can be derived

very plausibly within a predictive coding account of brain architecture. This view assumes a hierarchically organized cortical architecture that attempts to minimize prediction error for sensory stimuli by using internal models of the world to infer the causes of sensory events and, thereby, to formulate appropriate top-down predictions. The MMN is thought to arise from the prediction error that arises after sensory learning has taken place within the context of an oddball paradigm and the deviant stimulus does not match the prediction for the upcoming stimulus. The prediction error is subsequently propagated up the cortical hierarchy and thereby leads to model adjustment.

In summary, a perspective advanced most prominently by Pulvermüller and colleagues (among other researchers) assumes that ERP/ERF components are informative with regard to absolute timecourse information but proposes that the relevant effects occur in a time range prior to 200 ms and, therefore, precede typical language-related components such as the N400. Because these early effects are thought to arise from the near-simultaneous activation of word-specific cortical circuits, with differences in conduction delays (i.e., speeds of information transfer) giving rise to the apparent cascade of effects, this account essentially abolishes the idea of component mapping. As we suggested here, however, predictive processing may also play an important role in engendering—or at least modulating—the effects under discussion, and this aspect may help to link the relevant explanations to sentence-level processing.

49.3.3 The Crucial Role of Top-Down Predictions

The importance of top-down predictions is emphasized more strongly in an approach that has been championed by Dikker, Pylkkänen, and colleagues. Using MEG, these researchers have repeatedly shown that sentence-level (syntactic and semantic) incongruities engender modulations of the visual M100, a component that is typically localized to visual cortex (Dikker & Pylkkänen, 2011; Dikker et al., 2009; Dikker, Rabagliati, Farmer, & Pylkkänen, 2010; for an early report of auditory N100 differences in response to semantic incongruity in sentence processing, see Besson & Macar, 1987). In the syntactic domain, these early effects have been observed for word category violations such as those known from the ELAN literature (see Section 3.1), such as “The boys heard Joe’s about...” or “The tastelessly soda...”. In the semantic domain, they have been demonstrated using a picture–word matching paradigm (e.g., the noun phrase “the apple” following an image of an apple (+ predictive, + match), a picture of a banana

(+ predictive, – match), a picture of a shopping bag with many items (– predictive, + match), or a picture of Noah's ark with many animals (– predictive, – match)).

The early latency of the M100 and its likely source localization suggest that the effects in question may be indexing prediction mismatches at a rather early sensory level. In other words, if the predictive context is strong enough, predictions extend not only to abstract features of an upcoming linguistic item (e.g., word class, semantic category) but also to its sensory properties (i.e., a concrete word form). Similar effects have been observed in the auditory domain, as demonstrated by the so-called phonological mapping negativity (PMN). The PMN, previously labeled phonological mismatch negativity and analyzed by some as an instance of the N200 component (van den Brink, Brown, & Hagoort, 2001, 2006), is a negativity with a peak latency of approximately 250–300 ms that occurs in response to phonologically unexpected input (Connolly & Phillips, 1994). As recently demonstrated by Newman and Connolly (2009), the PMN is independent of whether the current input item is a word or a nonword, thus suggesting that it reflects a purely form-based expectation mismatch. At least to some degree, an account of language-related ERP components that focuses on sensory predictability shifts the burden of explanation for observed ERP or ERF effects from the current input item to the preceding linguistic context. In other words, when evaluating timecourse information, the properties of the current stimulus item may be less important than the predictive capacity of the context in which it is encountered.

This perspective is highly compatible with a hierarchically organized predictive coding architecture in which predictions are passed from higher to lower areas within the cortical hierarchy and, depending on their specificity, can lead to prediction errors at any hierarchical level. Thus, the prediction error signal itself is not necessarily diagnostic of any particular functional interpretation, but rather varies as a function of where within the overall architecture the prediction error is registered.

49.3.4 Integrating Multiple Information Sources During Multimodal Language Processing

The notion of prediction also plays a crucial role in an account of language-related ERP components—and specifically the N400—that abstracts away from timecourse information to a relatively large degree (Kutas & Federmeier, 2011). This perspective builds on the observation that the N400 is not parsimoniously described in relation to lexical (and prelexical,

postlexical, etc.) processing because, for example, it also responds to nonword stimuli as long as they are meaningful in a given context (Federmeier & Laszlo, 2009, for an overview), and that the N400 is remarkably stable with respect to its latency. Accordingly, Federmeier, Kutas and colleagues argue that the N400 should be viewed as indexing a period of convergence between multiple, multimodal information sources, during which meaning is constructed in a dynamic and context-dependent manner. In other words, the N400 indexes the “transition from unimodal to multimodal processing (e.g., from word form to the concept that word brings to mind)” and “reflect[s] the activity in a multimodal long-term memory system that is induced by a given input stimulus during a delimited time window as meaning is dynamically constructed” (Kutas & Federmeier, 2011, p. 640).

This perspective, too, emphasizes the crucial role of prediction during language processing, because linguistic context is assumed to preactivate particular linguistic features as well as their combination. This preactivation process modulates the dynamic construction of meaning as described and hence impacts N400 amplitude. Like the perspectives discussed in the preceding sections, it thus de-emphasizes the notion of component mapping and, although it does not focus on early language-related ERP components, it shares with Pykkänen and colleagues the assumption that predictive processing plays a crucial role in language comprehension. In view of the focus on the N400 and the fixed latency of this component, however, detailed timecourse considerations do not feature as part of this account.

49.3.5 The Interplay Between Top-Down and Bottom-Up Information Sources

In addition to the focus on prediction that has been central to the discussion in the preceding subsections, a range of findings now demonstrate that top-down predictability or “preactivation” is not the sole determinant of neurophysiological effects during sentence comprehension. Rather, the “balance” between top-down and bottom-up influences needs to be taken into account. Once again, a great deal of the relevant evidence stems from the N400 ERP component. A recent finding that shows that N400 amplitude is modulated by properties of the current stimulus rather than the preceding context was reported by Laszlo and Federmeier (2011). They showed that N400 amplitudes are higher for input items—both words and letter strings—with more or higher frequency orthographic neighbors and lexical associates. This result also provides compelling evidence against a view of the N400

as a correlate of lexical access or postlexical processing because accounts along these lines should predict differences between word and nonword stimuli.

The need to consider the integration of top-down and bottom-up information was further emphasized by Lotze, Tune, Schlesewsky, and Bornkessel-Schlesewsky (2011), who found that an unpredictable physical change from normal orthography to a capitalized sentence-final word almost completely neutralized an implausibility-based N400 effect on that word, whereas a change from all capitalized input to a lower case sentence-final word had no effect on the N400. Clearly, the attenuation of the N400 must be attributable to bottom-up stimulus features in this study, because top-down factors did not change between conditions. A somewhat similar result was reported by Delaney-Busch and Kuperberg (2013), who found that N400 effects for incongruous scenarios were neutralized when the critical word was an emotion word (of either positive or negative valence). A possible explanation for these results is that, in line with Bar's assumptions concerning visual object recognition (Bar, 2003 and see Section 2), very basic and salient stimulus features (e.g., sudden capitalization as a visual "pop out" or high emotional valence) are rapidly projected to prefrontal cortex (or other higher-level regions within the cortical hierarchy) via long-range feedforward connections, thus enabling these features to lead to a top-down modulation of plausibility or congruity effects.

If this proposal turns out to be viable, it could provide the basis for a new approach for inferring the organization of the neural language architecture. Rather than basing arguments on temporal precedence, investigations should focus more closely on *functional* precedence (see also our interpretation of the ELAN/N400 debate in Section 3.1): if an information source A can "block" the effects typically associated with a second information source B, this suggests that A takes functional (hierarchical) precedence over B. Depending on the particular type of manipulation examined, further inferences can be drawn regarding the likely nature of the blocking effect, that is, whether it results from a feedforward influence (as is likely the case for concurrent word category and semantic violations) or from a combination of long-range feedforward and feedback connections (as may be the case for the orthographic and emotional influences on semantic congruity effects).

49.3.6 The Emerging Picture

Although, as already noted at the outset of this chapter, our understanding of the timecourse of sentence processing in the brain is still woefully incomplete, and although we have a long way to go in advancing

toward a truly neurobiologically grounded perspective, the preceding discussion shows that substantial progress has been made. Here, we attempt to summarize some of the insights emerging from this overall picture:

- (a) ERP components appear to be less specific for particular cognitive—and, specifically, particular linguistic—representations and/or operations than was once thought. Accordingly, more and more accounts are adopting more general mechanistic interpretations of the components and are no longer emphasizing the distinction between them as much as used to be common.
- (b) The importance of top-down versus bottom-up information has emerged as a major topic in the literature on sentence processing (Federmeier, 2007; Federmeier & Laszlo, 2009; Kutas & Federmeier, 2011; Lotze et al., 2011; Newman & Connolly, 2009; Tune et al., 2014). This view includes a critical role for prediction (DeLong, Urbach, & Kutas, 2005; Dikker & Pykkänen, 2011; Dikker et al., 2010; Federmeier, Kutas, & Schul, 2010) and is also highly compatible with the assumption of a hierarchically organized neural (cortical) architecture with predictive coding and asymmetric forward and backward connections (Friston, 2005, 2010).

What are the consequences of these insights for our understanding of the timecourse of sentence processing in the brain? While the question remains difficult, we can draw at least the following minimal conclusion: if we want to think in cognitive terms, there is a high likelihood of a cascaded architecture (although an "imperfect" one due to the feedback connections and long-range feedforward connections described throughout this chapter). This also means that specific information sources are less important than was long thought for the processing of the current input item in comparison with their predictive capacity for upcoming input. This view essentially allows for a new synthesis of the classic modular and interactive views: it suggests that modular models placed too much emphasis on bottom-up information and a feedforward information flow, whereas interactive models placed too much emphasis on top-down information and a parallel information flow between all available information sources or representations.

49.4 BEHAVIORAL INSIGHTS

Before turning to some open questions arising from synthesis, we first briefly discuss how the neurophysiologically determined picture outlined relates to behavioral insights. To this end, we focus particularly on

measures of eye movements during natural reading for several reasons: eye-tracking has long been the most influential behavioral method for inferring timecourse information during sentence processing; like neurophysiological measures, it does not require an ancillary task; and eye movement measures have challenged timecourse estimates provided by ERP components such as the N400 by demonstrating earlier influences of parameters such as word frequency. Furthermore, from a neurobiological perspective, it has been suggested that eye movements play a crucial role in probing our environment to test hypotheses arising from the current internal model about that environment (Friston, Adams, Perrinet, & Breakpear, 2012). It appears plausible that eye movements during reading may play a similar role. Accordingly, eye movement data appear highly relevant for informing our understanding of the timecourse of sentence processing, and for allowing us to gain a better understanding of the link between brain and behavior during language processing.

Recent results appear to emphasize the problems regarding absolute timing and ERP/ERF effects briefly discussed in Section 49.3.1. A range of recent studies has investigated in fine detail the question of when exactly factors such as frequency, predictability, and stimulus quality influence the eye movement record (Reingold, Reichle, Glaholt, & Sheridan, 2012; Sheridan & Reingold, 2012a, 2012b; Staub, 2011; Staub, White, Drieghe, Hollway, & Rayner, 2010; White & Staub, 2012) and has led to the conclusion that factors such as frequency and predictability manifest themselves even earlier than previously thought. For example, effects of word frequency were found in fixations as short as 140 ms (Reingold et al., 2012), as were effects of predictability (Sheridan & Reingold, 2012a, 2012b) and of sentence context on the processing of homographs such as *bank* (Sheridan & Reingold, 2012a, 2012b). Recall from Section 49.3.1 that, for fixation effects, the time needed for saccade planning must also be taken into account. Thus, these effects are exceedingly early, even from the perspective of possible neurophysiological effects “before the N400” (see Section 49.3.2).

However, the fact that these different information sources appear to have an equally early influence on the eye movement record during natural sentence reading does not necessarily mean that they should be viewed as playing functionally identical roles in the language processing architecture. As demonstrated by Staub et al. (2010) using distributional analyses of fixation durations, word frequency affects both the mean of the distribution and its skew, with low frequency words shifting the distribution to the right but also leading to a more pronounced right tail (Staub et al., 2010). However, Staub (2011) found that low predictability shifts the distribution of first-fixation and

single-fixation durations to the right but has little effect on the shape of the distribution. This may amount to a “head start” in the word recognition process for predictability (Balota, Yap, Cortese, & Watson, 2008), which also affects skipping rates for a critical word and thus has an impact even before that word is fixated. In this regard, recent eye movement results are consistent with the conclusions drawn regarding the crucial role of prediction (or, more broadly speaking, top-down expectation) for our understanding of the timecourse of sentence processing. Intriguingly, however, the top-down/bottom-up balance manifests differently in the eye movement record than in ERP measures: although the effect of word frequency on the N400 is correlated negatively with the position of the critical word in the sentence (Van Petten & Kutas, 1990), frequency effects on fixation durations are reliably observed even in late positions within a sentence and many eye-tracking studies have failed to find a frequency by predictability interaction (Kennedy, Pynte, Murray, & Paul, 2013; Rayner, Ashby, Pollatsek, & Reichle, 2004). This suggests that eye movements reflect different aspects of the timecourse of sentence processing than neurophysiological measures, placing a stronger emphasis on bottom-up factors such as word frequency.

Regarding this possible functional discrepancy, we advance the following speculation. If Friston and colleagues are correct in their assumption that eye movements reflect experiments designed to test hypotheses arising from the current internal model about the external world (Friston et al., 2012), and if this perspective is also applicable to reading, then it appears entirely plausible that fixations during reading should be more sensitive to bottom-up characteristics of the input. If this were not the case, eye movements would be poorly suited to hypothesis testing. This assumption appears compatible with recent claims that eye movements during reading should be considered an “input system” rather than directly reflecting the cognitive processes associated with language comprehension (Kretzschmar, 2010; Kretzschmar, Bornkessel-Schlesewsky, & Schlewsky, 2009). Clearly, however, this currently speculative hypothesis will need to be tested explicitly in future research.

Regarding absolute timecourse measures and the dissociation between fixation durations and ERP latencies, a few considerations are also in order. First, the very early effects for parameters such as frequency are only applicable with a valid parafoveal preview of (the) upcoming word(s). As shown by Reingold and colleagues (2012), without a valid preview, the earliest effects of frequency on fixation times were observed in fixations of 250 ms in length. Because parafoveal preview is not available in most visual EEG or MEG studies, which typically use rapid

serial visual presentation (RSVP), this reduces the discrepancy between the methods somewhat. As demonstrated (Kretzschmar, 2010; Kretzschmar et al., 2009) using concurrent EEG and eye-tracking measures during natural reading, ERP patterns appear, under certain circumstances, to be qualitatively different during natural reading as opposed to RSVP, and this difference appears directly attributable to the presence versus absence of parafoveal preview. Second, as first proposed in Bornkessel and Schlesewsky (2006), if ERPs are viewed as resulting from phase resets within ongoing oscillatory activity in different frequency bands (Dogil, Frese, Haider, Roehm, & Wokurek, 2004; Makeig et al., 2002; Roehm, Bornkessel-Schlesewsky, & Schlesewsky, 2007), then it is possible that eye movements reflect (or are in some sense “triggered by”) the initial point of reset, whereas the latency of the corresponding ERP component will depend on the frequency band involved. This proposal, while potentially promising, requires integration within a more comprehensive neurobiologically grounded model of sentence reading for it to generate testable predictions. Such a model is currently lacking, with all existing neurobiological models of reading focusing on the single word level (Dehaene & Cohen, 2011; Price & Devlin, 2011; see also Carreiras, Armstrong, Perea, & Frost, 2014).

49.5 OPEN QUESTIONS/PERSPECTIVES FOR FUTURE RESEARCH

This chapter has perhaps raised more questions than it has answered. Nevertheless, we hope to have provided some insights into what we view as the current state of the art with regard to the timecourse of sentence processing in the brain.

One of the central points discussed in this regard is that we are currently unable to make absolute claims about the timecourse of sentence processing from a neurobiological perspective; rather than being able to label particular information sources or mechanisms as becoming accessible or applying at x ms, we have argued that we can currently only make assumptions about the overall structure of the processing architecture and the relative functional role of different information types or mechanisms within that architecture. A central goal for future research thus appears to lie in the development of appropriate experimental approaches to map out absolute timecourse information. However, in view of the fact that this may not be possible with noninvasive methods, it is not clear at present whether this is an entirely realistic goal.

A second crucial point within this chapter concerned the role of predictions and the interaction of top-down

and bottom-up information sources. Again, some of the crucial pieces to the puzzle are still missing in our understanding of these influences. First, future research must determine more definitively why some cues appear to be more highly predictive (top-down) or salient (bottom-up) than others, and under which circumstances bottom-up cues can “override” top-down cues. We have suggested here that the key to explaining at least the latter phenomenon may lie in the hierarchical organization of the neural language processing architecture, but this remains to be tested in detail. Second, with regard to the top-down/bottom-up balance, a number of influencing factors appear to contribute, including the properties of the specific language under consideration (Bornkessel-Schlesewsky et al., 2011; Tune et al., 2014). How these system-wide properties interact with more phasic influences—and how they are learned during development—is currently unknown.

Finally, given that top-down influences from previous input appear to play a particularly important role in influencing the timecourse of sentence processing in the brain, we clearly need to develop an understanding of the appropriate “cycles” of processing, which determine the influence of top-down processing from one input item to the next. Although words appear to be a natural and intuitive choice, they may not necessarily be the appropriate one. For example, approaches to sentence parsing in computational linguistics suggest that, in morphologically rich languages such as Turkish or Hindi, the use of morphologically based units smaller than the word improves parsing performance (Eryigit, Nivre, & Oflazer, 2008). This observation raises the intriguing complication that the relevant units may prove to be language-specific. From a neurobiological perspective, the notion of integration windows has also played an important role in several approaches. For example, Pulvermüller and colleagues argue for a window of approximately 200 ms as a “discrete processing step [...] in perceptual, motor, and cognitive processes” (Pulvermüller et al., 2009, p. 87). This claim is partially compatible with the long temporal integration window (approximately 150–250 ms) proposed by Poeppel (2003) as the basis for right hemisphere auditory processing (in contrast to the short temporal integration window of approximately 20–40 ms, which, according to this account, better describes auditory processing in the left hemisphere). The longer window, which aligns with theta oscillations, represents a timescale at approximately the syllable level (Giraud & Poeppel, 2012), an idea that appears potentially compatible with the assumption that units at a level below the word may ultimately prove appropriate for a more comprehensive understanding of the timecourse of sentence processing from a truly neurobiological perspective.

Composition of Complex Meaning: Interdisciplinary Perspectives on the Left Anterior Temporal Lobe

Liina Pylkkänen

Department of Linguistics, Department of Psychology, New York University, New York, NY, USA;
NYUAD Institute, New York University Abu Dhabi, Abu Dhabi, United Arab Emirates

The ultimate goal of the cognitive neuroscience of language is to fully characterize the computations by which complex meanings are constructed from sensory input in comprehension and the way such meanings are externalized as motor commands in language production. Thus, a complex semantic representation is the end product of comprehension and the starting point of production. What are the neural computations that construct these complex semantic representations from smaller, stored units of meaning? Addressing this question must begin with a definition of the relevant computations.

The simplest way to define semantic composition is as the process by which the meaning of a lexical item combines with its context. In a simple case, the comprehension of the noun phrase *black cat* requires us to create a mental representation of an entity that is both black and a cat. However, at least descriptively, composition clearly has a variety of forms, for example, to interpret the verb phrase *banks money*, we do not construct a mental representation of an entity that is both a bank and money, but rather take money to be an object affected by banking. Even if we keep the syntactic categories of the composing items constant, composition plays out in many different ways. For example, although a black cat is an individual that is both black and a cat, a possible murderer is not an individual who is both “possible” and a murderer—in fact, that person may not be a murderer at all. Or, if your colleague reports that an occasional student walked into their office, you do not take this to mean that a person who is occasionally a student visited the office, but

rather that the office was occasionally visited by students. In sum, the composition of natural language meanings is complicated. Nevertheless, our formal understanding of the nature of the relevant representations is highly detailed, thanks to decades of research within formal semantics, a sub-branch of linguistics with origins in philosophical logic and generative grammar (Portner & Partee, 2008).

If the empirical phenomena within natural language semantics are this complex and multifaceted, then we should consequently expect the brain profile of semantic processing to exhibit similar intricacies. However, the state of the art within the cognitive neuroscience of sentence level semantics is that we barely understand the composition of even the simplest of cases, such as *black cat*. How can this be at a time when a search for “brain” and “semantic integration” yields thousands of Google Scholar hits?

At least partly, the answer lies in the fact that instead of starting with the simplest cases, such as the composition of two simple elements, a major focus in the field has been to investigate rather complex phenomena, such as the processing of semantically anomalous expressions or ones containing complex embeddings. These large bodies of research have been inspired by the seminal and highly replicable findings of Kutas and Hillyard (1980) and Stromswold and colleagues (1996), who reported the electrophysiological N400 as a response sensitive to semantic incongruity and Broca’s area as a region supporting the comprehension of center-embedded structures, respectively. Although this work has provided invaluable insight to

our understanding of the interface between linguistic meaning and neighboring components of the mind, such as world knowledge and working memory, these rather complex phenomena have been addressed before developing a basic understanding of how words compose into larger meanings within simple well-formed expressions.

A second limiting factor for our understanding of the brain basis of meaning representation has been that the cognitive neuroscience of semantics, especially at the sentence level, has not been tightly connected with linguistic theory or psycholinguistics; thus, the brain science of meaning has not substantially benefited from the large bodies of results within these older disciplines. In fact, among the various representational and processing levels within language, semantics arguably exemplifies the starkest disconnect between brain research and corresponding theoretical work. Although sizeable bodies of cognitive neuroscience research have investigated the brain basis of theoretically motivated constructs such as phonological categories (Dehaene-Lambertz, 1997; Näätänen et al., 1997) or syntactic displacement (Grodzinsky & Friederici, 2006), terms from the semanticist's basic tool kit such as "function application" or "variable binding" (Heim & Kratzer, 1998) do not figure within the cognitive neuroscience of semantics.

In this chapter I first describe in more detail what "semantics" is typically taken to mean in cognitive neuroscience on the one hand, and in linguistics on the other. Within mainstream hemodynamic research on sentence processing, one popular paradigm, the so-called sentence versus list paradigm, arises as the most relevant for identifying brain activity related to basic composition; I discuss this experimental design from the point of view of formal semantics. Although it is unlikely that any type of composition would be accomplished by a single brain region—even experiments examining the composition of just two words have implicated at least three regions as sensitive to such composition, namely the left anterior temporal lobe (LATL), the ventromedial prefrontal cortex (vmPFC), and the angular gyrus (Bemis & Pykkänen, 2011, 2012, 2013; Pykkänen, Bemis, & Blanco Elorrieta, 2014; for relevant reviews, see also Binder & Desai, 2011; Friederici, 2012; Hagoort & Indefrey, 2014; Lau, Phillips, & Poeppel, 2008)—there is a single region, namely the LATL, within which combinatory effects have had a very high rate of replicability across studies, labs, and techniques. This has enabled a productive incremental research program aimed at characterizing the computational contribution of LATL activity in a way that has been harder for other regions whose contribution has been less systematic (Bemis & Pykkänen, 2011 vs. 2012)—clearly, the absence of an

effect even in an interaction setting can only be meaningful if the activity in question is known to generate few false negatives. At large, a combined body of hemodynamic and magnetoencephalography (MEG) results strongly implicate the LATL as a basic combinatory region supporting incremental sentence interpretation. In particular, MEG studies have enabled the characterization of the temporal profile of this activity, demonstrating that combinatory effects in the LATL peak relatively early, at 200–250 ms. However, in the latter half of the chapter, I review a body of recent results suggesting that this activity, despite its timing, is fundamentally semantic as opposed to syntactic in nature.

Given that this chapter mainly discusses MEG research, in which spatial resolution is fuzzier than in PET or fMRI, my primary focus is on time rather than precise spatial details. The MEG localization of LATL combinatory effects has varied somewhat, most consistently implicating the temporal pole and immediately adjacent tissue (Bemis & Pykkänen, 2011, 2012, 2013; Del Prato & Pykkänen, 2014; Leffel, Lauter, Westerlund, & Pykkänen, 2014; Pykkänen et al., 2014), conforming to relevant hemodynamic data (Baron & Osherson, 2011), but sometimes also localizing on the more lateral surface of left anterior temporal cortex (Westerlund & Pykkänen, 2014). A similar and somewhat variable picture arises from hemodynamic LATL research on single concepts (see Section 50.6.1), where semantic effects have occurred at least within the temporal pole (Gauthier, Anderson, Tarr, Skudlarski, & Gore, 1997), on the ventral surface of the anterior temporal lobe (Binney, Embleton, Jefferies, Parker, & Ralph, 2010; Visser et al., 2012), and more medially (Clarke, Taylor, & Tyler, 2011; Tyler et al., 2013). For the purpose of this chapter, the reader can assume that LATL refers to a somewhat large region covering the temporal pole (BA 38) and anterior portions of middle and inferior temporal gyri (BAs 20 and 21), because this is the area within which the LATL combinatory response systematically localizes in MEG. Thus, there is obviously more to be said about the internal organization of this large area, but such an understanding will likely come from techniques other than MEG.

50.1 "SEMANTICS" IN THE BRAIN SCIENCES VERSUS LINGUISTICS

The word "semantics" can be used in many different ways and, in particular, this term means something different for most cognitive neuroscientists than what it does for linguists. Traditionally, within the brain sciences, "semantics" has meant more or less what the

“man-on-the-street” might mean by it: the conceptual content of words and their combinations. Although one would not usually find this definition in publications, it is deducible from the nature of the stimulus manipulations that have been considered “semantic.” At the word level, relevant distinctions have included contrasts such as tools versus animals (Devlin et al., 2002; Ilmberger, Rau, Noachtar, Arnold, & Winkler, 2002; Vitali et al., 2005), living versus nonliving (Tyler et al., 2003), and abstract versus concrete (Noppeney & Price, 2004). Commonly, this literature has also aimed to modulate “semantics” by keeping the stimuli constant and varying the task; for example, an abstract versus concrete judgment might count as a semantic task and syllable counting might be considered as a phonological task (Poldrack et al., 1999). At the sentence level, semantic manipulations have mostly varied factors such as coherence—word salad sentences such as *the freeway on a pie watched the house and a window counting as incoherent expressions* (Humphries, Binder, Medler, & Liebenthal, 2006)—or plausibility, a similar variable that typically refers to the plausibility of a single lexical item in its context (Kutas & Federmeier, 2000). The origin of this approach to sentence semantics straightforwardly dates to Kutas and Hillyard’s (1980) pioneering discovery of the electrophysiological N400, a brain response to anomalous sentence endings such as *socks* as in their much-cited example *he spread the warm bread with socks*.

While this lexical-level literature has significantly advanced our understanding of the neural underpinnings of long-term semantic memory (in the sense of Tulving, 1972; for reviews see Binder & Desai, 2011; Kutas & Federmeier, 2000) and the sentence-level research has significantly advanced our understanding of the interface between sentence meaning and world knowledge (Hagoort, Hald, Bastiaansen, & Petersson, 2004; Pylkkänen, Martin, McElree, & Smart, 2009; Pylkkänen, Brennan, & Bemis, 2010), there is a crucial level of processing that has remained largely unaddressed by the majority of brain research on semantics: the computations that create the complex meanings of well-formed sentences. Characterizing the rule system that enables such computations is the primary subject matter of formal semantics in linguistics; thus, linguists typically find little of relevance to their research in the vast cognitive neuroscience literature on semantics. Specifically, the distinctions that dominate the lexical level literature in the brain sciences (i.e., differences such as the contrast between fruits and vegetables, or tools and animals) are precisely the types of factors that

are thought *not* to matter for the generative procedures that compose meanings together. Rather, the variables that do matter for these routines include contrasts such as the mass/count distinction (Chierchia, 1998; Link, 1983), the relationality of nouns (Barker, 1995), the internal temporal structure of the events described by verbs (Dowty, 1979), and the gradability of adjectives (Kennedy, 2007) (i.e., factors that matter for the possible distributions of lexical items within well-formed expressions). The majority of such variables have no corresponding cognitive neuroscience associated with them, with the mass/count distinction perhaps standing out as somewhat of an exception, having inspired several brain investigations (Chiarelli et al., 2011; Fieder, Nickels, Biedermann, & Best, 2014; Steinhauer, Pancheva, Newman, Gennari, & Ullman, 2001; Taler, Jarema, & Saumier, 2005).

In sum, the brain sciences have focused on the more conceptual aspects of meaning and formal semantics on the more grammatical ones. Consequently, the more grammatical aspects of meaning constitute a large and mostly uninvestigated terrain for the neurobiology of language.

50.2 THE SENTENCE VERSUS LIST PARADIGM

To characterize the brain basis of the computations that create complex meanings, one should vary the presence, number, or difficulty of those computations. One line of hemodynamic literature on sentence processing, situated outside the majority paradigms focused on anomaly, has in fact directly aimed to do this, although from the perspective of formal semantics; it is not entirely obvious whether and how the manipulation in question achieves this. In these studies, the critical contrast is always between a fully structured sentence and an unstructured list of words (Friederici, Meyer, & von Cramon, 2000; Humphries, Love, Swinney, & Hickok, 2005; Humphries et al., 2006; Jobard, Vigneau, Mazoyer, & Tzourio-Mazoyer, 2007; Mazoyer et al., 1993; Rogalsky & Hickok, 2009; Snijders et al., 2009; Stowe et al., 1998; Vandenberghe et al., 2002; Xu, Kemeny, Park, Frattali, & Braun, 2005), with the idea being that the sentence engages all the computations involved in sentence processing whereas the list does not, which of course should, at least in most cases, be true¹ (for discussion, see Brennan & Pylkkänen, 2012).

The version of this paradigm that is most relevant for *semantic* composition is one that also includes

¹The only hesitation arising from possibly divergent processing strategies when encountering a stimulus such as *the do the accept shopkeeper napkin* (from Vandenberghe, Nobre, & Price, 2002); it seems at least possible that the participant might still attempt to construct some kind of meaning from this.

conditions in which all the open class words within the stimuli are replaced by pseudowords, intended as a way to remove semantics from the experimental materials (Friederici et al., 2000; Humphries et al., 2006; Mazoyer et al., 1993; Pallier, Devauchelle, & Dehaene, 2011). This results in a contrast between pseudoword sentences and pseudoword lists, such as *the solims on a sonting grilloted a yome and a sovir* (pseudoword sentence) versus *rooned the sif into lilf the and the foig aurene to* (pseudoword list) from Humphries et al. (2006). On a descriptive level, this particular pseudoword sentence of course includes many constituents, and the first five words of the stimulus have the structure of a well-formed sentence in an informal register of English with subject dropping (e.g., *turned the water into wine*). This is common in the sentence versus word list literature; the list stimuli are usually not completely void of structure (though see Brennan & Pylkkänen, 2012) and therefore should be thought of as the stimulus that involves *less* structure (as opposed to no structure). More relevant for the current discussion is the extent to which the pseudoword sentence is free of meaning. If it does not engage the semantic combinatory machinery, which could be true if that machinery only took as its input existing words, then any effects elicited for the real-word sentence versus list contrast that were absent for pseudoword sentences would be good candidates for neural correlates of semantic composition.

However, formal semantic theories of the generative tradition make almost the opposite prediction: the semantic combinatory system operates to a large extent without caring much about the conceptual details of its input items. In other words, the meanings of the sentences *the cat chased the mouse* and *the mouse ate the cheese* compose exactly in the same way even though the direct objects in the two sentences differ in animacy. Further, the same routines could just as easily be applied to *the solim grilloted the yome*, yielding an assertion of the existence of a grilloting event with the solim as a likely agent (and less likely experiencer) and the yome as the affected party. This pseudoword sentence is void of actual conceptual content, but it is not void of meaning. It asserts the existence of an eventuality in the past and relates two event participants to that eventuality (Parsons, 1990).

50.3 AN EMPIRICAL QUESTION: DO CONCEPTS MATTER FOR COMPOSITION?

As the previous discussion illustrates, semantic composition within the formal semantics tradition refers to the logical aspects of meaning construction, accomplishing computations such as the saturation of

arguments (as in when a verb takes its direct object as an argument), the intersection of properties (the *black cat* type examples), or the binding of variables (assuring that in expressions such as *every diver defended himself*, “himself” refers to the divers) (Heim & Kratzer, 1998). The empirical question then is: is the brain as a composer of meaning like the linguist’s combinatory system, abstract and indifferent to the conceptual content of its input items, or do the types of contrasts traditionally used in the brain imaging literature in fact tap into the construction of complex meaning, contrary to what most formal semantic theories would necessarily predict? Although we do not have a definitive answer to this, a recent line of research approaching the brain basis of semantic composition from the linguist’s perspective has uncovered that the brain activity that is affected by composition, as linguists would define this notion, *is* in fact remarkably sensitive to the conceptual content of the input words. In what follows, I first define some prerequisites for a research program addressing composition and then summarize the main results of this body of work, relating it to the prior hemodynamic literature as well as neuropsychological research on semantic dementia (SD).

50.4 METHODOLOGICAL STARTING POINTS FOR THE COGNITIVE NEUROSCIENCE OF SEMANTIC COMPOSITION

Isolating brain activity that specifically reflects semantic composition is highly challenging given that semantic composition correlates with many other computations, all of which occur within a few hundred milliseconds on the introduction of a new word into an expression. Lexical access, syntactic composition, and pragmatic inferencing is a short list of such computations, and all of these are themselves complex processes.

Given this challenge, one can imagine two rather different starting points for an investigation aimed at revealing the brain basis of semantic composition: either one could design clever experiments that somehow only vary semantic composition or one could initially conduct simpler, more confounded experiments to extract a broader network of regions and then proceed to try to unpack that network. The sentence versus word list literature discussed could exemplify the latter approach, although few studies have taken steps toward the “unpacking” of the implicated network. One line of research pursuing this goal has focused on delineating the network of “sentence processing regions” into domain general versus more language-specific regions (Fedorenko, Duncan, & Kanwisher,

2012, 2013). More relevantly for semantic composition, Rogalsky and Hickok (2009) used the sentence versus list manipulation as an initial localizer and then examined what activity within the regions sensitive to this contrast showed an enhanced signal when subjects attended to either syntactic or semantic aspects of well-formed sentences. Their focus was on the LATL, where sentence over word list effects have localized the most consistently, but the results indicated only a subtle task effect. Although most of the left anterior temporal cortex responded similarly during the syntactic and semantic attentional demands, an anterior sub-region within the general region of interest responded more when semantics was attended to. As acknowledged by these authors, this experimental design clearly did not vary the presence of syntactic or semantic computations; rather, both types of composition played out fully for all stimuli. Thus, the rather subtle effects are perhaps not surprising.

Importantly, all the literature cited so far has used hemodynamic brain imaging techniques such as PET or fMRI, which only have temporal resolution in the order of seconds. This is clearly too slow for characterizing the rapid dynamics of linguistic computations, which happen at the millisecond scale. For example, it is not inconceivable that a single combinatorial region could combine both syntactic and semantic inputs but at slightly different times. This type of result would not be obtainable without both detailed timing and spatial information. Of currently available noninvasive cognitive neuroscience techniques, the best combination of both is offered by MEG, which measures the magnetic fields associated with neural activity. Although its spatial resolution is worse than that of PET or fMRI, it is at the centimeter scale and, crucially, MEG offers millisecond temporal resolution. This makes MEG ideal for research aimed at characterizing language processing not simply as a static brain image but also as a dynamic process unfolding over time.

50.5 THE LATL AS A COMBINATORY REGION: EVIDENCE FROM MEG

Decades of behavioral research have shown that sentence interpretation proceeds incrementally (Altmann & Kamide, 1999; Altmann & Steedman, 1988; Chambers, Tanenhaus, Eberhard, Filip, & Carlson, 2002; Kamide, Altmann, & Haywood, 2003; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). Thus, we should expect syntactic and semantic combinatorial operations to occur word-by-word as a sentence unfolds. Electrophysiological research using violations at various representational levels has conformed to this prediction (Friederici, 2002; Kutas &

Hillyard, 1980, 1984; Neville, Nicol, Barss, Forster, & Garrett, 1991), but measuring responses to violations does not necessarily address the computations that serve to build well-formed structure. As already discussed, from hemodynamic research we have learned that when the brain activity elicited by sentences and unstructured lists is compared, the most consistent activity increase for sentences systematically localizes to the LATL. To address whether this activity reflects some aspect of incremental combinatorial operations, as opposed to some computation occurring at a different time scale (e.g., clause-final wrap-up effects; Aaronson & Scarborough, 1976; Just & Carpenter, 1980; Rayner, Sereno, Morris, Schmauder, & Clifton, 1989), it is crucial to address whether LATL effects of sentential structure are a component of the usual brain response to words within a structured context. To investigate this, Brennan and Pylkkänen (2012) imported the sentence versus word list manipulation into a MEG setting and found that the LATL effect was reliable at the word level, alongside increases in a broad distributed network covering much of left temporal and frontal cortex. Thus, the LATL does in some way appear to participate in incremental sentence comprehension.

The distributed nature of the sentence versus list effect is not surprising given the coarseness of this contrast, which manipulates more or less every process-related sentence interpretation. As a more focused approach, a series of recent MEG studies has adopted a more controlled experimental paradigm aimed at contrasting conditions only in the presence of a single phrasal combinatorial step (Bemis & Pylkkänen, 2011, 2012, 2013; Del Prato & Pylkkänen, 2014; Pylkkänen et al., 2014; Westerlund & Pylkkänen, 2014). As an initial case study, a simple manipulation of adjectival modification was chosen, with color adjectives modifying nouns denoting concrete objects, as in *red boat* (Bemis & Pylkkänen, 2011). MEG activity was always measured at the noun, which in the control conditions was either presented without a linguistic context (the color word was replaced by an unpronounceable consonant string) or preceded by a noun that could not combine with it semantically, given the nature of the experimental task. Specifically, subjects engaged in both a combinatorial task, where they matched the just presented verbal stimulus (*red boat* or *xtp boat*) to a picture of a colored object, eliciting natural combinatorial processing, and a noncombinatorial list task, where the stimulus was either a pair of nouns (*cup, boat*) or a single noun (*xtp boat*), and the participants indicated whether a subsequent picture of a colored object was a match to any noun within the verbal stimulus. The intention in this latter task was to elicit a maximally noncombinatorial list-like interpretation (despite the logical possibility for interpreting any noun–noun

sequence as a noun–noun compound), and thus the design was in a sense a mini-version of the traditional sentence versus list contrast. Given this design, any neural effect that was unique to the adjective–noun phrases was considered a potential correlate of basic combinatory processes. The LATL showed such an effect, with responses showing a reliable increase only for the phrasal condition. The effect occurred relatively early, at approximately 200–250 ms after noun onset; according to a follow-up study, it was automatic in the sense that it was elicited even when adjective–noun combinations were presented within a task that discouraged composition (Bemis & Pykkänen, 2013). The same effect in a somewhat later time window was elicited auditorily (Bemis & Pykkänen, 2012) as well as during language production (Pykkänen et al., 2014), conforming to the hypothesis that this activity reflects a modality general stage of processing where the basic building blocks of language are combined into a complex, structured representation.

50.6 DELVING DEEPER: WHAT TYPES OF REPRESENTATIONS DOES THE LATL COMBINE?

50.6.1 Composition Versus Conceptual Specificity

None of the MEG results discussed yet speak to the computational details of LATL activity, such as whether it reflects syntactic or semantic composition, given that the processing of adjective–noun combinations obviously involves both. At the heart of a syntactic hypothesis is the prediction that for syntactically uniform structures, LATL effects should pattern similarly. However, this prediction has been disconfirmed by a study aimed at relating the LATL literature on composition to a thus far disconnected literature on the LATL and SD (Westerlund & Pykkänen, 2014). SD is a progressive neurodegenerative disorder characterized by loss of semantic memory and, crucially, the most common locus of cerebral atrophy in this population is in the LATL (Chan et al., 2001). SD patients have trouble recognizing and naming concepts (Hodges, Graham, & Patterson, 1995; Hodges, Patterson, Oxbury, & Funnell, 1992; Mummery et al., 1999, 2000; Patterson et al., 2006; Patterson, Nestor, & Rogers, 2007; Rogers et al., 2004) and, in particular, more “specific” concepts (e.g., swallow as compared to bird) are disproportionately affected (Done & Gale, 1997; Hodges et al., 1995; Rogers et al., 2004, 2006; Warrington, 1975). Additionally, when the types of tasks that SD patients struggle with have been conducted on healthy participants using fMRI or PET, the

LATL has shown increased activation for more specific category labels (Bright, Moss, Stamatakis, & Tyler, 2005; Moss, Rodd, Stamatakis, Bright, & Tyler, 2005; Rogers et al., 2006; Tyler et al., 2004). Because these results implicate the LATL for the processing of individual concepts, with no obvious combinatory components, the question arises whether the phrasal LATL effects could in fact be explained as conceptual specificity effects, given that adjectival modification typically increases the conceptual specificity of the noun. If this was the case, then the role of the LATL would clearly not be syntactic.

To test this, Westerlund and Pykkänen (2014) investigated the relationship between the composition and single word specificity effects in MEG by combining the basic composition paradigm of Bemis and Pykkänen (2011) with a manipulation of the conceptual specificity of the nouns. As before, participants read nouns with and without adjectival modifiers, but now the nouns were further divided into more and less conceptually specific classes (e.g., *blue canoe/boat*). If the previously observed composition effects in the LATL reflected the increased conceptual specificity associated with adjectival modification, then a similar conceptual specificity effect should have been elicited for the single nouns and, potentially, the combinatory and single word specificity effects could have been expected to add up in a somewhat linear fashion (causing the highest amplitudes for the adjectivally modified specific nouns). Alternatively, the conceptual specificity effect of the hemodynamic literature could be temporally and/or spatially distinct from the LATL composition effect; given that neither PET nor fMRI have sufficient time resolution to attribute an effect to a particular subpart of relatively quick trials, the prior literature does not yet tell us whether the specificity effects are associated with the processing of the noun itself or some other part of the trial, such as the match/mismatch judgment on the subsequently presented pictures. Although the spatial resolution of MEG is not sufficient to detect subtle differences in localizations, it is an ideal technique for assessing whether the two effects are timed similarly.

Single word specificity did affect LATL amplitudes at the nonmodified nouns in a way consistent with the hemodynamic literature, but statistically this was not a very robust finding. Instead, the strongest result was an interaction between the two variables: adjectival modification reliably increased LATL amplitudes only when the modified noun was less specific. In other words, adding a feature to a noun that was already conceptually quite specific, such as *canoe*, did not result in a boost in LATL activity; rather, an amplitude increase was only elicited when the noun itself did not convey a very specific meaning.

Although this result does not yet definitively settle the question of whether the composition effect might “reduce” to a specificity effect—the single word specificity effect was too weak for this to follow straightforwardly—it does demonstrate that the two variables are fundamentally connected: as a composer of new concepts, the LATL is not insensitive to the conceptual make-up of its input items. This simple finding strongly rules out a syntactic account of the LATL composition effect: no theory of phrase structure building would draw a difference between *blue boat* and *blue canoe*. More interestingly, no theory of semantic composition within formal semantics would either. In these systems, the composition of *blue* with either *boat* or *canoe* would yield an intersection of the two properties, picking out a set of entities in one’s mental model that have both the properties of being blue and being a boat/canoe (Heim & Kratzer, 1998). Thus, there is no combinatory routine within contemporary linguistic theories that would adequately model the function of the LATL, at least as it is implicated by the currently available MEG data.

50.6.2 Composition Versus Conceptual Combination

Although the sensitivity of the LATL’s combinatory response to conceptual specificity does not straightforwardly fit into theories of formal semantics, this functional profile of the LATL is potentially less surprising if approached from the perspective of classic psychological research on so-called “conceptual combination” (Hampton, 1997; Murphy, 1990; Smith & Osherson, 1984). Like work in formal semantics, research on conceptual combination has aimed to explain the meanings of linguistically complex expressions; unfortunately, these two approaches to meaning composition have had little contact [with the notable exception of Kamp and Partee’s (1995) extensive response to Osherson and Smith (1981)]. Compared with research in formal semantics, which explicitly aims to address the entire grammar (Bach, 1989; Chierchia & McConnell-Ginet, 1990; Gamut, 1991; Heim & Kratzer, 1998; Montague, 1970a, 1970b, 1973) with hopefully substantial crosslinguistic coverage (Bittner, 1994; Matthewson, 2001), work on conceptual combination has been quite focused on one particular domain, the modification of nouns (Costello & Keane, 2000; Hampton, 1997; Medin & Shoben, 1988; Murphy, 1990; Wisniewski, 1996), with little discussion on exactly what phenomena should more generally fall under the notion of “conceptual combination” (but see Hampton, 2011). Nonetheless, it is possible that the psychologist’s notion of conceptual combination may model the

function of the LATL better than the linguist’s notion of semantic composition, although this is still nothing but the crudest starting point. Importantly, the term conceptual combination has already been linked to the LATL in an fMRI study showing that the LATL activation elicited by a concept such as “boy” is correlated with the product of activations for concepts representing features that contribute to the meaning of “boy,” such as “male” and “child” (Baron & Osherson, 2011). Whereas the methodology of this work was very different from the MEG studies discussed here, it is clear that, like Westerlund and Pylkkänen’s (2014) findings, Baron & Osherson’s results are also neither syntactic in nature nor accountable in terms of semantic composition of the formal, conceptually blind kind.

If the input to the LATL function is something like a “concept” as opposed to a syntactic category or a semantic type, modulations of its activity by variables such as typicality or feature diagnosticity obviously become more expected (Costello & Keane, 2000; Medin & Shoben, 1988). For example, the lesser LATL effect of adjectival modification when combined with more specific nouns may relate to a lesser diagnostic value of adjectival modifiers in this context (Westerlund & Pylkkänen, 2014). However, for this functional hypothesis of the LATL to actually gain some predictive power, we must develop some understanding of the bounds and generality of the relevant LATL-housed computation: exactly what types of representations does it combine and how?

One task is to significantly expand the range of constructions under investigation. Initial steps toward this were taken by Westerlund, Kastner, Al Kaabi, and Pylkkänen (under revision), who tested for LATL composition effects in multiple different types of two-word phrases covering both cases of modification and argument saturation, results suggesting robust generality not only across constructions but also crosslinguistically. In contrast, computational limits on the function of the LATL have been established by a simple extension of the basic composition paradigm contrasting color modifications with numeral quantifications as in *red cups* versus *two cups* (Del Prato & Pylkkänen, 2014). Given that combinatory effects in the LATL had already been shown to extend to language production (Pylkkänen et al., 2014), the study was conducted as a production task because this allowed a manipulation of composition type while keeping the physical stimulus constant: subjects named pluralities of colored objects (e.g., a picture of two red cups) using either color modifiers (e.g., *red cups*) or numeral quantifiers (*two cups*), depending on task instruction. Noncombinatory list productions served as control conditions. It is clear that any version of semantic composition as construed in formal semantics would

predict both the color and number phrases to elicit a composition effect, because clearly both types of phrases involve semantic composition. However, whether *two cups* is an instance of conceptual combination because this notion is construed within the psychology literature is much less clear. The MEG results indicated that the LATL discriminates between the two cases: only adjectival modification, and not numeral quantification, increased LATL amplitudes. Thus, whereas the addition of a color feature to an object concept increased LATL amplitude, the enumeration of tokens belonging to a set did not. This provides further evidence that the LATL's combinatorial role may be limited to some version of "conceptual combination," the details of which are yet to be defined.

50.6.3 Absence of LATL Effects in Semantic Mismatch Configurations: Studies on Coercion

One notable manipulation that is semantic in nature but has systematically not elicited LATL effects is studies on coercion (i.e., configurations where a type mismatch triggers an inference for an implicit meaning). For example, although verbs such as *begin* describe the beginnings of eventualities, they do not necessarily require a direct object describing an event, as in *begin to write an article*, but rather they are perfectly well-formed when combined directly with an entity-describing noun phrase: *the author began an article*. When the object describes an entity, there is a strong intuition, supported by a sizeable psycholinguistic literature (Frisson & McElree, 2008; McElree, Pylkkänen, Pickering, & Traxler, 2006; Traxler, Pickering, & McElree, 2002), that the interpretation of the sentence nevertheless involves a covert activity (i.e., "the author began some activity involving a book"). Because the computation of the covert meaning is a combinatorial semantic process not corresponding to steps in syntactic processing, a series of MEG studies used constructions such as this one as a starting point for identifying activity related to semantic composition (Brennan & Pylkkänen, 2008, 2010; Pylkkänen, 2008; Pylkkänen & McElree, 2007; Pylkkänen Oliveri, & Smart, 2009). A systematic finding arose from these studies implicating MEG activity at approximately 400 ms localizing in vmPFC as sensitive to the construction of covert meaning. The LATL, however, showed no such effects, a finding that is somewhat at odds with the hypothesis that the LATL is a semantic combinatorial site. As for frameworks that would account for this null finding, one possibility is that semantic composition proceeds in

several stages, with the LATL at approximately 200 ms representing a very early stage during which only the most readily available features combine, whereas the computations at the vmPFC stage are more clearly post-lexical. Given that coercion configurations always involve an initial mismatch between the semantic requirements of two composing constituents, it is then conceivable that an early stage of composition would not be able to operate on such input; rather, composition would only succeed at a later stage, after the semantic mismatch has been resolved. Crucially, even when LATL effects are observed for seemingly simple expressions such as *red boat*, they are typically accompanied by later vmPFC effects, suggesting that, in the usual case, shallow early composition is followed by a later stage potentially incorporating more semantic detail. In production, we would expect the reverse, because the detailed message to be conveyed at least logically precedes more abstract levels of linguistic computation, a prediction that was born out in the production results of Pylkkänen et al. (2014). This type of proposal conforms to many extant theories, including old schema models of conceptual combination where an initial filling of feature slots is followed by an elaboration of the composed representation on the basis of world knowledge² (Cohen & Murphy, 1984; Murphy, 1988), good-enough parsing theories in psycholinguistics (Ferreira et al., 2002; Ferreira & Patson, 2007), as well as recent models within cognitive neuroscience proposing semantic activation to be gradient (Binder & Desai, 2011).

50.7 CLOSING REMARKS

In this brief chapter, I have aimed to illustrate that identifying a brain region as sensitive to composition is only a starting point. The real work lies in trying to characterize the details of the computation performed by the region. The rather vast hypothesis space capable of explaining any initial "combinatorial effect" can only be narrowed by systematic, incremental investigation replicating the initial, basic finding over and over again. In this endeavor, temporal information is crucial because, in the absence of a motivating hypothesis, one would not want to call, say, a LATL effect occurring at 200 ms the "same" as one occurring at 600 ms. Further, in the spirit of the initial mission statement of cognitive neuroscience, our hypothesis generation should take advantage of the vast bodies of results developed in older disciplines addressing the processing and representation of language. Without this

²Thanks to Masha Westerlund for pointing out this connection.

knowledge base to help us carve out the space of possibilities, characterizing the neural underpinnings of something as complex as semantics would simply be too hard.

Working Memory and Sentence Comprehension

David Caplan

Neuropsychology Laboratory, Department of Neurology, Massachusetts General Hospital, Boston, MA, USA

Sentence comprehension requires memory over time scales ranging from deciseconds through several seconds and more. Even adjacent words must be assigned a syntactic relationship, and syntactic relations often span many words. For instance, in (1), the subject and object of *grabbed*, the subject of *lost*, and the antecedent of *his* must be retrieved at the points at which *grabbed*, *lost*, and *his* are encountered (or later, if parsing and interpretation is deferred):

1. The boy who the girl who fell down the stairs grabbed lost his balance.

Historically, the memory system that has been most often connected to parsing and interpretation is “short-term memory (STM).” The hypothesis that the memory system that supports parsing and interpretation utilizes STM is intuitively appealing because the temporal intervals over which parsing and interpretation usually apply are approximately the same as those over which STM operates. In addition, STM is an appealing construct to apply to sentence memory because it is thought to have capacity and temporal limitations that might account for the difficulty of comprehending certain sentences. This chapter reviews research on the relation of STM and comprehension, focusing on syntactic processing, beginning with theories that relate components of models of STM to this process, then turning to studies of the retrieval mechanisms in STM tasks and STM capacity limits and their relation to parsing and interpretation. Throughout the presentation, I critique the evidence supporting the view that STM is the memory system that supports parsing and interpretation. I end this chapter by presenting an outline of an alternative model.

51.1 EARLY STUDIES OF STM/WM AND ITS RELATION TO COMPREHENSION

Baddeley’s model of ST-WM, an influential model of short-term and working memory, was one of the first that was related to comprehension. Baddeley’s initial model of ST-WM (Baddeley, 1986) contained two major components. A “Central Executive (CE)” maintained multidimensional representations and was also considered to have some computational functions. Some authors suggested these computational functions consisted, in part, of operations needed to activate and transform representations, particularly functional domains (such as syntactic procedures; Just & Carpenter, 1992); others suggested that these functions schedule the entry and removal of information in the limited-capacity central store (Engle & Kane, 2004). Visuo-spatial and verbal “slave systems” maintained domain-specific representations. The verbal slave system, the “Phonological Loop (PL),” consists of two components—a “Phonological Store (PS)” that maintains information in phonological form subject to rapid decay and an articulatory mechanism that rehearses items in the PS and transcodes written verbal stimuli into phonological form. Baddeley (2000) introduced a third type of store—the episodic buffer (EB)—that retained integrated units of visual, spatial, and verbal information marked for temporal occurrence. The slave systems and the EB had no computational functions themselves.

From approximately 1980 to 2000, a number of researchers sought to relate the memory system that supports aspects of sentence comprehension to components of the model of ST-WM developed by Baddeley and his colleagues. The main question that was considered was what component(s) of the ST-WM system,

if any, supported aspects of sentence memory; as noted, our focus is on the sentence memory that supports syntactic comprehension. Either the CE or the PL could play this role (the role of the EB, which had not been introduced at the time when much of this work was done, has not been investigated). The CE maintains abstract representations that could include syntactic and semantic information, making it suitable for this purpose. The PL maintains phonological representations that are linked to lexical items that contain the needed semantic and syntactic information, and it might be easier for the memory system to maintain such representations in the PL as pointers to the needed information than to maintain what are arguably more complex representations in the CE.¹

Data regarding these possibilities come from several sources: interference effects of concurrent tasks that required the CE or the PL on parsing and interpretation (King & Just, 1991; Waters, Caplan, & Hildebrandt, 1987); tongue twister effects (Acheson & MacDonald, 2011; Ayres, 1984; Keller, Carpenter, & Just, 2003; Kennison, 2004; McCutchen, Bell, France, & Perfetti, 1991; McCutchen & Perfetti, 1982; Zhang & Perfetti, 1993); effects of homophones on comprehension (Coltheart, Patterson, & Leahy, 1994; Waters, Caplan, & Leonard, 1992); correlations between measures of the capacity of the CE and performance in parsing and interpretation (Just & Carpenter, 1992; King & Just, 1991; MacDonald, Just, & Carpenter, 1992; Miyake, Carpenter, & Just, 1994; Waters & Caplan, 1996); associations and dissociations of effects of brain damage on the CE or the PL and parsing and interpretation (Caplan & Waters, 1996; Emery, 1985; Grossman et al., 1991; Grossman, Carvell, Stern, Gollomp, & Hurtig, 1992; Kontiola, Laaksonen, Sulkava, & Erkinjuntti, 1990; Lalami et al., 1996; Lieberman, Friedman, & Feldman, 1990; Martin, 1990; Natsopoulos et al., 1991; Rochon & Saffran, 1995; Rochon, Waters, & Caplan, 1994; Stevens, Kempler, Andersen, & MacDonald, 1996; Tomoeda, Bayles, Boone, Kaszniak, & Slauson, 1990; Waters, Caplan, & Hildebrandt, 1991; Waters, Caplan, & Rochon, 1995); and neural evidence in the form of differences in neural activation in high-span and low-span participants during parsing and interpretation and overlap or non-overlap of brain areas activated in tasks that involve the CE and ones that involve parsing and interpretation (Fiebach, Schleuwsky, & Friederici, 2001; Fiebach, Vos, & Friederici, 2004).

Caplan and Waters (1990) argued that these sources of data suggested that the PL did not support the memory requirements of the initial assignment of the preferred structure and interpretation of a sentence (what we called “first pass” parsing and interpretation), but they may play a role in supporting review and reanalysis of previously encountered information and in using the products of the comprehension process to accomplish a task (e.g., in maintaining a sentence in memory to later answer a question about its meaning). There is a general consensus that this view is correct; in an article relating the memory system that supports syntactic comprehension to ST-WM, Just and Carpenter (1992) explicitly say they are not advocating a role for the PL, only the CE, in this process.

The role of the CE in parsing and interpretation has been more controversial. Caplan and Waters (1999) argued that evidence of the sort described indicated that, like the PL, the CE does not support first-pass parsing and interpretation, but other researchers disagreed. Just and Carpenter (1992), for instance, developed a parsing model that included a limit on combined storage and processing capacity that they argued was derived from the CE.

51.2 CHANGES IN MODELS OF STM/WM

As noted, Baddeley’s model of the CE includes both a limited-capacity memory store of multidimensional representations and a computational capacity. However, aside from work by Engle and his colleagues on how representations are entered and removed from ST-WM, recent work in ST-WM has largely ignored the computational functions of the CE and has focused on its storage capacity. A second line of research has studied the nature of retrieval of items in STM tasks, a topic that had been studied prior to the Baddeley model but that had become less the focus of work since the advent of that model.

Seen as a storage system devoid of a computational function, the CE generally goes by the name “Central Store (CS)” (Cowan, 2000; Ricker, AuBuchon, & Cowan, 2010). The capacity of the CS has been estimated based on accuracy and speed of recall data. Using tasks that prevent the persistence of sensory stores and the use of rehearsal, the capacity of the CS based on accuracy has been estimated at between three

¹A store that is not part of Baddeley’s formulation of ST-WM but that has been argued to play a role in sentence comprehension is a “short-term semantic store” postulated by Martin, Shelton, and Yaffee (1994). Caplan, DeDe, Waters, Michaud, and Tripodis (2011) raise questions about the existence of this store. If it exists, then its role in generating STM phenomena has not been examined in detail. Martin and He (2004) have argued that the “short-term semantic store” is used when items in a sentence are not assigned propositional meaning, as in prenominal sequences of adjectives (*the old, rusty, twisted*. . .N). If this store exists, then this would be, at most, a minor role in sentence comprehension, given the incremental nature of comprehension.

and five items (see Cowan, 2000 for review). For instance, Saults and Cowan (2007) exposed participants to four spoken digits presented in four different voices by loudspeakers in four spatial positions, and four colored spots presented at four different locations in a recognition task. Participants recognized three to four items regardless of whether only the visually presented colors or both the visually presented colors and the auditorily presented digits had to be remembered. Temporal data result in a similar, but more subtle, picture. Based on data from Verhaeghen and Basak (2005) regarding reaction times (RTs) in the n -back task, Verhaeghen et al. (2007) argued one item was maintained in the focus of attention but that this could be expanded to four items in highly practiced tasks.

The capacity of ST-WM has also been studied through the analysis of speed–accuracy trade-offs (SAT), which also provide information about the nature of retrieval. In the SAT approach, participants are presented a stimulus followed by a probe at a variable lag and are required to make a two-alternative forced new–old choice within a very short time (usually less than 200 ms; responses less than 100 ms are discarded as anticipations). Asymptotic d' is considered to be a measure of the availability of an item, the temporal point at which d' rises above 0 (the intercept), and the slope of the rise of d' from the point at which it rises above 0 to its asymptotic level to reflect how an item is accessed. McElree and Doshier (1989) found that set size (3 and 5) affected asymptotic accuracy but not temporal dynamics, except for the set-final item, even when the probe was presented in a different font. McElree (1998) found that there were different retrieval speeds for probes drawn from the last and all other categories when triads of words in different semantic categories were presented. McElree (1996) found that recognizing rhyming words and semantically related words resulted in uniformly slower dynamics than recognizing previously presented words as wholes. McElree (2006) argued that ST-WM consisted of a focus of attention with one item, which was accessed by a “matching” procedure based on abstract (nonsensory) features of the retrieval cue, and items outside the focus of attention, in long term memory (LTM), that were accessed by a content-addressable retrieval mechanism, with “chunking” of the memory set in accordance with semantic features. Based on an analysis of the distribution of RTs in the n -back task, Verhaeghen et al. (2007) also argued that items outside the focus of attention are content-addressable, although only under what they called “ideal” circumstances—precisely predictable switching out of the focus of attention on the part of high-functioning individuals.

These two features of memory mechanisms in modern models of STM/WM have been considered for their possible relation to sentence comprehension: (i) the possibility that retrieval of information in parsing and

interpretation is content-addressable and (ii) the possibility that a small number of items—at most four or five—are maintained in a highly accessible form and that this number of available items sets a capacity limit in parsing and interpretation. I review the work on these topics in turn.

51.3 RETRIEVAL MECHANISMS IN PARSING

A productive approach to modeling parsing is “retrieval-based parsing.” In retrieval-based parsing, words serve as retrieval cues for previous portions of a sentence. In one well-known model (Lewis & Vasishth, 2005), parsing begins with lexical access, which places a new word and its features in a lexical buffer. The syntactic features of the current lexical entry combine with the structure in a control buffer that contains the categories that are needed to complete phrase markers already constructed to form retrieval cues, which may retrieve previously constructed constituents or symbols in long-term memory. Based on the retrieved item and the current lexical content, a production creates a new syntactic structure and attaches it to the retrieved constituent. This structure replaces the one in a problem state buffer that contains the existing constructed syntactic representation, the categories that are needed to complete phrase markers in this buffer are updated in a control buffer, and a production rule guides attention to the next word.

In this model, the retrieval process for lexical items and syntactic symbols is content-addressable. It consists of matching features of a retrieval cue to features of items in the memory set. Retrieval success is determined by the ratio of the match of the retrieval cue with the retrieved item divided by its match with other items in the memory set (Nairne, 1990a; Ratcliff, 1978), subject to noise. This model has two features: (i) items in the memory set that share features with a retrieval cue interfere with retrieval of a target and (ii) shared features of items in the memory set do not affect retrieval unless these features are part of the retrieval cue.

Evidence for this model comes from interference effects in online measures of parsing and interpretation, and from the SAT paradigm applied to sentence comprehension.

If retrieval success is determined by the ratio of the match of the retrieval cue with the retrieved item divided by its match with other items in the memory set, then retrieval difficulty will increase as a function of the extent to which nontarget and target items share features of the retrieval cue. This has been found for semantic and syntactic features of items.

Effects of the semantic similarity of noun phrases on online sentence processing measures have been described for both sentence-internal and sentence-external noun phrases. An example of sentence-internal interference is the report of [Gordon, Hendrick, and Johnson \(2001\)](#) regarding self-paced reading times in subject-extracted and object-extracted relative clauses (2a, b) and clefts (3a, b) with common nouns (definite descriptions), proper nouns, or pronouns:

- 2a. The banker that praised the barber/Sue/you climbed the mountain. . .
- b. The banker that the barber/Sue/you praised climbed the mountain. . .
- 3a. It was the banker/Sue that praised the barber/Dee. . .
- b. It was the banker/Sue that the barber/Dee praised. . .

The verb of an object relative creates a retrieval cue for its subject and object, and the verb of a subject relative creates a retrieval cue for its subject only, leading to more interference at the verb of the object than the subject relative clause. This was confirmed. In the relative clauses (2a, b), the sentence type effect was reported as being greater in the definite description (*the barber*) than either the pronoun (*you*) or the proper name (*Sue*) conditions. In clefts (3a, b), there was a greater sentence type effect in sentences in which the noun phrases (NPs) were matched for noun type (both definite descriptions or both proper nouns) than in sentences in which they differed.

An example of sentence-external interference is shown in the [Van Dyke and McElree \(2006\)](#) report of self-paced reading times for object clefts with or without concurrent recall of sets of three words that could or could not be integrated into the sentence, as in (4):

- 4: Word list: table-sink-truck
- Sentence: It was the boat that the guy who lived by the sea sailed/fixed in two sunny days.

If verbs create retrieval cues that include information about semantic features of their arguments, there should be more interference from the integrated than the nonintegrated sets of words. The authors found that reading times were longer in the integrated than the unintegrated conditions.

Syntactic interference effects would be expected to arise when intervening items have syntactic properties shared by the retrieval cue and the to-be-retrieved item. Lewis and his colleagues ([Lewis, 1996, 2000; Lewis & Vasishth, 2005; Lewis, Vasishth, & Van Dyke, 2006; Van Dyke & Lewis, 2003; Vasishth & Lewis, 2006](#)) have shown such effects in online processing. For instance, [Van Dyke and Lewis \(2003\)](#) presented sentences such as (5) and (6). Words in parentheses were omitted in half the presentations of the sentences

to produce ambiguities; we have annotated some words with subscripts for ease of reference.

- 5. Low interference
The secretary forgot (that) the student who was waiting for the exam was standing in the hallway.
- 6. High interference
The secretary forgot (that) the student who knew (that) the exam was important was standing in the hallway.

If *was standing* is a retrieval cue for a subject, then there should be more syntactic interference with retrieval of *the student* in (6) than in (5) because *the exam* is a subject in (6) and an object in (5). Van Dyke and Lewis presented four studies of accuracy and self-paced reading times in an acceptability judgment task with these sentences. In three of the four studies in which unambiguous versions of these sentences were presented, there was greater acceptance of well-formedness of (5) than (6) and longer self-paced reading times for the critical segment *was standing* in (6) than in (5).

Retrieval of information in sentences has also been studied using the speed-accuracy trade-off (SAT) technique. In applying paradigm to sentences, participants make judgments about the acceptability of sentences. The last word in the experimental sentence serves as a retrieval cue for an earlier word, and the position of the retrieved word and the number and type of potentially interfering items are varied across sentence types. Asymptotic d' is taken as a measure of the availability of the earlier word, and d' dynamics are taken as the measure of its accessibility.

McElree and his colleagues have used the SAT technique to study many types of sentences and found that d' measures are not affected by the number of potentially distracting items. For instance, [Martin and McElree \(2008, 2009\)](#) varied the distance between a verb phrase ellipsis and its antecedent (6a/b), the length and complexity of the antecedent (7c/d), and the amount of proactive or retroactive interference (7e/f).

- 7a. The editor admired the author's writing but the critics did not.
- b. The editor admired the author's writing but everyone at the publishing house was shocked to hear that the critics did not.
- c. The history professor understood Roman mythology but the principal was displeased to learn that the over-worked students attending the summer school did not.
- d. The history professor understood Rome's swift and brutal destruction of Carthage but the principal knew that the over-worked students attending the summer school did not.
- e. Even though Claudia was not particularly angry, she filed a complaint. Ron did too.
- f. Claudia filed a complaint and she also wrote an angry letter. Ron did too.

None of these variables affected SAT dynamics, indicating that retrieval is unaffected by the amount of proactive or retroactive interference or the complexity of the retrieved item. This implies that retrieval uses a content-addressable mechanism, similar to findings in ST-WM reviewed.

Despite these results, the effort to relate retrieval-based parsing models of STM/WM faces a number of challenges. One issue is how certain results are to be interpreted. For instance, the semantic similarity effects in studies such as those of [Gordon et al. \(2001\)](#) cannot be due to the interference-generating mechanism outlined, because the verb of an object relative clause cannot generate a cue to retrieve two noun phrases that share a common semantic property or an aspect of form such as being a common or proper noun. An alternative, suggested by [Lewis et al. \(2006\)](#), is that the semantic similarity effects in the studies by Gordon and his colleagues arose during encoding. If so, then encoding of words into memory during sentence processing appears to differ from encoding of words in ST-WM, where similarity effects appear to arise during retrieval ([Baddeley, 1968](#); [Neath, 2000](#)).

The comparison of the effects of semantic similarity in parsing/interpretation and in SAT studies also leads to a problem. Similarity of list items does not affect, and may slightly improve, retrieval of item information ([Baddeley & Hitch, 1974](#); [Nairne, 1990b](#); [Nimmo & Roodenrys, 2004](#); [Poirier & Saint-Aubin, 1996](#); [Postman & Keppel, 1977](#), exp 2; [Underwood & Ekstrand, 1967](#); [Watkins, Watkins, & Crowder, 1974](#); [Wickelgren, 1965, 1966](#)). Therefore, if semantic similarity effects arise at retrieval, then what must be retrieved is item and order information, as [Gordon et al. \(2001\)](#) suggest. However, the content-addressable retrieval suggested by the SAT dynamics results is consistent only with retrieval of item information in ST-WM, not order information ([Hockley, 1984](#), exp 3; [McElree & Doshier, 1993](#)). Because both the interference and SAT studies involve retrieval of NPs in the same structures (relative clauses), they must be characterizing the same retrieval process. If both sets of results arise during retrieval, then the difference between the two studies reflects strategic effects of task or other factors on retrieval mechanisms.

An issue that has been emphasized in recent literature is the absence of expected effects of potentially interfering items in situations where such effects would be expected if content-addressable retrieval occurs. One phenomenon that has been studied is the selective absence of illusions of grammaticality. For instance, many readers initially find sentence (8) grammatical ([Eberhard, Cutting, & Bock, 2005](#)), but readily report the ungrammaticality of (9) ([Dillon, Mishler, Sloggett, & Phillips, under review](#), cited in [Phillips, Wagers, & Lau, 2011](#)).

*8. The key to the cabinets are on the table

*9. The diva that accompanied the harpists on stage presented themselves with lots of fanfare.

[Phillips et al. \(2011\)](#) suggested that the difference between (8) and (9) is due to the nature of the retrieval cues established by the agreement markers on verbs and reflexives. They proposed that reflexives retrieve their antecedents using only structural cues, whereas verbs create retrieval cues that specify the features of the subject. In their view, this difference is due to the fact that a sentence subject reliably predicts a verb and its agreement features, whereas a reflexive cannot be reliably predicted.

Items in certain syntactic positions appear not to be contacted during the retrieval process even when the retrieval cue specifies their features. For instance, NPs in certain positions do not appear to be contacted when a verb of an object relative clause retrieves its object. [Traxler and Pickering \(1996\)](#) found evidence for a retrieval cue that specified semantic features of the object of the verb of a relative clause (similar to [Van Dyke & McElree, 2006](#)) in (10) in the form of longer reading times for *shot* in the anomalous version of that sentence (with the NP *garage*), but no prolongation of reading times for *wrote* in the version of (11) with the NP *city*:

10. That's the pistol/garage with which the heartless killer shot the hapless man.

11. We liked the book/city that the author who wrote unceasingly saw while waiting for a contract.

This suggests that *the city/book* are not in the list of items contacted by the retrieval cue established by *wrote* in (11). It has been suggested that this is because of the syntactic environment in which *the city/book* and *wrote* occur; *the book/city* is outside a syntactic "island" that contains *wrote*.

The implication of the last two sets of results is that there are several retrieval mechanisms in sentence comprehension. At times, items are retrieved on a content-addressable basis. At other times, a search process applies. In addition, there are mechanisms that are reasonably well-established in the ST-WM literature, such as Weber-compressed temporal intervals from retrieved item to retrieval cue or response ([Brown, Neath, & Chater, 2007](#)), positional activation gradients measured from both list-initial and list-terminal items ([Henson, 1998](#)), temporal oscillators that estimate list length ([Brown, Preece, & Hulme, 2000](#); [Henson & Burgess, 1997](#)), and others (for review, see [Henson, 1998](#)) that are not plausible candidates for mechanisms that support the memory requirements of parsing and interpretation. If there are mechanisms found in ST-WM and not in parsing and interpretation,

then parsing and interpretation at most select from memory mechanisms found in ST-WM.

Altogether, the relation between the memory mechanisms that have been documented in sentence comprehension and those that apply in STM/WM tasks is not clear.

51.4 CAPACITY LIMITS IN STM/WM AND SENTENCE COMPREHENSION

The idea that parsing is capacity-limited has been part of thinking about sentence comprehension for decades (Miller & Chomsky, 1963). If it is correct that capacity limitations of the parser/interpreter are those found in the capacity-limited portion of ST-WM, then this would tie a major feature of parsing and interpretation to a property of ST-WM. Lewis and his colleagues have proposed several such relations.

Lewis (1996) developed a model in which lexical items can be either heads or dependents (or both) in structural relations. Parsing consists of connecting heads and dependents under higher nodes. Lewis (1996) argued that capacity limits on parsing arise because the buffer can contain only two constituents of the same type. For instance, in an object relative clause such as (1b), when *the clerk* is encountered, the buffer contains the structure [DEPENDENT—SPEC-IP—*the manager; the clerk*], which is within the capacity of the buffer. However, in the double-center embedded structure (12):

12. It was the book that the editor who the secretary who quit married enjoyed at *the secretary*, the buffer contains the structure [DEPENDENT—SPEC-IP—*the book; the editor; the secretary*] and the sentence becomes difficult because three NPs in the buffer are assigned the value [DEPENDENT—SPEC-IP].

In a related vein, Lewis and Vasishth (2005) suggested that the structure of their retrieval-based parsing model with three buffers (a control buffer, a problem state buffer, and a retrieval buffer) “has much in common with conceptions of working memory and STM that posit an extremely limited focus of attention of one to three items, with retrieval processes required to bring items into focus for processing. (Lewis & Vasishth, 2005, p. 380).”

The relation of capacity and temporal limits in parsing and interpretation to ST-WM is also subject to question. Lewis’s (1996) limit of two on the number of items with the same relation that can be maintained in a buffer does not correspond to any suggestion about the size of a fixed-capacity, capacity-limited portion of ST-WM, which has been estimated as one by McElree

(2006) and as four or five by Cowan (2000). Lewis and Vasishth’s three buffers differ from the ST-WM concept of a single CS, and triple the capacity limit of the CS.

Another consideration is that Lewis’ (1996) model requires that the contents of buffers remain accessible, because new items must be able to attach within them. The transparency of chunks in Lewis’ model differs from applications of models of capacity limits of the CS to other cognitive phenomena. For instance, Halford, Cowan, and Andrews (2007) argued that the limits of the CS restrict human reasoning to problems with relational complexity (“arity”) of no more than four, but their model requires that the reasoning process cannot access items within a chunk. If the capacity limits in processing in various domains are to be explained because of capacity limits in the CS, then the characterization of how chunks are processed must apply universally.

A third issue is that capacity limits and content-addressable retrieval apply to different stores in models of ST-WM; capacity limits are features of the CS or an expanded focus of attention, and content-addressable retrieval applies to items outside the capacity-limited portion of ST-WM (i.e., to items in LTM). If capacity limits exist in parsing and interpretation, then this would require that they are due to items being stored in a store from which they are not retrieved by a content-addressable mechanism, a noticeable discrepancy across the models we have been discussing. A model of STM/WM that recognizes only a focus of attention, such as McElree’s, cannot maintain that parsing and interpretation retrieves items in STM/WM (the focus of attention), but requires that memory limits in parsing and interpretation arise because of interference effects during retrieval of information from LTM (see Van Dyke & Johns, 2012, discussion).

51.5 AN ALTERNATIVE FRAMEWORK FOR VIEWING THE MEMORY SYSTEM FOR PARSING AND INTERPRETATION

A central feature of the memory system that supports parsing and interpretation that emerges from this discussion of the recent literature is the domain-specificity of many aspects of memory in parsing and interpretation. Retrieval cues, aspects of retrieval processes, and any capacity limits that may apply in parsing and interpretation all have important domain-specific features. Domain-specific aspects of memory are characteristic features of cognitive skills that have been related to a different postulated memory system—“long-term working memory (LT-WM).”

The concept of LT-WM was proposed and developed by [Ericsson and Kintsch \(1995\)](#) as a response to two phenomena: (i) the greatly expanded working memory capacity of experts and skilled performers and (ii) the fact that skilled activities can be interrupted and later resumed without major effects on performance. Examples of activities supported by LT-WM in individuals with established expertise include using an abacus, mental calculation, memory of servers for orders, and memory of chess players for chessboard arrays, and examples of activities supported by LT-WM in individuals after training include expansion of span (to as much as 80 items). Considerable resistance of these memory performances to interruption has been documented in studies such as [Chase and Ericsson \(1982\)](#), who found only a small decrement in recall of 30 item lists due to proactive interference from other lists in a trained subject. Ericsson and Kintsch argue that several capacities are required for these memory performances. The individuals who show these memory skills must have a large body of relevant knowledge that allows them to store the incoming information in LTM, the activity must be familiar, and the encoded information must be associated with a “retrieval structure”—a domain-specific complex set of retrieval cues.

The phenomena that led to the concept of LT-WM are seen in parsing and interpretation: a large capacity for memory of items; domain-specific knowledge; and a high degree of familiarity on the part of performers. The imperviousness of parsing and interpretation to temporal interruption is unknown; the few available results ([Wanner & Maratsos, 1978](#)) suggest it is unexpectedly robust. Applying Ericsson and Kintsch’s model to parsing and interpretation would lead to a model in which input activates items in long-term memory; these items are related by knowledge-based associations, patterns, and schemas to establish an integrated memory representation, and what is maintained in a STM system are retrieval cues for these items. It is of interest to reexamine the model of Lewis and colleagues with this perspective in mind. The representation of syntactic knowledge in declarative memory in the model of Lewis and colleagues corresponds to the “knowledge-based associations, patterns, and schemas” that are the basis for establishing an “integrated memory representation” in Ericsson and Kintsch’s model. Both Lewis and Ericsson and Kintsch maintain that the application of “knowledge-based associations, patterns, and schemas” to the creation of an “integrated memory representation” is a domain-specific process. As noted, the operations of Lewis’ model involve procedural memory and declarative long-term memory; ST-WM is only invoked, questionably (I have argued), to account for capacity limits on parsing. [Van](#)

[Dyke and Lewis \(2003\)](#) say that “cues in the retrieval context are combined multiplicatively to produce a single retrieval probe...all cues are combined into a retrieval probe, which gives the strength of the relationship between each possible probe cue (Q_1, \dots, Q_m) and the memory trace.” This process has many similarities to the formation of cues in LT-WM, as described by Ericsson and Kintsch.

Placing the memory system that supports parsing and interpretation within the LT-WM/skilled performance framework captures the facts that much of encoding, storage, and retrieval of information in parsing and interpretation is unconscious and subjectively undemanding, and that the retrieval cues used in parsing and interpretation are domain-specific. The domain specificity of retrieval cues and aspects of the retrieval process contributes toward the degree of independence of skills in individual domains from skills in others (great servers are not particularly likely to be great chess players). This predicts that the skill of parsing and interpretation will not necessarily covary with other skills, and it accounts for the findings that measures of memory use in parsing and interpretation—such as online processing times at points at which parsing and interpretation require retrieval from memory—correlate poorly or not at all with memory performance on ST-WM tasks ([Caplan & Waters, 1999](#)). However, overlap of components of skills or their utilization of a common functional architecture for memory might lead to correlations between measures of online effects in parsing and interpretation and online implicit memory effects in selected implicit memory tasks, as has been shown for statistical learning tasks ([Conway, Karpicke, & Pisoni, 2007](#); [Conway & Pisoni, 2008](#); [Misyak, Christiansen, & Tomblin, 2010](#)) and to correlation of measures of online effects in parsing and interpretation with elementary speed of processing ([Caplan et al., 2011](#)), which is common to many skills.

I have suggested that LT-WM supports skilled parsing and interpretation. However, skilled parsing and interpretation occasionally breaks down. [Caplan and Waters \(2013\)](#) suggested that ST-WM plays a role in supporting memory demands of processes that occur at points of incremental comprehension failure. At these points, comprehenders at times review previously presented material that is held in memory. In spoken language comprehension and noncumulative self-paced or externally paced reading, the verbatim representation of the input must be retrieved from memory; no matter what the presentation method, the constructed representations exist only in memory (they are not part of the literal input), where they must be accessed and manipulated. Even when the input is available in written form, items appear to be accessed

in memory at times, rather than by visual reinspection of the text. Regressive eye movements that are targeted to within one word of an item that is relevant to the clarification of the structure and meaning of the sentence (Frazier & Rayner, 1982; Inhoff & Weger, 2005; Meseguer, Carreiras, & Clifton, 2002; Mitchell, Shen, Green, & Hodgson, 2008; von der Malsburg & Vasishth, 2011; Weger & Inhoff, 2007) have been taken as being controlled by a representation in memory of the words in a sentence that is linked to memory of their spatial coordinates (Inhoff & Weger, 2005; Weger & Inhoff, 2007).

Caplan and Waters (1999, 2013) argued that retrieval of items under these circumstances directly utilizes mechanisms that apply to STM/WM tasks involving retrieval of items in lists. One argument that this is the case is that immediate serial recall of words in sentences with two clauses shows serial position effects on word recall in each clause (Marslen Wilson & Tyler, 1976), pointing to an interaction of recall based on linguistic structures (reconstruction from a conceptual representation; Lombardi & Potter, 1992; Potter & Lombardi, 1990) and mechanisms that support recall of words in lists. Theoretically, retrieval in the service of reanalysis occurs when the input is incompletely structured syntactically and/or semantically, and therefore has structural properties more akin to those of words in lists, which is the case during successful comprehension.

Assuming this framework is basically correct, an important question is, “when does the specialized LT-WM memory support comprehension and when do mechanisms directly tied to retrieval of information in lists apply?” In Caplan and Waters (1999), we suggested that ST-WM supported retrieval of information when syntactic structures had to be revised. This suggests that one could identify points in sentences at which ST-WM supports retrieval on the basis of syntactic features and parsing considerations. The literature provides many hypotheses about structural and/or processing determinants of points of possible incremental parsing failure, such as very high surprisal values (Hale, 2001; Levy, 2008; Staub 2010), high integration costs (Gibson, 1998), the need for nonmonotonic parsing during revisions (Sturt & Crocker, 1996), memory capacity limits (as discussed), and others. However, Caplan and Waters (2013) argued that no purely structural or processing theory can determine points at which ST-WM may support retrieval because these points are determined by incremental *comprehension* failure, not incremental *parsing and interpretation* failure. An important determinant of the success of sentence comprehension is intentional context—the comprehender’s task and the criterion she/he sets for accomplishing the task. Tasks that require superficial

comprehension or low criteria for task performance can allow comprehension to succeed even if the parser/interpreter fails to generate a grammatically licensed meaning (e.g., if all that the comprehender needs to know is who participated in an action and not what thematic roles different participants played), and, conversely, comprehenders may not have achieved adequate comprehension when the parser–interpreter generates a well-formed, semantically coherent representation if criteria for successful comprehension are set high (as seen in “wrap-up” effects at clause and sentence boundaries). This view is closely related to Lewis’s idea of bounded optimality (Howes, Lewis, & Vera, 2009) and Ferreira’s views on “good enough parsing” (Ferreira, Engelhardt, & Jones, 2009; Ferreira & Patson, 2007). Models of structural and processing load can provide an upper bound to what can be comprehended by most individuals, but this only partially determines incremental comprehension failure.

To investigate the possible role of ST-WM in supporting processing that arises after incremental comprehension failure, it is therefore necessary to identify empirical markers of incremental parsing success and failure. Because comprehenders have great freedom with respect to their behaviors, it is not clear that there are any behaviors that are inevitably triggered by either of these two states. However, the converse may be the case: certain behaviors, if present, may reliably indicate incremental comprehension failure. Caplan and Waters (2013) suggested two such behaviors: (i) in whole sentence reading, regressive eye movements “targeted” to within one word of an item that is relevant to the clarification of the structure and meaning of the sentence (discussed above) and (ii) in noncumulative self-paced reading and listening, positive correlations between reading and listening times for segments and task performance mark points at which comprehension is incrementally unsuccessful and controlled processing occurs. The basis for this latter suggestion is that longer self-paced reading and listening times result from the reader doing more “work” at a point in a sentence and therefore will occur in less efficient parsers, leading to a negative correlation of self-paced reading and listening times and comprehension accuracy across individuals if the extra work done by less efficient processors does not fully compensate for their inefficiency, or no relation between self-paced reading and listening processing times and task performance if the extra work done by less efficient processors does fully compensate for their inefficiency. If longer self-paced reading and listening times are positively correlated with task performance across individuals, then some process other than less efficient processors working harder to accomplish the comprehension task to the average level must have applied. These processes include controlled

problem-solving operations such as deliberate application of “rules of grammar” that a comprehender has learned, readers’ revisions of mental intonation contours to help determine constituent boundaries, and others that require accessing representations of a presented sentence in memory (for discussion and relevant results, see [Caplan et al., 2011](#)).

51.6 A COMMENT ON THE NEURAL BASIS OF PROCEDURAL (LT-WM) MEMORY MECHANISMS UNDERLYING SENTENCE COMPREHENSION

The suggestion that parsing and interpretation rely on LT-WM has much in common with the suggestion that parsing utilizes procedural memory ([Ullman, 2004](#)). There is evidence that neural structures that support procedural memory include a network that includes the basal ganglia and cerebellum and likely frontal lobe structures ([Mizumori, Puryear, & Martig, 2009](#); [Nagao & Kitazawa, 2008](#)), and Ullman and others have suggested that these structures—especially the frontal-basal ganglionic portion of the network—support retrieval of information from memory in skilled parsing and interpretation.

The appeal of this hypothesis on theoretical grounds is tempered by the fact that, as reviewed, many features of memory in skilled parsing and interpretation are “domain-specific.” Rick Lewis (personal communication) has suggested that it might be most profitable to view the memory mechanisms that support parsing and interpretation as being tokens of types of mechanisms used more generally, pointing to the many memory phenomena to which the ACT-R architecture has been applied (list memory: [Anderson & Matessa, 1997](#); sentence memory: [Budiu & Anderson, 2004](#); expertise: [Anderson & Fincham, 1994](#); [Anderson, Fincham, & Douglass, 1999](#)). However, even if memory mechanisms that support different domain-specific skills are variants and specializations of a common functional architecture, there are substantial differences in the memory systems that support different tasks and skills. In Lewis’ terms, the “tokens” of a common memory system “type” differ significantly because of domain-specific representations in the set of to-be-recalled items, the nature of the task that creates the need for retrieval, the extent to which encoding, storage, and rehearsal are performed in isolation or while other operations (such as comprehension or applying the products of comprehension to a task) are performed ([Humphreys, Bain, & Pike, 1989](#)). Domain-specific procedural memory systems arise because different sets of mechanisms are used to satisfy the memory needs of performance under the conditions found in different domains. Skilled, incrementally successful parsing

and interpretation have a unique set of properties that are supported by one such domain-specific adaptation of memory mechanisms. It is therefore theoretically conceivable that aspects of the memory processes that are deployed during comprehension involve specialized areas of the brain, such as those that store lexical syntactic information in LTM or maintain transiently activated phrase markers during online comprehension.

The neural structures that support the memory processes that apply during skilled sentence comprehension need to be investigated empirically. To date, studies of the localization of comprehension of sentences that require parsing and interpretation have yielded contradictory results. For one structure—the contrast of object and subject relative clauses—a wide variety of patterns of activation have been reported: L inferior frontal gyrus (IFG) ([Stromswold, Caplan, Alpert, & Rosch, 1996](#)), Broca’s area and Wernicke’s area, and, to a lesser degree, in their right hemisphere homologues ([Just, Carpenter, Keller, Eddy, & Thulborn, 1996](#)), bilateral inferior temporal lobe ([Cooke et al., 2002](#)), medial anterior structures (cingulate, middle frontal and superior frontal gyri) and left thalamus, left superior parietal lobe, and right inferior frontal lobe ([Caplan, Alpert, & Waters 1998, 1999](#); [Caplan, Alpert, Waters, Olivieri, 2000](#); [Chen, West, Waters, & Caplan, 2006](#); [Waters, Caplan, & Yampolsky, 2003](#)), and superior temporal gyrus (STG) ([Ben-Shachar, Hendler, Kahn, Ben-Bashat, & Grodzinsky, 2003](#); [Just et al., 1996](#); see [Grodzinsky and Freiderici, 2006](#); and [Caplan 2006, 2007](#) for review). [Chen et al. \(2006\)](#) found that some effects attributed to processing syntactic structure were, in reality, due to semantic factors, and [Caplan, Chen, and Waters \(2008\)](#) and [Caplan \(2010\)](#) have provided evidence showing that how syntactic structure is processed depends on the task, which influences neural responses. The areas that are activated by encoding, storing, and retrieving information in memory during the process of skilled sentence comprehension, as well as controlled processing that applies when skilled comprehension fails, require more study.

Grounding Sentence Processing in the Sensory-Motor System

Marta Ghio¹ and Marco Tettamanti²

¹Institute for Experimental Psychology, Heinrich-Heine-University, Dusseldorf, Germany; ²Department of Nuclear Medicine and Division of Neuroscience, San Raffaele Scientific Institute, Milano, Italy

52.1 INTRODUCTION

Current neuroscientific models of sentence processing recognize the coordinate labor between perisylvian language areas in the frontal and temporo-parietal cortices and supportive brain networks supplying short-term memory and other executive functions. Together, they subserve the reversible mapping of phonological lexical forms onto semantic and syntactic information in language comprehension and production, respectively (Friederici, 2012; Kemmerer, 2015). The involvement of left-hemispheric middle and superior temporal, inferior-posterior parietal, as well as inferior frontal brain regions in various sentence comprehension tasks has been revealed by a host of neuropsychological and neuroimaging studies (Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004; Pallier, Devauchelle, & Dehaene 2011; Vigneau et al., 2006). Part of this supportive brain network is also the left-hemispheric lateral premotor cortex, sometimes extending more posteriorly into the primary motor area and more anteriorly into the middle frontal gyrus (Kemmerer, 2015; Vigneau et al., 2006). The involvement of the motor system in sentence processing is not only due to phonological and articulatory mapping (Pulvermueller & Fadiga, 2010)—aspects that are not dealt with in this chapter—because it also provides a grounding node for certain kinds of conceptual-semantic information. The motor system involvement in conceptual-semantic language processing has particularly intrigued researchers over the past decade and led to hotly debated divergent positions in the field. Activations in the sensory-motor system during processing of action-related conceptual knowledge have been interpreted in epiphenomenal terms or in “embodied”

terms. Although several variants of embodiment have been formulated (Meteyard, Cuadrado, Bahrami, & Vigliocco, 2012), here we refer to a more general assumption formalized within the theoretical framework of grounded cognition, namely that concepts are represented in multiple, distributed brain networks reflecting the quality of experience that is characteristic for the concepts’ referents. In contrast to other accounts, the grounded cognition framework makes explicit that evidence about action-related conceptual representations is just one instance regarding the much broader domain of conceptual-semantic representations, including object-related, emotion-related, and other types of even more abstract concepts. Following this more general perspective, the theoretical construct of “grounded cognition” incorporates not only bodily (embodied) states but also the physical, social, and linguistic environment, affective, and internal states (Barsalou, 2010; Pezzulo et al., 2013).

Grounded cognition provides a coherent and scientifically testable theoretical framework to account for the involvement of the sensory-motor and other experiential brain systems in conceptual-semantic processing. Research on grounded cognition has provided an increasing amount of empirical data in favor of the involvement of these brain systems in conceptual-semantic processing (Kiefer & Pulvermueller, 2012; Meteyard et al., 2012). Most studies focused on processing words in isolation, either nouns or action verbs (Hauk & Tschentscher, 2013), whereas much less attention has been given to multi-word utterances such as phrases and sentences. In this respect, it has been observed that the meaning of a word presented in isolation is often underspecified and is, in many cases, prone to different interpretations. Desai, Binder,

Conant, and Seidenberg (2010) claimed that the meaning of a verb like “to use” is closely related to its arguments, with “use the hammer” and “use the opportunity” conveying an action-related and an abstract meaning, respectively. Moreover, processing a verb in isolation involves not only its meaning but also the information conveyed by its syntactic structure, such as the arguments it takes and their typical meanings. Ferretti, McRae, and Hatherell (2001) found that verbs prime typical agents and patients (to arrest—cop, criminal), or typical instruments (to stir—spoon), but not location (to swim—ocean). Similar results have been found for nouns (McRae & Jones, 2013). Providing verbs and nouns within a sentence structure can thus be considered as a linguistically more constrained access to conceptual knowledge that disambiguates the meaning of a word by the sentential context and that, by keeping the syntactic form constant, allows for controlling the information conveyed by the syntactic structure of a word.

A further important aspect to be considered is that only at the multi-word level do certain aspects emerge, such as how the meanings of individual words embedded within a phrase or a sentence are compositionally combined into complex meanings. Only recently has the question of the compositional mechanisms of language understanding been addressed from a grounded perspective. A first, still poorly investigated issue regards the role of grammatical/morpho-syntactic information, not only in assembling the meanings of lexical-semantic units but also in modulating grounded representations of action meanings by giving focus to different aspects of the linguistically described action (e.g., verb tense and aspect, or affirmative versus negative sentences). A second issue regards the role of the sentential semantic context in which action-related words are embedded in modulating motor resonance, such as literal (e.g., “Grasp the hammer”) versus figurative metaphorical (e.g., “Grasp the idea”) or idiomatic (e.g., “Grasp the nettle”) language.

Thus, the experimental manipulation of multi-word compositional parameters cannot but extend the discussion on the flexible nature of conceptual-semantic grounded representations (Kiefer & Pulvermueller, 2012) by emphasizing the modulatory role of the sentential linguistic context.

In this chapter, we cover and review the fundamental observations that have demonstrated the grounding of action-related sentence processing in the sensory-motor system and the debate on its causal, necessary role (see Section 52.2). Furthermore, we address increasing evidence about context-dependent flexible modulations with respect to the modulatory role of grammar/syntax in grounded conceptual-semantic representations at the multi-word level (see Section 52.3)

and about action-related figurative language (see Section 52.4). Finally, we deal with attempts to provide a more overarching framework for the neural mechanisms underlying the conceptual-semantic processing of emotion-related (see Section 52.5) and other abstract concepts (see Section 52.6) that may be grounded not only in action and perception but also in other experiential brain systems.

52.2 GROUNDING OF ACTION-RELATED SENTENCE PROCESSING IN THE SENSORY-MOTOR SYSTEM

The idea rooted in philosophy and psychology that the coding of conceptual information in semantic memory is tied to inherent sensory-motor properties of real-world objects and to the kind of sensory-motor experience we maintain with those objects eventually begun being supported by neuroscientific observations, particularly with seminal studies using neuropsychological patients (Patterson, Nestor, & Rogers 2007; Warrington & McCarthy, 1987). Neuroimaging studies using healthy normal subjects further demonstrated that passive viewing or naming of manipulable tools activates the lateral frontal cortex in or in proximity of the premotor cortex (Martin, 2007). From the point of view of language processing, one of the first ideas to be tested with functional magnetic resonance imaging (fMRI) was that linguistic descriptions of motor actions evoke activations of the neural motor system (Hauk, Johnsrude, & Pulvermueller, 2004): somatotopically arranged activations in the primary motor and premotor cortex were found for reading mouth-, hand-, and leg-related motor verbs presented in isolated, infinitive forms. Other fMRI studies closely replicated these findings at the multi-word level, using either Italian subject-verb-object sentences (Tettamanti et al., 2005) or English verb-object phrases (Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni, 2006). Several methodological differences confound the comparison between the results of these three studies, such as reading (Aziz-Zadeh et al., 2006; Hauk et al., 2004) versus passive listening tasks (Tettamanti et al., 2005), and the syntactic structure of action-related linguistic stimuli. These ranged from having both the predicate’s subject and object unspecified (Hauk et al., 2004), to only the object specified (Aziz-Zadeh et al., 2006), to both subject and object specified (Tettamanti et al., 2005). This may, at least in part, explain why only in the latter study the activations in motor areas were clearly accompanied by the activation of a broader left-hemispheric network, including the supramarginal and the posterior middle temporal gyri. The involvement of a left-hemispheric premotor-parieto-temporal network for

listening to action-related, subject-verb-object sentences was confirmed by other studies (Boulenger, Hauk, & Pulvermueller, 2009; Desai et al., 2010), with some also showing effective connectivity interactions between these brain regions (Ghio & Tettamanti, 2010; Tettamanti et al., 2008). One likely advanced possibility is that this premotor-parieto-temporal network reflects the involvement of action representation processes known to involve the same brain regions. In this view, the linguistic specification of both the subject and the object of a goal-directed, action-related verb predicate appears to lead to functional interactions between premotor areas, coding for the action motor program, anterior parietal regions, coding for the object's affordance features, and posterior temporal regions close to visual areas coding for biological motion (Arbib, 2012). It is possible that using isolated words or simple phrases, leaving one or more thematic roles unspecified, leads to a more restricted activation spread within the action representation network. This may be either because some properties of the action's agents and recipients are not being represented or because activity reverberation within the broader network is hindered by compensatory activation in some network nodes for reconstructing the unspecified thematic role information. Compatibly with these lines of reasoning, an earlier fMRI study on action observation (Buccino et al., 2001) reported premotor-parietal activations for viewing transitive actions (i.e., directed toward a visible object goal), but only premotor activations and no parietal activations for viewing intransitive actions (i.e., pantomimes, lacking an object goal).

Whereas all these studies have regarded sentence processing as an integrated unitary process over time, mainly due to the coarse temporal resolution of fMRI, other techniques with higher temporal resolution may allow the breakdown of the specific neural dynamics that are instantiated as the processing of the sentence grammatical and thematic roles unfolds. Along these lines, Scorilli et al. (2012) delivered transcranial magnetic stimulation (TMS) to the left primary motor cortex while participants read action-related verbs followed by concrete nouns, together forming verb-object phrases. Semantic acceptability response times for experimental phrases, compared with nonsense control phrases, were faster when the TMS pulse was delivered during verb than during noun presentation. This facilitation effect suggests that the semantic processing of action-related verbs, but not that of the associated concrete object nouns, rapidly activates the left-hemispheric motor system. A limitation of this study is the lack of additional TMS target anatomical loci, for instance, to test the hypothesis of parietal involvement in the processing of manipulable object nouns in verb predicates.

More indirect (lacking any measurements or modulations of neural activity targeted anatomically to the motor cortex) evidence of the involvement of the motor system in sentence processing at the conceptual-semantic level came from behavioral studies testing the so-called action-sentence compatibility effect (ACE). Because the processing of action-related word meanings and congruent motor actions are thought to be subserved by partially overlapping neural networks, several experimental studies have tested whether the temporal proximity/overlap between language processing and action execution tasks can lead to facilitatory/interference effects. For example, Glenberg and Kaschak (2002) showed that hand movements toward or away from the body were facilitated by sentences describing a congruent (e.g., "He opened/closed the drawer," respectively) compared with an incongruent action. Boulenger et al. (2006) found that the processing of action-related verbs presented before a signal prompting for an upper-limb grasping movement facilitated movement kinematics, an effect that was ascribed to residual activation of motor areas by verb processing that lowered the amount of activation required by the subsequent grasping movement to reach threshold. In turn, when the action-related verbs were presented simultaneously to the start of the grasping movement, interference in kinematic parameters was observed; this interference effect was ascribed to language and action processing simultaneously competing for the same neural resources.

However, whether sensory and motor representations play a causal (i.e., necessary) role in conceptual processing is still a matter of debate between defenders of the epiphenomenal (Mahon & Caramazza, 2008) and strong embodiment views (Gallese & Lakoff, 2005). Somewhat in between, moderate and weak versions of embodiment proposed that semantic representations are at least partly constituted by sensory-motor information, although with a certain degree of abstraction (Binder & Desai, 2011; Meteyard et al., 2012) and with flexible dynamic modulations according to tasks, context, and situations (Kiefer & Pulvermueller, 2012).

The choice of experimental approaches to test the necessary role of sensory-motor representation is controversial. fMRI and electroencephalography/magnetoencephalography evidence of fast and automatic activations of grounded systems during semantic processing (Kiefer & Pulvermueller, 2012; Pulvermueller & Fadiga, 2010) is not considered to be conclusive, because these methodologies do not allow establishing whether the observed correlations between brain activities and cognitive functions are causal. More decisive evidence is generally thought to be provided from neuropsychological studies involving patients with various disorders involving the motor system.

For instance, a sentence processing study by [Ibáñez et al. \(2013\)](#) showed that, relative to healthy control subjects, the ACE effect is reduced in Parkinson's disease patients. Similarly, [Fernandino et al. \(2013\)](#) showed that Parkinson's disease patients were slower than healthy subjects in a comprehension task with hand action-related sentences. However, motor and premotor brain regions do not appear to play a necessary role in sentence comprehension because their damage does not incontrovertibly lead to massive comprehension deficits in large patient cohorts ([Kemmerer, 2015](#)). Altogether, neuropsychological studies have provided conflicting results, leaving the causality debate from this perspective still open.

An alternative approach to argue against a merely epiphenomenal influence of motor system activity on language processing, but one that does not deny its flexible modulatory nature, is to demonstrate that the processing of word meaning involves the activation of sensory-motor brain areas at a varying degree that determines the efficiency of conceptual-semantic language understanding. Two studies on sentence processing have substantially contributed advances in this direction. [Beilock, Lyons, Mattarella-Micke, Nusbaum, and Small \(2008\)](#), in a combined fMRI and behavioral study, showed that individual sensory-motor expertise can improve the comprehension of related concepts in a semantic language task. Expertise was positively correlated with higher activation of the left dorsal premotor cortex, a brain region supporting the selection of well-learned action plans. [Locatelli, Gatti, and Tettamanti \(2012\)](#) showed that sensory-motor expertise gained by training naive subjects to perform specific manual dexterity actions (e.g., origami, knot-tying) can lead to an improvement of cognitive-linguistic skills related to the specific conceptual-semantic domain associated with the trained actions. More specifically, the authors observed, after manual dexterity training, a speeding of reaction times in a sentence-picture semantic congruency judgment task that was selective for sentence-picture pairs semantically related to the trained manual actions versus unrelated sentence-picture pairs.

In sum, the investigation of sentence processing can substantially contribute to the debate on the grounding of action-related semantic processing in the sensory-motor system. Specifically, action-related sentences may help clarify the specific neural mechanisms for representing the subject and object thematic roles of an action's verb predicate. The debate regarding whether the involvement of the motor system in action-related sentence processing is obligate or optional continues, but researchers increasingly recognize—against a strictly epiphenomenal view—that the most relevant question is to

clarify when and how this flexible involvement occurs ([Willems & Francken, 2012](#)) and whether this involvement can be beneficial to language processing.

52.3 FLEXIBLE MODULATIONS OF SENSORY-MOTOR GROUNDING BY GRAMMATICAL AND SYNTACTIC ASPECTS

As discussed, the investigation of conceptual-semantic processing at the sentence level can help gain a better control over the polysemous and thematic ambiguities that individual words in isolation leave unspecified. However, when it comes to sentence-level language processing, as opposed to single words, a set of nonlexical variables markedly comes into play, including combinatorial and compositional semantics, verb tense and aspect, and syntactic structure. These variables could, in principle, influence the kind of grounded conceptual-semantic representations reviewed ([Bergen & Wheeler, 2010](#)). In this respect, some behavioral evidence has been provided showing that grammatical parameters, such as verb aspect or temporal markers, affect the ACE. [Zwaan, Taylor, and de Boer \(2010\)](#) asked subjects to read action sentences embedded in a text describing an event as ongoing (e.g., "He opened the bottle"), about to happen (e.g., "He was about to open the bottle"), or completed (e.g., "He had opened the bottle") while performing a knob rotation task. Results revealed ACEs (longer reading and longer knob rotating times) for both ongoing and completed action sentences, but not for about to happen sentences. [Bergen and Wheeler \(2010\)](#) investigated the role of verb aspect in modulating the motor representations in language comprehension. Based on simulations, they argued that progressive sentences (e.g., "Ashley is stretching her arms") result in the detailed simulation of the described action (and should yield ACEs), whereas perfect sentences (e.g., "Ashley stretched her arms") result in the simulation of the action end-state (and should not yield ACEs). Accordingly, they found evidence for ACEs in progressive sentences, but not in perfect sentences. Thus, it seems that the activation of the motor system can be modulated by grammatical/syntactic information related to verb tense and aspect.

Among the more straightforward instances of compositional semantic integration at the sentence level that have contributed to the view of the flexible nature of conceptual-semantic sensory-motor representations is the case of sentential negation. In sentential negation, an interaction occurs between a syntactic element (i.e., the negation operator *not*) and conceptual-semantic information (i.e., the scope of sentential

negation containing the negated information) (Tettamanti & Moro, 2012). Building on psycholinguistic evidence (Kaup, Zwaan, & Lüdtkke, 2007) indicating reduced speed in the access to lexical-semantic information under the scope of sentential negation, the initial experimental question addressed by Tettamanti et al. (2008) in an fMRI study was the following: given that the semantic processing of action-related sentences like “I grasp an apple” activates the left-hemispheric action representation system, can we measure any kind of modulations of such an activation when processing sentences with reversed negation polarity like “I do not grasp an apple”? They observed reduced activation and reduced effective connectivity within the left-hemispheric premotor-parieto-temporal action representation system for negative versus affirmative action-related sentences. This effect was interpreted as a reduced grounding in the sensory-motor system for the conceptual-semantic processing of negative action-related sentences, possibly driven by a drain of neuro-computational resources in favor of syntactic processing, given the greater syntactic and computational complexity of negative versus affirmative sentences (Christensen, 2009; Kaup et al., 2007).

Several other studies using different experimental techniques have yielded compatible observations. Tomasino, Weiss, and Fink (2010) showed that fMRI activations in the hand region of the primary motor and premotor cortices were reduced for negative hand action-related imperatives (e.g., “Don’t grasp!”) compared with affirmative counterparts (e.g., “Grasp!”). By means of TMS of the hand motor cortex and a concurrent reading task, Liuzza, Candidi, and Aglioti (2011) showed that the suppression of motor-evoked potentials (MEPs) from hand muscles observed for affirmative hand action-related sentences was reduced for negative sentences. A similar reduction of motor cortex activity for negative sentences was observed by Aravena et al. (2012) in a study in which they measured hand grip force continuously after target verb presentation; they found an enhancement of grip force for affirmative but not for negative hand action-related sentences.

On the basis of this motor cortex activity reduction due to sentential negation, Bartoli et al. (2013) postulated a “disembodiment” mechanism of sentential negation, by which the reduced grounding of conceptual-semantic processing in the sensory-motor system for negative action-related sentences leads to a computational load reduction in these brain regions, yielding a reduced interference in concurrent motor tasks. This mechanism was verified in a kinematic study in which participants listened to affirmative or negative action-related subject-verb phrases and immediately afterward performed a congruent upper-limb

movement (Bartoli et al., 2013). Negative sentences were found to interfere less with the movement kinematic parameters than matching affirmative sentences.

Froni and Semin (2013) measured electromyographic recordings from zygomatic muscles continuously after the presentation of face action-related subject-verb phrases (e.g., “I am smiling”/“I am not smiling”) and found muscle activation for affirmative sentences and muscle inhibition for negative sentences. These results suggest a possible neurophysiological mechanism by which the semantic comprehension of negative action-related sentences is encoded in terms of an inhibition of the muscles whose activation is negated.

Another sentence-level linguistic construction that is related to but distinct from sentential negation is that of counterfactuals—a linguistic combination of semantic and grammatical elements to express a given modality of the declarative state of affairs, namely that something does not occur but could have occurred under some hypothetical plausible circumstances. Evidence limited to one fMRI study (Urrutia, Gennari, & de Vega, 2012) using complex action-related sentences such as “If Pedro had decided to paint the room, he would have moved the photograph” showed higher activation of the fronto-medial cortex extending into the supplementary motor area for counterfactuals versus factuals (e.g., “Since Pedro decided to paint the room, he is moving the photograph”). Thus, the conceptual-semantic comprehension of counterfactuals appears to be grounded in the motor system in a manner that differs from that of sentential negation with respect to direction (higher versus lower activation) and anatomical location (fronto-medial versus premotor and primary motor cortex). The fronto-medial cortex has been implicated in the programming of actions that are withheld or not executed (Brass & Haggard, 2007).

All these instances of multi-word grammaticality underline the fact that future studies on sentence processing shall more and more disentangle relevant dimensions of sentence structure with reference to sentence processing anatomo-functional models and not treat anymore sentences as unitary blocks. As already discussed in the previous section, time-resolved neuroimaging techniques can provide a crucial complementary contribution in this respect.

52.4 FIGURATIVE LANGUAGE AS AN ABSTRACT SENTENTIAL-SEMANTIC CONTEXT FOR ACTION-RELATED VERBS

Figurative language forms still another traditional research topic within the domain of grounded

cognition having a focus on sentence processing, because figurative language is typically instantiated at the sentence level. Metaphors are linguistic utterances in which the intended conceptual meaning differs from the meaning conveyed by the literal combination of the individual lexical-semantic constituents, thus forming a conceptual-semantic representation at a somewhat more “abstract” level. Some proponents of embodied cognition theories (Gallese & Lakoff, 2005; Gibbs, 2006) have proposed that these more abstract concepts, particularly when formed by lexical-semantic constituents with a physical, sensory-motor meaning (e.g., “Grasp the idea”), are grounded in the sensory-motor, premotor-parietal system. In metaphoric expressions, the motivations for using a certain literal image or meaning are generally manifest to the communication recipients. On the contrary, more conventionalized figurative expressions, such as idioms, can present varying degrees of semantic transparency, ranging from transparent ones (e.g., “Smell a rat”) to more opaque ones (e.g., “Kick the bucket”). It is debated whether the comprehension of idioms compositionally entails the literal comprehension of the individual lexical-semantic constituents until some (e.g., contextual) cues prompt the idiomatic interpretation, or whether it is directly gained by retrieving a morphologically complex entry in the mental lexicon (Papagno & Caporali, 2007). Most empirical evidence suggests that idiom processing involves, to some extent, a decomposition into individual lexical units, even in the case of more opaque idioms (Papagno & Caporali, 2007; Romero Lauro, Tettamanti, Cappa, & Papagno, 2008). If so, then we should expect that figurative expressions of different sorts containing action-related verbs activate motor areas, and this should reveal the extent to which the motor system involvement in the processing of action-related words is lexically bound, independently of the global conceptual-semantic representation formed, or flexibly modulated depending on the type of literal versus figurative sentential context.

Evidence in support of either hypothesis until now has been somewhat inconsistent, although overall the number of studies that found an association between the motor system and specific types of figurative action-related language probably exceeds the number of those that did not (for an earlier review, including a coordinate meta-analysis, see Rapp, Mutschler, & Erb, 2012). An early fMRI study (Aziz-Zadeh et al., 2006) found no significant motor system activations for idiomatic phrases related to mouth, hand, or foot actions, despite a somatotopic effect for literal sentences. Negative fMRI evidence for idiomatic, but not for literal, sentences were also supplied by Raposo, Moss, Stamatakis, and Tyler (2009). Other fMRI studies, however, found a significant involvement of the

motor and/or premotor cortex in the processing of figurative action-related sentences. Boulenger et al. (2009) found arm/leg somatotopic effects for both idiomatic and literal sentences, effects that were confirmed in a magnetoencephalography study (Boulenger, Shtyrov, & Pulvermüller, 2012), showing a fast spread of activity in the motor cortex within 250 ms of latency. Desai, Binder, Conant, Mano, and Seidenberg (2011) found larger activations for idiomatic versus literal sentences in the motor cortex, as well as in the posterior superior temporal sulcus coding for biological motion; these effects displayed an inverse correlation with familiarity, such that unfamiliar sentences showed the strongest activation in these brain regions. An fMRI study by Romero Lauro, Mattavelli, Papagno, and Tettamanti (2013) included metaphoric and fictive motion (e.g., “The road runs through the valley”) sentences in addition to idiomatic and literal ones. Left premotor cortex activations were found for processing both literal (arm and leg somatotopy) and fictive motion sentences (only leg, because fictive motion cannot involve upper-limb verbs by definition); arm-related but not leg-related metaphoric sentences induced significant activations in the left premotor cortex, whereas idiomatic sentences only presented a trend toward significant left premotor activations when an upper-limb verb was involved. This gradient of the motor effects from literal to figurative conditions was also confirmed by another fMRI study (Desai, Conant, Binder, Park, & Seidenberg, 2013) and by an earlier TMS study (Cacciari et al., 2011) that found significant effects for literal, fictive motion, and metaphoric sentences, but not for idiomatic sentences. An ACE study by Santana and de Vega (2011) showed faster reaction times in the action-sentence matching condition for both literal and metaphoric sentences. Finally, a study on action-related figurative language in Parkinson’s disease patients (Fernandino et al., 2013, already discussed in Section 52.2) reported slower reaction times compared with healthy control subjects for literal and idiomatic sentences, as well as worse accuracy for metaphoric sentences.

Overall, multiple complementary techniques provide some convergent positive evidence for an involvement of the motor system in figurative action-related language processing. This conclusion can be drawn with somewhat greater confidence for figurative expressions that, as we have seen, undergo decomposition into individual lexical-semantic components, such as metaphors and fictive motion expressions. Idioms, although at least partially undergoing lexical decomposition, appear to activate motor areas in a less consistent manner, possibly inversely correlated with idiom familiarity. Therefore, at least to some extent, the literal versus figurative contexts in which action-related verbs

appear flexibly modulates the degree of grounding in the sensory-motor system.

As already discussed in relation to [Desai et al. \(2011\)](#) study, a quite consistent finding of action-related language fMRI studies, distinct from the activation of the motor cortex, is the involvement of the posterior temporal cortex coding for biological motion. Accordingly, fMRI studies on action-related figurative expressions, whether idiomatic, metaphoric, or more frequently involving fictive motion, have found consistent activation in posterior temporal brain regions ([Romero Lauro et al., 2013](#); [Saygin, McCullough, Alac, & Emmorey, 2010](#); [Wallentin, Lund, Ostergaard, Ostergaard, & Roepstorff, 2005](#); [Wallentin et al., 2011](#)). [Chen, Widick, and Chatterjee \(2008\)](#) reported a similar result for predicate metaphors (e.g., “The man fell under her spell”) but importantly distinguished this activation effect as being located more anteriorly along the posterior middle temporal cortex compared with the activation elicited by literal motion sentences. This gradient was interpreted as evidence that increasingly abstract motion knowledge progressively involves more anterior portions of the lateral temporal cortex.

The recent neuroscientific literature has shown that the tight functional link between sensory-motor conceptual knowledge conveyed by language and neural circuits mediating sensory-motor experience related to the concepts’ referents extends more in general to virtually every aspect of the perceptual domain ([Kiefer & Pulvermueller, 2012](#); [Patterson et al., 2007](#)). Within the realm of figurative language studies, a notable example of these more general grounded associations is an fMRI study on metaphors based on concepts related to object texture (e.g., “She had a rough day”), which showed a specific activation in the texture-selective somatosensory cortex in the parietal operculum ([Lacey, Stilla, & Sathian, 2012](#)).

52.5 EMOTION-RELATED LANGUAGE: ABSTRACT BUT PARTIALLY GROUNDED IN THE SENSORY-MOTOR SYSTEM

The use of multi-word expressions opens the possibility of combining concrete words to convey more abstract meanings, as we have illustrated. Abstract meanings, however, can also be conveyed by words or sentences referring to entities, events, or states that cannot be experienced through senses in the external world. The controversial possibility of grounding the processing of abstract knowledge in the sensory-motor system is best illustrated by emotion-related knowledge.

Emotion meanings (e.g., happiness, sadness) are generally considered abstract concepts because they

mainly refer to internal states and have no obvious referents in sensory-motor experience. From a grounded perspective, internal states can be as much the object of experience as external states and actions ([Kousta, Vigliocco, Vinson, Andrews, & Del Campo, 2011](#)). In addition to internal experiences—including affective states, introspection, interoceptions, and mentalizing—emotion concepts are also believed to be grounded in situations in which people experienced them—including settings, agents, objects, events, and even motor actions ([Barsalou, 2010](#); [Wilson-Mendenhall, Barrett, Simmons, & Barsalou, 2011](#)). The relative contribution of the internal and external sensory-motor experiences associated with a given emotion concept may vary ([Wilson-Mendenhall et al., 2011](#)). Accordingly, retrieving and processing abstract emotion knowledge conveyed by language should activate a distributed brain circuitry including (in addition to language areas) neural networks processing emotion and introspection and the sensory-motor system in a context-dependent manner ([Binder & Desai, 2011](#); [Kiefer & Pulvermueller, 2012](#)). As far as motor representations are concerned, it has been observed ([Winkelman, Niedenthal, & Oberman, 2008](#)), for example, that covert emotional states (e.g., anger) are often associated with overt motor behaviors, such as facial expressions (e.g., frown) and emotional hand/arm gestures (e.g., clenched fists).

Neuroimaging studies (for a review, see [Citron, 2012](#)) have provided evidence of activations in emotion brain networks during the processing of linguistic utterances conveying an emotional content, be it words denoting a specific emotion (e.g., sadness) or characterized by some emotional connotations (e.g., flower, war). On the contrary, data about the involvement of the sensory-motor system in emotion-related language are scant. Initial evidence came from an fMRI study ([Moseley, Carota, Hauk, Mohr, & Pulvermueller, 2012](#)) in which participants silently read single words denoting either emotions (e.g., “mock”) or sensory-motor emotional actions (e.g., “frown”), plus mouth- and hand-related words (e.g., “bite,” “pinch”) as a control. Both types of emotional words activated (in addition to emotion circuitries) the same motor areas activated by hand- and mouth-related verbs. These findings are compatible with the idea that processing emotion-related meanings is grounded in motor areas, even if words denote emotional states (“mock”), without explicitly referring to emotionally charged objects and actions (as in “frown”). At the sentence level, neuroimaging data are still lacking. In a rating study, we provided initial evidence that emotion-related sentences (e.g., “She mocks the disappointment”), although judged as abstract on a concreteness scale, exhibited a specific involvement of body parts and were more

associated with mouth, hand, and leg movements relative to other types of abstract-related meanings (Ghio, Vaghi, & Tettamanti, 2013).

One alternative (but partially compatible) view stresses the grounding of emotion meanings in sensory-motor systems, arguing that language and emotion are mutually related through action (Glenberg, Webster, Mouilso, Havas, & Lindeman, 2009; Niedenthal, 2007). Glenberg et al. (2009) showed that language understanding induces emotion-specific changes in the facial muscles. Participants read sentences describing angry, sad, and happy situations while recording electromyographic activity from the facial muscles involved in producing expressions of happiness (*zygomatic major* and *orbicularis oculi*) versus anger and sadness (*corrugator supercilii*). The muscles used in smiling were more active during reading of happy sentences, whereas the frowning muscle was more active during reading of sad and angry sentences. Havas, Glenberg, Gutowski, Lucarelli, and Davidson (2010) tested whether action simulations play a causal role in emotional sentence processing by evoking a reversible paralysis of the *corrugator supercilii* muscle used in expressing negative emotions through the injection of the botulinum toxin. During sessions before and after injections, participants read sentences describing angry, happy, and sad situations and then pressed a button. A sentence-by-session interaction was found, with reading times for sad and angry sentences being longer during sessions before injections than after injection, and there were no differences for happy sentences.

In sum, limited evidence supports the view of a grounding of emotion language processing in the sensory-motor system. More clearly, the broadening of the grounded cognition perspective to account for the linguistic processing of “abstract” emotion-related conceptual knowledge seems to require the involvement of distributed brain networks beyond the sensory-motor system.

52.6 ABSTRACT SENTENCE PROCESSING IS GROUNDED IN EXPERIENTIAL NEUROCOGNITIVE SYSTEMS

Contrary to traditional accounts positing that abstract knowledge relies on verbal representations only (Paivio, 1971; Schwanenflugel, Harnishfeger, & Stowe, 1988), grounded accounts postulate that, also in the abstract domain, the storage of conceptual knowledge may reflect the type of experience maintained with the concepts’ referents (Barsalou, 2010; Kiefer & Pulvermueller, 2012), as exemplified by emotion concepts. Among

grounded accounts, different nuances exist with respect to the type of experience considered characteristic for abstract concepts (Meteyard et al., 2012). According to a strong embodied view, abstract concepts are grounded in sensory-motor experience via conceptual metaphors (Gallese & Lakoff, 2005; Gibbs, 2006). However, criticisms have been raised about the generalizability of conceptual metaphors as foundational mechanisms to all abstract concepts (Barsalou, 1999; Vigliocco, Meteyard, Andrews, & Kousta, 2009; Tettamanti & Moro, 2012), and empirical evidence is limited to a set of specific conceptual domains (Boroditsky & Ramscar, 2002; Casasanto & Boroditsky, 2008). Another influential embodied view proposed that, in addition to sensory-motor information, abstract meanings rely on emotional and introspective information about internal states, such as interoception, mentalizing, beliefs, affects, self-thoughts, and intention recognition (Barsalou, 2008; Ghio & Tettamanti, 2010; Kiefer & Pulvermueller, 2012; Wilson-Mendenhall et al., 2011; Wilson-Mendenhall, Simmons, Martin & Barsalou, 2013). Also, linguistic information has been considered relevant for abstract meanings, either in the form of word associations resulting from co-occurrence patterns and syntactic information (Simmons, Hamann, Harenski, Hu, & Barsalou, 2008; Vigliocco et al., 2009) or in the form of social and normative linguistic boundaries in which words may express previous experiences (Prinz, 2002) but may also constitute actions/experiences in their own right (Borghi & Cimatti, 2012; Sakreida et al., 2013).

In general, a shared assumption of grounded accounts is that multiple experiential representations contribute to the processing of both concrete and abstract meanings, although in different proportions. Concrete meanings may more heavily rely on sensory-motor information, whereas abstract meanings may rely on affective and linguistic information, depending on context and tasks (Barsalou, 2008; Kiefer & Pulvermueller, 2012; Vigliocco et al., 2009).

Despite the existing variety of abstract meanings, the abstract domain has generally been regarded as an undifferentiated whole (Cappa, 2008; Wang, Conder, Blitzer, & Shinkareva, 2010). In this respect, grounded accounts seem to have a great potential in explaining such variety of abstract meanings, encompassing various entities and processes such as social relationships or facts, events, and introspective states (Cappa, 2008). Depending on the particular abstract concept, a specific combination of modalities and systems that process perception, action, language, emotions, and internal states may be more or less relevant. By extending this line of reasoning, recent theoretical advancements proposed that distributed neural representations of experiential information related to the concepts’ referents might distinguish concepts with fine-grained

specificity in the abstract domain by analogy to what has been demonstrated for action-related and object knowledge (Ghio et al., 2013; Wilson-Mendenhall et al., 2013). For example, as the processing of affective concepts conveyed by language appears to involve the emotion processing network—as discussed in the previous section—similarly, the processing of introspective concepts referring to mental states might activate the mentalizing neural network, and the processing of abstract social meanings (i.e., meanings referring to social behaviors like “convince” or psychological traits like “ambitious”) might activate brain regions underlying mentalizing and social cognition. Consistently, fMRI studies using either single words (e.g., Zahn et al., 2007) or sentences (e.g., Simmons, Reddish, Bellgowan, & Martin, 2010) referring to abstract social meanings have found comparable activations in brain regions typically implicated in social cognition (particularly the anterior temporal lobe, but also the temporal poles, the medial prefrontal cortex, the posterior superior temporal sulcus, and the precuneus/posterior cingulate).

Similarly, for the semantic processing of mathematical-related concepts, the grounded framework posited an involvement of the same brain areas involved in the actual processing of numbers and quantities, such as the horizontal intraparietal sulci (Piazza, Pinel, Le Bihan, & Dehaene, 2007). In an fMRI study, Wilson-Mendenhall et al. (2013) showed that the processing of the concept “arithmetic” compared with “convince” relies on the same brain regions activated by a numerical localizer task. Another line of research suggests that number cognition is grounded in the sensory-motor system, with number processing involving hand representations related to finger-counting, for example. Developmental, behavioral, and neuropsychological studies seem to indicate that finger-counting habits have an effect on numerical and arithmetic processing (Hauk & Tschentscher, 2013). At the neural level, several neuroimaging studies provided evidence of an anatomical overlap between activations in parietal and precentral areas for numerical and arithmetic processing and activations for grasping and pointing movements (Tschentscher, Hauk, Fischer, & Pulvermueller, 2012). Such overlap, however, has been differently interpreted as resulting either from the invasion of evolutionary older brain circuits by the more recent cultural invention of numeracy (Dehaene & Cohen, 2007) or from hebbian learning mechanisms (Tschentscher et al., 2012).

Altogether, the empirical evidence of grounding abstract knowledge expressed linguistically is still quite limited. What seems to emerge, however, is a more general grounded framework in which (in addition to sensory-motor representations) different kinds of experience-based representations tied in distributed

neural networks may contribute to abstract semantic processing to different degrees.

52.7 CONCLUDING REMARKS

Convergent experimental evidence has demonstrated that conceptual-semantic sentence processing is flexibly grounded in sensory-motor and experience-based brain networks. Further research should better clarify how the neural activity in experience-related brain systems is functionally coordinated with that of language perisylvian and other supportive brain regions and the impact of inter-individual differences in the quality and quantity of experience in modulating experience-based neural representations.

Discourse Comprehension

Jeffrey M. Zacks¹ and Evelyn C. Ferstl²

¹Department of Psychology, Washington University, Saint Louis, MO, USA; ²Institute for Informatics and Society, Centre of Cognitive Science, Albert-Ludwigs-University, Freiburg, Germany

Here is the opening to a story no one would ever write:

“Over to the Indian camp.” The Indian who was rowing them was working very hard, but the other boat moved further ahead in the mist all the time. “Oh,” said Nick. Uncle George sat in the stern of the camp rowboat. It was cold on the water. “There is an Indian lady very sick.” Nick lay back with his father’s arm around him. The Indians rowed with quick choppy strokes. Nick and his father got in the stern of the boat and the Indians shoved it off and one of them got in to row. Nick heard the oarlocks of the other boat quite a way ahead of them in the mist. The young Indian shoved the camp boat off and got in to row Uncle George. The two boats started off in the dark. The two Indians stood waiting. “Where are we going, Dad?” Nick asked. At the lake shore there was another rowboat drawn up.

What is wrong with this passage? All the sentences were written by Ernest Hemingway in his iconic spare style. The vocabulary should be accessible to most readers. However, because we have rearranged the order of the sentences, the passage as a whole is probably quite difficult to comprehend.

Here is the original as Hemingway wrote it (Hemingway, 2007):

At the lake shore there was another rowboat drawn up. The two Indians stood waiting. Nick and his father got in the stern of the boat and the Indians shoved it off and one of them got in to row. Uncle George sat in the stern of the camp rowboat. The young Indian shoved the camp boat off and got in to row Uncle George. The two boats started off in the dark. Nick heard the oarlocks of the other boat quite a way ahead of them in the mist. The Indians rowed with quick choppy strokes. Nick lay back with his father’s arm around him. It was cold on the water. The Indian who was rowing them was working very hard, but the other boat moved further ahead in the mist all the time. “Where are we going, Dad?” Nick asked. “Over to the Indian camp. There is an Indian lady very sick.” “Oh,” said Nick.

In Hemingway’s opening to “Indian Camp,” a situation and a sequence of events are described. A skilled reader appreciates the setting and the events without apparent effort. The rearranged version preserves the words, grammatical structure, and sentence-level organization, but it is much less comprehensible. In this chapter we give an account of those processes that allow readers to make sense of discourse not just at the level of the sentence but also at the level of a connected sequence of sentences that describe settings and events.

When readers and listeners comprehend a narrative prose passage, van Dijk and Kintsch (1983) proposed that they construct three types of representation. The *surface* representation is the reader’s mental representation of the specific wording and structure of the text. The *textbase* is the reader’s representation of the items of information, called propositions, that the text asserts, independent of their form. The *situation model* is a structured mental representation of a situation and set of events. For example, consider the sentence “Nick heard the oarlocks of the other boat quite a way ahead of them in the mist.” If the end was changed to “in the mist quite a way ahead of them” or “quite a way ahead of them in the fog,” then this would probably change the surface representation but not affect the textbase or the situation model; neither of those representations depends substantively on exact word choices or word order. If “heard the oarlocks” were changed to “heard the oars,” then this would likely change the surface representation and also the textbase, because the object of the proposition is “oarlocks” in the former case but “oars” in the second. However, this probably would not change the situation model because the sound in both cases comes from the oars working in the oarlocks, so the two propositions give alternate descriptions of the same

situation. Finally, changing “quite a way ahead of them” to “quite a way behind them” would change all three representations, because it changes the word itself, the information asserted, and the situation described by that assertion.

These three types of representation differ in the mechanisms that produce them, in their fidelity, and in the timecourse with which they are forgotten. Surface representations are notably incomplete and fleeting. After short delays, readers are quite poor at answering questions such as whether “in the mist” or “in the fog” was Hemingway’s choice of words (for a review, see Fletcher, 1994). Surface representations of the sentences in Hemingway’s opening should not be much affected by the scrambling we did in the example. However, scrambling sentence order should substantially disrupt the textbase and the situation model.

In this chapter, we consider mechanisms by which comprehenders construct representations of discourse, and, in particular, how comprehenders establish connections among components of a text at each of the three levels. We take a cognitive neuroscience perspective in which we view the construction of discourse representations as resulting from mechanisms that have both information-processing aspects and neurophysiological aspects, and we try to present both aspects in an integrated fashion. Neuroscientific methods lend themselves to the study of discourse processes because they enable the researcher to disentangle linguistic and cognitive components of comprehension. Furthermore, because they do not always require an explicit experimental task, they allow researchers to study language comprehension more naturalistically.

The most important methods are event-related potentials (ERPs) and functional magnetic resonance imaging (fMRI). ERPs are averaged electro-encephalograms, time-locked at the onset of stimuli of interest. They provide excellent temporal resolution and a dissociation of qualitatively distinct processes (see Kaan, 2007 for an introduction.). For example, it has been shown that the N400 component is sensitive to the semantic fit of a word in the context, whereas the P600, a later positivity, can be found, for example, when the integration or reanalysis of syntactically difficult materials is needed (Kutas & Federmeier, 2011). These components are an important tool in language processing research, which has been successfully applied to research on discourse comprehension and contextual integration (van Berkum, 2004).

Neuroimaging methods, in contrast, are useful for specifying the brain regions and networks involved during comprehension. Using quite extensive knowledge of the functional neuroanatomy accumulated to

date, it is possible to associate activation patterns with specific cognitive or linguistic processes. Although neuroimaging of discourse comprehension is a young field, several reviews are available (Bornkessel-Schlesewsky & Friederici, 2007; Ferstl, 2007, 2010; Mar, 2004; Mason & Just, 2006). In a meta-analysis, Ferstl, Neumann, Bogler, and von Cramon (2008) identified an extended language network of candidate regions involved during discourse comprehension, which is discussed in depth later in the chapter; however, briefly, in addition to the perisylvian language regions (left inferior frontal lobe and posterior temporal/inferior parietal lobe), bilateral anterior temporal lobe, and dorso-lateral prefrontal cortex play a role. Most importantly, the dorso-medial prefrontal and parieto-medial cortex have been shown to be active during processing of coherent language.

Although not included in the meta-analysis at the time (due to a relatively small database of studies), the question of right-hemisphere contributions to language comprehension is also crucial. Based on observations from clinical linguistics, it has been proposed that discourse processing requires the language-dominant left hemisphere right hemisphere homologues (Brownell & Martino, 1998; Jung-Beeman, 2005).

Although there are still open questions regarding the processes involved (Goldman, Golden, & van den Broek, 2007), the key psycholinguistic concepts used to organize this chapter are useful for describing the processes involved in comprehending discourse beyond the sentence level. It should be noted, however, that the comprehension of nonliteral language (e.g., idioms, metaphors, irony or verbal humor) is related to discourse comprehension but falls outside the scope of what we can cover in this chapter (for further readings see Papagno & Lauro, 2010; Schmidt & Seger, 2009).

53.1 COHESION

Connections between text elements at the surface level produce *cohesion* (Halliday & Hasan, 1976). Cohesion can be distinguished *coherence*, which refers to connections at the level of the text base or situation model. Cohesive markers, or “cohesive ties,” are words that directly signal the relationship between parts of sentences or between successive sentences. For example, in “The birthday girl unwrapped *her* presents *before* the guests ate the cake,” both the possessive pronoun *her* as well as the conjunction *before* help the reader to understand the relationships between the two actions (eating and opening), as well as between the concepts *girl* and *presents*. In addition, even the definite article “the” in “the cake” provides cohesion,

because it presupposes a given cake (the one that is usually part of a birthday celebration)—rather than introducing “a cake” as a novel concept in the discourse. Note that these relationships can easily be inferred in the absence of lexical markers just by using the order of the statements or by drawing on general world knowledge: presents, cakes, and guests are usually parts of birthday parties.

Psycholinguistic studies confirm that lexical cohesion facilitates comprehension when it is used appropriately. One of the first investigations of the comprehension of cohesion using neuroimaging was a study by Robertson et al. (2000). Short paragraphs with indefinite articles were compared with the same paragraphs with definite articles, which rendered the sentences more cohesive (i.e., more story-like). The indefinite article sentences included the following: “A grandmother sat at the table. A child played in the garden...A grandmother promised to bake cookies.” The corresponding definite article sentences were included: “The grandmother sat at the table. The child played in the garden...The grandmother promised to bake cookies.” Despite the subtlety of this manipulation, there were differential activations in the frontal lobes. The cohesive condition elicited more activation in right prefrontal regions. Ferstl and von Cramon (2001) used a 2 × 2-design, crossing cohesion (connections at the surface level) with coherence (connections at the level of the text base). When cohesive ties were falsely used in incoherent sentence pairs, thus rendering the sentences infelicitous, activation in bilateral inferior prefrontal regions was observed. This result was interpreted as reflecting task management processes, which are required for resolving the inconsistency between knowledge-based coherence and lexically signaled cohesion. In this study, both pronouns and conjunctions were used as cohesive ties.

Using electroencephalographic ERPs, Münte, Schiltz, and Kutas (1998) studied the use of conjunctions during sentence processing. Connecting two events with the conjunctions *before* and *after* renders the temporal order either consistent (“After x happens, y happened”) or inconsistent (“Before y, x happened”) with the order of mention. The latter sentence type elicited a slow negative shift, indicating higher cognitive demands. Converging evidence was provided by Ye, Habets, Jansma, and Münte (2011) in an fMRI study. Using similar sentences in a production task, they found extensive left middle temporal activations for *before* compared with *after* sentences. Prefrontal and hippocampal activations suggested that the cognitive demands are related to memory processes needed for rearranging the temporal sequence. These results show that cohesion plays a role both during comprehension and production.

The processing of pronouns has been investigated in a number of imaging studies. Very similar to the manipulation used by Robertson et al. (2000), Almor, Smith, Bonilha, Fridriksson, and Rorden (2007) compared short sentence sequences in which the discourse referent was repeated (e.g., “Anna went shopping. Anna wore a scarf. Anna liked ice cream”) with the same sentences using pronouns after the first mention (e.g., “Anna went shopping. She wore...”). The pronouns clearly signal continuity of reference, whereas repetition is less felicitous in natural discourse. A rather extended temporo-parietal network showed higher levels of activation for the repetition condition compared with the pronoun condition. This result confirms the sensitivity of the language processing system to these subtle pragmatic cues.

Using a distinction between grammatical and natural gender, Hammer, Goebel, Schwarzbach, Münte, and Jansma (2007) found that a mismatch of grammatical gender induced activation increases in left perisylvian regions including the left inferior frontal gyrus (IFG) and the superior temporal sulcus. In contrast, when both natural and grammatical gender were violated (e.g., “The woman was popular because he was attractive”), extensive right hemisphere activation emerged, particularly in the IFG and the inferior parietal lobe. Interestingly, very similar results were obtained in a study using gender stereotype nouns in English (Ferstl, Manouilidou, & Garnham, 2010), strengthening the interpretation that these regions are important for the processing of natural gender information, rather than for the integration of explicit grammatical gender marking.

Similarly, Nieuwland, Petersson, and van Berkum (2007) used simple sentences of the form “X told Y that he/she...”. Varying the gender of the two noun phrases, they created coherent (one unique referent), ambiguous (two possible referents—e.g., two women followed by “she”), and violation conditions (no possible referents—e.g., two women followed by “he”). Activations for the referential failure condition included bilateral inferior prefrontal regions, whereas ambiguity elicited activations in the posterior cingulate cortex (PCC) and the medial prefrontal cortex. This latter result suggests increased inference demands for the ambiguous sentences when pronoun reference is attempted in the absence of lexical cues (see next section).

Some evidence for a successful interaction of semantic and syntactic cues to reference comes from ERP studies on gender stereotype referents of reflexive pronouns (Osterhout, Bersick, & McLaughlin, 1997). Consider a sentence containing a cataphoric reference—a reference to a word that has not yet been mentioned—such as “After *she* thought about the

letter, the *minister* left London.” Readers encountering the word “she” in this sentence incur a processing cost when they are unable to find a referent yet mentioned for the pronoun. However, reflexive pronouns such as *himself* or *herself* are syntactically bound to the sentence subject, as in “After reminding *herself* about the letter, the *minister* left London.” This syntactic binding eliminates the need to search based on semantic fit for a referent, and thus when readers encounter them they do not incur processing costs (Kreiner, Sturt, & Garrod, 2008).

Taken together, these and similar findings suggest that cohesive ties are an important cue to discourse coherence. Articles, pronouns, and conjunctions have been shown to influence processing immediately. Because these different ties have dissociable functions, there is no unique set of brain regions specialized for establishing cohesion. However, it has been shown that fronto-parietal regions are important for the processing of gender information, and the inferior frontal cortex is important for the sequencing of events based on conjunctions in sentences. Furthermore, the use of cohesive markers directly influences the inference demands in text comprehension, which are required to derive semantic coherence.

53.2 COHERENCE

Even in the absence of cohesive ties, readers and listeners attempt to establish *coherence*. Coherence is a content-based connection between successive phrases, sentences, or utterances, manifest at the level of the text base or situation model. For example, readers might assume co-occurrence in time or space, as in the sentences from Robertson and colleagues described previously: After reading “A grandmother sat at the table...A grandmother promised to bake cookies,” readers might represent these as occurring continuously in time at the same location. Readers also might infer a causal relationship, as in the following example: “Dorothy poured the bucket of water on the fire. The fire went out” (Singer, Halldorson, Lear, & Andrusiak, 1992). These inference processes have been extensively studied in psycholinguistic research on text comprehension. Questions of interest are whether inferences are drawn automatically and online, if and how they depend on the comprehenders’ goals, and whether inference types can be classified into qualitatively different categories (such as bridging, causal, elaborative, or predictive inferences).

Neuroscientific studies on inferencing are usually less concerned with the fine-grained temporal resolution of these processes. Here, the assumption is that, due to the human drive to make sense of the world,

inferences are a core component of comprehension. Interestingly, specific deficits have been observed in patients with right hemisphere or frontal brain lesions, rather than in aphasic patients (e.g., Baumgärtner, Weiller, & Büchel, 2002; Beeman, 1993; Ferstl, Guthke, & von Cramon, 2002). Thus, one of the most important issues is the question of domain specificity. Do language-based inferences elicit activation in the perisylvian language cortex of the left hemisphere? Do they engage prefrontal regions related to problem-solving and executive functions? What is the role of the right hemisphere? Do the neuronal signatures of inferences during language comprehension resemble those of processes such as evaluation, reasoning, or social judgments?

To investigate these questions, the aforementioned study by Ferstl and von Cramon (2001) used sentence pairs a coherence judgment task. Participants evaluated whether the sentences were connected or unrelated. Coherent compared with incoherent sentence pairs elicited activations not in fronto-temporal language regions, but in left medial areas, particularly the dorso-medial prefrontal cortex (dmPFC) and the PCC, reaching into the precuneus (pCC/prec). This finding has since been replicated numerous times (e.g., Chow, Kaup, Raabe, & Greenlee, 2008; Ferstl, 2010; Ferstl et al., 2008; Frieze, Rutschmann, Raabe, & Schmalhofer, 2008), but the dmPFC has also been implicated in a number of other cognitive functions. Most notably, it has been considered part of the “default” network that is active in the absence of an overt task, or an engaging activity (Raichle et al., 2001). Of course, this overlap might be due to self-guided thinking when task demands are low. Other functions include Theory-of-Mind, that is, the process of making sense of other people by inferring their intentions and emotions (cf. Ferstl & von Cramon, 2002), aesthetic judgments, or the processing of self-relevant stimuli (see Ferstl et al., 2008 for more detail). Although it is beyond the scope of this overview to attempt to dissociate these proposals, it is clear that the dmPFC cannot be specific for language processes, but that its function is rather general. The most parsimonious account is that it is involved whenever someone needs to make a judgment based on their own background knowledge and self-calibrated evaluation criteria.

Several studies manipulated the degree of relatedness to vary inference demands gradually, rather than in an all-or-none fashion. Adopting a classical paradigm, Mason and Just (2004) used three conditions in which causal relationships were varied. For example, a target sentence “The next day he was covered in bruises” was preceded by a direct cause “Jane punched Larry,” by an intermediate condition (“Jane got angry at Larry”), or by a distantly related one

("Larry went to Jane's house"). Using region-of-interest analyses, they reported right-sided activation for the intermediate condition and bilateral frontal activation with decreasing relatedness of the sentences. Kuperberg, Lakshmanan, Caplan, and Holcomb (2006), again using an explicit judgment, showed an extended network of regions to vary with inference difficulty, including both medial and right hemisphere regions. With an individually defined empirical criterion (using participants' ratings of relatedness), Siebörger, Ferstl, and von Cramon (2007) also confirmed that dmPFC activation was related to the inference process, rather than to stimulus properties.

Finally, a number of studies used mid-length stories and tested activation patterns at certain inference points within the stories. For example, a story about someone getting ready for a wedding contained the sentences "The shirt was all wrinkled. He started work/ironing...The shirt was all smooth" (Virtue, Haberman, Clancy, Parrish, & Jung-Beeman, 2006). When the specific term "ironing" is used, inference demands are low. However, when the vague term "work" is used, the reader needs to infer that the person is probably ironing. If this inference is made, then the subsequent "smooth" is as easy as in the first condition, whereas it again elicits a backward inference when the earlier inference is missing from the discourse representation. Brain regions involved in these inferences included left-sided and right-sided temporal regions. With these longer stories, working memory demands increase. In a follow-up study (Virtue, Parrish, & Jung-Beeman, 2008), comprehenders with a high working memory capacity engaged the right-sided regions to a larger extent than readers with low working memory capacity.

Distinguishing the content of inferences (emotional, physical, intentional), Mason and Just (2009, see also 2006) argued that the dmPFC activation reflects a protagonist monitoring process during narrative comprehension. Inference processes are important for establishing local coherence. In the next section, we go beyond local coherence, that is, the connections between the current sentence or utterance and the immediately preceding context. Global coherence, that is, the overall structure and gist of connected text, requires setting up a situation model of the text.

53.3 SITUATION MODEL CONSTRUCTION

When one hears or reads a moderately coherent prose passage, one can construct a situation model representing the setting and events described by the passage. To the extent the text makes it easy to create a

situation model reading is faster, comprehension is easier and memory is better. These effects were first established in a famous series of studies of long-term memory conducted by Bransford and his colleagues. In one set of experiments, the memory of readers for sentences was tested using a recognition memory test that included previously read sentences and sentences that were altered to affect only the surface structure or the situation model (and textbase) along with the surface structure (Bransford, Barclay, & Franks, 1972). For example, a reader might encounter the sentence, "Three turtles rested on a floating log, and a fish swam beneath them," and then be tested with "Three turtles rested on a floating log, and a fish swam beneath it." This lure is very difficult to reject, presumably because changing "them" to "it" does not change the situation described. However, if the encoded sentence began "Three turtles rested *beside* a floating long...", then changing "them" to "it" changes the situation—and such a change is more easily detected during the memory test. (Of course, none of the words were italicized in the experiments.)

Another set of experiments manipulated the ability of the readers to construct a situation model during reading (Bransford & Johnson, 1972; see also Dooling & Lachman, 1971). For these studies, the researchers created passages for which it was difficult to form a situation model without the addition of a key element of context. For example:

If the balloons popped, the sound wouldn't be able to carry since everything would be too far away from the correct floor. A closed window would also prevent the sound from carrying, since most buildings tend to be well insulated. Since the whole operation depends on a steady flow of electricity, a break in the middle of the wire would also cause problems. Of course, the fellow could shout, but the human voice is not loud enough to carry that far. An additional problem is that a string could break on the instrument. Then there could be no accompaniment to the message. It is clear that the best situation would involve less distance. Then there would be fewer potential problems. With face to face contact, the least number of things could go wrong. (p. 719).

This passage makes little sense without the picture provided in Figure 53.1. As expected, readers found the passage much easier to read if it was preceded by the picture. Moreover, pre-exposure to the picture dramatically increased the amount that readers were able to recall from the passage. Interestingly, presenting the picture *after* reading had little effect.

How do situation models influence online reading? One thing they do is render relevant information more accessible for further processing. This was shown vividly in a study by Glenberg, Meyer, and Lindem (1987). Glenberg et al. asked participants to read

FIGURE 53.1 Picture specifying the appropriate context for the passage in Experiment 1 of Bransford and Johnson (1972).

passages that could be manipulated to change the situation such that a critical item was either associated with the main character or dissociated from her or him while controlling how recently the item was mentioned. An example passage follows: “John was preparing for a marathon in August. After doing a few warm-up exercises, he put on his sweatshirt and went jogging. He jogged halfway around the lake without difficulty. Further along his route, however, John’s muscles began to ache.” In this passage, the critical word is “sweatshirt,” and it is *associated* with John. In the *dissociated* condition, “put on his sweatshirt” was replaced with “took off his sweatshirt.” Memory for the critical object was tested using a yes–no recognition test, with probes placed immediately right after the sentence containing the critical word, or one or two sentences later. When tested immediately after presentation, recognition was fast independent of the associated/dissociated manipulation. After one or two sentences, however, responses were faster for words in the associated condition than in the dissociated condition.

As a narrative evolves, information about various dimensions of the situation changes. Comprehenders track these changes, incorporating the new information

into their situation model. The event-indexing model (Zwaan, Langston, & Graesser, 1995) gives an account of how readers monitor dimensions of the situation described by the discourse and update their situation models when these dimensions change. According to the model, updating a model takes time and cognitive resources, and information that is no longer in a situation model as a result of updating is less accessible. As a result, signatures of updating can be seen in reading time and in memory accessibility. For example, Scott Rich and Taylor (2000) asked participants to read short narrative passages that contained changes in the main character, in the spatial location, or in temporal location. In the first experiment, readers were asked about the overall coherence of the narrative. In the second experiment, readers were asked about the local cohesion of the sentences (“how well the sentence fits with the previous sentence”). In the third experiment, participants’ memory for recently presented actions was probed using a recognition test. In that experiment, it was also possible to measure reading time for the sentences that contained shifts and for control sentences. Changes in character, space, or time led readers to rate the text as less coherent and less cohesive. Actions from before a shift were responded to less quickly and less accurately than actions from since a shift. The three shifts did not function equivalently. Character changes produced the largest reductions in coherence and cohesion ratings, and led to memory responses that were more accurate but slower than the other changes. These results suggest that participants were putting more effort into tracking character information and incorporating it into long-term memory. This is surely not always the case, but tracking characters may be important under many reading conditions. Causality is another dimension that appears to be important for discourse comprehension under many conditions (van den Broek, Young, Tzeng, & Linderholm, 1999). For example, when the current sentence being read is more causally connected to the previous sentences, it is read more quickly (Myers, Shinjo, & Duffy, 1987). In contrast to characters and space, there is good evidence that comprehenders pay relatively less attention to the spatial dimension during normal reading for comprehension (see Radvansky & Zacks, 2014, Chapter 4 for a review).

Situation model updating can be conceptualized using a propositional—or language—like representational format, as originally proposed by Kintsch and van Dijk (1978). However, as van Dijk and Kintsch (1983) stressed, other domain-dependent representational formats (e.g., a map encoding spatial relationships) are perfectly plausible. Thus, approaches to situation model updating including the event-indexing model are commensurable with approaches

to representation that emphasize the embodied nature of conceptual representations. Embodied cognition theories propose that comprehension depends on representations that use the same format and representational elements as those for basic perception and motor control (Barsalou, 2008; Glenberg, 2007; Zwaan, 2004).

What mechanisms does the brain bring to bear to construct a situation model? Neurophysiological data have helped to answer this question. First, when a comprehender can construct a situation model, mechanisms that build coherence may be more active or more effective. This is associated with activity in the medial prefrontal cortex, consistent with the previous section. Second, the data suggest that constructing a situation model brings online unique processing, which is associated with increased activity in posterior medial regions, the PCC and the precuneus. An early proposal stemming from neuropsychological case studies was that the right hemisphere is selectively involved in situation model construction. The strongest support for this proposal comes from the Robertson et al. (2000) study described previously (see *Cohesion* noted previously), which varied whether sentences began with the indefinite article (e.g., “A grandmother”) or the definite article (“The grandmother”). Because the definite article indicates that the same grandmother is referred to in both sentences, this should encourage construction of an integrated situation model, whereas the indefinite article discourages this. Comparing these two conditions led to greater activation in the right IFG and inferior frontal sulcus. However, the right-hemisphere hypothesis has received mixed support in other studies (Ferstl, 2010).

One of the earliest neuroimaging studies to compare conditions that did or did not afford situation model construction was aimed at studying the comprehension of social information, or “theory of mind” (Fletcher et al., 1995). In this experiment, participants read paragraphs comprising unconnected sentences, narratives describing physical interactions among objects, or narratives describing social interactions. Comparing the social interaction paragraphs with the unconnected sentences revealed increased activity in the left dmPFC, the PCC, the left superior temporal gyrus, and the temporal poles bilaterally. A more recent study used a similar design to specifically investigate components of discourse comprehension. Yarkoni, Speer, and Zacks (2008) asked participants to read paragraphs interspersed with periods of rest. The paragraphs either were intact narratives or were composed by combining sentences from multiple narratives selected at random. Activity in the dmPFC bilaterally increased for the intact narratives but not at all for the scrambled narratives. This pattern was also

observed in the posterior cerebellum. Compared to the resting baseline, the PCC and precuneus were observed to decrease for both scrambled sentences and for intact stories, and were observed to do so more for the stories (note that this effect in the opposite direction as that reported by Fletcher et al.).

Several studies have used the confusing passage developed by Bransford and Johnson (1972). The first used ERPs (St. George, Mannes, & Hoffman, 1994). In this study, participants read confusing paragraphs with or without titles while the ERP to each word was recorded. The authors found that the N400 associated with processing each content word was larger when reading the untitled paragraphs, and they concluded from this that the readers had more difficulty integrating the words into the ongoing discourse.

An fMRI study using the same design found greater activity in the right temporal pole when reading paragraphs with titles (St. George, Kutas, Martinez, & Sereno, 1999). However, this work reported analysis only of inferior parts of the brain, so neither the dmPFC nor the precuneus/PPC was examined. Another fMRI study used the picture version of the Bransford and Johnson paradigm (Maguire, Frith, & Morris, 1999). Comparing reading a story preceded by a relevant picture to reading the same story without the picture led to greater activity in the precuneus/PCC.

In summary, studies comparing intact stories with unconnected sentences and studies comparing confusing stories with disambiguated stories converge in implicating medial frontal and posterior regions as important for constructing a situation model. The ERP results flesh out this picture, suggesting that word-by-word integration is easier when one can construct a situation model.

We have seen that local inconsistencies in language processing produce time-locked electrophysiological responses—a larger N400—and corresponding responses in fMRI. What about language that is locally consistent but inconsistent at the level of the larger situation? Such inconsistencies also produce N400-like responses. van Berkum, Hagoort, and Brown (1999) had participants listen to the beginning of a short narrative and then read the last sentence word-by-word. The final sentences were set up to contain a word that could be either consistent or inconsistent with the preceding story context. For example, in one story the context established that a boy had gotten out of bed and dressed earlier than expected; the final sentence then had his sister telling him he was either *quick* (consistent) or *slow* (inconsistent). Processing the inconsistent words led to an N400-like ERP. Subsequent studies found similar results when the critical sentences were heard rather than read (van Berkum, Zwitterlood, Hagoort, & Brown,

2003), and suggested that this effect reflects a specific influence of the discourse-level constraints rather than just priming of words related to the critical word (Otten & van Berkum, 2007).

Bicknell, Elman, Hare, McRae, and Kutas (2010) developed a paradigm to examine situation-level violations of expectation within a single sentence. They used agent/verb/patient triples such that the verb was held constant and the patient was either expected or unexpected given the noun. For example, following “journalist checked,” the noun “spelling” would be expected and “brakes” would be unexpected, but following “mechanic checked” the reverse would be true. They found that the unexpected nouns were read more slowly and produced a larger N400.

One important method to study situation model building is the inconsistency paradigm, in which the global fit of a locally acceptable word is varied. For example, Ferstl, Rinck, and von Cramon (2005) generated stories for an fMRI study that could be manipulated such that changing a word produced either a temporal inconsistency (e.g., “early” would be expected but “late” would be unexpected) or an emotional inconsistency (e.g., “happy” would be expected but “sad” would be unexpected). Activity time-locked to the inconsistent words was greater, compared with consistent words, in the right anterior temporal lobe. They also observed a sustained response in the dmPFC from the onset of the inconsistency until the end of the story as participants read the conclusions of the inconsistent emotional stories. This suggests that participants attempted to “fix” the inconsistency by an inference; a conclusion was strengthened by the fact that activity in the dmPFC was greater for those participants whose ratings agreed less well with the consensus of the group, suggesting they were working harder to integrate the inconsistent information. Using a similar paradigm, Hasson, Nusbaum, and Small (2007) showed that the extent of the medial activations was related to subsequent recognition memory for the stories.

More recent studies investigated the interactions between consistency on the local and global levels (Egidi & Caramazza, 2013). In an ERP study, Boudewyn, Long, and Swaab (2013) showed that the local effects of lexical association (a reduced N400) were delayed by an inconsistent global context.

Together, studies using the inconsistency paradigm suggest that how well a word fits into the larger discourse contributes uniquely to how much work it takes to process that word and to update the situation model accordingly. The fMRI results reinforce the importance of the dmPFC for this level of integration and also provide some support for a right-hemisphere role. Some studies also speak to how the process of assembling a

situation model makes contact with neural systems that are specialized for representing different kinds of knowledge. In the study by Ferstl, Rinck, and von Cramon (2005), emotional stories elicited activations in limbic regions, including the amygdala, and temporal stories were processed in a bilateral fronto-parietal network. In another study, Ferstl and von Cramon (2007) once more found evidence for content-specific activations. With shorter stories consisting of two sentences only, they again found that temporal information selectively activated frontal and parietal areas, whereas emotional stories selectively activated the left anterior temporal lobes. In addition, selective activation for spatial information was found in the parahippocampal cortex. Such results support the view that situation model construction depends on semantic networks that localize different types of knowledge in different brain areas.

53.4 SHIFTING AND MAPPING

Discourses are dynamic structures, not static scenes, and the processes of discourse comprehension reflect this. As one proceeds through a narrative, one constructs a series of situation models corresponding to the events in the story (Zwaan & Radvansky, 1998). Gernsbacher (1990) distinguished between two qualitatively different phases in this dynamic process. During the *mapping* phase, the comprehender has an established situation model that provides a good fit to the incoming information. New information is incrementally incorporated into the situation model, resulting in a series of small changes. For example, suppose you were reading a biography of the pianist Glenn Gould and found yourself in the middle of a description of a recording session. As you incorporate information about Gould’s repeated takes and conversations with the recording engineer, you would likely map the descriptive features and dialog into your current situation model. However, when the situation in the narrative changes substantially, it would be more adaptive to abandon one’s current model and construct a new one; this is called *shifting*. For example, if you were to read that Gould left the studio, this would be likely to prompt a shift. The dynamics of comprehension, then, consist of relatively extended periods of mapping punctuated by briefer periods of shifting. If a narrative presents a sequence of event descriptions, then this is an efficient processing strategy. Zacks and colleagues have argued that this pattern of stable situation model maintenance punctuated by new model construction not only is a feature of discourse processing but also is carried over from real-life event comprehension

(Zacks, Speer, Swallow, Braver, & Reynolds, 2007; Zacks & Tversky, 2001).

Ditman, Holcomb, and Kuperberg (2008) studied shifting using a time-shift paradigm. Consider the following excerpt: “Kelly scolded the child. After one second, the child whimpered to his mother.” The phrase “one second” denotes essentially continuous passage of time and is plausible in this context. In the sentence context, “one second” produced a larger N400 than “one day.” Ditman and colleagues also were able to test for the immediate consequences of shifting. They predicted that if readers were establishing a new situation model at “one day later,” the second instance of the direct noun anaphor “the child” would be pragmatically awkward, resulting in a larger N400 at the onset of “child.” That is exactly what they found.

Two studies have studied shifting using event-related fMRI. Whitney et al. (2009) asked participants to listen to a short novella during MRI scanning. They coded the text for changes in characters, time, spatial location, and action. They hypothesized that at such changes, participants would be likely to update their situation models. Comparing sentences with any of these changes to sentences without changes revealed activity in midline posterior cortical regions—specifically, the PCC and precuneus.

Speer, Reynolds, and Zacks (2007) asked participants to read short narratives presented one word at a time during scanning. The narratives were coded for changes in spatial location, objects, characters, causes, and goals. (The narratives used did not have changes in time, but the mention of time also was coded.) Following the scanning session, each participant was shown the narratives again and asked to segment them into meaningful events. Each participant segmented the narratives twice, once to identify fine-grained event boundaries and once to identify coarse-grained boundaries. Speer and colleagues, like Whitney et al., hypothesized that readers would be likely to shift to building a new situation model when changes in space, objects, characters, causes, and goals occurred. Behaviorally, this was evident in readers’ segmentation: event boundaries were more likely when more features changed (see also Zacks, Speer, & Reynolds, 2009). The fMRI results also provided evidence for shifting. Event boundaries were associated with increases in the precuneus and posterior cingulate, as reported by Whitney et al. (2009), and also in the right lateral temporal lobe (posterior superior temporal gyrus and anterior middle temporal gyrus) and in the right middle frontal gyrus. These regions also responded to changes on two or more of the situation dimensions, and the posterior cingulate/precuneus regions showed parametric increases such that they

responded more strongly when more features changed (Speer, Reynolds, Swallow, & Zacks, 2009).

Like the data from the inconsistency paradigms, data on situation model shifting suggest that situation model construction depends on semantic representations that localize different sorts of information in different brain areas. For example, in the Speer et al. (2009) study, changes in characters selectively activated the left temporo-parietal junction, left anterior temporal lobe, and the dmPFC, changes in goals selectively activated the lateral middle frontal gyrus bilaterally, changes in objects selectively activated the left premotor cortex, and changes in time selectively activated the left insula.

The ERP and fMRI results both provide evidence for transient neural processing at those points during comprehension at which shifting would be predicted to occur. The fMRI data suggest that midline posterior cortical regions may be particularly important for this processing. However, they leave an important question unanswered: Do these transient effects reflect shifting or mapping? Recall that shifting is proposed to be a global updating mechanism that results in the creation of a new situation model, whereas mapping is proposed to reflect the incremental incorporation of new information as features in the narrative change. The effects reported in these studies could reflect global shifting, happening concurrent with some or all of the feature changes coded, incremental mapping, or a mixture of both. In one behavioral study, Kurby and Zacks (2012) tested for both shifting and mapping using a think-aloud task. Participants read short narratives and paused after each sentence to describe what they were thinking. Their responses indicated that when a particular feature changed (e.g., a change of spatial location), readers were more likely to mention that feature dimension. Above and beyond this, at event boundaries readers were more likely to mention features that changed and features that did not change. This result argues that both shifting and mapping can occur in response to feature changes. An important question for future research is whether the neurophysiological responses correspond to shifting, mapping, or both.

53.5 CONCLUSION

The short review shows promising first steps toward a neurobiological theory of language processing at the discourse level. Based on a well-founded tradition of psycholinguistic models (Kintsch, 1998) and the formulation of novel approaches (e.g., Zwaan, 2004), a creative set of experimental tools for constructing and manipulating narrative structure is available.

Supplementing the rich set of behavioral data, the beginnings of an empirical database of neurophysiological results are emerging. Let us summarize the major theoretical and empirical results.

Cohesion and local coherence are the most basic means to connect successive utterances. Both fMRI and ERP experiments have provided evidence for the use of even subtle cohesive cues during comprehension. The findings confirm the comprehenders' sensitivity to these cues. However, it is less clear whether the activation differences reflect the processing of the function words (e.g., in left frontal lobe) or the result of the cohesive markers, that is, the increase in coherence induced by them (e.g., right temporal activations).

Inference processes required for setting up a locally coherent text representation engage regions extending beyond the left perisylvian language cortex (see, e.g., [Ferstl et al., 2008](#)). In particular, right-hemisphere areas and medial regions—particularly the dmPFC—are important. In line with studies on situation model processing, inference studies suggest that the right hemisphere activations are observed whenever local, semantically based connections are set up, whereas medial regions become important whenever nonautomatic, evaluation-based inferences are drawn. Furthermore, there is evidence for individual differences with respect to right hemisphere involvement. Further research is needed to evaluate these hypotheses.

Both behavioral measures and neurophysiological measures support the idea that situation model construction is a crucial component during the comprehension of narrative language. Constructing a situation model appears to depend particularly on the medial prefrontal cortex and the medial PCC and precuneus. It may sometimes be associated with differential activity in the right hemisphere; the data on this point are mixed. When a text affords construction of a situation model, this facilitates sentence-by-sentence reading. This can be seen in reductions in the N400 ERP component. Situation model construction is valuable—it supports better subsequent memory for the contents of the text.

The distinction we have made between cohesion, coherence, and situation model construction is a substantive one, and it reflects how the field has parsed the computations the brain performs during discourse comprehension. However, it is important to note that cohesion, coherence, and situation model construction are closely interwoven: inferences are needed establishing local coherence, and also for setting up a situation model, and the prior discourse model facilitates later inference processes. Furthermore, not only long

texts but also even short sentences can elicit a situation model representation.

When we read longer texts, a single situation model is not enough to represent the contents of the narrative. In this case, we need to construct a series of models, mapping information into the existing model when we can and shifting to a new model when we must. Shifting to a new model takes cognitive work, and we can see its signature in slowing in reading and in increased activity in multiple cortical areas. After we shift to a new model, some information that was maintained in the previous model becomes less accessible.

One important conclusion from the neuroscientific studies reported here is that theoretical approaches of text comprehension need to encompass cognitive mechanisms that are not specific to language. Whereas psycholinguistic models traditionally focus on the linguistic properties of text and the processes needed for interpreting them, the overlap of activation patterns with results from social cognitive neuroscience suggests that we need a more holistic approach to communication. Intentions, implications, Theory-of-Mind, and emotional connotations all need to be taken into account when studying language comprehension in context (see also [Hasson and Tremblay, Chapter 43](#)).

What will it take to move the field from this impressive but incomplete set of empirical regularities to a real theory? One useful approach is formal modeling that can make predictions about online reading processes and subsequent memory *at the discourse level*, sentence by sentence, clause by clause, and perhaps even word by word ([Kintsch, 1988](#); [van den Broek et al., 1999](#)). Building such models is a great scientific challenge because, as the other sections of this volume illustrate, “lower-level” mechanisms of language comprehension are fantastically complex in their own right. However, a number of frameworks are available to support developing such models, including production systems ([Anderson & Lebiere, 1998](#); [Goldman, Varma, & Côté, 1996](#)) and connectionist modeling systems ([Christiansen & Chater, 1999](#); [O'Reilly & Munakata, 2000](#)). It will be a challenge to utilize such models for making specific predictions about the functional neuroanatomy of discourse comprehension (cf. [Anderson et al., 2008](#)).

A second means to make considerable progress is the development of experimental designs that allow us to study reading closer to how it occurs “in the wild” ([Bailey & Zacks, 2011](#)). Many of the studies described in this chapter utilized what [Graesser and colleagues](#) have dubbed “textoids”—brief, contrived texts that allow an experimenter to manipulate discourse structure at a fine grain ([Graesser, Millis, & Zwaan, 1997](#)).

Such studies are valuable and, indeed, necessary. We agree with Graesser et al. that this approach needs to be complemented by approaches that use longer, more natural texts. In short, what is needed is data on situations in which people read narratives that are like the ones they read in real life, in a manner similar to how they read in real life. There is a major downside to using naturalistic materials and tasks: variables of interest are confounded with each other and with other variables. For example, at the single word level the number of meanings associated with a word (e.g., “box” can mean a container or what one does with gloves in a ring) is confounded with its length and frequency (Yap & Balota, 2009). At the discourse level, changes in characters’ goals are confounded with changes in spatial and temporal location (Zacks et al., 2009). The good news is that these confounds can be dealt with statistically—provided one has enough data. This suggests to us that a productive way forward will be to construct corpora of data from naturalistic comprehension tasks that are larger than the datasets typically collected to test individual hypotheses. Thankfully, naturalistic materials and tasks lend themselves to reuse. In our own research, we have been encouraged by the ability to mine naturalistic comprehension data to test novel hypotheses and language comprehension and perception (Magliano & Zacks, 2011; Speer et al., 2009; Yarkoni, Speer, Balota, McAvoy, & Zacks, 2008).

In short, processing discourse is a fascinating challenge. Our understanding of how the brain does so has benefited from a generation of behavioral research, which is now being complemented by neurophysiological measures. We look forward to much progress in the years to come.

At the Core of Pragmatics

The Neural Substrates of Communicative Intentions

Bruno G. Bara^{1,2}, Ivan Enrici^{1,2,3} and Mauro Adenzato^{1,2}

¹Center for Cognitive Science, Department of Psychology, University of Torino, Italy; ²Neuroscience Institute of Torino, Italy; ³Department of Philosophy and Educational Sciences, University of Torino, Italy

54.1 COMMUNICATIVE INTENTION: THE CORE FEATURE OF PRAGMATIC PHENOMENA

Cognitive theories of human communication are often theories of competence, that is, theories specified in terms of the mental states involved in communication independently of the means used to communicate. Examples of such theories were proposed by Strawson (1964), Schiffer (1972), Sperber and Wilson (1986), Airenti, Bara, and Colombetti (1993), Clark (1996), Tirassa (1999), and Bara (2010, 2011). Although different in many respects, these theories share the same logical assumptions as the pioneering work of Grice (1957) and Austin (1962), who proposed that human communication should be analyzed in terms of the role of mental states, such as intentions, beliefs, emotions, and desires, and the cognitive dynamics leading from one mental state to another. In particular, Grice (1957) described successful communication as the recognition of a specific set of mental states, including the intention to affect the communication partner and the higher-order intention that this intention is recognized. Although such conditions were subsequently strengthened by Strawson (1964) and Schiffer (1972), they remain at the core of the investigation of pragmatic phenomena (i.e., understanding the speaker's intention within a communicative exchange).

The key aspect of the approach proposed by Grice (1957, 1975) is that in communication, sentences are often underspecified with respect to what speakers intend to convey and, in a variety of pragmatic phenomena, there is a discrepancy between the literal and intended meanings, such as in indirect speech acts, conversational implicatures, sarcasm, metaphor, and

irony. In other words, successful pragmatic understanding of an utterance depends on recognizing the intention of the speaker within a social context (Grice, 1975). Starting from this theoretical standpoint, Airenti et al. (1993) and, more recently, Bara (2010) proposed that the key concept of communicative intention is a *primitive* mental state (i.e., communicative intention that is not reducible to simple intentions).

The importance of communicative intention for the study of pragmatics lies in the fact that this concept permits the clear distinction between two separate phenomena: communication in and of itself, and information extraction (or information attribution). Communication is a social activity that requires the combined effort of at least two participants who consciously and intentionally cooperate to construct the meaning of their interaction. When people use language (spoken or written), they intrinsically convey communicative intentions simply by using this expressive mean. Likewise, a key concept in the process of information extraction is the *sign* (Hauser, 1996). A sign is a parameter that can take on different values. It is produced by the individual, sometimes with a precise aim, but with no communicative goal. The concept of signs is intrinsically ambiguous, given that any evidence of human activity may become communication. For example, an unmade bed may be a sign that a person has slept in it. However, in certain circumstances, this sign could be fully communicative, that is, a symbol that has been deliberately left to let the observer know that the bed has been slept in. Thus, signs may easily become signals, as long as they are left intentionally.

Accordingly, genuine communication and information extraction are two distinct but equally important phenomena. Confusing these phenomena and, hence,

being unable to distinguish between them has a long tradition in communication sciences. The well-known first axiom of communication proposed by [Watzlawick, Bevin, and Jackson \(1967\)](#)—“one cannot not communicate”—is the manifesto of this confusion, because it denies the possibility of information extraction in which an agent influences the mental states of another agent through his/her behavior or by manipulating the material surroundings *without any intention to do so*. In sum, we speak of fully communicative phenomena when reciprocal intentionality is involved and of extracting information when one of the actors does not possess the intention to communicate but is simply moving and acting in the world based on private intentions.

54.2 NEURAL SUBSTRATES OF COMMUNICATIVE INTENTION: THE INTENTION PROCESSING NETWORK

According to our perspective, human communication is a cooperative activity among social agents who jointly and intentionally construct the meaning of their interaction within a shared context. Communication is a social action used to affect and modify the mental states of others, and communicative intention is the primary mental state involved in explaining other people’s communicative actions. For the study of the neurobiology of pragmatics, this means that full analysis of the processes involved in a communicative exchange cannot be limited to the study of the cognitive and neural mechanisms for coding and decoding words and phrases generated by actors, but should also include the context-based inferential processes involved in comprehending the agents’ communicative intentions. Thus, the process involved in understanding this form of intentions connects human communication and a more general type of social competence, such as Theory of Mind (ToM) ability ([Baron-Cohen, 1995](#); [Premack & Woodruff, 1978](#)). ToM is the ability to: (i) acknowledge that human beings possess mental states; (ii) attribute mental states to one’s self and to others; (iii) recognize that the mental states of others do not necessarily correspond to one’s own; (iv) understand that mental states can determine external behavior, such as decisions and actions; and (v) predict, describe, and explain behavior on the basis of these mental states.

Considering the role that the ToM neurocognitive system plays in understanding the communicative intentions underlying pragmatic phenomena, it is surprising that relatively few studies have investigated the neural substrates of the human ability to process this kind of social intention. In contrast, the study of the neural correlates of ToM for individual mental states, such as beliefs and desires, is a prosperous area

of research. To bridge this gap, in the past decade we have performed a series of neuroimaging studies and proposed the Intention Processing Network (IPN) model, according to which a set of brain areas are differentially involved in comprehending different types of intention, including communicative intentions. The IPN model introduces a theoretical distinction that differentiates private versus social dimensions of intention and the temporal dimension (present or prospective) of the social interaction. *Private intentions* only involve the actor satisfying a particular goal (e.g., picking a bunch of grapes to eat them). Conversely, in *social intentions*, the goal of the actor is satisfied only if at least one other person is involved. For social intentions, we can distinguish between present and prospective (future) interactions. When two agents interact, the social intention is shared in the present (e.g., asking the waiter for a mojito). The prototypical example of a social intention shared in the present is a *communicative intention*. When a given social interaction is not present at the moment but the action of a single agent preludes to it, the social intention is potentially shared in the future (e.g., preparing a flower bouquet to give it to someone). We define this type of social intention as *prospective social intention*.

In two fMRI studies ([Ciaromidaro et al., 2007](#); [Walter et al., 2004](#)), we used a story completion task presented in the form of a comic strip to show the progressive recruitment of the ToM network according to these theoretical dimensions. The brain areas associated with the IPN are shown in [Figure 54.1](#) and include the complex formed by the medial prefrontal cortex (MPFC) and precuneus, and by the bilateral posterior superior temporal sulcus (pSTS) and adjacent temporoparietal junctions (brain areas referred to collectively as TPJ in this work, for simplicity, but see [Gobbini, Koralek, Bryan, Montgomery, & Haxby, 2007](#); [Saxe, 2006](#) for the dissociation between the pSTS as a part of the action understanding system and the TPJ as a part of the ToM system). In particular, we demonstrated that the whole IPN was only activated during communicative intention processing, when two characters were depicted in a communicative interaction within a pragmatic context. In contrast, the activated network was limited to the right TPJ and precuneus, when the depicted character was acting according to a private intention, or when two characters were acting independently according to their own private intentions without any shared context. For prospective social intentions, our data show that although both private and prospective social intentions involve single agents acting by themselves, the recruitment of the right TPJ and precuneus does not suffice when an agent is manifesting a social intention to be shared in the future. We explain this result by the widely recognized fact that MPFC activation is observed whenever a social

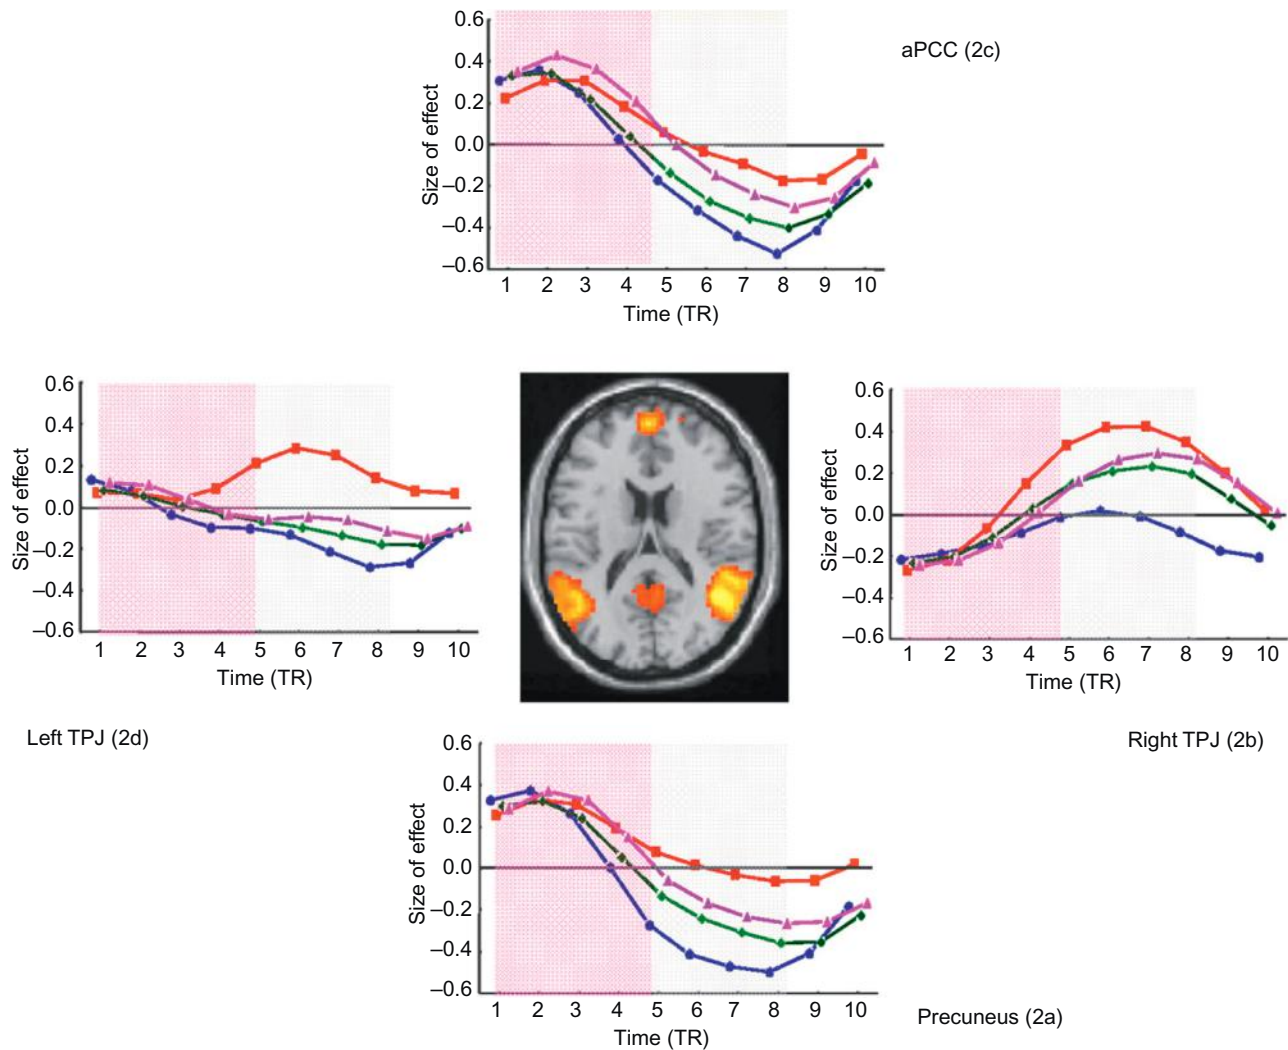

FIGURE 54.1 Signal time course for the three experimental conditions, private, prospective social, and communicative intention, and for control condition (physical causality) relative to rest for the IPN brain regions. The brain picture depicts the contrast communicative intention versus physical causality condition showing the four regions of interest, the aPCC (2c), precuneus (2a), and right and left TPJ (2b, 2d). Time courses were calculated by averaging across conditions within each participant (red curve for communicative intention, violet curve for prospective social intention, green curve for private intention, and blue curve for physical causality). The pink area represents the story phase and the grey area represents the choice phase of the comic strips task. aPCC, anterior paracingulate cortex (part of the MPFC); TPJ, temporoparietal junction. From *Ciaramidaro et al. (2007)* with permission from the publisher.

dimension is involved. For these reasons, we define the IPN model as the progressive recruitment of different brain areas (i.e., the precuneus and right TPJ, MPFC, left TPJ) according to, respectively, private, prospective social, and communicative intentions.

Different studies have provided independent evidence for the specific role of the IPN brain areas in social intention recognition and comprehension. For example, a meta-analysis (*Van Overwalle & Baetens, 2009*) suggested that the precuneus is crucial for elaboration of contextual information and identification of situational structure, and the TPJ is involved during the identification of end state behaviors. In particular,

the TPJ along with the precuneus and MPFC take part in a larger process of goal identification in a social context. *Van Overwalle (2009)* showed impressive consistency in the empirical evidence demonstrating MPFC engagement in social inferences, specifically its crucial role in understanding social scripts that do not concern a single actor, but that describe adequate social actions for all the actors involved in a particular context.

More interesting for the purpose of the present discussion, the IPN model has received support from neuroimaging studies aimed at investigating the neural correlates of processing different pragmatic phenomena. Specifically, phenomena in which the literal

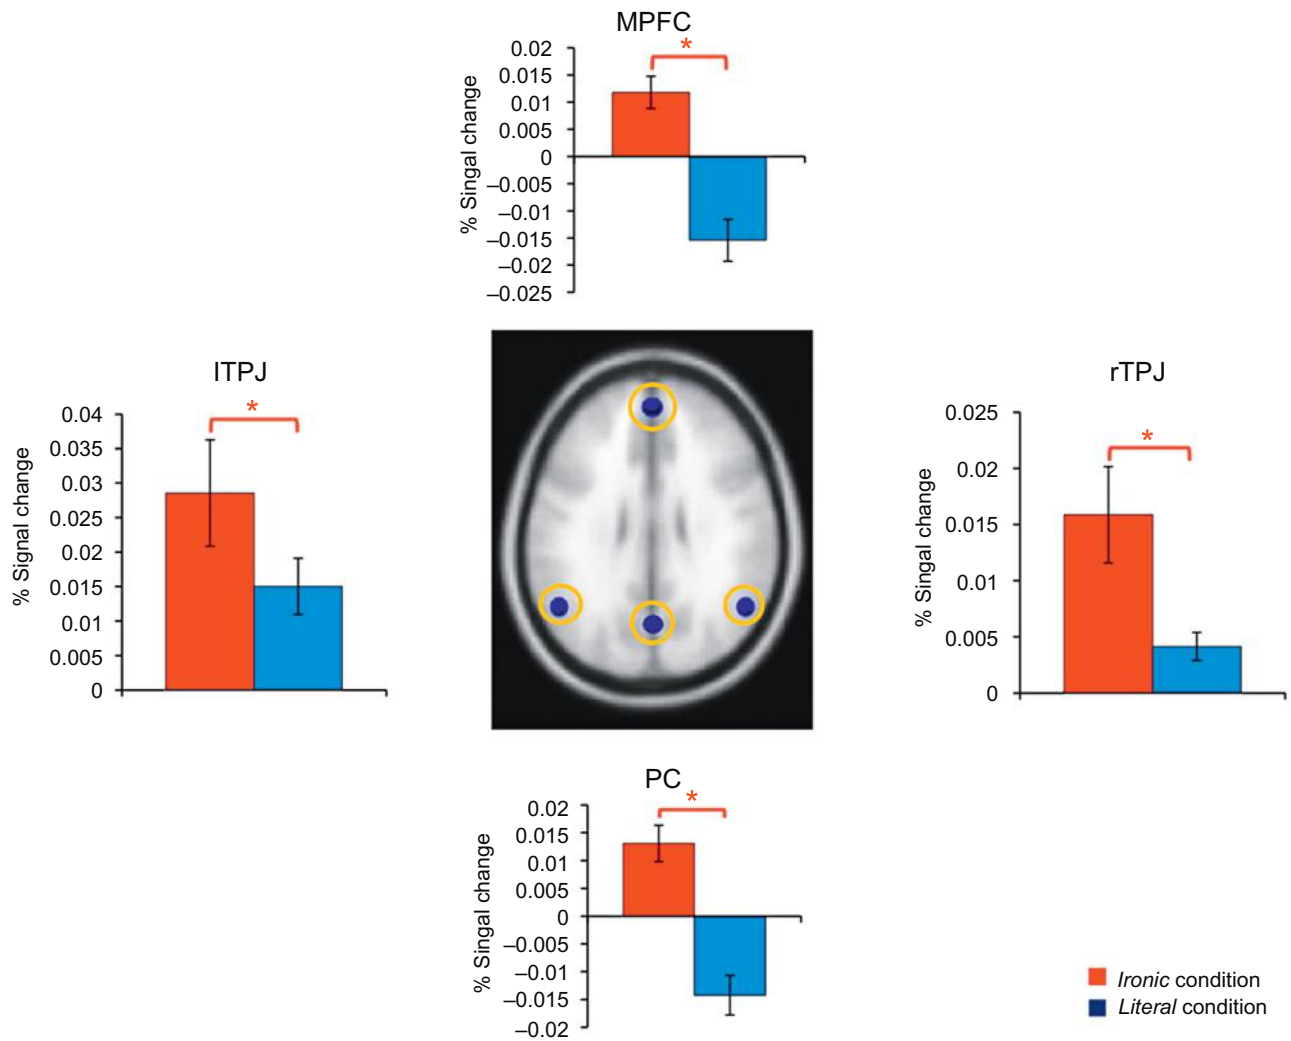

FIGURE 54.2 Regions of interest of the four main areas with significantly greater activity in the ironic than in the literal condition. MPFC, medial prefrontal cortex; ITPJ, left temporoparietal junction; rTPJ, right temporoparietal junction; PC, precuneus. From *Spotorno et al. (2012)* with permission from the publisher.

and intended meanings do not coincide, and inferences about the speaker's intended meaning are required.

It is unanimously agreed on that ironic remarks are typical examples of a high-level, pragmatic form of communication in which the literal and intended meaning do not coincide and, in fact, the communicative intention often corresponds to the opposite of literal meaning. Recently, *Spotorno, Koun, Prado, van der Henst, and Noveck (2012)* reviewed the neuroimaging work on irony and proposed a new methodological approach that overcomes the experimental problems in these studies, which show surprisingly little evidence for ToM network involvement in irony comprehension. In fact, although all of the studies reviewed found MPFC activation, none of them found TPJ activation, and only one reported precuneus activity. The main aim of *Spotorno et al. (2012)* was to

uncover a direct, online link between language processing and ToM through neuroimaging, and they chose to test irony for the reasons stated previously. The authors compared participants' comprehension of brief stories in which a target sentence (e.g., "Tonight we gave a superb performance") was made either ironically or literally based on the context in which it was expressed (e.g., a terrible performance in the ironic condition and an impressive performance in the literal condition). They found that the ToM brain areas of the IPN model were active when participants understood verbal irony (*Figure 54.2*).

The key role that both the anterior (particularly the MPFC) and posterior (particularly the right TPJ) cortices play in understanding a speaker's intended meaning was recently confirmed in other pragmatic phenomena. For example, *Prat, Mason, and Just (2012)*

demonstrated the involvement of these brain areas in understanding metaphors, and Bašnáková, Weber, Petersson, van Berkum, and Hagoort (2014) demonstrated their involvement in understanding indirect replies in spoken dialogue. In particular, Prat et al. (2012) manipulated figurativeness in metaphor comprehension (using three figurative conditions of increasing difficulty); they showed increased right TPJ and superior medial frontal activation for all figurative conditions compared with a literal condition. Bašnáková et al. (2014) demonstrated that compared with direct control utterances (in which the speaker's meaning was explicitly stated and corresponded to the literal meaning), indirect replies (in which the speaker's meaning was implicit and a pragmatic inference was necessary) engage a set of brain areas including mainly the MPFC and right TPJ.

Although neuroimaging evidence seems to support the IPN model as a neural substrate for the pragmatic comprehension of a speaker's intended meaning, it is important to note that neuroimaging findings are not a "smoking gun" when we want to ascribe a functional role to a specific brain area or brain network, such as the IPN. Neuroimaging techniques provide relevant information about the *involvement* of a brain area in a given task, but these methods are silent with respect to whether the brain structure is *necessary* for the task. Despite the inherent weaknesses of the neuropsychological approach, it continues to play an important role in complementing functional imaging techniques and in testing theoretical hypotheses about cognitive architecture (Rorden & Karnath, 2004).

A recent study by Cavallo et al. (2011) provided converging evidence for the role of the IPN in comprehending communicative intentions. The main aim of this study was to find neuropsychological evidence to complement neuroimaging findings that the MPFC, a key node of the IPN brain network, plays a crucial role in comprehending social situations in general and in comprehending communicative intentions in particular. To this end, they investigated how patients with amyotrophic lateral sclerosis (ALS) performed in an experimental protocol previously used in neuroimaging settings (Bara, Ciaramidaro, Walter, & Adenzato, 2011; Ciaramidaro et al., 2007; Walter et al., 2004, 2009). Although ALS was traditionally considered a neurodegenerative condition that exclusively affects the motor system with no cognitive repercussions, numerous studies have challenged this view demonstrating the presence of cognitive impairment in significant proportion of ALS patients (Abrahams, Leigh, & Goldstein, 2005). Accordingly, neuropathological investigations have shown the pathological involvement of prefrontal cortices (Maekawa et al., 2004). For this reason, the hypothesis driving the work by

Cavallo et al. (2011) was that ALS patients should perform significantly worse than healthy controls on tasks requiring comprehension of social and communicative intentions, whereas performance should be comparable for patients and healthy controls on tasks that do not require comprehension of social intentions (i.e., private intentions). The results confirmed this hypothesis was in line with the following neuropsychological findings: (i) people with MPFC lesions show deficits in inferring speaker intentions (Lee et al., 2010) and (ii) people with neurodegenerative diseases that affect the functioning of the frontal cortex, such as the fronto-temporal dementia, Tourette syndrome, and progressive supranuclear palsy (Eddy, Mitchell, Beck, Cavanna, & Rickards, 2010; Ghosh et al., 2012; Shany-Ur et al., 2012, for a review see Adenzato & Poletti, 2013; Poletti, Enrici, & Adenzato, 2012), show impaired comprehension of nonliteral language, such as sarcasm, metaphors, and indirect requests.

Other convergent evidence comes from patients with lexico-semantic impairments, such as in aphasia. These patients present profound language impairments with extensive damage to the traditional fronto-temporal language network, but without specific ToM deficits (see Willems & Varley, 2010, for a review). Accordingly, using alternative communicative resources, such as drawing, facial expression, and gesture, these patients are able to convey quite sophisticated messages (Siegal & Varley, 2006; Varley & Siegal, 2006). If language is crucially involved in communicative intention generation, then aphasic patients should not perform well on pragmatic tasks. However, patients with aphasia exhibited communication strategies that were comparable with those observed in the neurologically healthy population (Willems, Benn, Hagoort, Toni, & Varley, 2011).

54.3 COMMUNICATION IS MORE THAN LANGUAGE

To explain other people's communicative actions, communicative intention processing relies on different sources of information (i.e., linguistic or extralinguistic gestural means) to infer the underlying intended meaning. Viewed in this light, communication does not correspond with language competence, and lexico-semantic processing can be distinguished from communicative intention processing (Enrici, Adenzato, Cappa, Bara, & Tettamanti, 2011; Noordzij et al., 2009; Vicari & Adenzato, 2014; Willems et al., 2010; for a review see Willems & Varley, 2010). Thus, information acquired by different communicative modalities is equivalent from a mental processing standpoint, particularly when the actor's communicative intention has to be reconstructed.

Although different aspects of linguistic encoding (e.g., semantic and syntactic processes; see [Bookheimer, 2002](#); [Kaan & Swaab, 2002](#)) and gestural encoding processes ([Goldin-Meadow, 1999](#)) have been widely investigated, few studies have focused on the level at which a communicative intention is reconstructed within a specific pragmatic context. Moreover, although studies have investigated the reciprocal influences and cross-modal interactions between speech and emblem gestures (where the prevailing view is that speech and gesture share a unified decoding process at the semantic level; see [Willems & Hagoort, 2007](#) for a review), very few studies have addressed whether speech and gestures involve common processes at the pragmatic level, such as in communicative intention processing.

To answer this question, [Enrici et al. \(2011\)](#) performed an fMRI study that combined factorial and conjunction analyses to test two sets of predictions: (i) a common brain network is recruited for the comprehension of communicative intentions independently of the modality through which they are conveyed and (ii) additional brain areas are specifically recruited depending on the communicative modality, reflecting distinct sensorimotor gateways. Results clearly showed that the IPN is engaged in communicative intention processing, independently of the modality used, and that additional brain areas are specifically engaged by the particular communicative modality, for example, the peri-sylvian language network for the linguistic modality and the sensorimotor network for the extralinguistic gestural modality. Thus, communicative intention constitutes a shared pragmatic representation accessed by modality-specific gateways, which are distinct for linguistic versus extralinguistic expressive means.

Obviously, the IPN model does not exclude other levels of communicative processes (e.g., the lexico-semantic level) or other forms of shared representations (e.g., semantic representations). For example, [Xu, Gannon, Emmorey, Smith, and Braun \(2009\)](#) demonstrated that a shared semantic representation is accessed by distinct modality-specific sensory gateways by showing that communicative symbolic gestures and corresponding spoken glosses proposed by a single agent activated distinct modality-specific areas, but both engaged the left inferior frontal cortex and the posterior temporal cortex bilaterally to the same extent. The authors suggested that the peri-sylvian areas might function as a modality-independent semantic network linking *meaning* with *symbols* (both words and gestures). Similarly, we argue that the IPN might function as a modality-independent network, linking *shared meaning* with the actor's *intended meaning*.

[Ferstl, Neumann, Bogler, and von Cramon \(2008\)](#) have proposed an extended language network over and above the linguistic processes realized in left

peri-sylvian areas. Their meta-analysis found that brain areas belonging to the IPN take part to an extended language network (i.e., a variety of additional cognitive processes recruited in language comprehension in written form). Even though we agree that language entails more than the traditional semantic, syntactic, and phonological processes, we are sympathetic with [Willems and Varley \(2010\)](#) who reported that incorporating ToM abilities into an extended language network is not a helpful conceptualization: “the separation of linguistic and communicative abilities seems a more fruitful characterization rather than calling both language, and allows for some forms of communication that are not linguistic” ([Willems & Varley, 2010](#), p. 6).

Another important question concerns the roles of IPN brain areas and the mirror neuron system (MNS)—a system that allows action understanding without any explicit reflective mediation ([Gallese, Keysers, & Rizzolatti, 2004](#))—in intention processing. Work to date suggests a dual-process model of the brain systems underlying action understanding and social cognition, where the MNS supports a bottom-up process for automatic behavior identification and the ToM system supports top-down processes for controlled social causal attribution ([Keysers & Gazzola, 2007](#); [Spunt & Lieberman, 2013](#)). For example, in an interesting study, the kind of request the experimental subject had to respond to—namely *what*, *how*, or *why* an observed behavior was pursued (e.g., describing what an actor is doing, why he is doing it, or how he is doing it)—was manipulated. The results showed parametric variation in MNS and ToM network involvement in action identification ([Spunt, Satpute, & Lieberman, 2011](#)). These results suggest that the complex actions of others can be represented at multiple levels of an action hierarchy, and that ToM involvement varies parametrically: as the requested explanation for why an action is being performed becomes more plausible, the more ToM brain areas are recruited. Conversely, as the requested explanation for what or how an action is being performed becomes more plausible, the more MNS brain areas are recruited. Similarly, [Van Overwalle \(2009\)](#) and [Van Overwalle and Baetens \(2009\)](#) discussed which brain areas are responsible for understanding the actions of others and their underlying goals. These authors proposed a model in which actions and goals are organized hierarchically according to level of abstractness and that distinguishes between immediate goals that reflect the understanding of basic actions and long-term intentions that reflect the *why* of an action in a social context. The results of their meta-analysis provided additional evidence consistent with the role of the

IPN: although understanding basic actions requires the MNS, understanding social actions requires concurrent activation of the pSTS and TPJ areas as well as the precuneus and MPFC.

Different neuroimaging data support the assumption that both the MNS and IPN brain areas contribute to communicative comprehension particularly when extralinguistic communication ranging from imitation of social gesture (i.e., emblematic gesture; Mainieri, Heim, Straube, Binkofski, & Kircher, 2013) to hand sign recognition (Nakamura et al., 2004) is involved. Using magnetoencephalography, Nakamura et al. (2004) clearly showed that different systems are involved in symbolic (emblematic) hand sign recognition. These authors emphasized well-orchestrated regional electrical activity in multiple brain areas from the primary visual system to the object recognition system, as well as the MNS and IPN, indicating the involvement of a series of complex processes starting from visual gesture recognition and ending with inference of the underlying intended meaning. Different studies (Andric et al., 2013; Liew, Han, & Aziz-Zadeh, 2011; Noordzij et al., 2009; Schippers, Gazzola, Goebel, & Keysers, 2009; Spunt & Lieberman, 2013; Willems et al., 2010) found similar results suggesting that 1) the observation of communicative gestures relies on a combination of both MNS and IPN, 2) that there is a clear distinction between these systems on both neural and cognitive levels, and 3) that actual data do not support the view that the MNS alone provides the foundations for human communication.

Finally, Ciaramidaro, Becchio, Colle, Bara, and Walter (2014) investigated how mirror and ToM regions contribute to the implicit encoding of communicative intentions and whether activity in these regions is shaped and modulated by self-involvement. Their results revealed that the MPFC and bilateral premotor cortex are more active for second-person communicative intention (directed towards us) than for third-person communicative intention (directed toward others). Most importantly, they indicate that self-involvement may result in changes in functional connectivity between MNS and IPN regions.

In sum, data from recent neuroimaging research show that comprehending and generating communicative action is cognitively and neurally distinct from core linguistic processes (Willems & Varley, 2010). The information acquired by different communicative modalities is equivalent from a mental processing standpoint, particularly when the actor's communicative intention has to be reconstructed. Thus, communicative intention processing may build on different sources of information, such as language and gestures, to infer the underlying intended meaning.

54.4 COMMUNICATIVE EXCHANGE

Hamlet: Now, mother, what's the matter?

Queen Gertrude: Hamlet, thou hast thy father much offended.

Hamlet: Mother, you have my father much offended.

Hamlet, W. Shakespeare, Act III, Scene IV.

Communicative exchange involves constructing an acceptable interpretation of the reciprocal communication acts at all levels that participants consider significant. Although we may speak of a single agent when we refer to actions in general, we must always refer to at least one actor and a partner to whom the act is directed in the domain of communication. As well-known by Shakespeare, in this domain the meaning of a communicative exchange emerges from the mutual interplay of interactive agents embedded in their environment (Adenzato & Bucciarelli, 2008; Adenzato & Garbarini, 2006).

Very few neuroimaging studies have examined full communicative exchanges that include the action proposed by an actor and the concurrent reaction from a partner. Vice versa, most studies have focused on the comprehension of the early signals that convey an intention to communicate (Materna, Dicke, & Thier, 2008) (e.g., following someone's eye gaze or a pointing finger directed to the subject) or attempts to engage a communicative interaction (Kampe, Frith, & Frith, 2003) (e.g., looking directly at someone or calling their name). Moreover, other studies asked subjects to passively observe communicative actions (e.g., a gesture directed toward someone) performed by a single actor (Andric et al., 2013; Tylén, Allen, Hunter, & Roepstorff, 2012), such as placing a cup in front of them. Interestingly, in these studies, different areas of the IPN (such as MPFC or right TPJ)—but not necessarily the whole network—were recruited according to the kind of signal used to trigger a communicative interaction. It is important to underscore that within these experimental situations a communicative exchange between agents is merely put forward by the actor or character but does not actually take place.

Other studies focused on experimental tasks where the interaction between subjects consisted of different kinds of interaction by imitation, particularly gestural imitation (Nagy et al., 2010). For example, a recent study (Mainieri et al., 2013) required motor imitation of social (e.g., a "well-done" gesture with the thumbs up, or "wave a greeting"), nonsocial (e.g., gestures/mimes that depict common actions in the physical world, such as "take a note" or "cut something with scissors"), or meaningless gestures shown in short video clips with no speech. Neuroimaging results during both observation and execution (imitation) revealed activation in the core areas of the MNS, as well as in areas related to the IPN (e.g., middle frontal

regions and TPJ), suggesting that imitating social gesture requires both MNS and IPN. According to Maineri and colleagues, the representation of communicative intentions might require a capacity mediated by the MPFC and related to ToM, although other networks, such as the MNS, might play an additional role in extracting motoric meaning.

Many studies have used interactive paradigms that represent a communicative interaction situation, for example, competitive games in which participants are directly involved in social interaction. McCabe, Houser, Ryan, Smith, and Trouard (2001) scanned participants while they played two-person decision-making games in which they could either cooperate or compete with human or computer opponents. Participants who cooperated with their opponent showed increased MPFC activity when playing against a human compared with the computer, a differentiation that was not seen when participants did not cooperate with their opponent. Gallagher, Jack, Roepstorff, and Frith (2002) used a version of the rock-paper-scissors game where participants played against three different opponents: a human competitor, a computer following a simple rule, and a computer making random choices. The human condition evoked activity in frontal regions different from both computer conditions, including the MPFC. Kircher et al. (2009) applied an adapted variation of the Prisoner's Dilemma Game, with subjects instructed to play either a putative human or computer partner (in actuality both were programmed to use a random sequence). Neuroimaging results showed MPFC and right TPJ activations in both conditions compared with a low-level baseline (relax condition), although activation was significantly stronger when participants thought they were playing with a human partner. Noordzij et al. (2009) required experimental subjects to engage in a communicative interaction using the tacit communication game, where two players, a sender and receiver, move a token on a game board displayed on a computer monitor. Participants communicated the position and orientation of a visual token to another individual using limited visuo-spatial means. Neuroimaging data were collected for both sender and receiver. Interestingly, results showed that activation in right TPJ increased when the sender designed a communicative act for another person, as well as when the receiver interpreted the communicative act; moreover, TPJ was more co-activated with MPFC compared with a control condition (asking the sender to completely ignore the receiver's token). Finally, Schippers et al. (2009) required experimental subjects to play Charades. In this game, participants were presented with a word on the screen and instructed to communicate this word to his or her partner using gestures. Activation in a combination of MNS and ToM brain areas was found.

Lastly very few studies have used real interactive communicative situations in which a full communicative exchange was presented. Calarge, Andreasen, and O'Leary (2003) proposed an imaginative communicative scenario and asked participants to invent and say aloud stories describing imaginary encounters with strangers. The results showed that compared with a control condition in which participants read stories requiring no mental state attribution aloud, the imaginative communicative scenario was associated with brain activations quite similar to those of the IPN. The fMRI work by Sassa et al. (2007) was the first to use a linguistic interaction paradigm, even though the interaction was one-sided. The authors used short video clips of daily actions in which an actor who was using a tool or handling an object (e.g., playing guitar) glanced at the camera. Participants responded to these movie clips in two conditions as follows: in the communicative condition, they talked to the person on the screen in a casual communicative manner; and in the descriptive condition, they verbally described the actor's situation. It is important to note that both conditions involved speech production, but there was only specific and explicit communicative intent directed to the actor in the communicative condition. Comparison of communicative and descriptive trials showed increased activation in MPFC, and bilateral TPJ and temporal poles in the communicative condition (Figure 54.3). Moreover, MPFC and precuneus activations were stronger for video clips in which the actor was a close friend of the subject compared with clips in which the actor was unfamiliar. Finally, compared with baseline (where a picture of a tool or object that appeared in the action video clips was presented on a moving mosaic), both experimental conditions led to activation in parts of the traditional language production network (i.e., the left inferior frontal gyrus) but, interestingly, these regions were not sensitive to the communicative/descriptive manipulation.

To the best of our knowledge, the study by Willems et al. (2010) is the only study that considered a full communicative exchange in which both the communicative action proposed by an actor and the concurrent reaction from a partner are considered. Participants were engaged in a communicative interaction through an interactive game (Taboo). The subject inside the MR scanner generated verbal descriptions of target words without using predetermined "taboo" words, whereas the other player outside the MR scanner listened to these descriptions and guessed the target word. Interestingly, manipulating communicative intent, that is, changing whether the listener already knew the target word or not, and linguistic difficulty, that is, modifying the semantic relationship between the Taboo words and the target word, influenced activation

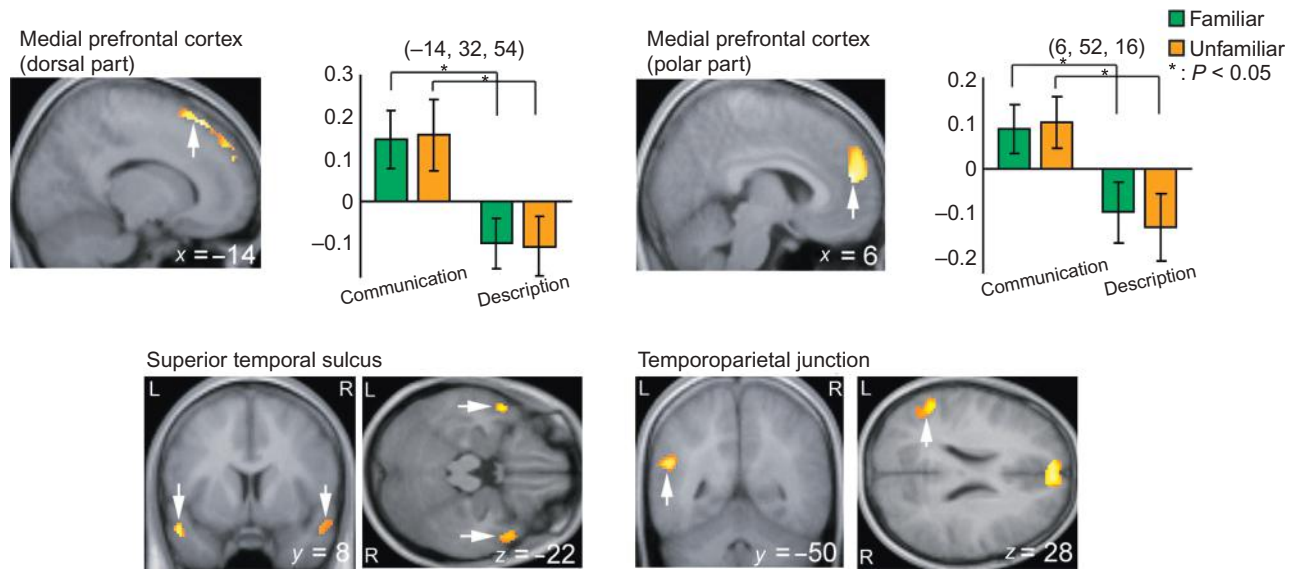

FIGURE 54.3 Regions of interest of the main areas with significantly greater activity during the communication relative to the description condition. From Sassa et al. (2007) with permission from the publisher.

patterns in different brain regions. Although MPFC activation was sensitive to the communicative intention manipulation, irrespective of linguistic difficulty, activation of the left inferior frontal cortex, a key region of language network, was sensitive to manipulations of linguistic demands but not communicative intention. In accordance with the aim of this work, this study provides an interesting neural evidence for a dissociation between communicative message generation and lexico-semantic language processes.

Taken together, we argue that these results reflect an experimental setting where a real interactive communicative situation occurred. Considering the complexity of the pragmatic dimension being investigated—communicative exchange between at least two people using different expressive modalities—we think that the more ecologically valid the study, the more pragmatic ability that is recruited. Hence, we argue that the most interesting findings in terms of the neurobiological bases of communicative comprehension competence will come from a more careful analysis of an ecological approach to the experimental setting.

54.5 STEPS TOWARD AN ECOLOGY OF COMMUNICATION

Communicative intentions are a core feature of any pragmatic phenomenon and, as mental states, they are irreducibly subjective entities (Searle, 1992). The intrinsic subjective nature of communicative intentions has relevant implications for the study of the neurobiology of pragmatics: the only judge of the intentionality of a

behavioral act is the actor who performs that act; sometimes the observer has no way of determining whether an act was intentional and, thus, communicative or not. Searle (1983) distinguished between prior intention and intention-in-action: prior intention represents the aim of the action, whereas intention-in-action is the cause of bodily movement. Bearing this difference in mind, we note that in typical ToM experimental paradigms the causal order of prior and motor intention is reversed from a first-person to a third-person perspective. A prior intention logically and temporally precedes the motor intention in the first-person perspective (e.g., in Dante's *Inferno*, Minos intends to send the damned to their circle of Hell and, hence, girds himself with his tail), whereas prior intentions in the third-person perspective are inferred after an action has been observed (e.g., based on the fact that Minos girds himself with his tail, Dante infers that Minos intends to send the damned to their proper circle).

These considerations require overcoming the artificial separation between speaker/hearer or actor/partner to move toward a communal construction of meaning (Chatel-Goldman, Schwartz, Jutten, & Congedo, 2013; Konvalinka & Roepstorff, 2012; Pickering & Garrod, 2004). The first revolution in the study of the neurobiology of pragmatics should involve devising experimental paradigms in which the agent involved is constantly changing roles, and where the perspective continuously switches between first person (I am saying something to you) and second person (you are saying something to me). The second ecological revolution will be the study of normal conversation, where each participant voluntarily takes his/her turn and freely expresses goals through

cooperative sharing of reciprocal mental states; only in this way will researchers gain access to the capacity for generating and comprehending effective communicative intentions. A technology that is able to monitor the brains of two agents online while they spontaneously interact is necessary for pragmatics concerned with ecological contexts.

Neurobiology of Speech Production: Perspective from Neuropsychology and Neurolinguistics

Sheila E. Blumstein¹ and Shari R. Baum²

¹Department of Cognitive Linguistic and Psychological Sciences, Brown University and the Brown Institute for Brain Sciences, Providence, RI, USA; ²School of Communication Sciences and Disorders and Centre for Research on Brain, Language & Music, McGill University, Montréal, QC, Canada

55.1 INTRODUCTION

For most of us, the production of speech appears to be effortless. And, yet, it is a multifaceted and complex process that requires access to different components of the language processing system. Although articulation of a word (i.e., patterns of articulatory movements of the vocal tract) may be the endpoint, the process begins with the conceptualization of a word, the selection of its lexical representation and corresponding sound properties from the mental lexicon, and the mapping of these phonological representations onto articulatory planning and implementation stages. Additionally, the speaker does not simply passively articulate speech, but rather he or she constantly monitors it on a moment-to-moment basis to adapt his/her output in either the short-term or the long-term based on both auditory and somatosensory feedback received from the production itself.

Although the details may vary, current models of the functional architecture of speech production typically identify these different aspects of speech production in terms of different stages of production. These stages are considered to be functionally distinct and hierarchically organized, with both feedforward and feedback mechanisms at each stage of processing (Figure 55.1). It is the goal of this chapter to examine current data and models of the speech production process, drawing from both neuropsychological and neurophysiological studies. To this end, we first provide a brief historical perspective drawn from the aphasia literature that has served as a

framework for much of the neurophysiological research. We then consider the proposed stages of production outlined, first reviewing phonological stages of production and then phonetic/articulatory stages of production, integrating results based on lesion and neurophysiological studies. Together, they indicate that speech production recruits a neural network that encompasses the language network, including temporal, parietal, and frontal structures.

55.2 HISTORICAL PERSPECTIVE: SPEECH PRODUCTION DEFICITS IN APHASIA

Early research from the 1970s and 1980s suggested that the patterns of production in patients with aphasia reflected different stages of the speech production process. Patients with lesions to frontal structures displayed articulatory planning and implementation deficits, and patients with lesions to posterior structures displayed phonological deficits. One of the presenting clinical features long recognized in defining the aphasia syndromes is the nature of speech production output (Goodglass & Kaplan, 1972) (for discussion of clinical syndromes of aphasia, see Chapter 73). In particular, patients presenting with Broca's aphasia or apraxia of speech typically have nonfluent speech output characterized by distorted speech production, sound errors of various types, and a diminution of the prosodic range of speech. In contrast,

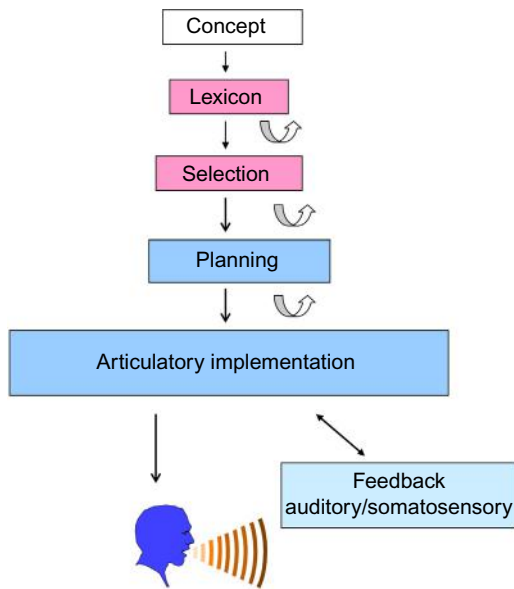

FIGURE 55.1 Functional architecture of stages of speech production processes. Colors in pink indicate phonological processes; those in blue indicate phonetic processes.

patients presenting with Wernicke's and conduction aphasia show fluent, well-articulated speech output. Nonetheless, these patients, and particularly those clinically diagnosed with conduction aphasia, make speech production errors characterized by sound substitutions and the misordering and transposition of sounds within and across words.

Studies examining the acoustic patterns of speech production of these patients largely supported this dichotomy. Acoustic measures of a number of parameters of speech, including voice-onset time (VOT) in stop consonants (Blumstein, Cooper, Goodglass, Statlender, & Gottlieb, 1980; Gandour & Dardarananda, 1984; Kent & Rosenbek, 1983), amplitude of voicing in fricative consonants (Kurowski, Hazen, & Blumstein, 2003), murmur duration, amplitude of the first harmonic at consonant release in nasal consonants (Kurowski, Blumstein, Palumbo, Waldstein, & Burton, 2007), and temporal parameters of consonant and vowel production (Baum, Blumstein, Naeser, & Palumbo, 1990) showed that patients with frontal lesions displayed deficits. They also displayed deficits in laryngeal control as shown by impairments in amplitude properties of nasals, fricatives, and prosody. In contrast, patients with posterior lesions showed normal patterns of production in the analysis of these parameters.

Although this dichotomy between phonological and phonetic stages of speech production is supported by more recent neuropsychological and neurophysiological studies, early on, studies of speech production in aphasia indicated that the picture was more complicated. These studies showed that in addition to phonetic (articulatory)

deficits, those with Broca's aphasia and patients with apraxia of speech produced phonological errors similar to those made by those with fluent aphasia with posterior lesions (Blumstein, 1973; Canter, Trost, & Burns, 1985; Haley, Jacks, & Cunningham, 2013). For example, the patterns of phoneme substitution errors (e.g., pipe → bipe) made by those with Broca's, conduction, and Wernicke's aphasia were similar across groups, as were the distributions of different error types such as phoneme substitutions (e.g., teams → keams), deletions (e.g., brown → /bawn/), additions (e.g., papa → /papra/), and transpositions (e.g., degree → /gədri/). Acoustic analysis revealed that both Wernicke's and conduction aphasics showed increased variability in the implementation of a number of acoustic parameters of speech, despite the fact that they showed normal patterns of articulatory implementation (Baum et al., 1990; Ryalls, 1986; Vijayan & Gandour, 1995). Taken together, these findings indicate that speech production recruits an integrated functional and neural system, one in which damage to one area has consequences throughout the system affecting stages of production both upstream and downstream from it.

55.3 PHONOLOGICAL PROCESSES IN SPEECH PRODUCTION

There is a rich literature that has examined the representations and processes involved in accessing words from the lexicon in spoken word production. Results from this research generally support the view that words are represented in terms of abstract, context-independent, phonological (phonemic and/or syllable-sized) units and that the mental lexicon and access to it is influenced by the phonological properties of individual words and the network of word representations that share structural properties with the word candidate (Dell, 1986; Gaskell & Marslen-Wilson, 1999). Information flow throughout the speech production system is considered to be interactive. Activation of a lexical candidate activates its associated phonological units, and these phonological units, in turn, boost the activation of the word candidate as well as those shared phonological units of other words in the lexicon. With this view, the selection of the phonological representation of a word is modulated by the number of phonological "neighbors" a word may have (Dell & Gordon, 2003), and this has a cascading effect on its articulatory implementation (Baese-Berk & Goldrick, 2009; Goldrick & Blumstein, 2006).

Evidence from aphasia has generally supported this view. Although these studies provide evidence in support of many of the theoretical claims about the functional architecture of spoken word

production, most fail to provide information about or focus on the underlying neural substrates. Additionally, there have been surprisingly few functional neuroimaging studies examining these issues. With this limitation in mind, we now turn to a brief review of the extant neuropsychological and neurophysiological findings examining phonological processes in speech production.

55.3.1 Nature of Representations

Similar to individuals without brain damage, patients with aphasia show sensitivity to the sound structure properties of the lexicon in spoken word production. In a study of the production of speech errors in picture description and picture naming tasks in 43 aphasic patients (unselected for syndrome or lesion), [Gordon \(2002\)](#) showed that there were fewer errors produced for word targets that had many lexical neighbors than words that did not. These facilitative effects occur presumably because words from dense neighborhoods share phonological structure with the target, and the phonological similarities among the target word and its neighbors provide a further boost to the activation of the lexical target. That the effect is driven by lexical factors is further supported by the fact that errors were more likely to result in words (of similar sound shape) than in nonwords (see also [Laganaro, Chetelat-Mabillard, & Frauenfelder, 2013](#)).

As indicated, the general consensus in the spoken word production literature is that words are represented in terms of abstract phonological units. These units may include both sound segments and properties of sound segments (i.e., phonological/phonetic features). Evidence suggesting that these units are segmental comes from detailed analyses of the patterns of phonological errors produced by aphasic patients in spontaneous speech as well as in more controlled tasks such as repetition and naming ([Blumstein, 1973](#); [Lecours & Lhermitte, 1969](#)). Results show that phoneme substitutions, the most common error produced by those with Broca's, conduction, and Wernicke's aphasia involve the replacement of a single phoneme by another; whether this happens within a word, such as *teams* → /kimz/, is the result of misordering of sounds within a word, such as *"degrees"* → /gədriz/, or is a sound substitution between words, such as *roast beef* → /rof bif/.

Additionally, the pattern of substitution errors suggests that phonological features of sounds are fundamental representational units. In particular, the large majority of substitution errors reflect the replacement of a single phonetic feature, with very few errors occurring between sounds distinguished by two or more features. For example, there are more voicing, place of

articulation, or manner errors than combinations of these features. These findings are consistent with early work by [Jakobson, Halle, and Fant \(1967\)](#), who proposed that a finite set of distinctive features can be used to characterize the phonological systems of language and the acquisition or dissolution of language ([Jakobson, 1968](#)).

Although it may be the case that phonological units may be abstract and are represented independent of the phonetic context in which they occur, there must be a processing stage where the abstract sound shape is coded into fine "episodic" details that take into account the context in which the sounds appear. These details are ultimately used for motor planning and execution. Evidence from aphasia supports this two-stage process ([Blumstein, 1973](#)).

Consider the words "pill" and "spill" in English. The abstract representation of the /p/ in these two words is the same. However, their phonetic realization differs; /p/ in initial position in English is aspirated and has a long VOT (i.e., [p^h]), whereas /p/, following /s/ is unaspirated and has a short VOT (i.e., [p]). It is of interest to determine what happens when an aphasic patient simplifies a consonant cluster, particularly what happens when a patient deletes the /s/ in a word like "spill." Will the resultant production of the /p/ be produced with an aspirated and long VOT, consistent with the notion that the deletion of the /s/ occurred during phonological processing (i.e., before motor plans for a cluster are implemented), or will it be produced with an unaspirated and short VOT, consistent with the notion that the production reflected the contextually determined phonetic realization of the cluster /sp/ followed by the deletion of the initial fricative? A study by [Buchwald and Miozzo \(2011\)](#) measured the VOT productions of two aphasic patients who deleted /s/ in /sp/, /st/, and /sk/ clusters and compared these with the phonetic realization of correctly produced stop consonants in both singleton and cluster environments (i.e., "pill" and "spill"). Results showed two different patterns of production, with one patient producing the initial stop consonant of the word with a long VOT (similar to the realization of /p/ in "pill") and the other producing it with a short VOT (similar to the realization of /p/ in "spill"). These findings suggest that the errors of the former patient were phonologically based and the errors of the latter patient were phonetically based. Similar findings were shown examining duration properties of nasal consonants when deleted in /sn/ and /sm/ clusters ([Buchwald & Miozzo, 2012](#)).

55.3.2 Cascading Activation

During the stages of speech production, information flows from the more abstract properties of speech to

more detailed phonetic representations required for articulatory planning and articulation. Recent research with normal individuals has suggested that there is a cascading flow of information with phonological properties of words influencing their fine-grained phonetic realization (Goldrick, 2006). For example, it has been shown that the implementation of voicing in stop consonants is influenced by whether the words have a voicing minimal pair (Baese-Berk & Goldrick, 2009; Goldrick & Blumstein, 2006). There is a longer VOT for initial voiceless stop consonants in words having a voiced minimal pair (e.g., “tart” versus “dart”) compared with words that do not (e.g., tar versus *dar).

A recent neuroimaging study (Peramunage, Blumstein, Myers, Goldrick, & Baese-Berk, 2011) examined the neural substrates of this lexically conditioned phonetic effect. While in the scanner, participants read words with initial voiceless stop consonants that either had or did not have a voiced minimal pair. None of the voiced minimal pairs were included in the set of words produced by the participants. Filler words beginning with a variety of consonants were also included. Acoustic analysis of the productions replicated the behavioral effects showing longer VOTs for voiceless stop consonants in words that had a minimal pair compared with words that did not. fMRI results revealed reduced activation for minimal pair words compared with nonminimal words in a neural network, including the left posterior superior temporal gyrus (STGp), supramarginal gyrus (SMG), inferior frontal gyrus, and precentral gyrus.

These findings suggest that lexically driven differences in the activation of phonological representations in temporoparietal areas (posterior superior temporal and supramarginal gyri) modulate subsequent articulatory processes in frontal areas (the inferior frontal and precentral gyri). Moreover, they are consistent with the view that reduced activation for minimal pair words is a facilitatory process reflecting the overlap in shared phonological properties between the target word and its minimal pair (MP) neighbor. Of interest, a subsequent study (Bullock-Rest et al., 2013) examining the effects of lesions to the SMG extending into the STGp or to the inferior frontal gyrus on the production of minimal pair and nonminimal words using the Peramunage et al. (2011) stimuli showed that both groups of patients demonstrated the minimal pair effect. Of importance, this effect emerged for correct productions, suggesting that despite damage to the network, Broca’s and conduction aphasic participants were still sensitive to the lexical properties of the target words and this, in turn, affected their phonetic output. Nonetheless, both groups showed a pattern of errors consistent with the view that they had a deficit in the spoken word production system. They made more

errors on nonminimal pair words than minimal pair words and made phoneme substitution errors on the target words that were largely single-feature substitutions, and when such errors occurred, the production was more likely to be a word than a nonword.

Perhaps more compelling evidence comes from a recent study examining the origin of phonemic paraphasias (i.e., phoneme substitution errors) in aphasic patients (Kurowski & Blumstein, in preparation). The question asked here was whether phonemic substitution errors (e.g., [s] → [z]) reflect a planning error, where the wrong phoneme is selected and ultimately implemented correctly, or whether it reflects the simultaneous selection and activation of a mis-selected phoneme and the original target phoneme. In this latter case, the resulting production, although perceived by the listener as a phonemic paraphasia (i.e., a clear-cut substitution error), is a hybrid, realized acoustically as a phoneme substitution but with an acoustic trace of the original target phoneme. To examine this question, acoustic measures were performed of voicing in the fricative consonants [s z] produced in a consonant–vowel (CV) environment by seven aphasic participants, three clinically diagnosed with Broca’s aphasia, three with conduction aphasia, and one with Wernicke’s aphasia. Results showed that the phonemic paraphasias of the patients left traces of the original target phoneme. These findings suggest that the production of phonemic paraphasias reflect the simultaneous selection and activation of competing phonemes that subsequently influence articulatory planning and implementation stages downstream from it (see also Baum & Slatkovsky, 1993; Buckingham, 1992; Buckingham & Yule, 1987).

55.4 PHONETIC PROCESSES IN PRODUCTION

55.4.1 Articulation

Identifying the neurostructural and neurofunctional correlates of speech production at the articulatory phonetic level requires an understanding of both speech motor programming and sensorimotor integration. Until relatively recently, the majority of work on the neural networks underlying overt speech production relied primarily on evidence from studies of patient populations. In early years, symptomatology exhibited by stroke patients was coarsely correlated with lesion sites based on CT scans (Baum & Boyczuk, 1999; Blumstein et al., 1980; Blumstein, Cooper, Zurif, & Caramazza, 1977). As imaging technology improved, so did the accuracy with which symptoms were associated with lesion sites (Baum et al., 1990). In what has

become a landmark study, [Dronkers \(1996\)](#) compared the lesions of 25 individuals diagnosed with apraxia of speech (in a chronic state) in an effort to identify a common area of infarct responsible for the phonetic implementation deficit. The only lesion site common to all patients was in the precentral gyrus of the insula, leading to the suggestion that this region was important in articulatory coordination and control ([Dronkers, 1996](#); see also [Dogil et al., 2002](#); [Wise, Greene, Buchel, & Scott, 1999](#)). However, more recent studies have implicated the pars opercularis, suggesting that the insula is part of a network involved in articulatory control ([Hillis et al., 2004](#); [Leonardo et al., 2006](#)). Easier access to high-quality functional neuroimaging has permitted a far more detailed and broadly encompassing understanding of the neural substrates of speech production to emerge.

It is self-evident that the networks implicated in speech production include the cortical and subcortical regions involved in motor control more generally (i.e., primary motor cortex, supplementary motor area [SMA], regions within the basal ganglia, and the cerebellum). Numerous investigations over the past 15 years have attempted to identify the specific roles of each of these regions and others, including areas within auditory and somatosensory cortices, because each contributes to the neural network subserving speech production. We first review studies focused on the production of syllables and syllable sequences, and then we turn to sensorimotor integration in speech production.

In comparison with the vast literature on word production (e.g., as reviewed in [Indefrey & Levelt, 2000](#)) and a growing literature on covert speech production (e.g., [Price, 2012](#), for review), far fewer neuroimaging studies have investigated overt articulation. Based on his well-developed DIVA model of speech production ([Guenther, 1994, 1995](#)), [Guenther](#) and colleagues have proposed and begun testing the neural bases of certain aspects of the model (e.g., [Bohland & Guenther, 2006](#); [Guenther & Ghosh, 2003](#); [Guenther, Ghosh, & Tourville, 2006](#); and others). Broadly speaking, the DIVA model consists of two primary control systems—a feedforward system including areas involved in articulatory implementation (speech sound system and stored motor programs, hypothesized to be represented in left ventral premotor cortex [PMC]), articulatory positioning commands generated in motor cortex, and timing coordinated in the cerebellum, and a feedback system that allows for error detection and monitoring and sensorimotor integration based on both auditory (temporal cortex) and somatosensory (inferior parietal cortex) input, with bidirectional links between the two control systems ([Guenther et al., 2006](#)). In one of the first tests of the hypothesized neural correlates of the

model's components, [Guenther et al. \(2006\)](#) conducted an event-related sparse sampling fMRI study in which 10 speakers produced monosyllabic or bisyllabic stimuli based on orthographic representations (i.e., reading aloud). Scans were acquired during silent intervals after syllable production, timed to co-occur with the idealized peak of the associated hemodynamic response function (HRF), and activation was compared with passive viewing of a string of Xs. Activation was found in a widespread bilateral network including primary motor cortex, primary auditory and sensory cortices, the cerebellum, left inferior prefrontal gyrus, SMA, SMG, and area Spt ([Hickok & Poeppel, 2004](#))—all areas in keeping with the predictions of the model (see also [Blank, Scott, Murphy, Warburton, & Wise, 2002](#); [Price, Crinion, & MacSweeney, 2011](#); [Price, Moore, & Frackowiak, 1996](#)).

In a related study focused on the production of syllable sequences, [Bohland and Guenther \(2006\)](#) compared patterns of activation during production of syllables varying in complexity based on number of onset consonants (in this case, syllable length was also modified) and syllable sequences of varying complexity (i.e., the same CV repeated three times or three different CVs appended to one another). Subjects were required to overtly produce the stimuli for a subset of trials and to prepare to produce (but not actually do so) in others (through use of a go/no go task). A conjunction analysis of all speech conditions again yielded a broad bilateral network, including the bilateral central sulcus, precentral and postcentral gyri, anterior insula, superior temporal cortex, medial premotor areas (SMA and pre-SMA), the basal ganglia, thalamus, cerebellum, and left frontal operculum ([Bohland & Guenther, 2006](#); see also [Peeva et al., 2010](#)). The increase in syllable complexity (which inherently entailed an increase in length) yielded increased activation in medial premotor regions, the frontal operculum bilaterally, and the left posterior parietal lobe. The increase in sequence complexity yielded increased activation in bilateral medial premotor regions, left frontal cortex, anterior insula bilaterally, left posterior parietal lobe, bilateral inferior posterior temporal lobe, bilateral cerebellum, anterior thalamus, and caudate nucleus ([Bohland & Guenther, 2006](#); but see [Dogil et al., 2002](#) for data suggesting that increased complexity yields reduced activation).

Based on these findings, the authors suggest that the inferior frontal sulcus may be the region where the motor programs required for the production of phonological units or syllables are represented. Given the increase in activation during complex sequences in the left IFGpo (see also [Papoutsi et al., 2009](#); [Park, Iverson, & Park, 2011](#); [Soros et al., 2006](#)), the authors suggest that this region houses the “speech sound map”—the

phonetic codes for specific phonemes or syllables. The anterior insula—the region identified by [Dronkers \(1996\)](#) as common to all her patients who presented with apraxia of speech—was active in all overt speech tasks, but activation was not modulated by sequence or syllable complexity ([Bohland & Guenther, 2006](#); see also [Ackermann, Mathiak, & Ivry, 2004](#), but see [Frenck-Mestre, Anton, Roth, Vaid, & Viallet, 2005](#); [Riecker et al., 2000](#); [Soros et al., 2006](#) for studies showing an absence of anterior insula activation during speech production). According to [Bohland and Guenther \(2006\)](#), the anterior insula may have a role in speech initiation (see also [Shuren, 1993](#)) but is not likely to be involved in the representation or implementation of syllable sequences (for yet a different perspective, see [Moser et al. \(2009\)](#) for data suggesting that the anterior insula has a role in speech implementation for *novel* motor programs). A nearby region that did show sensitivity to complexity was between the anterior insula and the frontal operculum; the authors conclude that this region is involved in syllable sequence representation, perhaps as a site of integration of lower and higher level representations of speech ([Bohland & Guenther, 2006](#)).

Other investigators have made similar but slightly different claims about the role of the IFGpo. For instance, based on a positron emission tomography (PET) study comparing silent speech to oral (non-speech) movements, [Price et al. \(2011\)](#) suggest that the IFGpo (along with posterior superior temporal sulcus [STS]) is involved in predicting acoustic and motor consequences of speech articulation, that is, in the feedforward (internal model) system—not altogether different from [Bohland and Guenther's \(2006\)](#) speech sound map, but with a somewhat different precise localization. This predictive coding would then, hypothetically, be passed on to temporal regions (posterior STS and planum temporale) where it could be used in an optimization loop to limit both perceptual and production errors. The authors admit that functional connectivity analyses would be required to confirm this hypothesis. In this study, activation of the superior temporal plane region was not found to be specific to speech production (i.e., it emerged during oral, non-speech movements as well), suggesting this region may play a more general role in sensorimotor integration ([Price et al., 2011](#); see [Hickok & Poeppel, 2004](#); [Hickok, Okada, & Serences, 2009](#); [Peschke, Ziegler, Eisenberger, & Baumgaertner, 2012](#)).

In a meta-analysis of 19 fMRI and PET studies of overt speech production, [Eickhoff, Heim, Zilles, and Amunts \(2009\)](#) reported consistent activation in left inferior frontal gyrus (IFG), the face region of primary motor cortex, the anterior insula, lateral premotor cortex, the cerebellum, and the basal ganglia. They

propose that the anterior insula is involved in preparation for speech, possibly in translating a phonetic “concept” obtained from left IFG into articulatory motor patterns, whereas the left IFG represents the site of the final stages of lexical retrieval that initiates the articulatory process. They further suggest that the basal ganglia and cerebellum are involved in the selection and implementation of motor programs, including timing and the incorporation of sensory feedback, whereas the premotor cortex combines the information from these two sources (basal ganglia and cerebellum) to convert into a specific movement (muscle contraction) plan. The involvement of primary motor cortex relates to actual execution via connections to lower motor neurons ([Eickhoff et al., 2009](#)).

As suggested in the description of the meta-analysis reported by [Eickhoff and colleagues](#), additional regions that have been the focus of intense investigation regarding their role in speech production include several premotor regions, notably the pre-SMA, SMA proper, and dorsal and ventral premotor regions ([Ackermann & Ziegler, 2010](#); [Guenther et al., 2006](#); [Hartwigsen et al., 2013](#); [Peeva et al., 2010](#); [Saur et al., 2008](#); [Soros et al., 2006](#); [Tremblay & Gracco, 2006](#)). The pre-SMA has long been claimed to be important for speech initiation, based, in part, on evidence from lesion studies ([Ackermann & Ziegler, 2010](#); [Ziegler, Kilian, & Deger, 1997](#)) and data from investigations of nonspeech motor control highlighting its role in movement initiation ([Shima & Tanji, 2000](#)). Dorsal and ventral premotor areas have frequently been found to be activated during speech production and are presumed to be implicated in the conversion of phonetic codes to articulatory implementation or execution ([Guenther et al., 2006](#); [Hickok, Houde, & Rong, 2011](#)). Using dynamic causal modeling (DCM) to explore effective connectivity and diffusion tensor imaging (DTI) to examine anatomical connectivity, [Hartwigsen et al. \(2013\)](#) investigated the roles of these frontal premotor areas during real-word and pseudoword repetition. The investigators hypothesized that if pre-SMA is truly important in speech initiation, then the DCM model with the best fit to the data should include “driving input” into pre-SMA, with a strong influence of pre-SMA on dorsal and ventral premotor areas. The effective connectivity analyses did demonstrate such a pattern, with a stronger influence of pre-SMA on the dorsal premotor region for pseudowords relative to real words. DTI analyses revealed direct fiber connections between pre-SMA and both dorsal and ventral premotor cortex. Based on their findings, the authors propose that the pre-SMA is involved in the sequencing of motor programs for articulatory initiation, the dorsal premotor cortex is implicated in conversion of an abstract sequencing plan to an actual motor-

articulatory plan (see also Alario, Chainay, Lehericy, & Cohen, 2006), and the ventral premotor cortex provides predictions of the auditory representations of common speech sounds and syllables (Hartwigsen et al., 2013; see also Guenther et al., 2006).

One final brain region that clearly plays an important role in speech production is the cerebellum, which has connections to both basal ganglia and sensorimotor cortex, as well as to premotor regions and the insula (Ackermann, 2008). Unfortunately, it has received substantially less attention in the literature. However, based on studies of patients with cerebellar lesions, some recent neuroimaging data, and studies of non-speech motor control, the cerebellum has been argued to be involved in the temporal organization and sequencing of syllables, as well as the control of speech rate (beyond a certain speed) (e.g., Ackermann, 2008; Ackermann, Mathiak, & Riecker, 2007; see also Ivry & Keele, 1989; Ivry, Spencer, Zelznik, & Diedrichsen, 2002). Interestingly, parts of the cerebellum have also shown to be sensitive to speech perceptual demands, particularly in temporal discrimination (Ackermann, 2008; Mathiak, Hertrich, Grodd, & Ackermann, 2002, 2004; Petacchi, Laird, Fox, & Bower, 2005). The precise integration of cerebellar processing with cortical and subcortical processing for speech production remains to be determined.

55.4.2 Sensorimotor Integration

The integration of sensory and motor signals is a crucial component in sensorimotor learning and the establishment of perceptuo-motor representations. Speech production is, by nature, a sensorimotor behavior. Such behaviors require monitoring of input from one or more sensory systems to update or modify motor plans, either on a moment-by-moment compensatory basis (online sensorimotor control) or via longer-term adaptation (sensorimotor learning). In most models of speech production, sensorimotor feedback is compared with a predicted outcome to control ongoing movement and program future articulation; this process of internal feedforward models (efference copy) is proposed in one form or another in the DIVA model of Guenther (1995) and in the state feedback control model of Houde and Nagarajan (2011), among others (Price et al., 2011).

One means of addressing questions of sensorimotor integration is through empirical studies of imposed sensory-based manipulations. For example, it has frequently been demonstrated that the speech production system is able to compensate for many perturbations to the vocal tract—both predictable and unexpected—to achieve phonetic goals (e.g., Abbs, 1986; Lindblom,

Lubker, & Gay, 1979, among many others); nonetheless, the extent of compensation varies depending on the nature of the perturbation and the specific speech sounds targeted (Aasland, Baum, & McFarland, 2006; Baum & McFarland, 1997, 2000). These findings suggest that speakers are generally able to adapt to modifications of somatosensory (kinesthetic or proprioceptive) feedback to produce perceptually adequate speech. Recently, a great deal of attention has been focused on speech adaptation to alterations of auditory feedback as well. As in the visual modality in studies of prism adaptation (Redding, Rossetti, & Wallace, 2005; Redding & Wallace, 1996; Rossetti, Koga, & Mano, 1993), investigations have demonstrated adaptive speech motor output in the face of auditory feedback that has been modified to yield what is perceived as a production error on the part of the speaker (Houde & Jordan, 1998, 2002; Jones & Munhall, 2005; Larson, Altman, Liu, & Hain, 2008; Larson, Burnett, Kiran, & Hain, 2000; Purcell & Munhall, 2006; Shiller, Sato, Gracco, & Baum, 2009). Adaptation in this context is not complete, in that the speech output does not fully compensate for the perceived target error (Jones & Munhall, 2005). The reasons for incomplete adaptation are complex (Shiller et al., 2009), but the limited adaptive response indicates online sensorimotor integration and suggests a recalibration of perceptual and motor responses (Baum & McFarland, 1997, 2000; Houde & Jordan, 1998, 2002; Jones & Munhall, 2005; Nasir & Ostry, 2009). Functional neuroimaging studies that investigate the neural mechanisms involved in such sensorimotor adaptation for speech are only beginning to emerge (Baciu, Abry, & Segebarth, 2000; Guenther et al., 2006; Ito, Kimura, & Gomi, 2005; Tourville, Reilly, & Guenther, 2008); thus far, they support a broad cortical and subcortical network, including both left and right hemisphere regions underlying the adaptation process, as detailed here. Other approaches to exploring the integration of perceptual and production processes have also been undertaken. For instance, Hickok and colleagues (Buchsbaum, Hickok, & Humphries, 2001; Hickok, Buchsbaum, Humphries, & Muftuler, 2003; Hickok et al., 2009, among others) have used nonword repetition tasks to tap into sensorimotor integration processes. These studies have identified the Spt, a region in the planum temporale, as a critical hub to this process (see also Hickok, 2014, for an overview).

In one of the earliest neuroimaging investigations to use feedback manipulations to examine sensorimotor integration for speech, Tourville et al. (2008) made use of an auditory feedback manipulation in the production of a series of consonant–vowel–consonant (CVC) stimuli, all of which included the vowel /ε/. Within a string of productions, an unexpected shift (up or down) of the F1 frequency in the vowel was induced

(following Purcell & Munhall, 2006; Houde & Jordan, 1998). Speakers compensated for the unexpected perturbations, as expected. The neural regions that demonstrated increased activation under conditions of auditory perturbation and resulting compensation included bilateral STGp, planum temporale, left ventral motor and premotor cortex, and antero-medial cerebellum. Activation in these regions is consistent with a role for both secondary auditory and motor areas in the compensatory process. In another recent fMRI study investigating the neural substrates invoked during speech adaptation (i.e., speech motor learning) to consistent auditory feedback perturbation, Gracco, Sato, Shiller, and Baum (in preparation) found increased activation during the adaptation (hold) phase in bilateral IFG, premotor gyrus (PM), STS, posterior STG, posterior inferior temporal gyrus (pITG), right angular gyrus/posterior parietal gyrus (rAG/pPG), and left inferior parietal lobule/supramarginal gyrus (IPL/SMG).

Based on these findings, coupled with results in prism adaptation studies implicating a role for inferior parietal cortex in the control of adaptive movements (Redding et al., 2005), Gracco and colleagues (Dangler, Shiller, Baum, & Gracco, in prep; Shum, Shiller, Baum, & Gracco, 2011) conducted two rTMS studies stimulating this region prior to an auditory feedback manipulation/speech adaptation task. In a first study in which inhibitory stimulation was applied to left SMG (Shum et al., 2011), results revealed that those participants who had undergone transcranial magnetic stimulation (TMS) to this region produced a significantly reduced adaptive response as compared with individuals who had undergone sham stimulation. In contrast, Dangler et al. (in preparation) applied inhibitory TMS to the right hemisphere IPL and found a faster adaptive response subsequent to stimulation that was, however, of comparable magnitude in both experimental and control (sham) participant groups. The findings of both experiments were interpreted to suggest that the left inferior parietal region plays an important role in sensorimotor adaptation and integration, whereas the right hemisphere homologue seems to normally inhibit activity in the left IPL; in other words, when right IPL was inhibited, adaptation occurred more quickly (Dangler et al., in preparation; Gracco et al., 2012; Shum et al., 2011).

There have also been several recent investigations of the neural bases of sensorimotor integration with a focus on alteration of somatosensory feedback, rather than auditory feedback. For instance, Baciú et al. (2000), as reviewed in Golfinopoulos et al. (2011), made use of a lip tube to inhibit lip movement during rounded vowel production in an fMRI study. The static perturbation yielded increased activation in a

bilateral distributed network that included frontal, parietal, and temporal areas, as well as the cerebellum; interestingly, there was an increase in the role of the right hemisphere during the perturbed trials. Using TMS to the left primary motor cortex, Ito et al. (2005) examined responses to unexpected jaw perturbation during speech and, not surprisingly, found an important role for that region in the compensatory response. Also, examining compensation to unexpected blocking of jaw movement via a pneumatic device, Golfinopoulos et al. (2011) reported increased activation in right anterior SMG, pre-SMA, SMA, IFG, precentral gyrus, thalamus, and cerebellum under perturbed speaking conditions. They also investigated effective connectivity and found increased connectivity between left and right anterior SMG, as well as between left anterior SMG and right ventral premotor cortex in the perturbed relative to the unperturbed conditions. Similarly, increased connectivity was found between right anterior SMG and right IFGpt, as well as bidirectionally between right ventral premotor cortex and right ventral primary motor cortex. The authors conclude that bilateral anterior SMG is involved in somatosensory error detection and correction (in keeping with the DIVA model of Guenther (1995); see also Golfinopoulos, Tourville, & Guenther, 2010, and a recent study by Schwartz, Faseyitan, Kim, and Coslett (2012), a voxel-based lesion symptom mapping analysis supporting the role of SMG in phonological error production in aphasia). Golfinopoulos et al. (2011) further suggest that whereas left IFG may be important for prelearned or automatized phonetic coding, right IFGpt may serve to maintain sensorimotor representations and assist in the adjustment of ongoing speech movements in response to sensory feedback (Golfinopoulos et al., 2011). This latter suggestion appears inconsistent with that proposed by Gracco and colleagues (2012); however, it must be borne in mind that the experiments were investigating different types of compensatory responses, in one case in response to unexpected somatosensory perturbation (Golfinopoulos et al., 2011) and in the other in response to static auditory feedback perturbation (Gracco et al., 2012; Shum et al., 2011).

55.5 SUMMARY

It has been the goal of this chapter to review neuropsychological and neurophysiological studies of speech production. Together, this research has shown a complex tapestry that includes different stages of production that ultimately map abstract phonological structures onto articulatory commands. This production system is integrated with both auditory and

somatosensory systems, allowing it to maintain stability, and to adapt, as necessary, based on both immediate and longer-term perturbations. Speech production then requires both feedforward and feedback mechanisms where information flow is bidirectional. Not surprisingly, then, the speech production system recruits a large frontotemporoparietal cortical and subcortical network of left and right hemisphere regions, many of which have also been identified in language processing more generally. Future research holds much promise to provide further insights into the processes and mechanisms involved in speech production and their underlying neural mechanisms as ever-increasing sophisticated techniques become available for mapping lesions in neuropsychological studies and for examining the neural substrates of speech production in participants with and without lesions.

Word Production from the Perspective of Speech Errors in Aphasia

Myrna F. Schwartz¹ and Gary S. Dell²

¹Moss Rehabilitation Research Institute, Elkins Park, PA, USA; ²University of Illinois, Urbana-Champaign, Beckman Institute, Urbana, IL, USA

A common strategy for understanding the inner workings of a complex system is to study the ways in which it breaks down. Research in naturally occurring speech errors (“slips of the tongue”) and research in aphasia both take advantage of this strategy. Language scientists study speech errors for insight into the workings of the cognitive system that enables the skilled production of words and sentences. Neuroscientists study language deficits in aphasia to learn how the mechanisms of language processing are represented in the brain. This chapter presents research that falls at the intersection of these two historical traditions. The studies we highlight use computational models to simulate the cognitive mechanisms responsible for speech errors in aphasia and large-scale lesion-symptom mapping to link those cognitive mechanisms with brain regions.

Naturally occurring speech errors are the product of momentary, functional disruption within a normal language system. Aphasia causes structural damage that has persistent functional consequences. The most important of these, for the present purposes, is exacerbation of the normal tendency to occasionally select the wrong word or the wrong phonological segments when speaking (Dell, Schwartz, Martin, Saffran, & Gagnon, 1997; Ellis, 1985; Freud, 1953). Aphasia creates vulnerability to speech errors in spontaneous speech and in single word production tasks, such as spoken object naming and auditory word repetition. The high degree of experimental control afforded by naming and word repetition tasks has made them the vehicle of choice for studying how patients’ error types and error frequencies vary in relation to target properties (Cuetos, Aguado, Izura, & Ellis, 2002; Kittredge, Dell, Verkuilen, & Schwartz, 2008; Nickels & Howard, 1994,

1995) and clinical profiles (Blumstein, 1973; Jefferies & Lambon Ralph, 2006; Romani & Galluzzi, 2005). Furthermore, computational models of word production have been used to simulate lesions in aphasia and test competing theories of how errors arise. We exemplify this strategy with our own computational studies of naming and repetition.

56.1 SPEECH ERRORS IN APHASIA: THE NEUROLOGICAL TRADITION

The long history of neurological research in aphasia has been dominated by the classical syndromes or subtypes. These include, but are not limited to, Broca’s aphasia (BA), Wernicke’s aphasia (WA), Conduction aphasia (CA), and Anomic aphasia (AA). Patients are assigned to subtypes based primarily on how they perform on clinical examination of expressive language (fluency, grammar, naming), receptive language (comprehension of spoken words and sentences), and repetition (of words and sentence). Within this framework, BA is considered primarily a disorder of expressive speech, featuring dysfluency, altered and inconsistent articulation (“apraxia of speech”), and simplified grammar. WA is primarily a disorder of speech comprehension, CA is primarily a disorder of repetition, and AA is primarily a disorder of word retrieval.

Speech error tendencies also enter into the diagnosis of WA and CA. Patients with WA characteristically produce speech that is fluent but replete with errors (historically, “paraphasias”) that particularly distort the semantic and also phonological content, sometimes to a degree that obscures the intended meaning. CA patients are less compromised in their functional

communication. Their comprehension is quite good and their speech is more semantically coherent. Their primary deficits are inability to repeat spoken speech, reduced auditory-verbal short-term memory span, and vulnerability to phonemic errors in all types of production tasks. Whereas WA patients are generally unaware of their errors, errorful productions in CA are often accompanied by successive repair attempts, referred to as “conduit d’approche.”

The following speech samples exemplify paraphasic speech production in WA (Ex. 1) and CA (Ex. 2). The patients were asked to describe the *Cookie Theft* picture, which shows a woman washing dishes at an overflowing sink while a girl and boy, the latter perched on a tipping stool, grab cookies from a cabinet (Goodglass & Kaplan, 1983).

- (1) “So the two boys work together an one is sneakin’ around here, making his. . .work an’ his further funnas his time he had.”
- (2) “Well this um. . .somebody’s. . .ah mather is takin the. . .washin’ the dayshes [material deleted] and there’s a. . .then the girl. . .not the girl. . .the boy who’s getting the cooking is on this ah. . .stool and’ startin’ to fall off.”

The aphasia syndrome classification is rooted in the 19th century Broca–Wernicke–Lichtheim model of language and brain. The well-known claims of the model are that motor and auditory speech engrams localize to the left inferior frontal gyrus (IFG) and left posterior superior temporal gyrus (pSTG), respectively; these sensory and motor engrams are interconnected through the arcuate fasciculus. IFG lesions give rise to the expressive deficit in BA, pSTG lesions to the comprehension deficit in WA, and arcuate lesions to the repetition deficit in CA. The paraphasic speech patterns of WA and CA patients arise because the intact motor speech engrams are deprived of governing input from the speech comprehension center due to direct damage (WA) or disconnection (CA) (Compston, 2006; Geschwind, 1965).

The aphasia syndromes and classical model have an enduring legacy. The contemporary Dual Stream theory of auditory language processing (Hickok & Poeppel, 2004, 2007) bases its characterization of the dorsal stream on neuroimaging data and evidence concerning CA. The theory assigns to the dorsal stream the function of mapping between auditory and articulatory representations in speech. It identifies an area in the posterior Sylvian fissure at the temporoparietal boundary (area Spt) that plays a central role in this dorsal stream specialization and postulates that lesions here give rise to the CA symptom complex. Phonemic paraphasia in the speech of CA patients features importantly in the theory, providing evidence that

normal speech depends on the integrity of the auditory-articulatory mapping served by the dorsal route (for discussion and evidence, see Buchsbaum et al., 2011).

Apart from the Dual Stream theory, the legacy of the classical aphasia model is seen in modern empirical studies of the relationship between aphasia syndromes and speech error patterns. This issue was featured in Blumstein’s (1973) seminal monograph, “A phonological investigation of aphasic speech.” The monograph’s linguistic analysis of phonemic paraphasias in the speech of those with Broca’s, Wernicke’s and Conduction aphasia revealed surprising uniformity in the patterns of phonological breakdown. For example, in all three groups, phonemes were substituted more often than they were added or deleted, substitutions were strongly constrained by similarity in acoustic-articulatory features, and errors tended to replace marked structures (i.e., more complex, less frequent, and later acquired) with less marked ones.

Blumstein (1973) recognized that the mechanism for paraphasia might well be different in the three aphasic groups, notwithstanding their linguistic similarities. In line with this, researchers who study phonemic errors in WA often start from the assumption that these patients suffer from a central lexical deficit that impacts the retrieval of phonological and semantic information in language production, as it does in comprehension. In contrast, researchers who study phonemic errors in CA tend to emphasize that such errors occur even in tasks with an optional or obligatory “direct” route that bypasses the lexicon (e.g., repeating and reading words). On this basis (and others), it has been argued that phonemic paraphasia in at least some CA patients arises subsequent to lexical processing (i.e., at a postlexical phonological or phonetic stage of word production) (Caplan, Vanier, & Baker, 1986; Garrett, 1984; Goldrick & Rapp, 2007; Pate, Saffran, & Martin, 1987).

The notion that different mechanisms underlie the phonemic paraphasias of CA, WA, and BA patients is difficult to reconcile with the homogenizing impact of partial recovery. Experience suggests that some patients who are diagnosed in the acute phase with WA or BA in time evolve either to the CA profile, with its characteristic pattern of phonemic paraphasia and *conduit d’approche*, or to AA. This reminds us that what looks to be a difference in kind (e.g., phonemic errors, which resemble a plausible target, vs. neologisms, which do not) may actually be one of degree. Moreover, a particular diagnostic feature may become salient only on resolution of another symptom that initially masked or distorted its expression, as when the resolution of apraxia of speech reveals the presence of phonemic paraphasia in BA.

In our own cognitive studies of phonological and other errors in aphasia, we classify and interpret errors without regard to the speaker's aphasia subtype by applying a theoretical model that ascribes word-level substitutions to the lexical-semantic stage of lexical access and sublexical deviations to the lexical-phonological stage. The following section explains this further.

56.2 TWO STAGES OF LEXICAL ACCESS IN PRODUCTION

In the 1970s and 1980s, linguistic analysis of normal speech errors gave rise to a seminal psycholinguistic theory of sentence production (Dell, 1980; Fromkin, 1971; Garrett, 1975, 1980; MacKay, 1972; Shattuck-Hufnagel, 1979; Stemberger, 1985). The theory holds that planning a sentence involves the construction of multiple successive representations. A conceptual semantic representation is constructed first, followed by two linguistic levels that use syntactic and phonological information, respectively. Construction of the two linguistic levels involves building structure-representing frames and inserting content that is retrieved from the mental lexicon. The lexical units that fill slots in the syntactic frame are semantically and syntactically specified *words*. The units that fill slots in the phonological frame are phonological *segments*. It follows that entries in the mental lexical have multilevel representations and are retrieved in stages. Speech errors, according to the theory, arise when the wrong word/segment is retrieved from the lexicon, or the right word/segment is retrieved but inserted into the wrong slot.

The application of this theory to aphasia followed quickly. Researchers used the sentence planning framework to explain grammatical deficits (Saffran, 1982; Schwartz, 1987) and the multistage lexical retrieval model to explain aphasics' errors in word production (Buckingham, 1980, 1987; Butterworth, 1979; Ellis, Miller, & Sin, 1983; Garrett, 1984; Miller & Ellis, 1987; Pate et al., 1987; Schwartz, Saffran, Bloch, & Dell, 1994). The incorporation of interactive activation principles into multistage lexical models added to their range and power for explaining aphasic production errors. An early, excellent example is Ellis' (1985) proposal for how disruption of lexical dynamics could give rise to phonemic errors.

Ellis's informal (i.e., nonimplemented) model of word retrieval featured three cognitive components: a conceptual semantic system; a speech output lexicon

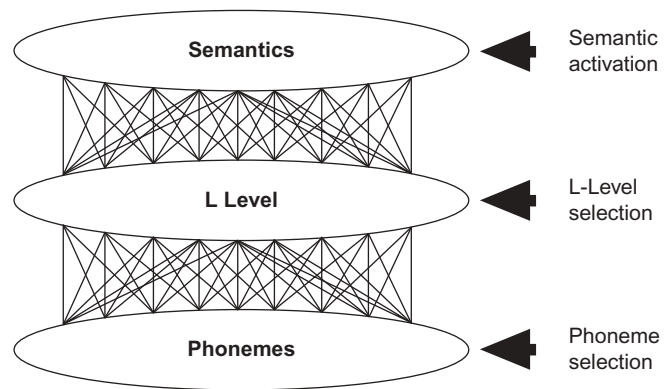

FIGURE 56.1 The generic two-stage account of spoken naming. Distributed semantic concepts map onto lexical nodes, which, in turn, map onto phonemes. (From Rapp and Goldrick (2000). Reprinted with permission from the publisher (American Psychological Association)).

with units or nodes representing known words¹; and a component that represents articulable phonemes. He hypothesized that damage-induced reduction in the flow of activation between the lexical-semantic system and the speech output lexicon would compromise the competitive dynamics among nodes in the speech output lexicon. This would impact the spread of activation down to the phoneme level, resulting in utterances comprising “correct phonemes intermingled with inappropriate ones” (p. 132). Addressing the sources that contribute to the activation of inappropriate phonemes, Ellis discussed top-down, cascading activation from the lexical-semantic layer, feedback loops between phonemes and output lexicon, and persistence of activation from prior utterances. Addressing why some neologisms have strong overlap with the target while others are more remote, he speculated that the mix of inappropriate and appropriate phonemes might be related to patient factors (i.e., severity of the lexical access deficit) as well as target factors (long, infrequent targets more likely to yield remote neologisms).

Ellis' informal model laid the groundwork for later computational models that implemented many of its features. The basic architecture of several such models is shown in Figure 56.1 (from Rapp & Goldrick, 2000). This is a generic two-stage account of spoken naming, in which distributed semantic concepts map onto lexical nodes, and these, in turn, map onto phonemes. The first stage of naming is about selecting the lexical node that corresponds to the semantic concept; the second stage is about selecting the phonemes. The many-to-one mapping from distributed semantics to lexical units creates competition among semantic neighbors

¹Ellis (1985) chose to remain agnostic on the question of whether the units in the “speech output” lexicon are the same lexical units that are accessed in comprehension. This was an important issue at the time (Allport, 1984) and it remains so today (Gow, 2012; Hickok, 2012).

and sets the stage for semantic and other lexical substitution errors to arise during step 1. Competition at the phoneme level, induced by processes described by Ellis (1985), invites phoneme substitution errors, most of which create nonwords. Models that use a noisy activation function can produce errors even in the unlesioned (default) state. Models that simulate aphasia do so by altering parameters of the model to reduce the efficiency of activation spreading and thus increase the impact of noise.

56.2.1 The Interactive Two-Step Model of Lexical Access in Naming

The generic model glosses over important differences in how alternative models formalize the semantic level and the lexical level, and how much they integrate or separate the processing that goes on at each level (for discussion, see Rapp & Goldrick, 2000). Dell's interactive two-step model of normal and aphasic naming (Dell & O'Seaghdha, 1991; Dell et al., 1997; Foygel & Dell, 2000) occupies a middle ground

TABLE 56.1 Taxonomy of Error Types^{a,b}

Semantic: Real word response that is a synonym, category coordinate, superordinate, subordinate, or strong associate of the target (e.g., <i>bus</i> for van; <i>leash</i> for dog)
Mixed: Real word response that qualifies as a semantic error and that meets the criterion for phonological similarity (e.g., <i>snake</i> for snail)
Formal: Real word response that meets the criterion for phonological similarity (e.g., <i>shaft</i> for fish)
Unrelated: Real word response that is neither semantically nor phonologically similar to the target (e.g., <i>camp</i> for banana)
Nonword: String of phonemes that does not constitute a word in the language. Most such errors pass the phonological similarity criterion, and, depending on the study, this can be a requirement for inclusion (e.g., <i>goath</i> for goat (phonologically similar); <i>tuss</i> for cane (dissimilar))

^aRoach et al. (1996).

^bThe criterion for phonological similarity is that response and target share at least one phoneme in corresponding syllable or word position or two phonemes in any position, not counting unstressed vowels.

between discrete-stage theories, which do not allow any cross-stage influences (Levelt, Roelofs, & Meyer, 1999) and highly interactive models in which the mapping between meaning and the output of lexical forms is achieved in a single settling step (Plaut & Shallice, 1993).

In its current form, the interactive two-step model assumes that aphasia affects naming by weakening connections between semantics and L-level (*s*-weight lesion) and/or those between L-level and phonemes (*p*-weight lesion). *S*-weight lesions instantiate a lexical-semantic disorder; *p*-weight lesions instantiate a lexical-phonological disorder. Most patients have both, but the severity of each lesion can vary independently of the other, and the two together determine what types of errors are seen and in what proportions.

Our evaluations of the model have mostly used computational case series methods (Dell et al., 1997; Foygel & Dell, 2000; Schwartz, Dell, Martin, Gahl, & Sobel, 2006). This starts with systematic collection of behavioral measures from a large sample of chronic left hemisphere stroke survivors representing all the major subtypes. All have self-reported language deficits confirmed by the *Western Aphasia Battery* (WAB; Kertesz, 1982) or other language evaluation. Among the battery of tests that each participant performs is the 175-item test *Philadelphia Naming Test* (PNT) (Roach, Schwartz, Martin, Grewal, & Brecher, 1996), which assesses basic-level naming of line-drawn objects. PNT responses are categorized into six categories: correct responses and the five error types shown in Table 56.1, which are expressed as proportions (relative to all responses). For each patient in the series, the model is fit by finding the values of the *s*-weight and *p*-weight parameters that give the best match to the patient's actual response proportions (see Table 56.2 for example). The model is evaluated for the goodness of the quantitative fits and whether there are patients with particular response patterns that the model cannot fit well (called "deviating patterns").

A study performed in 2006 fits the interactive two-step model to the naming response proportions of 94 patients with diverse aphasia presentations

TABLE 56.2 Naming Response—Category Proportions from a Sample Patient from the Moss Database^a and the Model's Simulated Proportions Generated When Best Fitting Parameters Are Chosen

Response categories	Correct	Semantic	Formal	Mixed	Unrelated	Nonwords
Examples	"cat"	"dog"	"cabin," "mat"	"rat"	"log"	"cag," "gat"
Patient naming	0.49	0.07	0.04	0.05	0.04	0.30
Model naming	0.52	0.07	0.08	0.02	0.04	0.26

^aMirman et al. (2010).

Best fitting parameter values: $s = 0.020$; $p = 0.016$ (root mean squared deviation = 0.03).

The example responses assume that the target is a picture of a cat.

(Schwartz et al., 2006). The model explained 94.4% of the total variance in naming proportions. There were two deviating patterns. One was attributable to the model's failure to account for perseverations. The other deviant pattern featured low rates of correctness with errors largely restricted to the categories of semantic errors and omissions. This "pure semantics" pattern of deviation highlights limitations in the model's treatment of semantic errors (Dell et al., 1997; Foygel & Dell, 2000; Rapp & Goldrick, 2000). We consider this further in the following section.

56.3 MODEL-INSPIRED LESION ANALYSIS OF SEMANTIC ERRORS

The case series methods we used in the model-fitting studies is well-suited to group-level voxel-based lesion-symptom mapping (VLSM: Bates et al., 2003; for discussion of case series methods, see Schwartz & Dell, 2010). VLSM aims to identify brain voxels anywhere in the brain that carry a correlation between lesion status and symptom severity of sufficient strength to pass a statistical threshold that corrects for the thousands of voxels tested. VLSM was inspired by functional neuroimaging, and the resulting brain maps resemble those produced in fMRI studies. Where fMRI maps tell us which areas activate during a particular cognitive task or process, VLSM maps tell us where lesions cause derailments in that task or function. We used this technique to address controversies surrounding the cognitive and neural basis of semantic error production.

The interactive two-step model associates all semantic errors with the transmission of activation from semantic to lexical representations (i.e., the error locus is *postsemantic* and *production-specific*). Many, ourselves included, have questioned the adequacy of this account. Studies have shown that some patients, including some with the "pure semantics" naming pattern, exhibit semantic difficulties in comprehension as well as production (Cloutman et al., 2009; Gainotti, Miceli, Caltagirone, Silveri, & Masullo, 1981; Hillis, Rapp, Romani, & Caramazza, 1990; Rapp & Goldrick, 2000; Schwartz et al., 2006). This raises the possibility that in stroke aphasia, as in some degenerative dementias, semantic naming errors might be due to compromised semantic representations. A second possibility is that aphasics' semantic errors result from an executive function disorder that affects the regulation of competition in the semantic system or more generally (Badre & Wagner, 2007; Corbett, Jefferies, & Lambon Ralph, 2011; Hamilton, Martin, & Burton, 2009; Jefferies & Lambon Ralph, 2006; Noonan, Jefferies, Corbett, & Lambon Ralph, 2010; Schnur, Schwartz, Brecher, & Hodgson, 2006; Schnur et al., 2009; Thompson-Schill,

D'Esposito, Aguirre, & Farah, 1997; Whitney, Kirk, O'Sullivan, Lambon Ralph, & Jefferies, 2012).

Although most of the evidence for an executive-deficit account of semantic errors comes from experimental paradigms that exaggerate semantic competition and, hence, the need for executive control, Jefferies and Lambon Ralph (2006) argued that an executive deficit may be responsible for semantic errors in conventional naming as well. They supported this with evidence that the naming errors of stroke aphasics included semantic errors like apple → "worm," where target and error are related to one another thematically rather than taxonomically, as is typical of most semantic errors (e.g., apple → pear). Jefferies and Lambon Ralph hypothesized that thematic error production in conventional naming is symptomatic of failure to access semantic representations in accordance with task goals—an executive function deficit they attributed to damage in left frontal and/or temporoparietal regions (Corbett et al., 2011; Noonan et al., 2010).

We examined these alternative accounts in a study that used VLSM to map the lesions that correlated with rates of taxonomic and thematic semantic errors on the PNT (Schwartz et al., 2011). As noted, taxonomic errors are the most common type of semantic error in naming; such errors are categorically related to the target as coordinate, superordinate, or subordinate. Much rarer is the thematic semantic error in which the target and error are from different categories but often play complementary roles in events and sentences. Most error-coding schemes combine taxonomic and thematic errors into a general semantic error category; this is also true of the PNT coding scheme (Table 56.1). For the 2011 study, we subdivided the semantic error corpus by means of expert and normative judgments.

Separate counts of taxonomic and thematic errors were derived for the 86 aphasic individuals who participated, and their shared variance was regressed out of each measure. For both measures, we also regressed out the shared variance attributable to performance on a semantic comprehension test with a high requirement for semantic control (*Camel and Cactus Test* or CCT; Bozeat, Lambon Ralph, Patterson, Garrard, & Hodges, 2000; Jefferies & Lambon Ralph, 2006). We then conducted separate VLSM analyses on each of the dependent measures.

As expected, taxonomic errors ($N = 645$) predominated over thematic errors ($N = 134$). Many patients made all or mostly taxonomic errors, but none did the reverse. Anatomically, however, there was a clear taxonomic-thematic double dissociation (Figure 56.2). Taxonomic errors localized to the left anterior temporal lobe, including clusters of supra-threshold voxels in

FIGURE 56.2 (A–C) The VLSM t -maps for *taxonomic semantic errors*, residualized for thematic semantic errors and for a measure of semantic comprehension. (D–F) The map for *thematic semantic errors*, residualized for taxonomic errors and semantic comprehension. Both maps were thresholded at a false discovery rate correction, $q = 0.02$; critical t -value for taxonomic errors was 3.58 and critical t -value for thematic errors was 3.66. Maps are rendered on the MNI-space Colin27 template, at x -coordinates $X = -60$ (A, D); $X = -56$ (B, E); $X = -52$ (C, F). (Redrawn from Schwartz et al. (2011)).

temporal pole (BA 38) and anterior portions of the middle and inferior temporal gyri (BA 20 and BA 21). Thematic errors, in contrast, localized to left temporoparietal cortices (TPCs), with the largest concentration of supra-threshold voxels in the angular gyrus (BA 39).

The ATL and TPC regions identified in these analyses are known from both neuropsychological and neuroimaging research to play important roles in multimodality semantic processing. Both have been cited as possible semantic “hubs” or high-level “convergence zones” (Binder & Desai, 2011; Binder, Desai, Graves, & Conant, 2009; Damasio, Tranel, Grabowski, Adolphs, & Damasio, 2004; Patterson, Nestor, & Rogers, 2007). However, because the analyses by Schwartz et al. (2011) statistically controlled for semantic comprehension, the implication for cognitive theory would seem to be that taxonomic and thematic semantic errors arise at a level of the production system that does not share resources with semantic comprehension. This goes along with the model’s claim that semantic errors arise subsequent to semantic processing in the course of retrieving the correct word.

Schwartz et al. (2011) suggested that the anatomical double dissociation between taxonomic and thematic errors might be evidence of complementary semantic hubs in ATL and TPC, the former specialized for taxonomic (similarity) relations and the latter specialized for thematic (contiguity) relations. Although there is

some supporting evidence for this position (Kalénine et al., 2009; Mirman & Graziano, 2012), much more research is required to establish whether the ATL and TPC process complementary semantic information, and whether these regions are best conceived as multimodality convergence zones or amodal hubs (Binder & Desai, 2011; Patterson et al., 2007). Schwartz et al.’s (2011) finding that regions within the left ATL and left TPC are uniquely or disproportionately concerned with semantically driven production would seem to argue for modality specificity, at least within left hemisphere sectors of these bilateral networks (for related evidence and discussion, Schwartz et al., 2009; Walker et al., 2011). However, Ueno, Saito, Rogers, and Lambon Ralph (2011) have proposed an alternative account of the ATL locus of semantic errors in naming that may be compatible with the amodal account of ATL semantics.

Finally, we return to the suggestion that the TPC is involved in executive control, and that the production of thematic errors in naming is symptomatic of an inability to access semantic processing in accordance with task demands. Two pieces of evidence in the Schwartz et al. (2011) study argue against this interpretation. First, regressing out the shared variance with CCT scores controlled for deficits in task-appropriate semantic selection affecting comprehension. Second, the study also included a VLSM of semantic

circumlocution errors (e.g., apple → “they’re crunchy to eat”). From a semantic control perspective, circumlocutions and thematic errors are both “off task” (circumlocutions describe rather than name the object; thematic errors express a frequent associate). Nevertheless, the VLSM findings indicate that circumlocutions are cognitively closer to taxonomic errors in that they strongly localize to the ATL. These data oppose the view that the left TPC subserves semantic control in a task general manner. Either it plays no role in semantic control or its role is modulated by task (production rather than comprehension) and the type of semantic information that is regulated.

As we noted, the study by Schwartz et al. (2011) of semantic errors confirmed the model’s claim that these errors arise at a postsemantic, production-specific stage of lexical access. It reached this conclusion by controlling for alternative sources of semantic errors. However, insofar as all of these alternative sources contribute to observed semantic error counts, we would expect them to be absorbed into the fitted *s*-weight (hereafter, *s*) parameter and reflected in lesion sites that correlate with *s*. We examined this as part of a recent investigation of the lesions that correlate with the model parameters (Dell, Schwartz, Nozari, Faseyitan, & Coslett, 2013). We found that the voxels that correlated with *s* were widely distributed in the left hemisphere; in addition to ATL and TPC, there was a large concentration of such voxels in the prefrontal cortex (middle and inferior frontal gyri). Whether these prefrontal regions are part of a large distributed semantic-feature network or play a specific role in semantic control is a question for future research. What is clear, though, is that *s* itself is affected by processing at the semantic level in addition to the production-specific mapping from semantics to words.

56.4 SUMMATION DUAL-ROUTE MODEL OF REPETITION

This section takes a detailed look at the model’s account of phonological errors in naming and its close relative, repetition. As in the discussion of semantic errors, we start by describing the relevant components of the model and how the implemented model was used to fit data from patients, followed by examination of the neural loci for the parameters fit by the model.

In the development of the interactive two-step model, naming and repetition have been linked through the assumption that the model’s second step (lexical-phonological retrieval) is used in both; therefore, for a given patient, the status of lexical-phonological retrieval in naming (as indexed by the proportion of phonological errors, or by the fitted

p-weight, hereafter, *p*) should be predictive of his or her accuracy in repeating words. This claim has been tested in multiple single case and case series model-fitting studies (Dell et al., 1997; Hanley, Dell, Kay, & Baron, 2004; Martin, Dell, Saffran, & Schwartz, 1994; Nozari, Kittredge, Dell, & Schwartz, 2010), resulting in successive refinements of the model and the theory of repetition that frames it.

The current model instantiates a *summation dual-route* theory of repetition. Words are repeated via a lexical route and a nonlexical route. The lexical route corresponds to step 2 in the naming model; the nonlexical route is contained in the connections from auditory input directly to the output phoneme units. Activation generated over both routes combines in the phoneme units to generate the final response.

An example will make the summation dual-route model’s mechanisms and parameters more concrete. Let us start with the patient whose error pattern in naming is given in Table 56.2. This individual makes many nonword errors in naming (0.30). In the model, these errors can only arise during the retrieval of phonological units; therefore, a high rate of such errors suggests difficulty in lexical-phonological retrieval or in other processes involving sublexical units. The low value of the fitted *p* parameter (0.016, where more than 0.040 is normal) captures this difficulty in the model. If word repetition were performed using the lexical route alone, then we would expect that this individual would make a comparable number of nonword errors in that task as well, because lexical-route word repetition is, in the model, nothing more than the second step of naming. We can use the model to make this prediction precise by running just that step of the model using the *s* and *p* parameters determined from the person’s naming performance:

(3) Predicted word repetition from lexical route model for sample patient:

Correct	Semantic	Formal	Mixed	Unrelated	Nonwords
0.65	0.00	0.07	0.01	0.00	0.27

Notice that the predicted proportion of nonwords for this patient from this model of repetition is similar to what it was for naming (Table 56.2). It turns out, though, that a pure lexical-route approach to repetition does not work in this case. The individual’s actual word repetition is considerably better than predicted:

(4) Obtained word repetition:

Correct	Semantic	Formal	Mixed	Unrelated	Nonwords
0.95	0.00	0.01	0.00	0.00	0.04

Thus, it is possible that a nonlexical route to repetition is contributing to word repetition. We can show this by first measuring the effectiveness of this person's nonlexical route, and then by using the model to see if that route can explain the good repetition performance.

To measure the nonlexical route, we test the individual's ability to repeat nonword stimuli that are of similar phonological complexity as the naming targets. This yields:

(5) *Obtained nonword repetition:*

Correct	Lexicalization Errors	Nonword Errors
0.37	0.33	0.30

Notice that repetition of nonwords is considerably worse (0.37 correct) than words (0.95 correct), a consistent finding in aphasia that demonstrates at least some lexical contribution to word repetition. Because of this fact, we know that the nonlexical route cannot alone explain word repetition ability.

Next, we set up the model so that it has a nonlexical route to repetition, that is, connections between the auditory representation of the stimulus and phoneme nodes that mediate its production (e.g., as in Hanley et al., 2004). Specifically, we make the strength of these connections (the model's nl parameter) just as strong as necessary to simulate the patient's nonword repetition ability:

(6) *Predicted nonword repetition ($nl = 0.026$; $s = 0.020$; $p = 0.016$):*

Correct	Lexicalization Errors	Nonword Errors
0.36	0.22	0.42

Now, we can finally simulate dual-route word repetition by running the model so that it combines the activation generated by the lexical route and that coming from the nonlexical route:

(7) *Predicted word repetition from summation dual-route model ($nl = 0.026$; $s = 0.020$; $p = 0.016$):*

Correct	Semantic	Formal	Mixed	Unrelated	Nonwords
0.91	0.00	0.02	0.00	0.00	0.07

In this case, the predicted repetition (0.91 correct) is quite close to what was obtained (0.95), thus supporting the dual-route approach to repetition.

The dual-route model of word repetition has been tested in studies that have duplicated the steps that we just illustrated with actual patient samples (Abel, Huber, & Dell, 2009; Dell, Martin, & Schwartz, 2007). In these studies, word repetition performance is often better predicted by the dual-route than a pure lexical route, or pure nonlexical route model. Moreover, the assumption that the two routes sum to create the output (Hillis & Caramazza, 1991) appears necessary to explain the findings of Nozari et al. (2010). They found that in a large group of patients, the contribution of the nonlexical route was strong enough to reduce the rate of nonword errors in repetition (in comparison to naming), yet its contribution did not detract from the strength of the lexical frequency effect. By this we mean that in repetition, just as in naming, low-frequency targets elicited more nonword errors than high-frequency targets; the difference for high- versus low-frequency targets was as large for repetition as for naming.

56.4.1 Behavioral and Neural Predictors of Dual-Route Model Parameters

The essential claim of the dual-route model is that word repetition is achieved by the sum of activations over the lexical route (largely determined by parameter p) and the nonlexical route (parameter nl). Thus, aphasics' success in repeating words should be predicted primarily by nl and p . Dell et al. (2013) tested this prediction with data collected from 103 patients. They developed a regression model with word repetition accuracy as the dependent variable, and parameters, p , nl , and a variety of neuropsychological measures (nonverbal semantic comprehension, verbal semantic comprehension, short-term memory, apraxia of speech) as independent variables.² The resulting model had adjusted $R^2 = 0.61$, with strong and significant contributions from both model parameters, nl and p . nl independently contributed 14% of the variance explained; p independently contributed 5%, a smaller but significant value. A composite measure of verbal semantic comprehension also contributed a small amount to the model, demonstrating an indirect influence of semantics on repetition, a result expected from the interactive property of the model. None of the other variables was significant.

When Dell et al. (2013) used the same dataset to explore the relationship between p and nl , they found an association between the parameters ($r = 0.46$) that was not expected. The model assumes that each parameter indexes the strength of a different set of

²All of the behavioral and lesion-mapping analyses performed by Dell et al. (2013) involving fitted parameters used the square-root transform of the values, which made parameter variation more equal across the scale and also made the distributions more normal.

weights, and that each set of weights can be damaged independently of the others. This assumption holds for s and p : these parameters were indeed uncorrelated in this data set. However, the scatterplot relating p and nl revealed that patients with weak p -weights also tended to have weak nl weights, and there was a notable lack of patients with low values of nl (reflecting poor non-word repetition) who had high values of p .

To further explore this association between the parameters, as well as the contributions of other psycholinguistic and neuropsychological measures in our test battery, Dell et al. (2013) conducted regressions with each parameter as the dependent variable. They found that the sole (positive) predictors of nl were parameter p and auditory discrimination. p was predicted positively by nl and negatively by the presence of speech apraxia (i.e., presence of apraxia predicts low values of p [weak p -weights] reflecting many non-word errors). These results suggest that the nonlexical repetition route, whose strength is indexed by nl , reflects a production ability that is shared with parameter p , along with the ability to process auditory input. The association of low p with speech apraxia indicates the involvement of some sort of articulatory motor process in the mapping from words to phonemes.

These relationships have been further studied with VLSM (Schwartz, 2014; Schwartz, Faseyitan, Kim, & Coslett, 2012) and voxel-based lesion-parameter mapping (VLPm; Dell et al., 2013). “Symptom” in this context refers to one of the response proportions generated from naming or repetition. “Parameter” refers to the values of s , p , or nl that the model assigns to individuals based on their response proportions.

Parameters reflect the overall response distribution in ways that can be quite complex, so it is of interest to know how the two sets of results compare. The VLSM and VPLM analyses of phonological processes tell a similar story, and so we restrict the present discussion to the VLPm results reported by Dell et al. (2013).

Figure 56.3 shows the voxels whose damaged status predicted the values of the p and nl parameters in the study by Dell et al. (2013). The two lesion maps overlap substantially, with most of the shared voxels occupying the anterior, inferior parietal lobe (supramarginal and postcentral gyri). Voxels unique to nl were found in superior temporal auditory regions, specifically STG, the posterior third of the planum temporale, and the cortex at the juncture of the parietal and temporal lobes, including area Spt. Voxels unique to p occupied more superior regions of the parietal lobe along with portions of the insula, which is considered important for speech articulation (Dronkers, 1996). Notice how these findings accord with the previously presented behavioral data in which the values of nl and p were positively correlated, but nl was uniquely predicted by auditory discrimination and p was uniquely predicted by the presence/absence of apraxia. Dell et al. (2013) also identified the voxels associated with word repetition, and these were found to be closely associated with the nl and p voxels, as expected from the dual-route approach to word repetition. To be specific, the dual-route model predicts that word repetition should be most closely related to the sum of the nl and p parameters, because the model’s output sums nonlexical and lexical sources of activation. Figure 56.4 illustrates the close similarity between

FIGURE 56.3 VLPm analyses of p -weight (red-yellow scale) and nl -weight (light blue to dark blue), both thresholded at a false discovery rate correction ($q = 0.05$), rendered on the MNI-space Colin27 template. The critical t -value for p -weight is 2.69, and for nl -weight it is 2.97. (A) A sagittal slice at MNI coordinate $x = -54$. (B) A coronal slice at MNI coordinate $y = -28$. (Based on data reported in Dell et al. (2013) with permission from the publisher (Elsevier)).

FIGURE 56.4 Lesion masks derived from the VLSM analyses of repetition accuracy (in red) and the VLSM analysis of $sum\ nl + p$ (in blue; overlap shown in green). Statistical maps used to create masks were thresholded at a false discovery rate correction ($q = 0.05$) and rendered on the MNI-space Colin27 template. The critical t -value for repetition accuracy was 2.42 and for $sum\ nl + p$ it was 2.69. Sagittal slices are at MNI coordinate $x = -54$, $x = -46$, $x = -38$; coronal slices are at MNI coordinate $y = -28$. (From Dell et al. (2013) with permission from the publisher (Elsevier)).

repetition voxels and those that associated with the $nl + p$ sum.

Parameter p is not just associated with word repetition, though. Recall that it is derived from naming, not repetition. Specifically, in the model, p indexes step 2 of the lexical access process in naming, as determined largely on the basis of phonemic errors. It should come as no surprise, then, that a VLSM of phonemic errors in naming yielded a map very similar to the one shown here for p (i.e., centered on frontoparietal sensory-motor cortices) (Schwartz et al., 2012). What is puzzling, though, is that p was not found to be associated with Wernicke's area and surrounding posterior temporal and TPCs that are the long-hypothesized locus for lexical-phonological forms (Wernicke, 1874/1969; and more recently, Graves, Grabowski, Mehta, & Gupta, 2008; Indefrey & Levelt, 2004; Wilson, Isenberg, & Hickok, 2009). We explore this again in the following section of this chapter. First, though, we consider the implication of these findings for the model itself.

We learned from the regression and lesion mapping analyses that parameters nl and p are not as separate as the model originally claimed. On this basis, Dell et al. (2013) suggested a revision of the model that expands both p 's and nl 's functions such that they have a common function and distinct ones. The common function includes phonological representation. In the implemented model, the units of phonological representations were phonemes. However, finding that the p - nl overlap localizes to parietal cortices (supermarginal and postcentral) generally associated with sensory-motor processes invites speculation that phonological representations have a sensory motoric character (Gow, 2012). This is not inconsistent with linguistic theory, where the role of audition and articulation in shaping phonological generalizations is readily acknowledged (Cole & Hualde, 2003). Moreover, the theory of articulatory phonology (Browman &

Goldstein, 1992) assumes that phonological forms consist of temporally coordinated gestures rather than abstract discrete segments. This approach to phonology is increasingly being used to interpret both linguistic and psycholinguistic data (Goldstein, Pouplier, Chen, Saltzman, & Byrd, 2007).

The distinct functions of nl and p also appear to be grounded in sensory-motor processes: nl 's distinct function includes the auditory processing of speech and its translation into phonological units, whereas p 's distinct functions include the mapping from lexical forms to phonemes (i.e., the original p -weights) and aspects of articulation. The partial sensory-motor characterization is supported by nl 's positive association with auditory discrimination ability and the association of apraxia of speech with low values of p .

Dell et al. (2013) also discussed the necessity of revising the model's treatment of the s parameter in light of the broadly dispersed temporal and frontal areas comprising the lesion map for s (see their Figure 7). They suggested that s not only is the lexical-semantic connections but also includes semantic representations and processes that control them. This treatment of s retains the original model's claim that s is a separate parameter from p , as supported by the finding of no correlation between the parameter values and little similarity in their brain maps.

56.5 IMPLICATIONS FOR NEUROCOGNITIVE MODELS OF LANGUAGE

The model's account of cognitive processes in naming and repetition and the lesions that compromise those processes have much in common with the Dual Stream theory (Hickok & Poeppel, 2004). In particular, the distribution of nl and p is consistent with the

dorsal route's central role in the repetition of non-words (here, represented by *nl*) and words (both *nl* and *p*). More specifically, we propose that *p* and *nl* together represent the action of the dorsal stream and its role in the repetition of verbal stimuli (Baldo, Katseff, & Dronkers, 2012; Buchsbaum et al., 2011; Fridriksson et al., 2010; Hickok & Poeppel, 2004). The dorsal stream is largely distinct from the processing associated with parameter *s*, which indexes semantic processes (in the ventral stream) and their use during production. Given that parameter *p* is derived solely from performance in the naming task, this means that the part of the dorsal stream associated with *p* plays an important role during language production from meaning.

To flesh out this proposal, we now turn to two recent models that extend the Dual Stream framework in ways that make useful contact with the present approach. The *Lichtheim2 model* of Ueno et al. (2011) and Hickok's (2012, 2014) *hierarchical state feedback control* (HSFC) model are computational, neurally specified models that deal with both word retrieval from meaning and repetition of phonological forms. Each has points of convergence with the models and data presented in this chapter.

The *Lichtheim 2 model* of Ueno et al. (2011) is a multi-levelled parallel-distributed processing (PDP) model of language that links model processes with dorsal and ventral pathways in the brain. The name, Lichtheim 2, reflects the fact that this model, like its namesake, is concerned with the major aphasia syndromes. Ueno et al. trained the model to name, comprehend, and repeat a large set of words, after which they lesioned it at different points along its dorsal and ventral route to simulate the qualitative profiles of impaired and spared task performance typical of BA, WA, and CA.

To appreciate how Lichtheim 2 relates to our model, some further details are necessary. In Ueno et al.'s implementation, the dorsal path includes auditory cortex and surrounding areas, the inferior SMG, and insular-motor cortex. The ventral path also links auditory and insular-motor cortex, but through the temporal and frontal lobes. The model's connections link the various layers of these pathways, and their strengths are learned through training. To repeat words, the model learned to map from the auditory input to motor output layers; to produce them, it learned to map from the semantic layer (associated with the ventral anterior temporal lobe) to motor output. Because of the model's learning algorithm and its interactive architecture, which allows for activation to flow bidirectionally, both the dorsal and ventral paths contribute to both repetition and naming. Nonetheless, there is some specialization in the paths. The dorsal path is more important for the systematic mapping between

sound and articulation, whereas the ventral path is specialized for the unsystematic mapping between word meaning and word form.

Lichtheim 2's dorsal pathway specialization makes it well-suited for explaining our finding that *nl* and *p* mapped to dorsal stream areas, and particularly the SMG, which the Lichtheim 2 model associates with extracting and representing the statistical structure shared between speech sounds and phonotactics. Moreover, the role of *p* in naming is expected in that model from the fact that the dorsal path also makes a contribution to naming. The model also provides a good account of our finding that parameter *s* is strongly associated with temporal and frontal cortex. Finally, the fact that verbal semantic ability has a positive effect on word repetition is expected from the interactive property of the model.

Hickok's (2012, 2014) HSFC model links psycholinguistic approaches to production theories of motor control in speech. Word forms are retrieved and spoken through a control network involving phonological targets at both the syllable and phoneme level; the control network involves corresponding motor programs for these units and acoustic and somatosensory feedback to the target representations (Guenther, 2006). The crucial part of the HSFC model for our purposes is that it hypothesizes different brain circuits for programming syllable and phoneme-level units. The retrieval of whole syllable units involves a mapping between Wernicke's area (pSTG), which contains auditory syllable targets, and BA44, which is part of Broca's area containing syllable motor programs. Retrieval of phoneme units proceeds through the anterior supramarginal gyrus, which contains somatosensory phoneme targets, to vBA6-M1 for phoneme motor programs.

The HSFC model's phonemic control circuit corresponds well with our lesion map for *p* and with the overlap of *p* and *nl*. Parameters *p* and *nl* derive largely from phonemic errors, that is, responses such as "cap" or "cag" for CAT. So the fact that these parameters are more in line with the phonemic control circuits than with the syllabic control circuits supports this fundamental division in the HSFC model and associates its sensorimotor representations of phoneme targets with phonological error production. This allows us to explain why these parameters mapped to parietal regions rather than to Wernicke's area.

56.6 CONCLUSION

The central notion of this chapter is that data from aphasia provide a key link between behavioral studies of speech errors and neurocognitive models of

language production. We reviewed how patterns of slips by unimpaired speakers led to models that identified representations and processing mechanisms in production. These models were then made concrete by developing computational implementations, such as our interactive two-step model. Once these computational models had been set up to explain speech error patterns, they could be altered (or “lesioned”) to explain aphasic error patterns. Our model incorporates a two-step lexical access process and a nonlexical process for accessing phonology directly from auditory input. It attributes the variety of aphasic error patterns to variation in model parameters: the semantic (*s*), phonological (*p*), and nonlexical (*nl*) parameters. In a final step, we have mapped the lesions that correlate with error patterns and parameters in large numbers of individual patients to link model processes with brain areas.

Results of these studies have ramifications for contemporary neurocognitive accounts of language and brain. For example, we identified regions of the left anterior temporal and temporoparietal regions where lesions disrupt semantically driven word production (step 1 retrieval) over and above their impact on semantic comprehension. Lesions in these regions render the system vulnerable to mis-selection of words that share a categorical (anterior temporal region) or thematic (temporoparietal region) relation to the target. These regions may be part of complementary semantic hubs for language. They are also part of the ventral pathway for language, showing that, in addition to its well-established role in comprehension, the ventral route makes an essential contribution to the retrieval of words based on their meaning.

Lesions in the dorsal brain pathway also compromise the production of words from meaning (e.g., naming), but here the disruptive effect of lesions centers on step 2 processes. We found that parameter *p*, which indexes step 2 processes in naming and repetition, correlated with lesions in the left frontoparietal cortex and insula. The lesion map for *nl*, which indexes the nonlexical contribution to repetition, overlapped with *p* in postcentral and supramarginal gyri and extended into posterior dorsal route sectors in Spt and STG. We propose that the area of overlap identifies the brain’s representation of phonological units accessed in production and that its anterior parietal distribution indicates that these representations might have a sensory-motor character.

Like all methods, ours have their limitations. From one perspective, the case series on which we based the analyses are too restrictive. Limiting the sample to patients with stroke aphasia guaranteed poor lesion coverage in areas such as the inferior temporal lobe and fusiform gyrus. These areas have been implicated

in lexical-phonological retrieval (DeLeon et al., 2007; Lüders et al., 1991) but are generally spared in aphasia-producing strokes. Thus, our methods may underestimate the contribution to aphasic speech errors from these (and other) underpowered brain regions.

From another perspective, our case series samples may suffer from being overly inclusive. By grouping together evidence from patients of all different types, our analyses may have obscured differences in the mechanisms and corresponding lesion sites of phonological errors produced by patients with CA versus BA, for example (Romani & Galluzzi, 2005). This goes back to the long-standing debates about the relevance of the clinico-anatomical model, with which we began the chapter. However, there is good reason to be optimistic that the resolution to these debates is within reach. Case series methods can accommodate increases in *both* breadth and depth of analysis (i.e., broader lesion coverage and examination of effects in different subgroups; Schwartz & Dell, 2010). The limiting factor is sample size, but the expansion of institutional recruitment infrastructures and multisite collaborations makes this a surmountable problem. The most important reason for optimism is the range of sophisticated tools that are available to aphasia researchers today. Our group’s work exemplifies the application of computational modeling and voxelwise mapping of model-defined symptoms and processing parameters. Others are correlating behavioral deficits with fMRI and with a multimodal characterization of tissue damage (e.g., structural damage, hypoperfusion, and/or white matter connectivity: Crinion, Warburton, Lambon Ralph, Howard, & Wise, 2006; Fridriksson et al., 2010; Han et al., 2013; Hillis et al., 2001; Turken & Dronkers, 2011). These advances in the neurocognitive characterization of impaired language complement neuroimaging studies of normal performance, making aphasia research as central to theory development today as it has been historically.

Acknowledgments

Preparation of this chapter was supported by grant RO1 DC000191-32 from the National Institute on Deafness and Other Communication Disorders (NIDCD), National Institutes of Health (NIH).

Motor-Timing and Sequencing in Speech Production

A General-Purpose Framework

Sonja A. Kotz^{1,2} and Michael Schwartze¹

57.1 FORMAL AND TEMPORAL PREDICTION: FUNDAMENTALS IN SPEECH PROCESSING

The primary purpose of language in general and speech in particular is to communicate meaning. Yet, whatever constitutes the meaning of an utterance, it is conveyed in the form of an acoustic signal that uses spectral and rhythmic variations of sound to transmit respective information. Speech rhythm is a trivial phenomenon in this regard. However, speech rhythm is a much more complex phenomenon in every other respect. Accordingly, just as there are different concepts of meaning in linguistics, there are different notions of rhythm, which already diverge in the way they reflect on a rhythm's inherent temporal structure (Martin, 1972). In the first instance, basic forms of rhythm in speech should be differentiated from meter (i.e., variations at the syllabic level such as the alternation of stressed and unstressed syllables). Further, rhythm is not synonymous with regularity because any temporal pattern—even a random one—may be considered rhythmic as long as it does not prevent perceptual grouping (Repp, 2000). Somewhat avoidant of the ubiquitous discussion of temporal regularity, Fraisse (1982) simply noted that there is rhythm if we can predict on the basis of what is perceived. In other words, predictions concerning future events, based on past events, are considered inherent to the concept of rhythm (Martin, 1972). This line of thought shifts the perspective of rhythm and timing from a descriptive level to psychological and functional interpretations of

rhythmic variation, including a neurofunctional assessment of rhythm and prediction in speech processing.

Generally speaking, the ability to form predictions based on rhythmic features is equally important for both speech production and perception. It bears the potential for allowing an individual to anticipate what will happen and when it will happen, and to adapt its behavior not only appropriately but also in an anticipatory fashion. As such, prediction is more and more recognized as one of the primitives of brain function and in opposition to a reflexive operating mode (Arnal & Giraud, 2012; Friston, 2012; Friston, Kilner, & Harrison, 2006; Raichle, 2010).

Prediction is crucial for the adequate selection and identification of behavior (“what dimension”), as well as for the optimal timing of behavior (“when dimension”). However, although prediction plays a role in both dimensions, it is necessary to accentuate the fundamental difference between them, such as the fact that it is entirely possible to generate predictions that specify the type of future events independent of predictions that specify the timing of the very same events. For example, when an utterance such as “Good morning, ladies and . . .” is expressed, a listener can use past acquired knowledge to predict the completion of the utterance by “gentlemen.” This specific type of prediction has become a standard in language research in the form of cloze probability testing (Taylor, 1953). Yet, at the same time, the listener can rely on past knowledge to predict when this particular speech event will occur. Dependent on intentional and/or contextual parameters that ultimately impact

on speech tempo, the respective time point when this speech event will occur may differ considerably. In other words, predictive mechanisms can build on prior knowledge and coherent information about the type or form of speech events (i.e., the formal structure of events) and/or prior knowledge and coherent information about their temporal arrangement (i.e., the temporal structure of events). Naturally, these processes should go hand-in-hand to achieve successful speech processing.

The example illustrates that both formal and temporal predictions are crucial in speech processing. Research along these lines led to detailed knowledge about the role of prediction, for example, in the identification of lexical speech events under normal or adverse listening conditions (Gagnepain, Henson, & Davis, 2012; Sohoglu, Pelle, Carlyon, & Davis, 2012). The underlying processes include a context-sensitive, predictive top-down component that guides lexical speech perception (Hannemann, Obleser, & Eulitz, 2007; Sohoglu et al., 2012; Strauß, Kotz, & Obleser, 2013). This predictive component implies prior knowledge that, to provide any substantial behavioral benefit, has to exploit some form of regularity extracted from the speech signal. However, the speech signal is flexible enough to convey various types of formal and temporal regularity at once. To infer meaning, speech processing may reveal itself equally flexible and capable of using different kinds of information as it becomes available.

57.2 A SYNCHRONIZED SPEECH PROCESSING MODE

Regularized formal structure may give rise to predictions at several levels of description, including segmental, semantic, or syntactic relations. In a similar vein, temporal structure may give rise to predictions at several timescales. In addition to the issue of hierarchical versus strictly serial order, this fact inevitably introduces the dimensions of weighting and granularity (i.e., leading to questions of whether predictions on one level or scale are more important than others and whether predictions are generated simultaneously at all of these levels). Moreover, as indicated, formal and temporal structure may interact across different levels to guarantee smooth processing and optimal behavior. This rather complex background rules out simplistic mappings between the two primary areas of interest, the speech signal and neural processes. Accordingly, recent years have seen a continuous increase in refined theoretical and empirical work that aims at linking these domains on the basis of oscillatory mechanisms (Ghitza & Greenberg, 2009; Giraud et al., 2007; Peelle

& Davis, 2012). This work provides support for functional links between specific properties of the speech signal and neuronal oscillations across different frequency bands. For example, it is considered that oscillations in the beta and gamma bands play a role in the processing of phonetic features, whereas the processing of syllables and words has been linked to oscillations in the theta band (Ghitza, 2012).

One of the novel concepts that emerge from this work is the so-called “theta-syllable” (Ghitza, 2012, 2013). The theta-syllable is defined as “a theta-cycle long speech segment located between two successive nuclei” (Ghitza, 2013, p. 5). The theta-syllable has been suggested to assume a function in speech decoding as part of a hierarchical window structure, which uses cascaded oscillations to synchronize with the input signal (Ghitza, 2013). As such, the concept of the theta-syllable seems largely compatible with the notion of a constant attempt to synchronize internal and external oscillations and to form predictions on the basis of “speech events such as the rhythmic succession of vocalic nuclei” (Kotz & Schwartz, 2010). Thus, in addition to the dimensions of weighting and granularity, the question arises regarding whether one particular rhythmic level may guide different processes, such as memory access or word segmentation (Ghitza, 2013), and/or the allocation of limited resources, such as attention during the perceptual integration of information retrieved from memory (Kotz & Schwartz, 2010; Schwartz & Kotz, 2013). Furthermore, one may speculate that the dissociation of formal and temporal structure also holds true in this specific case. That is, the proposed function of the theta-syllable embedded in a cascade of oscillations in speech decoding may be related to the processing of formal structure and the identification of specific elements in memory, whereas the more isolated oscillatory function in the allocation of attention may be related to the processing of temporal structure and the temporally predictive adaptation of behavior (Schwartz, Tavano, Schröger, & Kotz, 2012). However, although these accounts assign different functions to the same phenomenon, they both ground their reasoning in the multitier, syllable-centric perspective of speech processing proposed by Greenberg, Carvey, Hitchcock, and Chang (2003; Greenberg, 2006). This theory developed around the “STeP” (spectrotemporal profile), which depicts the fluctuation of acoustic energy across time and frequency that is associated with the syllable and the articulatory circle (i.e., the opening and the closing movements of the mouth during speech production). The energy level typically increases to a peak close to the syllabic nucleus, reflecting maximal oral aperture. Thus, the contour of the energy fluctuation approximates an arc, which extends from the syllabic onset

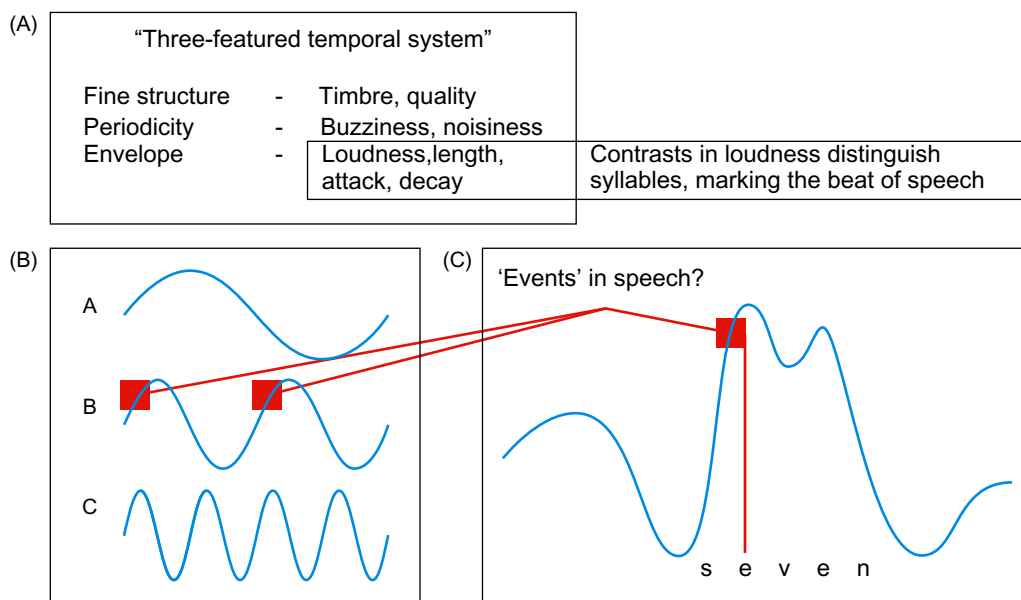

FIGURE 57.1 Different timescales in speech. Successive speech events such as phrases, words, syllables, or phonemes generate temporal structure at different timescales ranging from milliseconds to seconds. Physiological limits in temporal resolution set aside, the informational content of temporal structure may still be neglected at some scales, but it may contribute to successful speech processing on others. The value of temporal structure in this context probably varies with situational constraints. For example, the use of temporal structure may be more relevant under adverse conditions or, when perceived, regularity of temporal structure can be used to establish a predictive processing mode. Such a predictive mode may reflect a more general strive for optimal adaptation to a dynamic environment. It stands to reason whether there is a "default" scale that proves to be behaviorally most beneficial and, furthermore, whether auditory processing interacts with dedicated temporal processing at such a scale. To address these issues, the speech signal has to be decomposed on the basis of its temporal characteristics. [Rosen \(1992\)](#) suggests a "three-featured temporal system" (A) based on dominant fluctuation rates, which comprises fine structure, periodicity, and envelope levels. The envelope level (2–50 Hz) reflects acoustic features such as intensity, duration, rise and fall time, and their respective auditory correlates (loudness, length, attack, decay). A relative contrast in loudness distinguishes rhythmically prominent syllables, thus marking the "beat" of speech ([Kochanski & Orphanidou, 2008](#)). In a similar vein, [Tillmann and Mansell \(1980\)](#) propose a three-fold dissociation based on modulation rates into "ABC-prosody" (B). Slow modulations (A, melodic contour) and also fast modulations (C, intrinsic sound characteristics) convey a continuous impression, whereas intermediate rates are perceived as a series of pulses (B, rhythmic succession of syllables). This impression may be likened to a "perceptual beat" ([Port, 2003](#)) that occurs near the onset of vowels and that establishes a particularly salient event within a continuous speech stream. This notion is also central to the multitier framework introduced by [Greenberg \(2006\)](#), in which the nucleus of a syllable (especially stressed ones) sets the interpretational register for the whole syllable ([Greenberg et al., 2003](#)). Figure (C) is based on the time course of the so-called STeP (spectrotemporal profile; adapted from [Greenberg et al., 2003](#)), which has been derived from the energy contour of hundreds of individual realizations of the digit "seven." The relative increase in energy on or just prior to the peak in the vocalic nucleus may instantiate a distinct "event in speech" (red). Such events are the prime candidates for a nonlinear representation of the speech signal, and their scale and temporal structure may form the basis for an interaction between speech processing and dedicated temporal processing.

via the nucleus to the coda. The relative prominence of the nucleus, usually a vowel, is supposed to set a "register" for the decoding of other constituents of the speech signal. This functional interpretation of the STeP combines fundamental characteristics of speech production and speech perception in one cohesive conceptual framework. Accordingly, numerous links to other theories in both domains can be established.

Perhaps two of the more obvious points of contact exist in terms of the frame/content (f/c) theory of evolution of speech production ([MacNeilage, 1998](#); [MacNeilage & Davis, 2001](#)) and in work related to the so-called perceptual-center phenomenon (p-center; [Marcus, 1981](#); [Morton, Marcus, & Frankish, 1976](#)). Based on the dissociation of syllabic "frames" and segmental "content" elements, the former discusses the

role of a simple biomechanical mechanism, that is, the mandibular cycle, in the acquisition and evolution of speech ([MacNeilage & Davis, 2000](#)). Essentially, this "register" versus "other constituents" dichotomy and the "frame" versus "content" dichotomy suggest hierarchies that may complement each other in speech processing, whereas they are anchored at different temporal levels or scales ([Figure 57.1](#)). In other words, whereas the notion of a register implies one event per syllable, a syllabic frame is defined by two events. However, the critical aspect in terms of the current discussion is the fact that temporal predictions based on the former scale would be predictive of intersyllabic temporal relations in the sense of the theta-syllable, whereas the latter would be predictive of intrasyllabic temporal relations (i.e., the duration of a syllable).

In principle, such a distinction may be relevant for different concrete realizations of speech, for example, the dissociation of stress-timed and syllable-timed languages. At a more abstract level, however, this difference raises the fundamental question regarding when a speech event such as the syllable becomes perceptually salient—is it at the point of the physical onset, corresponding to the starting point of an articulatory cycle, its end, or at an intermediate point in time? At least for English, the aforementioned p-center phenomenon can be interpreted as pointing to the latter explanation.

The term p-center has been coined to describe “that what is regular in a perceptually regular sequence of speech sounds” (Marcus, 1981). The p-center marks the subjective moment, or point of occurrence, of an acoustic stimulus (Scott, 1998; Scott & McGettigan, 2012). Crucially, even for simple digit sequences, these points in time do not correspond to physical onset regularity (Morton et al., 1976). It is thus the perceived p-center regularity, rather than onset regularity, which may give rise to temporal predictions. In line with this proposal, Port (2003) discusses the p-center in the context of a neurocognitive system in which stimulus-driven internal oscillations create attractors in time for salient events. These, in turn, establish a framework for the processing of phonological units such as syllables and segments. One of the common denominators between such a system and the multitier framework based on the STeP is once more a hierarchical perspective of the speech signal and speech processing in which a particularly salient event sets the stage for the perceptual integration of other events. In terms of temporal structure, this perspective corresponds to a dissociation of a slower timescale or slower dynamic that guides processing on a faster dynamic timescale. A basic mechanism like this is probably not limited to speech perception. Likewise, it may be relevant in speech production in the sense that a speaker may involuntarily or voluntarily adjust slower dynamics to qualitatively adapt to the processing capacity of the listener. For example, regarding the p-center, speakers have been found to produce the asynchronies that are necessary to perceive a temporally regular sequence of speech events (Fowler, 1979). Moreover, on this basis, fundamental aspects of speech production and perception can be reflected on within a broader context (i.e., a communicative, general-purpose framework).

In previous work, we have discussed how the perceptual prominence of particular speech events, including the p-center, may serve to guide the predictive allocation of attention in time, which is expected to establish a “synchronized” and at the same time optimized speech processing mode (Kotz & Schwartz, 2010). From this integrative perspective, speech processing interacts with dedicated temporal processing

mechanisms in an extended subcortical network to efficiently exploit the temporal structure of speech (Kotz & Schwartz, 2010; Kotz, Schwartz, & Schmidt-Kassow, 2009; Schwartz, Tavano, et al., 2012). However, although the conceptual premise of this framework is equally applicable to perception and production, the primary focus, so far, has been on speech perception. In the following, we elaborate on its implications for speech production.

57.3 TIMING SPEECH: SUBCORTICAL INTERACTIONS

In this context, “temporal processing” refers broadly to the neural mechanisms that underlie the encoding, decoding, and evaluation of temporal structure. Neuroimaging research in this domain suggests several core anatomical substrates for temporal processing, including prefrontal cortical regions, the supplementary motor area (SMA), the basal ganglia (BG) and associated thalamocortical circuits, as well as the cerebellum (for recent reviews and a meta-analysis, see Allman, Teki, Griffiths, & Meck, 2014; Coull, Cheng, & Meck, 2010; Merchant, Harrington, & Meck, 2013; Spencer & Ivry, 2013; Wiener, Turkeltaub, & Coslett, 2010). It is important to note that these classical motor brain areas play a role in both the production and perception of temporal structure. A basic assumption in most of this research is that temporal processing engages some form of a specialized or dedicated system that is capable of representing the temporal relationship between events (Ivry & Schlerf, 2008). Another key aspect concerns the dissociation of event-based and interval-based mechanisms that have been proposed to rely primarily on the cerebellum and cortico-striato-thalamo-cortical loops, respectively (Buhusi & Meck, 2005; Spencer, Zelaznik, Diedrichsen, & Ivry, 2003). However, although temporal processing, articulatory processing, and auditory processing are naturally overlapping, the corresponding link is not particularly well-defined in terms of speech production.

As indicated, focusing on the temporal and essentially rhythmic nature of speech is more or less trivial if temporal structure is considered a mere by-product of “processing in time.” Yet, the preceding sections have provided strong arguments in favor of a different viewpoint. Thus, temporal structure is considered to represent a valuable source of information in its own right. Moreover, the use of temporal structure serves the overarching goal to optimize predictive timing of behavior. The consequences arising from this perspective pose a serious challenge to neurofunctional models of speech processing. Any such model is incomplete unless it provides an adequate explanation with respect to how the temporal structure of the speech signal is generated, how

it maps onto the temporal structure of neural processes, and how temporal information is used in predictive adaptation. Moreover, the immanent challenge of adding an explicit temporal dimension to the coordination between two dynamic systems (i.e., the acoustic signal and the brain) is further aggravated by the (at times) unspecific use of the term “temporal” in the context of speech processing, despite the fact that the time axis is the only common denominator across the various visual approximations that are typically used to capture the fleeting impression of the speech signal (McGettigan & Scott, 2012). However, there are some straightforward accounts (Schirmer, 2004) that discuss the putative connection between temporal processing and speech processing in a more detailed manner, for example, in terms of the cerebellar temporal processing system (Ackermann, Mathiak, & Riecker, 2007). The cerebellum and, more specifically, a right-cerebellar left-prefrontal loop have been proposed to play a specific role in the decoding of durational patterns in speech and nonspeech input in perception, and it appears to also engage in the temporal “shaping” of syllable templates in production (Ackermann et al., 2007). However, interactions between the cortico-striato-thalamo-cortical temporal processing system and speech processing are less specified, although it has been generally acknowledged as important to the ability to temporally structure the use of language and speech processing in particular (Allman et al., 2014; Buhusi & Meck, 2005).

The ability to temporally structure speech is, even though undoubtedly crucial, just a specific aspect of speech production. However, instead of summarizing in detail what is known about the neural correlates of speech production from neuroimaging research (for reviews and a meta-analysis, see Poeppel, Emmorey, Hickok, & Pylkkänen, 2012; Price, 2012; Scott, 2012; and Indefrey & Levelt, 2004, respectively), we focus on the proposed contribution of the dedicated temporal processing system to speech production. Likewise, we also refrain from an in-depth discussion of the well-documented role of the BG in motor control. Rather, on the basis of the preceding considerations, the goal here is to establish a functional link between theories in different domains that base their rationale on the same, or at least on overlapping, cortical and subcortical anatomical substrates (Figure 57.2).

Speech production is a complex multistage process linking intentions and conceptual ideas to articulation (Price, 2010). According to Levelt (2001), speech production involves processes of lemma selection, syllabification, and prosodification. These operate on the basis of a phonological code, which, in turn, comprises phonological segments that are incrementally inserted into a “morphological target frame.” Concatenated frames are then

expressed by means of appropriate articulatory gestures. However, to work efficiently, such processes require precise temporal coordination, because frames have to be “opened” and potentially “closed” or “filled” with segments differing in type as well as in number and “implemented.” Moreover, speech production is essentially a sensorimotor process; speakers constantly operate a dual system (Indefrey & Levelt, 2004). This means that production and perception develop at the same time, thus adding another dimension of spatial, that is, (neuro)anatomical as well as temporal complexity. Hence, it is important to again emphasize why two neighboring domains such as speech processing and temporal processing need to be linked while acknowledging the fact that the picture is far from complete and that ultimately a much more fine-grained dissociation will be necessary. However, whereas the ability to generate predictions to optimize behavior already establishes a common ground in terms of conceptual development in both domains, potential cross-fertilization is also evident at the physiological level. Notwithstanding the vast literature on functional and anatomical differentiation in classic speech processing areas such as Broca’s area or Wernicke’s area, this aspect can be illustrated using the example of the SMA, where the relationship to dedicated temporal processing is perhaps most obvious.

The SMA comprises at least two subareas, the more rostral pre-SMA and the more caudal SMA proper (Matsuzaka, Aizawa, & Tanji, 1992; Picard & Strick, 2001). The SMA proper is connected to the primary motor cortex, whereas the pre-SMA is densely connected with prefrontal regions (Akkal, Dum, & Stick, 2007). Activation of the SMA in speech production can be distinguished along a rostrocaudal gradient associated with lexical selection, linear sequence encoding, and the control of motor output, respectively (Alario, Chainay, Lehericy, & Cohen, 2006). In the context of the f/c theory, the SMA engages in the primary control of the speech frame (MacNeilage & Davis, 2001). This basic function in linear sequencing can be further differentiated with respect to more explicit temporal characteristics as well as in relation to other structures, including the BG. For example, Riecker, Kassubek, Gröschel, Grodd, and Ackermann (2006) discussed the role of the SMA as the “starting mechanism” of speech production. In a similar vein, the Directions Into Velocities of Articulators (DIVA) model of speech production (Guenther, 2006; Guenther, Ghosh, & Tourville, 2006) suggests that the SMA and the BG provide a “GO signal” that controls the speaking rate (Guenther & Vladusich, 2012). More specifically, Bohland, Bullock, and Guenther (2009) assign the encoding of structural frames at an abstract level to the pre-SMA, whereas the SMA proper plays a role in the initiation and release of planned speech

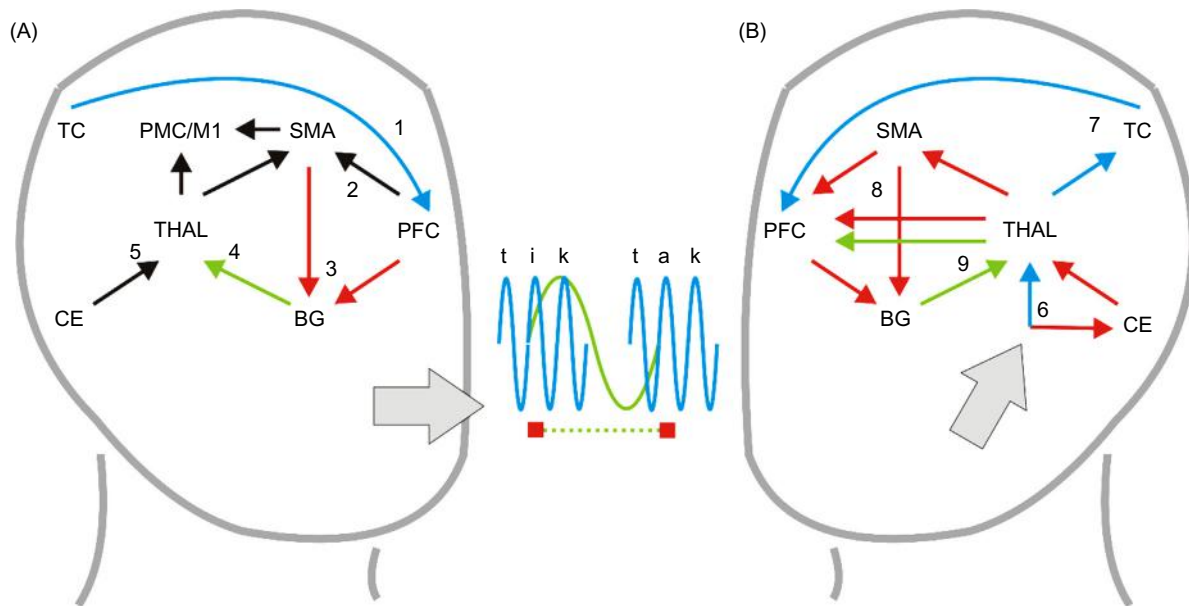

FIGURE 57.2 Schematic of the interaction of speech processing and dedicated temporal processing. (A) Once the decision to produce an utterance, that is, a time-varying sequence of speech events has been made (prefrontal cortex, PFC), speech production interacts with dedicated temporal processing in an extended subcortical network (for further discussion, see [Kotz and Schwartz, 2010](#)). In accordance with the intentions of the speaker, elements from memory have to be retrieved, sequenced, and produced. The retrieval of memory elements (1) engages connections between PFC and temporal cortices (TC, blue). Hierarchical sequencing mechanisms in the sense of (morpho-)syntactic operations specify the combination of these elements, thus generating the formal structure of the utterance. Dedicated temporal processing is part of linear sequencing mechanisms that specify the temporal structure of the utterance. For this purpose, the PFC calls on the SMA (2) and, more specifically, its rostral portion, the pre-SMA, as well as the BG and associated thalamocortical circuits. In concert, these structures establish a temporal “grid” (3) that determines the global temporal structure of an utterance (green). In other words, the dedicated temporal processing system functions as a “pacemaker,” that is, it provides a slower dynamic that serves as a reference for the subsequent, temporally precise shaping of faster dynamics and their actual implementation (4). The latter function engages the cerebellum and its connections to premotor (PMC) and primary motor (M1) cortices (5), and potentially also indirect connections to these areas via the caudal portion of the SMA (SMA proper). In line with the notion of a “spectrotemporal register” that holds the constituents of a syllable together ([Greenberg et al., 2003](#)), the pacemaker function maps onto the temporal structure expressed in the rhythmic succession of syllabic nuclei in the speech signal (i.e., the relation between “i” and “a” in the example). Similar mechanisms may be recruited during speech perception (B). Via its connections to the earliest stages of auditory processing, the cerebellar temporal processing system is expected to encode a temporally precise, event-based, nonlinear representation of temporal structure (6) that it rapidly transmits to frontal cortices, including the SMA, passing the thalamus (red). The ascending auditory pathway via the thalamus to the TC is expected to preserve a detailed representation of formal structure to guarantee stable memory access (blue). The nonlinear stimulus representation establishes a register for the perceptual integration (PFC) of elements retrieved from memory (7). However, it also serves as a trigger for oscillatory mechanisms (8) that explicitly encode the temporal relation between successive events, including the dedicated cortico-striato-thalamo-cortical temporal processing system (9, green). If the temporal relation between these events is perceived as regular, then the system may start to operate in a synchronized, predictive mode. On this basis (i.e., the separation of slower and faster dynamics), speech processing and dedicated temporal processing may interact not only to control the encoding of spatially distributed memory representations into a temporal sequence during speech production ([Lashley, 1951](#)) but also to optimize the processing of a sequential signal during speech perception.

acts. The pre-SMA then provides input to a planning loop involving the BG. Taken into a broader context, these functions may, to some extent, reflect the differential engagement of pre-SMA and SMA proper in temporal processing within, but also outside, the speech domain ([Kotz & Schwartz, 2011](#); [Schwartz, Rothermich, & Kotz, 2012](#)).

57.4 CONCLUSION

In the most general sense, the proposed role of the pre-SMA as part of a corticostriatal “pacemaker” relates

to establishing a slower temporal dynamic that guides the generation of faster temporal dynamics. While this function links speech processing and temporal processing, it also implies that speech processing builds on mechanisms that are essentially not domain-specific. Dedicated temporal processing is, per definition, a universal mechanism most likely serving the goal of optimizing predictive behavior. However, the integrative perspective discussed here offers a chance to ground speech processing in progressive general theories about brain function such as “predictive coding” ([Friston, 2005, 2012](#)) that build around a similar distinction and functional interaction of dynamics anchored at different

timescales to recover information from time-varying signals. In this context, speech processing may reveal itself as the most sophisticated time-varying signal that recruits temporal processing mechanisms to optimize production and perception.

Neural Models of Motor Speech Control

Frank H. Guenther¹ and Gregory Hickok²

¹Department of Speech, Language, and Hearing Sciences, Department of Biomedical Engineering, Boston University, Boston, MA, USA; ²Department of Cognitive Sciences, Center for Language Science, Center for Cognitive Neuroscience, University of California Irvine, Irvine, CA, USA

58.1 INTRODUCTION

Speech production is a highly complex motor act involving the finely coordinated activation of approximately 100 muscles in the respiratory, laryngeal, and oral motor systems. To achieve this task, speakers utilize a large network of brain regions. This network includes regions involved in other motor tasks, such as the motor and somatosensory cortical areas, cerebellum, basal ganglia, and thalamus, as well as regions that are more specialized for speech and language, including inferior and middle prefrontal cortex and superior and middle temporal cortex. Our goal in this chapter is to describe the critical role of the auditory system in speech production. We first discuss the role of sensory systems in motor control broadly and summarize the long history of ideas and research on the interaction between auditory and motor systems for speech. We then describe current research on speech planning, which strongly implicates the auditory system in this process. Two large-scale neurocomputational models of speech production are then discussed. Finally, we highlight some future directions for research on speech production.

Movement is absolutely dependent on sensory information. We know where and how to reach for an object because we *see* its location and shape; we know how much force to exert while we are holding the object because we *feel* the pressure of the object on our hand and the weight on our limb; and we know how to initiate any of these movements because our sensory systems tell us where our limb is in relation to our body and the object. British neurologist and physiologist Henry Charlton Bastian (1837–1915) wrote on the topic of movement control in 1887, stating, “It may be regarded as a physiological axiom, that all purposive movements of animals are guided by sensations or by afferent

impressions of some kind” (Bastian, 1887, p. 1). Experimental work over the decades backs these claims. This work has found, for example, that blocking somatosensory feedback from a monkey’s limb (while leaving motor fibers intact) causes the limb to go dead. With training, the monkey can learn to reuse it clumsily, but only with visual feedback; blindfold the animal and motor control degrades dramatically (Sanes, Mauritz, Evarts, Dalakas, & Chu, 1984). Similar symptomology can be found in humans suffering from large-fiber sensory neuropathy, which deafferents the body sense while leaving motor fibers intact (Sanes et al., 1984).

Speech is no different. Without the auditory system, as in prelingual-onset peripheral deafness, normal speech development cannot occur. Importantly, it is not just during development that auditory information is critical. Experimental or naturally caused manipulations of acoustic input can have dramatic effects on speech production. For example, delayed auditory feedback induces nonfluency (Yates, 1963), altering feedback in the form of pitch or the formant frequency structure results in automatic and largely unconscious compensation in speech articulation (Burnett, Freedland, Larson, & Hain, 1998; Houde & Jordan, 1998; Larson, Burnett, Bauer, Kiran, & Hain, 2001), and exposure to a different linguistic environment can induce changes in the listener-speaker’s articulation (picking up accents; Sancier & Fowler, 1997). Furthermore, although individuals who become deaf as adults can remain intelligible for years after they lose hearing, they show some speech output impairments immediately, including impaired ability to adjust pitch loudness in different listening conditions; over time, their phonetic contrasts become reduced (Perkell et al., 2000) and they exhibit articulatory decline (Waldstein, 1989).

The speech research literature contains numerous theoretical proposals that strongly link speech perception

and speech production. Notable examples include the motor theory of speech perception (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Liberman & Mattingly, 1985), which posits that speech perception involves translating acoustic signals into the motor gestures that produce them, as well as acoustic theories of speech production (Fant, 1960; Stevens, 1998), which highlight the importance of acoustic or auditory targets in the speech production process. In the following sections we elaborate on the roles of auditory information in recent neural models of speech planning and execution.

58.2 THE PLANNING OF SPEECH MOVEMENTS

Although it may seem obvious that auditory information is in some way involved in speech production—the lack of normal speech development in the absence of auditory feedback provides incontrovertible evidence of this—there has been much debate in the speech motor control literature over exactly what role(s) auditory feedback plays. Much of this debate revolves around the following central question: what exactly are the goals, or *targets*, of the speech production planning process?

To produce a goal-directed movement, the nervous system must generate a complex muscle activation pattern that satisfies the goals of the movement. For example, reaching to a target position in three-dimensional (3-D) space requires coordinated activation of muscles in the arm, wrist, and hand that move the hand in space to the target position. Various explanations have been put forth regarding how this complex task may be solved by the nervous system, ranging from a *motoric planning* extreme to a *task space planning* extreme. In a motoric planning solution, the nervous system translates the desired spatial position of the hand into a corresponding target in motoric terms, such as a set of joint angles or muscle lengths that place the hand at the appropriate position in 3-D space. Movement planning is then performed simply by interpolating between the current set of muscle lengths and the target set (Bullock & Grossberg, 1988; Rosenbaum, Engelbrecht, Bushe, & Loukopoulos, 1993; Rosenbaum, Loukopoulos, Meulenbroek, Vaughan, & Engelbrecht, 1995). In a task space planning scheme, the movement is planned in a reference frame that is much further removed from the musculature. In reaching, for example, a 3-D spatial reference frame may be used to plan a hand path to the target. Muscle activation patterns must still be generated to move the arm and hand, and different proposals for this transformation have been put forth. In one solution, the spatial movement *direction* needed to keep the hand moving along the planned spatial trajectory is transformed

into appropriate muscle *velocities* during the reach (Bullock, Grossberg, & Guenther, 1993; Guenther, 1992). An important consequence of this form of planning is that it does not involve a specific target configuration of the arm for a given spatial position of the hand.

To understand the planning of speech movements, the relationship between articulator configuration and acoustic signal must be understood. At any point in time, the 3-D shape of the vocal tract (i.e., the shape of the “air tube” that exists from the vocal folds to the lips) is determined by the locations of speech articulators such as the tongue, lips, jaw, larynx, and the soft palate (velum). This shape manifests itself in the speech signal as a set of peaks in the envelope of the frequency spectrum of the acoustic signal; these peaks are referred to as *formants*. Roughly speaking, the *first formant frequency*, or *F1*, corresponds to the degree of constriction formed by the tongue in the vocal tract, which in turn is closely related to tongue height. The *second formant frequency*, *F2*, is related to the location of the tongue constriction along the length of the vocal tract, with higher *F2* values corresponding to constrictions closer to the lips. These characterizations are rather crude “rules of thumb” that do not apply to all vocal tract configurations and leave out many important aspects of the relationship between speech articulation and acoustics. The relationships between the third and higher formant frequencies and vocal tract shape become increasingly complex and are not easily related to articulator positions.

Evidence from studies of speech movements indicate that speech sounds (e.g., phonemes or syllables) are not encoded as muscle length or articulator configuration targets (i.e., the speech motor system does not use a purely motoric planning strategy as defined). Instead, a large amount of variability is seen in the vocal tract configurations used to realize a particular phoneme. A stark example is the American English phoneme /r/. This phoneme is characterized acoustically by a deep dip in the third formant frequency; this formant frequency transition is highly consistent across phonetic contexts (Boyce & Espy-Wilson, 1997). Although the acoustic signal characterizing /r/ remains nearly constant, completely different articulatory gestures are used in the different contexts (Delattre, Freeman, 1968; Guenther et al., 1999; Nieto-Castanon, Guenther, Perkell, & Curtin, 2005). Figure 58.1 illustrates this articulatory variability. The top row shows tongue configurations at the start of /r/ production (dashed lines) and at the acoustic “center” of the /r/ (bold lines) when spoken by an American English participant in three different phonetic contexts (/ar/, /dr/, and /gr/). In the /ar/ context, the participant raises the tongue tip to produce the /r/. In the /dr/ context, the speaker uses a backward movement of the tongue. In the /gr/ context, the speaker uses a downward movement of the tongue.

FIGURE 58.1. Articulatory variability during American English /r/ production. Measured (top) and simulated (bottom) tongue movements during production of the phoneme /r/ when preceded by the phoneme /a/ (left column), /d/ (center), and /g/ (right), shown in the midsagittal plane. Outline of the palate is shown for reference. Each connected line (bold or dashed) represents a tongue configuration; each circular or square data point corresponds to the position of a movement transducer on the tongue (tongue tip on the left; dorsum in the center; back on the right). The gesture used to produce /r/ is represented by the transition between the dashed and bold tongue configurations. Entirely different tongue gestures are used by both the human subject and the model in the three contexts. Simulations of the DIVA model utilizing a common auditory target for the three contexts capture this articulatory variability. Adapted from Nieto-Castanon et al. (2005).

The articulatory variability seen for /r/ can be accounted for in a straightforward manner by a task space planning scheme in which the targets of speech are auditory rather than articulatory. The bottom row of Figure 58.1 shows the results of computer simulations of the Directions Into Velocities of Articulators (DIVA) model of speech motor control (Guenther, 1995a; Guenther, Ghosh, & Tourville, 2006; Guenther, Hampson, & Johnson, 1998; Guenther & Vladusich, 2012; Tourville & Guenther, 2011; described further) when producing /r/ in the three phonetic contexts. The same auditory target is used for /r/ in the three contexts, and articulator movements are planned in auditory space (see Nieto-Castanon et al., 2005 for details). This simple planning scheme accounts for the disparate tongue gestures seen in the three phonetic contexts, providing strong evidence for the use of an auditory planning space.

58.3 BRAIN REGIONS INVOLVED IN SPEECH ARTICULATION

Figure 58.2, adapted from Tourville, Reilly, and Guenther (2008), illustrates neural activity in the cerebral cortex and cerebellum during a simple speech task (monosyllabic word production) contrasted with

FIGURE 58.2. Neural activity in the cerebral cortex and cerebellum during production of monosyllabic words contrasted with a silent baseline. In the lateral views of the cerebral cortex (top panels), bilateral activity can be seen in the precentral gyrus of the frontal lobe, the postcentral gyrus of the parietal lobe, and the STG of the temporal lobe. Medial surfaces (middle panels) reveal activity in the SMA. Slices through the cerebellum (right column) indicate activity in the superior paravermal cerebellum, primarily in lobules V and VI. Additional activity in the basal ganglia and thalamus is not visible in this figure.

a baseline task of silently viewing letters. As in most speech production neuroimaging studies, activity is seen in the ventral precentral gyrus (motor and premotor cortex), ventral postcentral gyrus (somatosensory cortex), superior temporal gyrus (STG) (auditory cortex), supplementary motor area (SMA), and superior paravermal cerebellum (primarily lobules V and VI). Although not visible in Figure 58.2, the basal ganglia and thalamus are also active during speech. In the following sections we discuss the roles of these regions within the context of neurocomputational models of speech production.

58.4 NEUROCOMPUTATIONAL MODELS OF SPEECH PRODUCTION

The extensive library of results from neuroimaging studies provides important insights into the roles of a large number of cortical and subcortical areas in speech production. In isolation, however, these results do not provide an integrated, mechanistic view of how the neural circuits engaged by speech tasks interact to produce fluent speech. To this end, computational models that both suggest the neural computations

performed within specific modules and across pathways linking modules and propose specific neural correlates for these computational elements bridge this critical gap. Furthermore, these *neurocomputational* models lead to specific hypotheses that may be tested in both imaging and behavioral experiments, leading to a continuous cycle of model refinement that provides a unifying account of a wide range of experimental findings. We describe the DIVA model of speech motor control, which has been developed, tested, and refined by Guenther and colleagues over the past two decades, as well as an extension to that model, termed GODIVA, which begins to account for higher-level phonological processes involved in speech planning. Our discussion of neurocomputational models ends with a treatment of the Hierarchical State Feedback Control (HSFC) model of Hickok (2012), which addresses data from studies of conduction aphasia and internal correction of upcoming phonemic errors before they are articulated.

58.5 THE DIVA MODEL

The DIVA model, schematized in Figure 58.3, provides the most detailed and thoroughly tested account of the neural processes underlying speech motor control. Each box in the diagram corresponds to a set of neurons, or *map*, and arrows correspond to synaptic projections that transform one type of neural representation into another. The model learns to control movements of a simulated vocal tract that produces an acoustic signal (Maeda, 1990). The results of numerous computer simulations of the model have been shown to account for a wide range of findings regarding the brain activity, sound output, and movements produced by human speakers, as detailed elsewhere (Callan, Kent, Guenther, & Vorperian, 2000; Ghosh, Tourville, & Guenther, 2008; Guenther, 1995b; Guenther et al., 1999, 1998; Nieto-Castanon et al., 2005; Peeva et al., 2010; Perkell, Guenther, et al., 2004; Perkell, Matthies, et al., 2004; Tourville et al., 2008).

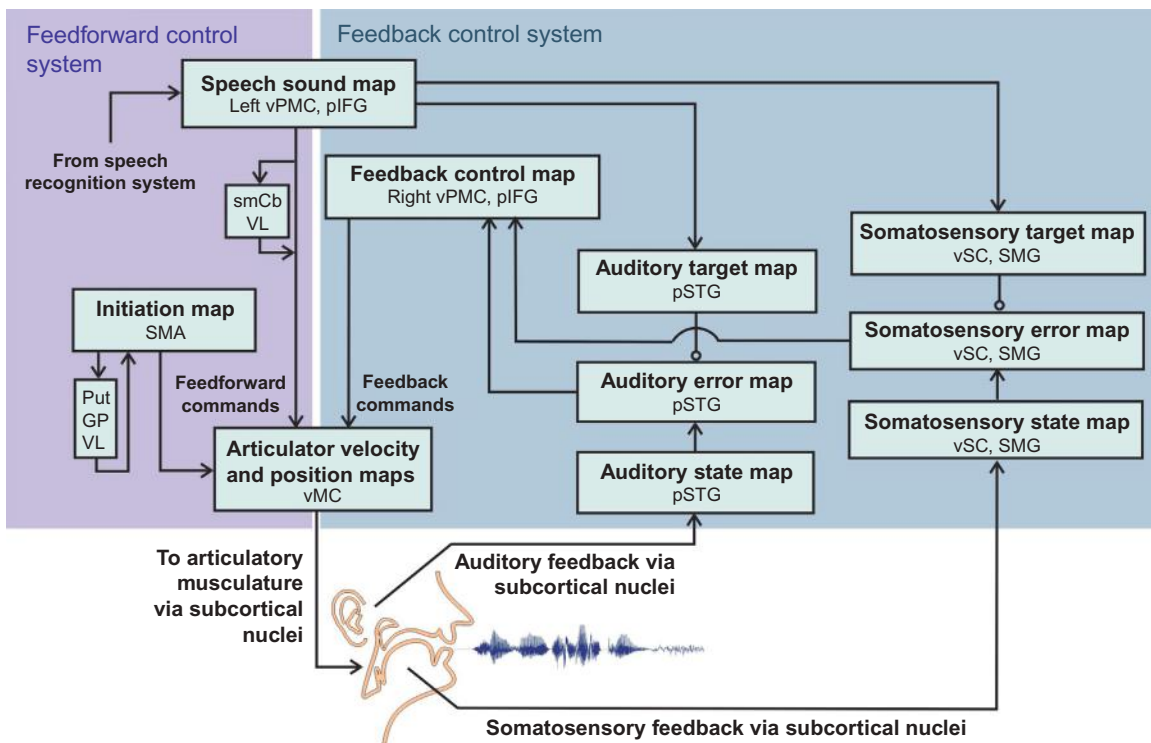

FIGURE 58.3. Schematic overview of the DIVA model of speech production. Each box in the diagram corresponds to a group of neurons; arrows represent excitatory axonal projections and empty circles represent inhibitory projections. The model breaks the control of speech production into a feedforward control system and a feedback control system, with the latter further broken into auditory and somatosensory feedback control subsystems. See text for details. GP, globus pallidus; Put, putamen; pIFG, posterior inferior frontal gyrus; pSTG, posterior superior temporal gyrus; smCb, superior medial cerebellum; SMA, supplementary motor area; SMG, supramarginal gyrus; VL, ventral lateral nucleus of the thalamus; vMC, ventral motor cortex; vPMC, ventral premotor cortex; vSC, ventral somatosensory cortex.

The production of a speech sound in the DIVA model starts with activation of neurons associated with that sound in the model's speech sound map. A "speech sound" in this map is defined as a segment of speech that has its own motor program, with the syllable being the most typical unit represented. The term "sound map" is used to highlight the fact that speech movement planning appears to aim at auditory targets rather than articulatory targets, as described in the preceding section. In the computer implementation of the model, each neuron in the map represents a different speech sound. When a new sound is encountered, a new neuron that codes for that sound is added to the speech sound map.

Activation of the speech sound map leads to articulator movement commands that arrive in primary motor cortex via two control subsystems. The feedforward control system projects directly, as well as indirectly, via a side loop through the cerebellum, from the speech sound map to primary motor cortex. The feedback control system, including both an auditory feedback control subsystem and a somatosensory feedback control subsystem, involves indirect projections passing through sensory brain areas.

The DIVA model provides a description of how an infant learns to produce speech sounds through babbling and imitation processes. According to the model, a combination of motor, auditory, and somatosensory information generated during early random and reduplicated babbling is used to tune the synaptic projections of the feedback control system. The sensory-motor transformations learned during babbling allow detected sensory errors to be mapped into corrective motor commands during the subsequent imitation stage, when feedforward commands are learned for the speech sounds of the infant's native language.

The imitation stage describes how syllable-specific learning occurs when an infant is presented with a new speech sound to learn, corresponding to an infant learning a new syllable from his/her parent, for example. Detection of a novel sound leads to activation of a new speech sound map neuron that will represent that sound. This is presumed to occur via projections from the speech recognition system in the auditory cortical areas to the left ventral premotor cortex (vPMC). Although not specified in the model, these projections may be part of the dorsal auditory stream (involving the superior longitudinal fasciculus or arcuate fasciculus) or the ventral stream (involving the uncinate fasciculus).

The model first learns an auditory target for the new sound from sound samples that it is presented. This auditory target is encoded in the synaptic projections from the speech sound map to the auditory target map

in [Figure 58.3](#). The model then repeatedly attempts to produce the sound, improving the feedforward command for the sound with each iteration. The functions of the feedforward and feedback control systems are further detailed in the following sections.

Since its inception ([Guenther, 1992](#)), the DIVA model has hypothesized the existence of a speech sound map in premotor cortex that is activated both during speech perception (when it is necessary for learning sensory targets for speech sounds) and speech production (when it is necessary for driving speech articulator movements via the feedforward and feedback control systems). Cells in premotor cortical areas that are active during both action perception and production of a motor act have since been identified in numerous electrophysiological studies in animals (see [Rizzolatti & Craighero, 2004](#) for a review) and in fMRI studies showing activity while listening to speech in ventral premotor cortical areas involved in speech production ([Buchsbaum, Hickok, & Humphries, 2001](#); [Hickok, Buchsbaum, Humphries, & Muftuler, 2003](#); [Wilson, Saygin, Sereno, & Jacoboni, 2004](#)).

58.5.1 Auditory Feedback Control

As described, auditory feedback plays an important role in tuning the speech motor control system. According to the DIVA model, axonal projections from speech sound map cells in the left inferior frontal gyrus (IFG)/vPMC to the higher-order auditory cortical areas (via the dorsal auditory stream; [Hickok & Poeppel, 2004](#)) embody the auditory target region for the speech sound currently being produced. That is, they represent the auditory feedback that should arise when the speaker hears himself/herself producing the sound. This representation of expected auditory consequences is referred to as the *auditory target map*, and the model's auditory target consists of a temporally varying region of auditory space that encodes acceptable auditory variation for the current sound. The use of target regions, rather than points, is an important aspect of the DIVA model that provides a unified explanation for a wide range of speech production phenomena (see [Guenther, 1995b](#) for details). Projections such as those between the speech sound map and auditory state map in [Figure 58.3](#), which predict the sensory state resulting from a movement, are often referred to as *forward models* ([Davidson & Wolpert, 2005](#); [Desmurget & Grafton, 2000](#); [Guenther, 1995a](#); [Guenther et al., 1998](#); [Kawato, 1999](#); [Miall & Wolpert, 1996](#)), and they are closely related to the much older concepts of efference copy (originally proposed by von Helmholtz in the mid-19th century; see [von Helmholtz, 1925](#)) and corollary discharge (a term coined by [Sperry, 1950](#)).

The model's *auditory state map* represents the incoming auditory signal of one's own speech. This map is hypothesized to include a combination of relatively low-level auditory features such as pitch represented in the primary auditory cortex (Bendor & Wang, 2005; Kumar & Schönwiesner, 2012), located in Heschl's gyrus, as well as more complex auditory representations such as a speaker-normalized formant representation hypothesized to reside in higher-order auditory cortical areas in the planum temporale and posterior STG (including the superior bank of the superior temporal sulcus).

The auditory feedback control system detects speech errors, represented in the *auditory error map*, by comparing the auditory target map and auditory state map. Specifically, the auditory target map inhibits auditory error map cells, whereas the auditory state map excites auditory error map cells. If the incoming auditory signal is within the target region, then the inhibition from the auditory target cancels the excitatory effects of the auditory state map. If the incoming auditory signal is outside the target region, then the inhibitory target region will not completely cancel the excitatory input from the auditory periphery, resulting in activation of auditory error map cells. Evidence of inhibition in auditory cortical areas in the STG during one's own speech comes from several different sources, including recorded neural responses during open brain surgery (Creutzfeldt, Ojemann, & Lettich, 1989), MEG measurements (Houde, Nagarajan, Sekihara, & Merzenich, 2002; Numminen & Curio, 1999; Numminen, Salmelin, & Hari, 1999), and PET measurements (Wise, Greene, Buchel, & Scott, 1999). The auditory error map is hypothesized to reside in the same cortical areas as the auditory state and target maps; these regions include the Sylvian parietal temporal (Spt) area, which has been shown to become active during both speech perception and production (Buchsbaum, Hickok, & Humphries, 2001; Hickok & Poeppel, 2004).

Activation of the auditory error map during speech leads to corrective motor signals in the model via projections to the *feedback control map* in right vPMC. This map is responsible for transforming auditory errors into movements that correct these errors; such a transformation is often referred to as an *inverse model* (Kawato, 1999). The DIVA model derives its name from the particular form of inverse model used: a mapping from Directions (in sensory space) Into Velocities of Articulators. Such a mapping, which approximates the pseudoinverse of the Jacobian matrix relating changes in the auditory signal to the velocities of the speech articulators, results in many desirable properties, including motor equivalence (Guenther et al., 1998, 1999, 2006; see simulations of /r/ production in previous section) and efficient movement trajectories (Guenther et al., 1998).

Once the model has learned appropriate feedforward commands for a speech sound, it can successfully produce the sound using just those feedforward commands. That is, no auditory error will arise during production, and thus the auditory feedback control subsystem will not be activated. However, if an externally imposed perturbation occurs, such as a real-time "warping" of the subject's auditory feedback so that he hears himself producing the wrong sound (Houde & Jordan, 1998), then the auditory error cells will become active and attempt to correct for the perturbation through projections to the feedback control map in the right inferior frontal cortex. These predictions were verified by Tourville et al. (2008) in an fMRI study involving unexpected perturbations of auditory feedback during speech—specifically, upward or downward shifts of F1 by 30% on randomly dispersed trials. As illustrated in Figure 58.4, perturbed speech led to increased activity in the posterior STG bilaterally and in the right frontal cortex. These regions correspond to the auditory feedback control system in the schematic of the DIVA model (Figure 58.3).

58.5.2 Somatosensory Feedback Control

Like auditory information, somatosensory information has long been known to be important for speech production (Lindblom, Lubker, & Gay, 1979). The DIVA model posits a somatosensory feedback control subsystem operating in parallel with the auditory feedback control subsystem. The model's *somatosensory state map* corresponds to the representation of tactile and proprioceptive information from the speech articulators in primary and higher-order somatosensory cortical areas in the postcentral gyrus and supramarginal gyrus (SMG). The model's *somatosensory target map* and *somatosensory error map*, which play roles analogous to their auditory counterparts, are hypothesized to reside primarily in the SMG, a region that has been implicated in phonological processing for speech perception (Caplan, Gow, & Makris, 1995; Celsis et al., 1999), and speech production (Damasio & Damasio, 1980; Geschwind, 1965). This hypothesized role for inferior parietal cortex in the integration of motor commands and sensory feedback during speech production is analogous to the visual-motor integration role associated with more dorsal parietal regions during limb movements (Andersen, 1997; Rizzolatti, Fogassi, & Gallese, 1997).

According to the model, cells in the somatosensory error map become active during speech if the speaker's tactile and proprioceptive feedback from the vocal tract deviates from the somatosensory target region for the sound being produced; this prediction is supported

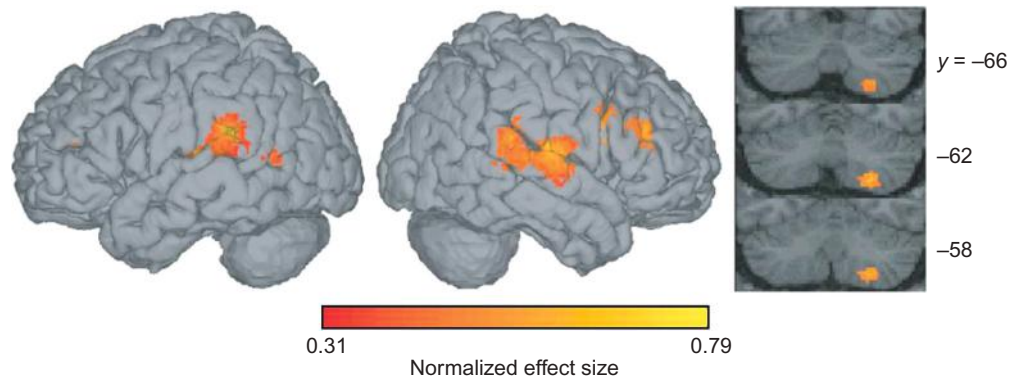

FIGURE 58.4. Auditory feedback control network for speech production. Areas of increased brain activity for auditorily perturbed speech compared with normal speech are indicated on the left and right lateral cortical hemispheres and coronal slices through the cerebellum (see [Tourville et al., 2008](#) for details). The auditory perturbation consisted of a 30% increase or decrease of the first formant frequency (F1), which has the effect of making the vowel in a word like “bet” sound more like “bat” or “bit.” This perturbation occurred in real time (i.e., the perturbed speech signal was delivered to the subject over headphones within 16 ms of the actual acoustic signal from his/her own voice), and it was applied in a random subset of trials. Subjects partially compensated for this perturbation by shifting their produced F1 in the direction opposite the perturbation. Increased activity was found bilaterally in the auditory cortical areas of the posterior STG during perturbed speech, supporting the DIVA model prediction of auditory error neurons in these areas. Increased activity was also seen in inferior frontal regions, with a right hemisphere bias; according to the DIVA model, these regions are involved in generating corrective motor commands.

FIGURE 58.5. Somatosensory feedback control network for speech production. Areas of increased brain activity for speech produced with an unexpected blockage of the jaw contrasted with normal speech are indicated on the left and right lateral cortical hemispheres and coronal slices through the cerebellum. The unexpected jaw constraint caused bilateral activity in the postcentral gyrus and SMG, supporting the DIVA model prediction of a somatosensory error map in these regions. Increased activity was also seen in inferior frontal regions, with a right hemisphere bias; according to the DIVA model, these regions are involved in generating corrective motor commands.

by brain activity measured with fMRI during unexpected jaw perturbations as illustrated in [Figure 58.5](#), which is adapted from [Golfinopoulos et al. \(2011\)](#). This study found increased activity bilaterally in the SMG and postcentral gyrus when contrasting the perturbed and unperturbed speaking conditions. The output of the somatosensory error map then propagates to the feedback control map in right vPMC, which transforms somatosensory errors into motor commands that correct those errors in a manner analogous to the auditory feedback control system (i.e., using an approximation to the pseudoinverse of the Jacobian matrix relating changes in the somatosensory state to velocities of the speech articulators).

Although the auditory and somatosensory feedback subsystems are implemented separately in computer simulations of the DIVA model, the existence of multisensory neurons that encode both auditory and somatosensory information during speech has been hypothesized ([Guenther et al., 2006](#)). Interactions between different sensory modalities involved in speech have been noted in a number of studies; for example, it has been shown that somatosensory stimulation can modulate auditory perceptual responses under some conditions ([Ito, Tiede, & Ostry, 2009](#)), auditory stimulation can alter skin sensation ([Ito & Ostry, 2012](#)), and viewing speech articulation can alter auditory perception, a phenomenon referred to as the McGurk Effect ([McGurk & MacDonald, 1976](#)).

58.5.3 Feedforward Control

According to the DIVA model, projections from left vPMC to primary motor cortex, supplemented by a cerebellar side loop between these two regions involving the superior paravermal region of the cerebellar cortex, constitute the feedforward motor commands for speech production. The primary motor and premotor cortices are well-known to be strongly interconnected (Krakauer & Ghez, 1999; Passingham, 1993). Furthermore, the cerebellum is known to receive input via the pontine nuclei from premotor cortical areas, as well as higher-order auditory and somatosensory areas that can provide state information important for choosing motor commands (Schmahmann & Pandya, 1997), and it projects heavily to the primary motor cortex via the thalamus (Middleton & Strick, 1997).

The DIVA model's feedforward commands constitute a form of motor program and, as such, they are closely related to the concepts of a *gestural score* (Browman & Goldstein, 1989) and *mental syllabary* (Levelt & Wheeldon, 1994). A gestural score is a stored representation of properly timed vocal tract gestures (defined primarily as constrictions in the vocal tract) needed to produce a phonological message. The mental syllabary is a repository of motor programs (or gestural scores) for the most frequently used syllables in a language. The DIVA model's conception of feedforward commands differs from these characterizations primarily in the choice of representation for the motor programs (in the DIVA model these programs command articulator movements to hit auditory targets rather than constriction targets) and size of the motor programs (the DIVA model allows for phonemic motor programs as well as syllabic and multisyllabic motor programs for frequently used phoneme sequences).

Prior to the development of speech, infants do not possess fine-tuned motor programs for producing the sounds of their language; in other words, their feedforward control system is not yet tuned. Only by attempting to produce the sounds of their language can accurate feedforward commands be learned. In the DIVA model, feedforward commands for a syllable are tuned on each production attempt. On the first attempt to produce a new sound, the model relies very heavily on auditory feedback control to produce the sound because its feedforward commands are inaccurate, thus resulting in auditory errors that are detected by comparing the stored auditory target for the sound with the auditory feedback generated by the production attempt. These auditory error signals activate the feedback control subsystem, which leads to corrective motor commands via the feedback control map. The corrective commands issued by the auditory feedback control subsystem during the current attempt to produce the

sound become stored in the feedforward command for use on the next attempt. The superior paravermal region of the cerebellum is hypothesized to be involved in this process (see Guenther et al., 2006 for details). Each subsequent attempt to produce the sound results in a better feedforward command and less auditory error, until the feedforward command is capable of producing the sound fluently (i.e., without producing any auditory error), at which point the auditory feedback subsystem no longer contributes to production unless speech is perturbed in some way or the sizes or shapes of the articulators change. As the speech articulators get larger with growth, the auditory feedback control subsystem continues to provide corrective commands that are subsumed into the feedforward controller, thus allowing the feedforward controller to stay properly tuned despite dramatic changes in the sizes and shapes of the speech articulators over the course of a lifetime.

A second component of the feedforward control system schematized in Figure 58.3 is a basal ganglia-thalamo-cortical loop involving an Initiation Map in SMA. The SMA is strongly interconnected with lateral motor and premotor cortex and the basal ganglia (Jurgens, 1984; Lehericy et al., 2004; Luppino, Matelli, Camarda, & Rizzolatti, 1993; Matsumoto et al., 2004; Matsumoto et al., 2007), and a number of investigators have proposed that the SMA plays a critical role in controlling the initiation of speech motor commands (Alario, Chainay, Lehericy, & Cohen, 2006; Bohland & Guenther, 2006; Jonas, 1987; Ziegler, Kilian, & Deger, 1997). Each speech sound is represented by a different neuron in the model's *initiation map*, and activation of a sound's initiation map cell leads to readout of the feedforward commands for that sound via projections to ventral premotor and primary motor cortex (Tourville & Guenther, 2011). The basal ganglia, which receive input from a wide range of sensory, motor, and association areas of the cerebral cortex (not shown in Figure 58.3), are ideally suited for determining the proper sensorimotor and behavioral context for launching the feedforward commands for the next sound to be produced. This is hypothesized to occur via the basal ganglia-thalamo-cortical loop with SMA in Figure 58.3.

The feedforward control system of the DIVA model provides a mechanistic account for three disorders of speech motor control: apraxia of speech, ataxic dysarthria, and stuttering. Apraxia of speech is hypothesized to occur with damage to the speech sound map and/or projections from this map to primary motor cortex; such damage would impair the readout of speech motor programs, resulting in speech errors such as groping and syllable reduction that are associated with apraxia of speech (Ames, 2009). This account is consistent with the finding that damage to the brain regions thought to contain the speech sound map, left IFG and

vPMC, is strongly associated with apraxia of speech (Hillis et al., 2004). Damage to the superior paravermal region of the cerebellar cortex results in ataxic dysarthria, a motor speech disorder characterized by slurred, poorly coordinated speech (Ackermann, Vogel, Petersen, & Poremba, 1992). This finding is in accord with the model's inclusion of this region for providing precisely timed feedforward commands necessary for fluent speech. Stuttering is hypothesized to arise from impairment of the basal ganglia-thalamo-cortical loop involving the initiation map in SMA (Civier, Bullock, Max, & Guenther, 2013). Alm (2004) provides a detailed treatment of the wide range of evidence implicating the basal ganglia in stuttering.

Interestingly, a number of auditory feedback manipulations have been shown to improve fluency, at least temporarily, in people who stutter. These include noise-masked auditory feedback (MacCulloch, Eaton, & Long, 1970), delayed auditory feedback (Van Riper, 1982), and frequency-altered feedback (Hargrave, Kalinowski, Stuart, Armson, & Jones, 1994). Alm (2004) proposes that such manipulations decrease the automaticity of speech and thereby reduce dependency on the impaired basal ganglia circuit; Civier, Tasko, and Guenther (2010) propose that such alterations prevent the speaker from hearing his/her own auditory errors, which when perceived may prohibit the basal ganglia from recognizing the proper sensory state for launching the next sound's feedforward commands.

58.6 THE GODIVA MODEL OF SPEECH SOUND SEQUENCING

The DIVA model accounts for production of individual speech motor programs, each corresponding to a different speech sound, with the typical unit of motor programming being the syllable. Additional brain areas, particularly in the left prefrontal cortex, become involved for longer speech utterances, which require the generation of an appropriately timed sequence of phonemes and syllables corresponding to a phrase or sentence. Here, we briefly treat some of the key areas involved in speech sound sequencing and introduce an extension to the DIVA model, called gradient order DIVA (GODIVA), that addresses the neural computations underlying speech sound sequencing.

The pre-SMA, like the SMA that lies immediately posterior to it in the medial frontal cortex, has been implicated in movement sequencing (Clower & Alexander, 1998; Shima & Tanji, 2000), including the sequencing of speech movements (Bohland & Guenther, 2006). Shima and Tanji (2000) found cells in pre-SMA that code for an entire sequence to be produced and other cells in pre-SMA that fired for the n th movement (e.g., the third

movement) of a sequence regardless of the type of movement. Bohland and Guenther (2006) found increased activity in pre-SMA when the number of unique syllables in an utterance was increased, as well as when the complexity of the individual syllables was increased.

The lateral prefrontal cortex has been implicated in many studies of language and working memory (D'Esposito et al., 1998; Fiez et al., 1996; Gabrieli, Poldrack, & Desmond, 1998; Kerns, Cohen, Stenger, & Carter, 2004) and in serial order processing (Averbeck, Chafee, Crowe, & Georgopoulos, 2002, 2003; Petrides, 1991). Bohland and Guenther (2006) noted increased activity in lateral prefrontal cortex, specifically the region around the inferior frontal sulcus (IFS), with increased syllable sequence complexity of a spoken utterance.

The basal ganglia, particularly interactions between the cortex and the basal ganglia, are organized into multiple loop circuits (Alexander & Crutcher, 1990; Alexander, DeLong, & Strick, 1986; Middleton & Strick, 2000), including the *sensorimotor loop* described. The basal ganglia are known to be involved in sequencing motor acts (Harrington & Haaland, 1998), and abnormalities in the basal ganglia and/or associated circuitry can impact speech production (Kent, 2000; Murdoch, 2001), with some patients having particular difficulty fluently sequencing articulatory movements (Ho, Bradshaw, Cunnington, Phillips, & Iansek, 1998; Pickett, Kuniholm, Protopapas, Friedman, & Lieberman, 1998).

The GODIVA model (Bohland, Bullock, & Guenther, 2010) provides an account of how the pre-SMA, IFS, and basal ganglia interact with the speech motor control network described by the DIVA model to produce utterances containing multiple syllables. Briefly, left IFS acts as a phonological working memory that buffers the phonemes in an upcoming utterance, organized by their location within the syllable. Projections from left IFS to vPMC are responsible for choosing the speech sound map representation for the next syllable. Left pre-SMA is responsible for the sequencing of items within a syllable; specifically, pre-SMA represents the syllabic frame structure of the upcoming syllables (MacNeilage, 1998) without regard for the particular phonemes involved. Projections from pre-SMA to SMA activate, in the proper sequence, the appropriate neurons in the initiation map, thus leading to the readout of the feedforward commands for the next syllable via projections to the speech sound map. Loops through the basal ganglia are proposed to play central roles in the activation of pre-SMA, IFS, SMA, and vPMC neurons.

58.7 THE HSFC MODEL

DIVA is by far the most detailed and explicit model of speech motor control as well as the most influential

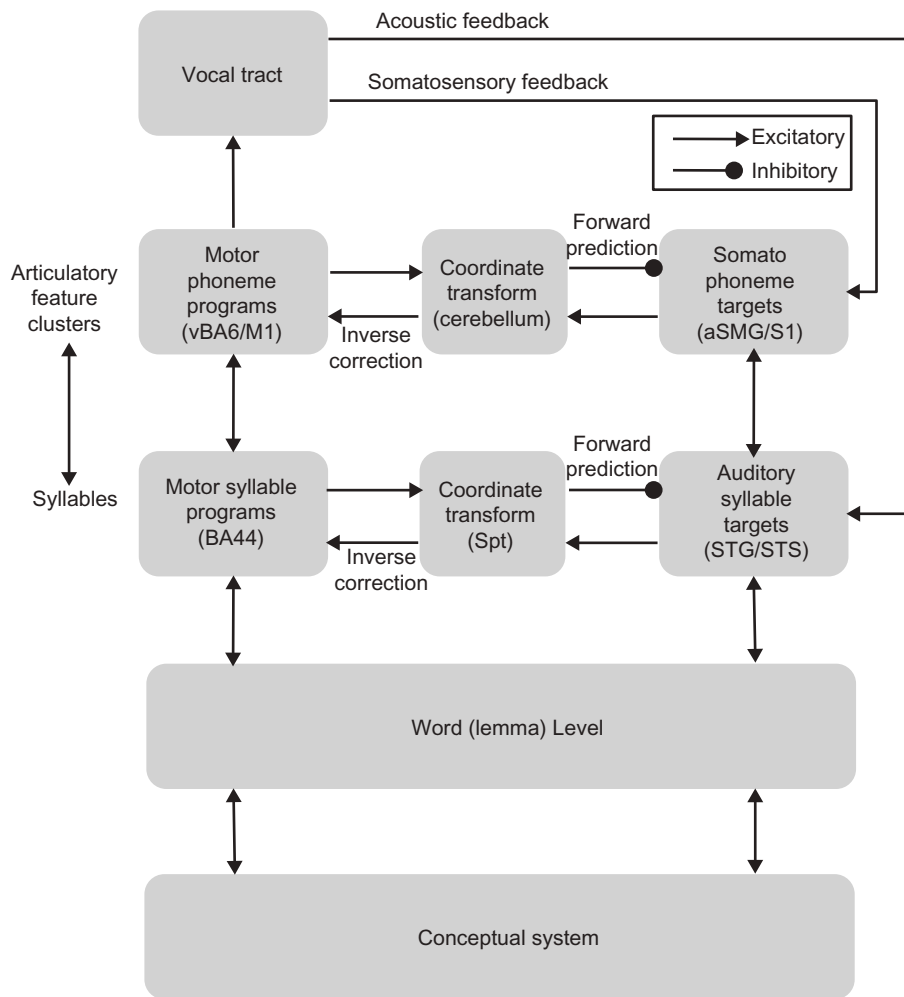

FIGURE 58.6. The HSFC model. The HSFC model includes two hierarchical levels of feedback control, each with its own internal and external sensory feedback loops. As in psycholinguistic models, the input to the HSFC model starts with the activation of a conceptual representation that, in turn, excites a corresponding word (lemma) representation. The word level projects in parallel to sensory and motor sides of the highest, fully cortical level of feedback control, the auditory–Spt–BA44 loop. This higher-level loop, in turn, projects, also in parallel, to the lower-level somatosensory–cerebellum–motor cortex loop. Direct connections between the word level and the lower-level circuit may also exist, although they are not depicted here. The HSFC model differs from the state feedback control (SFC) model in two main respects. First, “phonological” processing is distributed over two hierarchically organized levels, implicating a higher-level cortical auditory-motor circuit and a lower-level somatosensory-motor circuit, which approximately map onto syllabic and phonemic levels of analysis, respectively. Second, a true efference copy signal is not a component of the model. Instead, the function served by an efference copy is integrated into the motor planning process. BA, Brodmann area; M1, primary motor cortex; S1, primary somatosensory area; aSMG, anterior supramarginal gyrus; STG, superior temporal gyrus; STS, superior temporal sulcus; vBA6, ventral BA6. The HSFC model is squarely within the tradition of the DIVA model in that it assumes that the targets of speech gestures are coded in auditory space and that feedback control is a key computational operation of the network. HSFC differs from DIVA in three respects: (i) it assumes an internal as well as an external feedback detection/correction mechanism; (ii) it situates auditory and somatosensory feedback loops in a hierarchical arrangement (auditory loop being higher-level and somatosensory loop being lower-level); and (iii) it assumes a modified computational architecture for the feedback loops.

to date. As noted, DIVA uses feedback control architecture to detect and correct overtly produced errors. However, there is evidence in the motor control literature generally (Shadmehr & Mussa-Ivaldi, 1994; Tian & Poeppel, 2010; Wolpert, Ghahramani, & Jordan, 1995) and in the speech production literature more specifically for *internal* feedback control, that is, detecting and correcting internal coding errors prior to overt

speech production. We describe one such model here, the HSFC model illustrated in Figure 58.6.

The empirical motivation for an internal feedback loop in the speech domain comes from three sources. One is simply that we can imagine speaking and hear ourselves in our “mind’s ear.” Experimental research on such inner speech has shown that imagined speech can contain inadvertent errors that are internally

detected. Further, the types and distribution of such errors are similar to what is observed in overt speech (e.g., phonemic errors show a “lexical bias” (Nozari, Dell, & Schwartz, 2011; Oppenheim & Dell, 2008). A second source is that talkers correct partially articulated speech errors faster than they should be able to if they were relying on overt auditory feedback alone (Nozari et al., 2011); it is an open question whether somatosensory feedback may explain this phenomenon. The third source is conduction aphasia, a syndrome characterized by fluent speech output and intact speech perception abilities but with a higher than normal rate of phonemic errors in production. Crucially, affected individuals can readily detect their own errors once spoken but have trouble correcting them, even after they have been overtly detected (Goodglass, 1992). This pattern of speech behavior can be explained by a damaged internal error detection and correction loop (leading to the higher error rate) with an intact external feedback loop (allowing for detection of overtly produced errors).

The HSFC model, like DIVA, assumes that a basic planning unit in auditory space is approximately at the syllable level. The somatosensory circuit, however, is hypothesized to code sensory targets at a lower level. The basic idea is that speech production involves a cyclic opening and closing of the vocal tract (approximately corresponding to vowels and consonants respectively) and that the somatosensory system defines the targets of these opening or closing gestures (Gracco, 1994; Gracco & Lofqvist, 1994) similar to the somatosensory target map in the DIVA model but involving targets for individual phonemes rather than a single target for a whole syllable. The HSFC model holds that the internal auditory loop comprises a fully cortical network including auditory regions in the STG, motor regions in the IFG, and an auditory-motor interface network, Spt, in the posterior planum temporale region (of course, the external feedback loop involves noncortical structures). The somatosensory loop comprises somatosensory regions in the inferior parietal lobe, lower-level motor regions in primary motor cortex and/or Brodmann area 6, and a somatosensory-motor interface in the cerebellum. The hypothesis that the cerebellum is part of the lower-level sensory-motor circuit is motivated by the nature of speech deficits after cerebellar damage, which tend to be fairly low-level dysarthrias compared with the higher-level phonological deficits found in conduction aphasics with cortical damage (Ackermann, Mathiak, & Riecker, 2007; Baldo, Klostermann, & Dronkers, 2008; Buchsbaum et al., 2011; Kohn, 1984).

Architecturally and computationally, the HSFC (Figure 58.6) differs somewhat from DIVA (Figure 58.3).

In the HSFC there are two sensory-motor feedback loops, both of which involve three components, sensory target representations, motor codes for “hitting” those targets (learned via external feedback), and a sensory-motor coordinate transform network. The latter is assumed to compute the relation between sensory and motor representations of speech units. In DIVA, speech production begins with the activation of a speech sound map in the frontal lobe; in HSFC, production begins with the activation of both auditory and motor units corresponding to the intended word. The auditory units comprise the target for motor unit selection in the same sense that a visually perceived object might comprise the target for activating motor units to execute a reaching action. The difference with speech is that the sensory (auditory) target is not physically present in the environment but is instead a (re-)activated mental representation of the sensory target (i.e., a sound pattern). During motor activation, the accuracy of motor unit selection is checked, internally, prior to speech articulation. If motor and sensory units match, then articulation proceeds. If there is a mismatch, then a correction signal can be generated prior to articulation. Computationally, this internal “checking” mechanism is instantiated via excitatory connections from auditory target units to their previously learned corresponding motor units (via the interface network) and via inhibitory feedback connections from motor units to their corresponding auditory units. When the motor and auditory units match, the motor units will inhibit the auditory target units and carry on with their activation pattern. When there is a mismatch, motor units will inhibit nontarget units in the auditory network, allowing the target auditory units to persist in exciting the correct motor units; this is the “error signal.” Although a full-scale implementation of this architecture has not yet been demonstrated, a small-scale computational simulation has shown the feasibility of this architecture for internal error detection and correction (Hickok, 2012). A similar mechanism is assumed to hold at the various levels of the sensory-motor control hierarchy.

This architecture explains conduction aphasia as damage to the cortical interface network. Production is fluent because motor units are fully intact and can be activated directly from higher-level word representations. However, because of damage to the auditory-motor interface, motor unit activation cannot be checked against their auditory targets and an increase in error rates is observed. Once the conduction aphasic overtly produces an error, it is immediately detected via external feedback because the auditory target network is intact and the appropriate units are activated. However, subsequent attempts to correct such errors often fail, again because of the damage to the auditory-motor interface. Analysis of the relation between the

lesions that typically cause conduction aphasia and the anatomical location of Spt, the auditory-motor interface, has shown good correspondence, lending further support for the proposed model (Buchsbbaum et al., 2011).

The advantage of the HSFC model is that it incorporates an internal feedback loop that has some explanatory power regarding a speech disorder that has proven difficult to explain. It also includes a computational architecture that integrates auditory target activation, error detection, and error correction into a single process, which has some appeal from a parsimony standpoint. However, the model is far less developed than DIVA.

Although the models described herein can account for a wide range of experimental phenomena, it is important to note that these models are incomplete in their characterization of the vastly complex neural processes involved in speech production. An iterative process of generating testable predictions from a neurocomputational model, experimentally testing that prediction, and modifying the model as necessary to account for the experimental findings will lead to increasingly accurate accounts of the neural computations underlying speech.

58.8 FUTURE DIRECTIONS

The advent of noninvasive functional neuroimaging techniques such as PET and fMRI in the late 20th century has led to greatly accelerated progress toward understanding the neural mechanisms underlying speech production and perception. In more recent years, investigators have used multiple neuroimaging techniques in the same subject pool to overcome limitations in any given technique. For example, fMRI data, which have high spatial resolution but low temporal resolution, can be combined with either EEG or MEG, which have high temporal resolution but relatively low spatial resolution. New structural neuroimaging techniques such as diffusion-weighted imaging provide another dimension, namely the ability to correlate differences in brain function with differences in brain anatomy. We anticipate a continued increase in the use of multiple neuroimaging modalities as these neuroimaging technologies become more widely available and tools for analyzing the combined datasets improve.

The recent literature has seen a rapid increase in the number of publications that utilize electrocorticography (ECoG) to study the functioning human brain. ECoG involves electrodes placed on the surface of the cerebral cortex (either subdural or epidural); this technique is currently limited almost exclusively to

epilepsy patients undergoing presurgical functional mapping to guide the surgical intervention. Despite the relatively limited opportunities for ECoG use, ECoG during speech production has already been used to investigate temporal lobe activity in response to one's own voice (Creutzfeldt et al., 1989), to compare spoken and sign language (Crone et al., 2001), to identify the time course of activity across the speech network during overt (Leuthardt et al., 2012; Pei et al., 2011) and covert (Pei et al., 2011) word repetition, and to identify the spatiotemporal pattern of activity in articulatory representations in sensorimotor cortex (Bouchard, Mesgarani, Johnson, & Chang, 2013). We expect this trend to continue due to ECoG's unique combination of high spatial and temporal resolution.

Early EEG studies identified correlations between mental state or behavior and brain rhythms (e.g., alpha rhythm, delta rhythm, etc.), which are quasi-oscillatory neural activity patterns that can be identified by peaks in the frequency spectrum of the recorded signals. The higher spatial resolution afforded by MEG and ECoG compared with EEG has led to the development of computational methods aimed at analyzing interactions between large-scale brain rhythms in different cortical areas, or in different frequency bands within the same cortical area. Among other things, these techniques can identify functional connectivity between different brain regions or functional coupling across frequency bands within a brain region. An increasing number of studies are now reporting relationships between brain rhythms and speech processing (Giraud et al., 2007; Leuthardt et al., 2011; Luo & Poeppel, 2007). We expect this trend to continue as MEG and ECoG data become more widely available.

The development of speech prostheses involving brain-computer interfaces is another promising area of future research in speech production. Guenther et al. (2009) utilized intracranial electrodes in the speech motor cortex to produce the first real-time speech prosthesis, a system that allowed an individual suffering from locked-in syndrome to produce vowels with a speech synthesizer using auditory feedback from the synthesizer to guide speech "movements." In this study, the DIVA model prediction of a spatiotemporal formant frequency trajectory in the speech premotor/motor cortex was first verified from electrophysiological recordings during attempted speech. A decoder was then built to translate brain activity into predicted formant frequencies, which were then synthesized into a speech signal using a formant synthesizer (Klatt, 1980). The delay between neural firing and corresponding sound output was 50 ms, which is approximately the delay from motor cortical activity to sound output in neurologically normal individuals. This real-time audio feedback allowed the

users to improve their performance substantially with a small amount of practice. ECoG has also shown preliminary promise for brain–computer interfaces; for example, Leuthardt et al. (2011) developed an ECoG-based brain–computer interface that used activity in the speech network to control 1-D movement of a cursor.

59.1 INTRODUCTION

Speech is one of the most distinguishing human traits. It represents a model neural system for studying a range of human characteristics from sensorimotor control to cognition. It uses a complex control system optimized for sequential output and is used for both self-expressive and interactive communication. The production of speech reflects a complex and dynamic process dependent on the interaction among multiple cortical and subcortical regions for the fine control of more than 100 muscles located in the oral cavity, neck, and abdomen (see [Figure 59.1](#) for an overview). In the following, we identify the set of processes involved in speech production as well as their neural substrate.

59.2 NEUROBIOLOGY OF SPEECH MOTOR CONTROL

59.2.1 Speech Representations

From a linguistic perspective, a number of potential candidate constructs may be represented in the neural processes associated with the production of speech. One view in the psycholinguistic literature is that grammatical encoding, or the creation of lexical items within a syntactic frame, and phonological encoding, including the specification of prosodic structure, are the two fundamental processes that create the phonetic plan ([Garrett, 1993; Levelt, 1992, 1993](#)). The phonetic plan

interfaces seamlessly with speech motor processes that generate the sequence of sounds specified in the plan.

One approach to associate these broad psycholinguistic processes with their neural substrates comes from studies using speech errors. Speech errors can provide valuable insights regarding the linguistic principles that are involved in the production of speech because these errors are generally consistent with language-specific phonological rules ([Goldrick & Daland, 2009](#)). Based on speech error analyses, some researchers have postulated that the units of speech planning are individual phonological features ([Mowrey & MacKay, 1990](#)), whereas others propose that these units are bigger [e.g., phonemes ([Roelofs, 1997, 1999; Stemberger, 1982](#)), syllables ([Levelt, 1999](#)), or words]. Recently, Peeva and colleagues ([2010](#)) used functional magnetic resonance imaging (fMRI) and a repetition–suppression (RS) paradigm ([Grill-Spector, Henson, & Martin, 2006; Grill-Spector & Malach, 2001](#)) to study speech representations. Capitalizing on the RS phenomenon in which the repetition of a stimulus leads to reduced neural activity ([Henson & Rugg, 2003](#)), the authors varied the repetition rate of phonemes, syllables, and pseudowords expecting that areas sensitive to the processing of a specific type of phonological unit would show specific RS effects. Sensitivity to phonemic information was found in the supplementary motor area (SMA), the left pallidum (in the basal ganglia or BG), the left posterior superior temporal gyrus (STG), and the left superior posterior lateral cerebellum. Sensitivity to syllable

FIGURE 59.1 Simplified illustration of the motor speech system including main cortical components and their connectivity, subcortical loops (cortico-striatal-thalamic loops and cortico-cerebellar-thalamic loops), as well as peripheral components (cranial and spinal nerve innervations to speech-related structures in the face, oral cavity, neck, and abdomen).

level information was found in the ventral premotor cortex (vPMC), which was also sensitive to phonemic information. Finally, sensitivity to supra-syllabic information was found in the right superior posterior lateral cerebellum. These results suggest that multiple levels of representations, including phonemic and syllabic, are involved in the production of speech sounds.

59.2.2 Speech Motor Planning and Programming

During speech production, phonological encoding is the retrieval of the phonological code that consists of segmental (phonemes, syllables) and suprasegmental information (such as stress). This information is used to build a representation of the syllabified word form. The syllabified word form provides the framework for the planning of a motor act. Although models of speech production converge on the notion that the output of phonological encoding is a phonological word in which metrical, syllabic, and segmental properties are fully specified, models of speech production differ with regard to whether the retrieval of the phonological code is presyllabified. For some, the syllabification

is computed online depending on the context (Levelt, Roelofs, & Meyer, 1999), whereas for others the phonological code is presyllabified (Dell, 1988). Regardless of the theoretical perspective, phonological encoding is associated with the process of speech motor preparation, which involves the activation and translation of phonological representations into multiple domain-general mechanisms, including response selection, response sequencing, and movement initiation. These important mechanisms, often referred to as “supra-motor functions” or “motor cognition” (Freund, Jeannerod, Hallett, & Leiguarda, 2005), are not specific to speech production but instead are part of the planning of all voluntary actions. Speech production builds on common action control mechanisms consistent with the notion that the speech system is an overlaid functional system that “[...] gets what service it can out of organs and functions, nervous and muscular, that have come into being and are maintained for very different ends than its own” (Sapir, 1921).

59.2.2.1 Response Selection

Response selection in spoken language production is the process by which a set of lexical units forming a message is transformed into motor programs, that is, stored

motor routines. Several neuroimaging studies have examined the process of selecting nonspeech motor responses (such as finger and hand movements) and revealed activation in the presupplementary motor area (pre-SMA) (Brodmann's medial area 6) in which the increase in activation is commensurate with demands on response selection. For instance, activation in pre-SMA is enhanced when participants are free to choose a motor response from among several alternatives compared with when they are required to execute a specific, stimulus-driven, motor response (Deiber, Ibanez, Sadato, & Hallett, 1996; Lau, Rogers, & Passingham, 2006; Weeks, Honda, Catalan, & Hallett, 2001). Consistent with the nonspeech literature, several fMRI studies have shown that manipulating response selection during single word production modulates distributed brain networks including the pre-SMA, but also the adjacent cingulate motor area (CMA) and the vPMC (Crosson et al., 2001; Nagel, Schumacher, Goebel, & D'Esposito, 2008; Tremblay & Gracco, 2006; Tremblay & Small, 2011). Importantly, the pre-SMA is involved in selecting single words (Alario, Chainay, Lehericy, & Cohen, 2006; Tremblay & Gracco, 2006) but also noncommunicative oral motor gestures (Braun, Guillemin, Hosey, & Varga, 2001; Tremblay & Gracco, 2010), revealing a domain-general selection mechanism. Moreover, transcranial magnetic stimulation (TMS) to the pre-SMA leads to impaired voluntary selection of actions, including words and noncommunicative oral motor gestures (Tremblay & Gracco, 2009), supporting the notion of a domain-general selection process. Taken together, these results suggest that the pre-SMA plays a central role in selecting motor responses for speech production. The pre-SMA has a connectivity pattern that is ideal for linking higher-level cognitive (including linguistic) and motor processes, a *sine qua non* for the implementation of response selection, with important projections from the prefrontal cortex, particularly the dorsolateral prefrontal cortex or DLPFC (Lu, Preston, & Strick, 1994; Luppino, Matelli, Camarda, & Rizzolatti, 1993), and connections with several nonprimary motor areas, such as the SMA-proper and the PMC (Luppino & Rizzolatti, 2000), for controlling motor output. Recent fMRI evidence suggests a role for the caudate nucleus in response selection for speech production (Argyropoulos, Tremblay, & Small, 2013), consistent with evidence on the anatomical connectivity of the caudate, which connects with the prefrontal as well as the SMA/pre-SMA (Di Martino et al., 2008; Lehericy et al., 2004), suggesting that response selection is implemented through cortico-striatal connections between the pre-SMA and the caudate nucleus.

59.2.2.2 Response Sequencing

In his classic article on serial order, Lashley described the problem of organizing component parts of an action

into movement sequences as the *action syntax problem* (Lashley, 1951). The manifestation of action syntax can be seen in a multitude of behaviors ranging from human thought (Marsden, 1984) to grooming behavior in rats (Aldridge, Berridge, & Rosen, 2004). For speech, action sequences can be organized around multiple components (phonemes, syllables, words, phrases, etc.); without appropriate timing, in terms of either initiating the action or sequencing the action units, communication would be difficult. fMRI studies have shown that motor sequencing is implemented in a network of regions organized around nonprimary motor areas (SMA-proper, PM), the cerebellum, and the BG (Bengtsson, Ehrsson, Forssberg, & Ullen, 2005; Gerloff, Corwell, Chen, Hallett, & Cohen, 1997; Macar et al., 2002). Repetitive TMS of the SMA-proper results in sequential timing disruptions in a complex finger movement task (Gerloff et al., 1997); SMA-proper activation accompanies tasks requiring the processing of temporal patterns (Macar et al., 2002). Using fMRI, Bohland and Guenther (2006) showed a bilateral network including the SMA, the anterior insula, and the superior cerebellum that was more strongly recruited for the production of complex sequences of syllables (ka-ru-ti) compared with the production of simpler sequences, which consisted of repeating the same sound three times (ta-ta-ta), consistent with the nonspeech literature. Although there remains a number of issues regarding the implementation of selection and sequencing mechanisms for speech, the available empirical evidence, though limited, suggests that speech production relies on common action control mechanisms centered on the pre-SMA, SMA, and vPMC.

59.2.2.3 Motor Programming

Preparing speech production also involves fine-tuning of the planned motor routines, including adjustments of velocity, muscle tone, movement range, and direction. Motor programming is necessary because even though a closed set of syllables is available in each language and probably stored as a set of motor routines, syllables and words are never produced identically, they are co-articulated and modulated as a function of the linguistic, environmental, emotional, and social contexts. Motor programming is usually believed to involve both online feedback-based and feedforward control systems. According to Van der Merwe (2009), regions involved in programming include the cerebellum, SMA-proper, M1, and the BG, but experimental evidence is lacking. The issue of feedback-based motor control is discussed in Section 59.3.

59.2.2.4 Movement Initiation

The initiation and termination of an action is fundamental to all voluntary motor behaviors. For speech production, starting and stopping speech movements

is associated with a diverse range of communicative actions such as turn-taking, producing a list of words, and the insertion of pauses for emphasis. The SMA-proper has been previously identified as contributing to speech timing (Brendel et al., 2010; Gracco, 1997) and, more generally, has been associated with sequence timing as well as the perception of time. Recently, using functional connectivity analysis, and evaluating the temporal dynamics of the BOLD signal, two separately organized networks for speech production have been proposed (Brendel et al., 2010; Riecker et al., 2005) with the SMA and the insula identified as network components contributing to motor timing. For example, TMS to the SMA results in sequential timing disruptions (Gerloff et al., 1997), varying rate of stimulus presentation during reading results in modulation of SMA-proper activity (Price, Moore, Humphreys, Frackowiak, & Friston, 1996), and SMA activity accompanies tasks requiring the processing of temporal patterns (Bengtsson et al., 2005; Macar et al., 2002). Similarly, damage to the insula results in speech initiation impairments (Shuren, 1993) and apraxia of speech (Dronkers, 1996), a disorder of temporal sequencing, although there is controversy surrounding the role of insula in motor sequencing (Hillis et al., 2004). One possibility is that the SMA-proper and insula may be working to coordinate and time sequential actions, possibly through priming and then triggering motor cortex output. Speech and oral movements are localized around the central sulcus of the insula in an area that does not have direct projections onto lower motor neurons but does connect to frontal regions, including the DLPFC as well as the SMA and the sensorimotor portions of the striatum (Augustine, 1996). The DLPFC on the right hemisphere is known to modulate lower level systems (Shallice, 2004) and activity in the right DLPFC may be contributing to speech timing and/or temporal processing of action sequences (Coull, Frackowiak, & Frith, 1998; Vallesi, Shallice, & Walsh, 2007). It appears that the insula and SMA-proper form an integrated network component, operating in concert with peripheral feedback systems, to time sequential speech motor output. When there is a need for explicit timing control, prefrontal cortex participation is recruited.

Another way to study movement initiation is to compare the manner in which movements are triggered, whether externally by sensory events or at will. Movements initiated by external stimuli produce reliable activity in SMA-proper (Lee, Chang, & Roh, 1999; Thickbroom et al., 2000; Wiese et al., 2004) as well as in the left dorsal PMC (Krams, Rushworth, Deiber, Frackowiak, & Passingham, 1998; Lepage et al., 1999; Weeks et al., 2001), suggesting that these areas are involved in initiating actions based on external sensory

triggers. In humans, TMS to the left PMC results in a response delay and a disruption in the early stage of reaching and grasping (before movement execution), suggesting a role in the onset of movement (Schluter, Rushworth, Passingham, & Mills, 1998). Importantly, the contrast of self-initiated and externally triggered movements reveals activation in the pre-SMA (Deiber et al., 1996; Jenkins, Jahanshahi, Jueptner, Passingham, & Brooks, 2000; Tsujimoto, Ogawa, Tsukada, Kakiuchi, & Sasaki, 1998), suggesting a role for this region in the generation of an internal trigger to move, which supports a role for the SMA/pre-SMA in the timing and initiation of actions. Another potentially important region for the timing of actions and the generation of a movement trigger is the BG. In patients with Parkinson's disease (PD), a disorder of BG, there is a clear decline in the ability to initiate movements at will without a concomitant reduction or slowing of externally triggered actions (Cunnington, Iansek, & Bradshaw, 1999; Freeman, Cody, & Schady, 1993; Praamstra, Stegeman, Cools, Meyer, & Horstink, 1998). Other BG dysfunctions lead to difficulty starting, stopping, or sustaining movements including speech (Speedie, Wertman, Ta'ir, & Heilman, 1993), as well as abnormal rate, regularity, and temporal ordering of speech movements (Ludlow, Connor, & Bassich, 1987; Skodda, 2011; Skodda & Schlegel, 2008; Volkman, Hefter, Lange, & Freund, 1992), demonstrating the importance of BG for the timing of speech actions.

59.3 SPEECH MOVEMENT EXECUTION

The final output for speech comes mainly from the ventral part of the primary motor cortex (vM1), which contains the neurons controlling the vocal tract (Penfield & Boldrey, 1937). It has been estimated that approximately 100 striated and visceral muscles, distributed across the abdomen, neck, larynx, pharynx, and oral cavity, are involved in the production of speech, reflecting the immense complexity of this functional system, which, in mature speakers, may produce as many as 14 phonemes per second (i.e., between six and nine syllables per second) (Kent, 2000).

The pyramidal system, which includes the corticospinal and corticobulbar tracts, is one of the most important efferent pathways for the control of voluntary muscle contractions. It connects neurons in the cortex (upper motor neurons, UMN) to alpha (lower) motor neurons (LMN) located in the brainstem and spinal cord. LMN innervate the muscle fibers located in the face, neck, and abdomen. M1 is the cortical area that contains the largest number of pyramidal fibers (Kuyppers, 1973; Murray & Coulter, 1981; Ralston & Ralston, 1985), particularly the giant Betz cells located in cortical layer V.

However, anatomical studies have shown that M1 is connected through long and short association fibers to multiple nonprimary motor areas, including the SMA (Dum & Strick, 1991, 1996; Muakkassa & Strick, 1979) the CMA located just beneath the SMA on the dorsal and ventral banks of the cingulate sulcus (Dum & Strick, 1991; Muakkassa & Strick, 1979) and the dorsal and ventral PMC (Barbas & Pandya, 1987; Dum & Strick, 1991; He, Dum, & Strick, 1993). Importantly, these nonprimary motor areas contain a high density of corticospinal and corticobulbar neurons, directly projecting to the spinal cord through the pyramidal tract (for a review of the connectivity of nonprimary motor areas, see Picard & Strick, 1996, 2001), and thus each has the potential to influence the generation and control of movement independently of M1 (Dum & Strick, 1991). Electrical stimulation of the SMA (Fried et al., 1991; Morris, Dinner, Luders, Wyllie, & Kramer, 1988; Penfield & Welch, 1951; Talairach & Bancaud, 1966) and CMA (von Cramon & Jurgens, 1983) induce vocalization and speech arrests in humans, suggesting a role in the control of phonation and articulation for these regions.

The corticospinal tracts innervate motor nuclei located in the spinal cord, whereas corticobulbar fibers innervate motor nuclei located in the brainstem. Because the motor nuclei involved in the control of respiration (mainly expiration), phonation, and articulation are located in the pons, down to the lumbar portion of the spinal cord, the production of speech depends on the integrity of both the corticospinal tract, for the innervations of the muscles of respiration in the abdomen, neck, and shoulder, and the corticobulbar tract, for the sensorimotor innervations of laryngeal and supralaryngeal muscles (for reviews, see Jurgens, 2002, 2009) through six pairs of cranial nerves (CN V: trigeminal; CN VII: facial; CN IX: glossopharyngeal; CN X: vagus; CN XI: accessory; CN XII: hypoglossal).

All cortical axons (originating from M1, SMA, CMA, and PMC) forming the corticobulbar and corticospinal tracts converge into the internal capsule, located between the thalamus and BG, with fibers originating from ventral areas located rostrally to those originating from more dorsal areas (Beever & Horsley, 1890; Dejerine, 1901). Most pyramidal fibers cross from one side to the other before entering the spinal cord at the level of the medulla oblongata (i.e., the pyramidal decussation); corticobulbar fibers cross at the level of the brainstem, although there are substantial bilateral innervations of the CN motor nuclei. The exceptions include contralateral innervations of ventral cell groups of the motor nucleus of the facial nerve (CN VII), which supply muscles of the lower quadrants of the face (e.g., the orbicularis oris muscle), and the hypoglossal nucleus (CN XII), which supplies the intrinsic and extrinsic muscles of the tongue.

It has been suggested that vocalizations are controlled through two distinct cortical-subcortical pathways, one involving a circuit formed by the CMA, the periaqueductal gray matter (PAG), and the reticular formation for the control of innate vocal patterns (e.g., crying, laughing, and moaning), and another connecting M1 to the phonatory motoneurons through the reticular formation for the control of patterned speech and singing (Hsieh, Petrosyan, Goncalves, Hickok, & Saberi, 2011; Jurgens, 2002). This second circuit involves the cortico-striatal motor loop. Thus, M1 is connected not only to multiple nonprimary motor areas in the frontal lobe but also to the BG and cerebellum through the thalamus, and also to the reticular formation in the brainstem, controlling multiple aspects of speech production including respiration, vocalization, and articulation.

59.4 FEEDBACK PROCESSING AND SENSORY-MOTOR INTEGRATION

Early in the developmental process, the functional connection between speech perception and speech production is established and the ability to modify this coupling reflects the neural plasticity that continues throughout the life span. The resultant sensorimotor learning is the substrate on which developmental stages of speech and language develop, and one in which sensory feedback plays a crucial role (Mowrer, 1952). Somatosensory information from the lips and jaw have real-time access to modulate the spatial (Abbs & Gracco, 1983; Abbs, Gracco, & Cole, 1984; Gracco & Abbs, 1985; Shaiman & Gracco, 2002) and temporal aspects of speech sequences (Gracco & Abbs, 1989; Saltzman, Lofqvist, Kay, Kinsella-Shaw, & Rubin, 1998). Similar kinds of results are obtained from unanticipated alteration of auditory feedback for pitch (Burnett, Freedland, Larson, & Hain, 1998; Jones & Munhall, 2000) and formants (Purcell & Munhall, 2006a, 2006b). The overarching conclusion is that sensory and motor systems for speech are in a constant state of interaction and integration and, most importantly, the sensorimotor integration forms the basis for successful and efficient speech production (Gracco, 1991).

From a control perspective, speech production can be conceptualized as representing a hybrid control scheme consisting of feedforward and feedback-like neural processes (Abbs et al., 1984; Guenther, Ghosh, & Tourville, 2006; Hickok, 2012; Houde & Nagarajan, 2011; Tourville, Reilly, & Guenther, 2008). Feedforward control is used to compute, before movement onset, the necessary motor commands that will achieve generally a desired movement goal given the system's current state. That is, the feedforward controller assembles a basic motor plan prior to movement onset and sends

the commands to the appropriate musculature for execution. In contrast, feedback processes are used to adjust and correct motor commands that are planned or executed by the feedforward controller. However, if such adjustments would depend solely on afferent input signals, there would be an unavoidable delay that may be too long for movements as fast as those involved in many skilled actions, including speech production. Feedback control processes can also be used to *predict* the sensory consequences of movements by making use of a copy of the prepared motor commands (efference copy or corollary discharge) (Sperry, 1950; Von Holst & Mittelstaedt, 1973). As such, information from somatosensory and auditory systems contributes in multiple ways. First, as part of the feedforward process, the sensory systems provide information about the initial conditions such that the motor commands for a desired outcome can be successfully achieved given the state of the vocal tract. Second, as part of the predictive process, they interact with the control signals to estimate the consequences of the planned action. Finally, as part of the feedback process, they modulate, in real time, adjustments to the motor commands based on re-afferent input during movement execution as well as signaling the achievement of the desired action.

The neural substrate associated with the sensorimotor aspects of speech production involves a mostly bilateral network of brain regions, including vM1 and sensory areas (somatosensory cortex, STG), nonprimary motor areas (vPMC, SMA-proper, CMA, and the insula), and subcortical regions associated with sensorimotor control (putamen, cerebellum, thalamus) (Ackermann & Riecker, 2004; Argyropoulos et al., 2013; Grabski, Tremblay, Gracco, Girin, & Sato, 2013; Riecker et al., 2004, 2005; Riecker, Wildgruber, Dogil, Grodd, & Ackermann, 2002; Tremblay, Deschamps, & Gracco, 2013; Tremblay & Gracco, 2006, 2009; Wise, Greene, Büchel, & Scott, 1999), areas that are known to receive afferent input from auditory and somatosensory areas. For example, in the macaque, the vPMC receives projection from sensory areas, including associative somatosensory area SII (Matelli, Camarda, Glickstein, & Rizzolatti, 1986) and the posterior STG (Chavis & Pandya, 1976; Schmahmann et al., 2007), whereas the SMA-proper receives important projection from the superior parietal lobule (area PEci, in the cingulate sulcus), which contains a complete somatosensory map of the body (Pandya & Seltzer, 1982) as well as from areas SII and SI (Luppino et al., 1993; McGuire, Bates, & Goldman-Rakic, 1991a, 1991b). Projections to the putamen have been reported from regions within the supratemporal plane and the STG (Yeterian & Pandya, 1998). The rostral and medial parts of STG project to rostroventral and caudoventral portions of the putamen, whereas the caudal portion of STG projects to caudal

putamen. Recently, using resting state functional connectivity in humans, the dorsal portion of the putamen has been shown to connect with regions of the temporal cortex (Di Martino et al., 2008). As such, reafference may be an important source of information to assist in both the spatial and timing adjustments for the dynamic modulation of speech motor output as well as signaling successful achievement of speech motor goals (Gracco & Abbs, 1989).

For the cerebellum, bilateral posterior lobe activation in the vicinity of hemisphere lobule VI (Schmahmann et al., 1999) has been consistently reported during speech production (Ackermann, Mathiak, & Riecker, 2007; Riecker et al., 2002; Wise et al., 1999), most likely reflecting cortico-ponto-cerebellar projections from and to M1 (Kelly & Strick, 2003), possibly as part of an efference copy signal. A second area of activation on the inferior portion of the cerebellar hemisphere lobule VIIIA has been associated with auditory (Tourville et al., 2008) and somatosensory (Golfinopoulos et al., 2011) perturbations, as well as with rhythmic orofacial movements (Corfield et al., 1999) and sequencing non-meaningful syllables (Bohland & Guenther, 2006; Riecker, Kassubek, Groschel, Grodd, & Ackermann, 2006). The posterior lobe of the cerebellum receives sensory input from the trigeminal nerve (which provides sensorimotor innervations of the muscles of mastication) as well as the auditory system (Huerta, Frankfurter, & Harting, 1983; Ikeda & Matsushita, 1992; Pastor et al., 2002), and this area of the cerebellum may be implicated in multisensory rather than motor processing (Stoodley & Schmahmann, 2009; Thickbroom, Byrnes, & Mastaglia, 2003). Hence, sensory information from the dynamics of speech articulation has access to multiple brain regions through cortico-cortico, cortico-striatal, and cortico-cerebellar control loops.

59.5 CONCLUSION

In this chapter, we have shown that the neural system that controls speech production is immensely complex at all levels of the nervous system, involving multiple sensorimotor regions for motor planning and execution including M1, PMC, SMA, pre-SMA, CMA, the insula, and the supratemporal and inferior parietal cortices. Loops of internal control involving the BG, thalamus, and cerebellum are also involved in several aspects of speech movement preparation, including sequencing and temporal ordering. All these regions work in concert to assemble complex, temporally ordered, and co-articulated sequences of speech movements; motor commands are sent through corticospinal and corticobulbar tracts involving seven cranial nerves, multiple spinal nerves, and more than 100 striatal and

visceral nerves. Despite this remarkable complexity, the chain of events that leads to the production of speech occurs within several hundreds of milliseconds.

Sentence and Narrative Speech Production: Investigations with PET and fMRI

Richard J.S. Wise and Fatemeh Geranmayeh

Computational, Cognitive and Clinical Neuroimaging Laboratory (C³NL), Imperial College London,
Hammersmith Hospital, London, UK

60.1 INTRODUCTION

An interview with Sir Christopher Woodhead, a former (and somewhat controversial) Chief Inspector of Schools for the English education system was recorded recently (http://www.bbc.co.uk/iplayer/episode/b040hx66/No_Triumph_No_Tragedy_Chris_Woodhead/). In 2000, he developed the first symptoms of motor neuron disease, a form that has resulted in slow but progressive weakness of the limbs; until now it has largely spared his axial musculature. Therefore, he is able to speak normally while confined to a wheelchair with tetraplegia. Although without the ability to walk and climb (he was formerly an enthusiastic rock climber), he remains able to control the many muscles that allow fluent speech production: he can control expiration, essential to the production of connected speech; he can control his larynx to produce sounds of appropriate pitch and loudness; and he can filter this sound by rapid, accurate sequential movements of his articulators remains unimpaired, with no hint of motor imprecision (i.e., dysarthria). Most importantly, his cognitive functions essential for producing an eloquent account of his plight, including quotations from literature and poetry, remain intact—there remains nothing wrong with his ability to retrieve words and construct sentences to express concepts about disability, the medical profession, and assisted dying. Then, a point was reached in the interview when Sir Christopher said that the time when he no longer wishes to go on living will come when he loses the power to speak.

Daniel Wolpert has famously said, in a recording for a TED broadcast, that the one and only reason we have a brain is to produce adaptable and

complex movements (https://www.ted.com/talks/daniel_wolpert_the_real_reason_for_brains)—and the ability to move the muscles that result in fluent speech must rank as one of the most important functions of the human brain. That is clearly Sir Christopher's view, and it is seen in the frustration and despair expressed in angry gestures by patients with nonfluent progressive aphasia that has progressed to near mutism.

This preamble is to signal the conviction that one of the more important contributions functional neuroimaging can make to “systems neuroscience” is the study of speech production. This chapter addresses our views of the progress that has been made in the attempts to reveal the functional anatomy of “normal” propositional speech.

60.1.1 The Limitations

To date, progress has been slow. One reason is the unacceptable levels of noise introduced by articulation extended over time. It is evident that muscle artifact must intrude on electroencephalographic (EEG) and magnetoencephalographic (MEG) recordings, creating problems for analyzing recordings made during continuous speech. Therefore, MEG studies have largely been confined to exploring the responses to utterances of syllables or single words (Salmelin, 2007), one active area of research being the modulation of the response of auditory cortex to the sound of the participant's own utterances, heard unaltered or with distortion, such as changed pitch (Curio, Neuloh, Numminen, Jousmäki, & Hari, 2000; Kort, Nagarajan, & Houde, 2014; Niziolek, Nagarajan, & Houde, 2013). Artifacts generated by overt

speech also have a major impact on magnetic resonance images (MRI) using conventional blood-oxygen level-dependent contrast imaging (BOLD fMRI) (Gracco, Tremblay, & Pike, 2005; Mehta, Grabowski, Razavi, Eaton, & Bolinger, 2006), although the technique of fMRI, which uses arterial spin labeling (ASL), offers promise, albeit with less sensitivity (Kemeny, Ye, Birn, & Braun, 2005). Previous studies of overt single word production using BOLD fMRI demonstrated that whole-head movements contribute relatively little to the noise in the functional images (Huang, Carr, & Cao, 2002; Palmer et al., 2001). The study by Kemeny and colleagues (2005), which used overt sentence production, concluded that the major source of artifact using BOLD fMRI was the susceptibility effect generated by inhomogeneities in the magnetic field because of continuous changes in airflow and movements of the tongue and jaw. This speech-related artifact was greatest in anterior temporal regions bilaterally, impinging on ventral frontal and anterior insular cortices. The authors stressed the difference between these changes and the susceptibility artifacts related to air–bone interfaces above the nasal sinuses and the petrous temporal bone, which are always present and do not change across behavioral conditions. Speech-related signal obtained with ASL was not marred by anterior temporal artifact. On a personal note, when we attempted continuous data acquisition during narrative speech production using BOLD fMRI, conventional contrast between conditions—overt propositional speech production (we used picture description) and nonpropositional speech (counting)—was marred by unacceptable levels of noise (unpublished results), although this was rather more widespread than that observed by Kemeny and colleagues (2005). Rims of artifact were included around the edge of the brain and within the ventricular system. We attempted to clean the images using independent component analysis (ICA), which was successful in the sense that the multivariate analysis separated much of the noise from neural signal (Beckmann & Smith, 2004). However, those few components containing signal that was plausibly largely neural in origin were confined to lateral and midline premotor cortices, primary sensory-motor cortices, and paravermal cerebellum; in other words, signal from higher-order cortices involved in the selection and formation of a concept, which involves access to both episodic and semantic memory representations, and its transformation into a verbal message prior to actual articulation, were not visualized. However, improvements in denoising imaging datasets (Griffanti et al., 2014) may allow greater recovery of lost signal in future similar studies.

In contrast, artifact during single syllable or single word production, movements that only occur over a few hundreds of milliseconds, may be acceptably

low; therefore, these tasks can be used with continuous data acquisition to visualize activity associated with motor-sensory and lexical retrieval processes, both cortical and subcortical, involved in speech production (Parker-Jones et al., 2014; Peeva et al., 2010). However, self-evidently these tasks bear a limited relationship to normal conversational speech production. An alternative for sentence-level speech production, and one that we and others have used, is “sparse” temporal sampling. Originally introduced so that participants could listen to auditory stimuli without interference from scanner noise (Hall et al., 1999), this technique relies on acquiring single volumes of brain images only at the end of stimulus delivery or speech response. Thus, in a typical study investigating speech production, a participant might be required to speak for ~7 s before being prompted to stop. Then, ~1 s later, a single T2*-weighted, gradient echo, echoplanar imaging (EPI) sequence with whole-brain coverage is performed over 2 s. The sequence can then be repeated as often as required. Although “sparse” temporal sampling can be performed at a faster rate, this is only appropriate for single-word rather than sentence-level speech production. This “slow” event-related design, which relies on the temporally extended hemodynamic response function (HRF) over ~15 s to obtain signal, is not as sensitive as continuous image acquisition, because it misses the peak of the HRF. It also requires a longer study to obtain sufficient functional imaging volumes and, therefore, more stoical participants. The gain is avoidance of some (but by no means all) of the artifacts. In fMRI studies using “sparse” temporal sampling that contrasted sentence production with various baseline conditions, regions active only during sentence production were revealed in midline and left frontotemporal cortical regions (Dhanjal, Handunnetthi, Patel, & Wise, 2008) and anterior striatum (Argyropoulos, Tremblay, & Small, 2013). Therefore, this data acquisition technique allows the visualization of signal associated with sentence-level speech production that is otherwise obscured by noise using BOLD fMRI and continuous data acquisition.

However, there is a downside when speech is elicited in short epochs when using “sparse” temporal sampling. Regular periodic speech controlled by external stimuli to start and stop the flow of speech is quite unlike normal speech production. For example, in the study of Dhanjal et al. (2008), it was deemed too “unnatural” to expect the participants to produce continuous narrative speech that was interrupted by these externally directed pauses during image acquisition. It was predicted that the results would have revealed activity dominated by “go”/“stop” cognitive control (it is easier to interrupt counting, the baseline task, periodically than the flow of a good narrative). Instead, names

of objects were used as stimuli to prompt speech, and the participants were required to describe in one short sentence the attributes of each depicted object. Thus, the word “car” might elicit “*It’s a way of getting around, it has four wheels, it runs on petrol/gas,*” a verbal-semantic task that requires speeded selection from among all the properties that a participant associates with a car. It does not feel like spontaneous speech, but more akin to a verbal fluency task, such as, “Think of action words (verbs) that you associate with the word “apple,” which might elicit the response “*buy, eat, peel, cut, slice*”.

It might be considered that this may not matter much in terms of visualizing activity associated with sentence production. However, prior knowledge would predict a different distribution of activity associated with this task than may be present with normal narrative speech. This was evident from a study of continuous overt narrative speech production using positron emission tomography (PET) and radiolabeled water to assess regional cerebral blood flow as a marker of underlying net synaptic activity (Blank, Scott, Murphy, Warburton, & Wise, 2002). Artifact associated with continuous speech is less of a problem with PET; some artifacts are of course there, but they are disguised by the lower spatial and temporal resolution of this technique and the absence encountered with EPI fMRI of local magnetic field inhomogeneities. It has proven to be a technique that is capable of revealing relatively noise-free activity throughout widely distributed regions during the production of free narrative speech (Awad, Warren, Scott, Turkheimer, & Wise, 2007; Blank et al., 2002; Braun, Guillemin, Hosey, & Varga, 2001; Brownsett & Wise, 2010). In the study of Blank and colleagues (2002), the results acquired during narrative speech were contrasted with those from an earlier PET study in which participants had been required to generate verbs in response to noun prompts (Warburton et al., 1996). Activity in much of the left dorsolateral prefrontal cortex and in the dorsal anterior cingulate cortex (dACC) was present during verb generation but not during narrative speech production. This example demonstrates that word retrieval during a fluency task and during normal speech are not the “same thing” when it comes to frontal executive functions. Therefore, even when the data are reliable and (relatively) noise-free, there is always the problem of interpretation.

This is further exemplified in a study by Tremblay and Small (2011). Multiple conditions were included, but an important contrast was between sentence generation in response to object picture stimuli and repetition of heard sentences. Although increased activity in the midline dorsal prefrontal cortex, in the presupplementary area (pre-SMA) and adjacent cingulate sulcus, was interpreted as motor response selection during

overt speech production, the authors discussed differences in the demands on lexical and semantic selection between the two tasks and how this may have influenced the results. Even then, the discussion remained within the limitations of speech-specific and language-specific processes. Those working on the systems neuroscience of domain-general attention and cognitive control could point out that this midline region, or at least a closely overlapping component of it, is involved during the performance of many cognitive tasks (Fedorenko, Duncan, & Kanwisher, 2013); task-dependent sentence generation is just one more “problem-solving” task that will engage domain-general as well as domain-specific processes.

Of course, the visualization of cognitive control during speech production may be a goal in itself. We have argued that at least some of the frontal activity elicited by language tasks observed in recovering aphasic stroke patients relative to normal control subjects is as likely to be the consequence of more domain-general cognitive control as domain-specific language processing (Geranmayeh, Brownsett, & Wise, 2014a), on the basis that the patients find the language activation tasks more difficult than the normal controls. In one study (Brownsett et al., 2014), we showed that reducing performance in the normal controls by degrading the language stimuli resulted in increased activity in midline frontal cortex, and to the same level as aphasic patients performing the task with normal stimuli. The proposal that functional imaging studies may reveal parallel activity in systems involved in more domain-general cognitive control during speech comprehension is also being considered (Fedorenko, 2014).

Therefore, the second difficulty with functional imaging studies of speech, and with language studies in general, is separating language from other processes, such as cognitive control in the examples cited. As importantly, communication in sentences and narratives is only a “normally” executed act if there is access to declarative memory systems, both episodic and semantic. The inevitable visualization of these systems in many studies will become evident in later examples. A univariate analysis comprising a contrast between conditions will reveal, to an extent determined by the nature of the activation and baseline conditions, both domain-specific and domain-general systems—language, memory, attention, and cognitive control—as an undifferentiated single “system,” with interactions between them that may influence the effect size of signal observed (Friston et al., 1996). However, this is not all bad, because the composite reveals the many parallel processes, linguistic and nonlinguistic, that support meaningful human communication.

Perhaps it would be helpful at this stage to illustrate the previous arguments with one error of interpretation

that our group made in the past; in hindsight, we might consider that the reinterpretation is potentially more interesting than the original interpretation. Although some have criticized the statistical power of functional neuroimaging studies in general (Button et al., 2013), we consider this is less of a problem than the manner of interpretation of what is, in fact, genuine signal. This means that past work can be read for the value of their results even if the original interpretation of the results might benefit from revision. Thus, Blank, Bird, Turkheimer, and Wise (2003) (with the first author of this chapter as senior author on the work) published a PET study that showed greatly increased activity in the right homologue of Broca's area during narrative speech production in patients who had partially recovered from a left posterior frontal stroke. Since the time of Paul Broca it has been dogma that recovery from a nonfluent aphasic stroke depends on a "laterality shift" of expressive language function from left to right frontal operculum (and currently the adjacent anterior insula would be included—FOp/aI). This was our interpretation (and confirming dogma gives one an easy time with reviewers); however, the one (major) inconsistency was that activity in the right FOp/aI did not correlate with the rate at which the patients were able to generate narrative speech, which remained more or less impaired in all subjects. Since then, there has been growing literature on the "cingulo-opercular" network, comprising both left and right FOp/aI and the dACC and the adjacent pre-SMA. Although there is debate about the precise function of this dorsal frontal network (Aron, Robbins, & Poldrack, 2014; Dosenbach et al., 2007; Hampshire, Highfield, Parkin, & Owen, 2012; Menon & Uddin, 2010), no one thinks that it is a domain-specific language system; rather, it is involved in aspects of domain-general cognitive control. This is not to deny that a component of the *left-lateralized* FOp/aI (Broca's area) is language-specific, although even in this "classic" language area it would appear that other anatomically overlapping components are involved in the more domain-general control of non-language tasks (and, quite possibly, the cognitive control of language in addition to language processing *per se*) (Fedorenko, Duncan, & Kanwisher, 2012). One might speculate on this evidence that evolution has resulted in part of a domain-general cognitive control system, namely Broca's area, developing a local language-specific component, but not in right Broca's area. In light of these insights from "non-language" systems neuroscience, the inference that the right FOp/aI signal in the patient population assembled by Blank and colleagues (2003) represented a "laterality shift" of language function looks much less secure; just as likely, when speech production becomes difficult as the result of a stroke, the observed signal may reflect compensatory upregulation of cognitive control

networks rather than activity in "reorganized" language processors. Fortunately, this reinterpretation does not demean the original observation as a valueless epiphenomenon; as discussed, we now propose that the function of the cingulo-opercular system may contribute to recovery from aphasic stroke (Brownsett et al., 2014; Geranmayeh, Brownsett, & Wise, 2014).

The following sections attempt, as much as possible, to separate the different systems—linguistic, declarative memory retrieval (both semantic and episodic), and cognitive control (particularly the cingulo-opercular network)—involved during sentence and narrative production. As will become apparent, the context in which the participants are required to speak can have a major impact on the observed distribution of activity in univariate statistical analyses. When interpretation cannot be achieved through prior knowledge of which functions are located where, a more recent analytical method, which separates overlapping signal from multiple functional systems, is the introduction of multivariate analyses, such as ICA, to functional neuroimaging (Beckmann & Smith, 2004). A whole-brain ICA analysis can help distinguish between the different systems as they function together in a task-dependent manner (Geranmayeh, Wise, Mehta, & Leech, 2014b). In addition, ICA can reveal multiple separable spatiotemporal signals within any one brain region, each with different functional roles (for examples of this, see Leech, Braga, & Sharp, 2012; Simmonds et al., 2014). This overlap could be the result of the presence of spatially adjacent but functionally different neurons in that region, or of neurons that are flexibly involved in different functional networks. Lack of activity in a brain region on a univariate contrast does not necessarily mean that the region is not involved in the task.

60.2 WHAT HAVE WE LEARNED FROM META-ANALYSES OF LANGUAGE STUDIES

We should start with a review of some of the meta-analyses of functional neuroimaging studies of language, not least to determine whether we have anything further to add to their conclusions. Therefore, it is worth first considering the manner in which they presented their findings before discussing specific examples of speech production in later sections of this chapter. One such meta-analysis included 129 PET and fMRI studies and identified 730 activation peaks distributed over the neocortex of the left cerebral hemisphere based on univariate statistical analyses (Vigneau et al., 2006). These peaks were sorted into those that could broadly be interpreted as being associated with phonology, semantics, or sentence

processing. For each of these three processes, the peaks were distributed across posterior frontal, lateral temporal (from posterior to anterior), and inferior parietal cortices, with considerable overlap. These peaks were then transformed into a smaller number of clusters that spatially separated one process from another. However, this did not alter the observation that all three processes appeared to be distributed across all three lobes of the left hemisphere. Most of the studies included were designed to investigate speech perception and/or comprehension, at the syllable, lexical, and sentential levels, with fewer studies available that had investigated speech production; however, what was apparent was that no one language function was restricted to one lobe of the left hemisphere. In the words of the authors of the meta-analysis, “these results argue for large-scale architecture networks rather than modular organization of language in the left hemisphere.”

A more recent meta-analysis (Price, 2012) investigating both modalities, auditory and visual, of language perception and comprehension and speech production resulted in a figure that depicted the left cerebral hemisphere as a detailed patchwork of cortical regions, each associated with processing at different levels of language processing. This was somewhat reminiscent of a much earlier meta-analysis (Indefrey & Levelt, 2004), when PET was the dominant imaging methodology, that attempted to relate patches of left cerebral hemisphere cortex with processes that originated from an influential model of lexical access during speech production, largely based on evidence from chronometric experiments (Levelt, Roelofs, & Meyer, 1999). Regions associated with processes termed lemma selection and retrieval, syllabification, and others were also labeled with times at which these processes occurred in relation to one another (gleaned from chronometric data using other methodologies, because PET has a temporal resolution of many seconds). Price’s map of language was much more detailed in its boundaries and distributions and used broader, less theoretically derived processing terms; but in many ways it looks superficially like a similar “neophrenology” of language processing. However, the author was careful to emphasize that “a distinction can be made between processes that are localized to specific structures (e.g., sensory and motor processing) and processes where specialization arises in the distributed pattern of activation over many different areas that each participate in multiple functions. Future studies will undoubtedly be able to improve the spatial precision with which functional regions can be dissociated, but the greatest challenge will be to understand how different brain regions interact with one another in their attempts to comprehend and produce language.” We entirely agree and might argue that there is somewhat of a

discord between these conclusions and detailed mapping of language functions as specific, tightly delineated patches of cortex. However, the author was only presenting the results of several decades of functional neuroimaging research on language as it had been presented in the original publications, as activated “blobs” with precise coordinates in anatomical stereotactic space.

One obvious problem with these meta-analyses is knowing whether the resulting composite maps have allowed activation sites to be included that do not represent a language-specific function. We have already discussed how this might occur in a patient population, but results from studies on normal participants included in meta-analyses are equally vulnerable to misinterpretation. Functional neuroimaging studies are performed almost exclusively on literate adults who, from the age of 2 years, have spent much of their daily lives comprehending and producing narrative language, both spoken and written. As a consequence, the distributed systems that support the many linguistic components of language, their dependent relationship with declarative memory systems (without which there is nothing to say), and the cognitive control systems that are variably engaged depending on the communicative context must be strongly “hard-wired” together. Under these constraints, even dissociating domain-specific language networks from these others may prove as uncertain as trying to identify a “module” for phonology or syntax.

And even after 150 years of localizing language, there remain disagreements on fundamentals. Years ago at an editorial board meeting of *Brain and Language*, one of the editors of this volume, Steven Small, made a comment about research on the functional anatomy of language—“we’re still arguing about it 150 years after Broca, but at least we are certain about one thing: the left parietal lobe is involved.” And yet a widely cited review of the functional anatomy of language, with the other editor of this volume, Greg Hickok, as first author, did not include any node in left inferior parietal cortex associated with any linguistic aspect of language. The authors of this chapter were initially in accord with the Hickok and Poeppel (2007) view on this issue, and we were inclined to relate parietal cortical functions (of which, of course, there are many) to processes associated with memory (working and declarative) rather than language *per se*. Indefrey and Levelt (2004) also made no mention of a function for left parietal cortex in word production. However, the meta-analyses of Vigneau et al. (2006) and Price (2012) have come to different conclusions. Unfortunately, lesion-deficit analyses are not a means to settle this dispute, because strokes restricted exclusively to the left supramarginal and/or angular gyrus

are vanishingly rare, and almost invariably there will be associated infarction of the adjacent posterior temporal lobe or the frontal lobe (for example, although a study of language comprehension rather than production, see the patient series described in [Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004](#)). In our clinical practice it has been very rare to come across a patient with an isolated left parietal lesion and anything other than a transient aphasia. However, this is an anecdotal opinion. Large databases analyzed with appropriate statistical methods that relate lesion site and extent on anatomical images to behavioral measures of persistent aphasic deficits will have the power to confirm or refute this anecdotal impression ([Mah et al., 2014](#); [Price, Seghier, & Leff, 2010](#)). Even then, a confound will be that strokes damage white matter tracts as well as gray matter, and the behavioral effects of anatomically disconnecting intact cortical and subcortical regions remote from the stroke may not be readily apparent. In view of these uncertainties, there was no good evidence, at least in our minds, about language processes that were dependent on left inferior parietal function—notwithstanding Geschwind's speculations that the angular gyrus is the interface between words (or, at least, object words, both heard and spoken) and the mental representations of their meaning, a hypothesis apparently supported by modern imaging of white matter tracts ([Catani & ffytche, 2005](#)). However, the advent of newer studies subjected to ICA (an example of which is shown later) has led us to be more inclined to believe Steven Small's assertion.

60.3 NARRATIVE SPEECH PRODUCTION

[Braun et al. \(2001\)](#) published a PET study that investigated narrative language production in speech and sign language using the same group of participants for the two modalities. These were adults with normal hearing but who were fluent in sign language as the result of being the children of deaf parents. The baseline control conditions were non-communicative movements of the articulators and the limbs. The two communicative conditions activated a common system that consisted of "classic" Broca's and Wernicke's areas in the left cerebral hemisphere and, in addition, a small region of activity in the homologue of Wernicke's area in the right hemisphere and in the left superior frontal gyrus. Notably, there was activity in midline posterior cortex, centered on posterior cingulate cortex, but with adjacent retrosplenial cortex and anterior precuneus possibly included, and both left and right angular gyri.

A further PET study of narrative speech production was published the next year, but one that used the

recital of overlearned nursery rhymes and counting as baseline tasks ([Blank et al., 2002](#)). In many respects this reproduced the results of [Braun and colleagues \(2001\)](#). The conjunction of activity for all three speaking conditions contrasted with a nonspeech condition revealed the expected activity in bilateral premotor, primary sensorimotor, and auditory cortices, with left-lateralized peaks in the pars opercularis, anterior insula, and medial planum temporale, and bilateral peaks in subcortical nuclei and in paravermal cerebellum. This distributed, largely motor-sensory, system controlling overt articulation is covered in detail in other chapters. The main interest in this study was the distributed activity associated with free narrative speech relative to both overlearned automatic speech (reciting nursery rhymes) and nonpropositional speech (counting). The distribution of this activity is shown in [Figure 60.1](#). Left-lateralized activity was distributed along the superior frontal gyrus, from the presupplementary area forward, the posterior middle frontal gyrus, lateral anterior temporal cortex, and the mid-fusiform gyrus. There was bilateral activity in the angular gyri and posterior midline cortical activity, which again was described as being located in posterior cingulate cortex, but it may have included retrosplenial cortex. Additional activity was also observed in the ventral left temporal lobe and right lateral cerebellum, possibly regions that were outside the field of view in the study of [Braun and colleagues \(2001\)](#). The only subcortical region that survived the statistical threshold and spatial resolution of the technique was the right lateral cerebellum, so no activity was observed in the basal ganglia or thalami.

Uncontroversially, the results from these two studies could be interpreted as demonstrating that Broca's and Wernicke's areas are core linguistic nodes, because activity in these regions was evident during speech but was matched by the activity generated when narrative production was the result of reciting familiar nursery rhymes. So, what to make of all the extrasylvian activity depicted in [Figure 60.1](#) and observed across both PET studies? A further PET study that compared narrative speech comprehension with narrative speech production demonstrated conjunctions of activity for both tasks in the same extrasylvian regions ([Awad et al., 2007](#)); clear evidence that the comprehension and production of narrative speech depend on many of these same, or closely overlapping, cortical regions.

In all three studies, the production of narratives was based around personal past experiences (e.g., "describe where you lived as a child"). The participants spoke for ~1 min, beginning a few seconds before the intravenously injected bolus of positron emitting water ($H_2^{15}O$) arrived at the brain and continuing as the head counts

FIGURE 60.1 Schematic drawing of activity observed during a PET study of narrative speech production contrasted against shared activity during automatic and non-propositional speech baseline tasks (Blank et al., 2002). Top and middle panels show the lateral and medial views of both hemispheres, respectively. Bottom panel shows the ventral surface of the brain. Left-lateralized activity was seen in the superior frontal gyrus (orange), lateral anterior temporal cortex (light blue), and the mid-fusiform gyrus (dark blue). There was bilateral activity in the angular gyri (green) and posterior cingulate cortex/retrosplenial cortex (yellow). Additional activity was also observed in the right lateral cerebellum (red).

peaked and then began to decline due to washout of the radiolabeled water and its decay (half-life, 122.2 s). This relatively slow temporal resolution (although it is not as slow as it may seem, as the estimate of cerebral blood flow is weighted toward the period when the build-up of head counts is most rapid, over ~ 10 s) meant that the noise from physiological variables (such as small fluctuations of arterial carbon dioxide tension as the result of breathing-for-speech) could be ignored, as could (as mentioned previously) noise from small head movements “masked” by the technique’s relatively low spatial resolution (~ 5 – 6 mm).

Although the studies were about speech production, important in terms of interpreting the results was not minimizing that narrative speech production depended on the continuing retrieval of both personal (autobiographical) and knowledge-based (semantic) meanings

over many seconds. The posterior activity (the left and right angular gyri and the posterior midline cortex) forms the posterior components of the default mode network (DMN). The DMN is often considered as a single system, responsible, among other things, for internally generated thoughts and ruminations, which, of course, include thinking about past events, planning future events, and concerning ourselves about how we stand in relation to others in our personal and professional lives (for review, see Buckner, Andrews-Hanna, & Schacter, 2008). Reminiscing aloud is cognitively similar to reminiscing silently; therefore, it is no surprise that much of this network is active during narrating past events in one’s life. By some accounts, it is also one component in the generation of creative narratives that are, of course, not created out of a void but depend on reformulations of one’s own knowledge and past

experiences (Shah et al., 2013). Of course, some of the accounts told by the participants in the PET studies may have been more fictional than factual.

Components of the DMN are the most richly connected “hubs” in the brain (Braga, Sharp, Leeson, Wise, & Leech, 2013), and the DMN probably has many diverse roles. Importantly, for the purposes of this discussion, much distributed activity that conforms to the known boundaries of the DMN appear in a meta-analysis performed on functional imaging studies that were considered to rely on semantic memory processes (Binder, Desai, Graves, & Conant, 2009). Other than inclusion of more ventral anterior midline cortex, the distribution of activity described in this meta-analysis was closely similar to that observed in the three PET studies under discussion. Components of the DMN are strongly associated with processes involving episodic memory, such as retrosplenial cortex (Aggleton, 2010), but the distinction between the classic *what?*, *when?*, and *where?* of episodic memory and fact-based general knowledge are only two extremes of a declarative memory continuum. It may be more accurate to refer to at least partially dissociable subcomponents of the angular gyri and posterior midline cortex when considering distinctions between autobiographical and semantic memory retrieval. Therefore, there is not necessarily a “disconnect” between those studies that relate these regions to episodic memory retrieval (Sestieri, Corbetta, Romani, & Shulman, 2011) and their inclusion as part of the semantic memory system. This issue is discussed in detail by Binder and his colleagues in their two publications (2009, 2011). To re-emphasize, neophrenological interpretations should not enter into discussions of the functions of anatomically defined cortical regions such as “classic” language areas like Broca’s area or the left angular gyrus, which may contain subcomponents that are both separately and jointly involved in domain-specific processes such as language and memory and more domain-general attentional and control processes (Fedorenko et al., 2012; Seghier, Fagan, & Price, 2010).

60.4 FUNCTIONAL MRI STUDIES OF SENTENCE PRODUCTION

An example is illustrated in Figures 60.2–60.4, and these exemplify many of the points already made. They originate from an fMRI study previously published in *Brain and Language* (Geranmayeh et al., 2012). The univariate contrasts with sentence production (viewing the name of an object and describing it in ~7 s) contrasted with two different baseline conditions: noncommunicative repetitive movements of one of the articulators, the tongue, which is one of the control conditions used in the study by Braun et al. (2001),

and a rest condition. In a sense, this is a rather “disappointing” result, showing much frontal activity, temporal lobe activity that can largely be attributed to auditory processing of own speech, and no activity in more posterior cortex. It looks most unlike what one would expect from the PET studies (Awad et al., 2007; Blank et al., 2002; Braun et al., 2001). Further, there is prominent activity in the cingulo-opercular network, which implies that the sentence production task depended on appreciable cognitive control. The sentence production task was similar to that previously mentioned in relation to the study by Dhanjal et al. (2008), namely describing attributes elicited by viewing a written text of an object, which is a task we consider more akin to verbal fluency than free narrative speech production, but a necessary constraint because of the requirement for “sparse” temporal sampling.

The ICA analysis illustrated in Figure 60.3 offers quite a different picture. One component includes bilateral auditory cortex along with bilateral lateral premotor cortex and the cingulo-opercular network. This can be reasonably interpreted as temporal coherence between a cognitive control network, higher-order premotor planning of the complex movements required for connected speech as opposed to repetitive tongue movements, and the auditory cortical response to own speech. Other processes, such as lexical selection and retrieval, may also be functions of subcomponents of this network, but this cannot be determined given the cognitive “differences” between the two tasks; attempts to further subdivide this network by increasing the number of components in the ICA were not successful. The other component in which sentence production was greater than tongue movements revealed an extensive left-lateralized dorsolateral prefrontal, posterior inferolateral temporal, and inferior parietal network, with small regions of signal in the right inferior parietal cortex and posterior midline cortex.

The left fronto-temporo-parietal network has considerable correspondence with the results of the meta-analysis by Vigneau et al. (2006) of many language studies. A further analysis, illustrated in Figure 60.4, is a schematic drawing of the univariate contrast of the participants making repetitive tongue movements—a monotonous task and one that can be expected to not deactivate the DMN (Buckner et al., 2008)—with the sentence generation task. In this contrast, there was greater activity in the posterior midline cortex and in the posterior lateral parietal lobe on the right. Of note, however, was the absence of a significant difference of activity in the left inferior parietal cortex.

Therefore, it was evident that the sentence production task was quite different from the narrative speech conditions used in the earlier PET studies. The reduced activity in posterior regions can be attributed to an absence of autobiographical memory recall, although

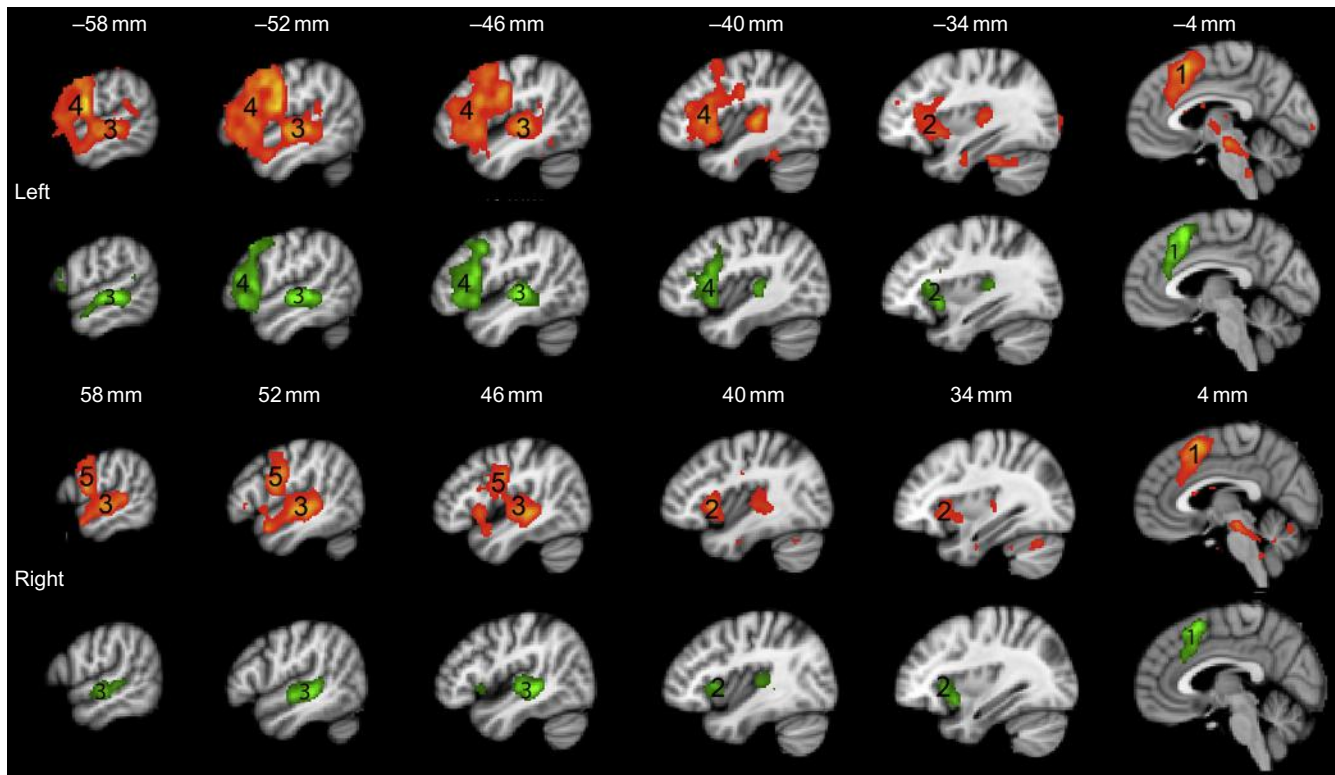

FIGURE 60.2 Standard sagittal T1-weighted anatomical slices through the left and right cerebral hemispheres overlaid with activity from the contrast of spoken language (sentence) production (a rest condition; red/yellow) and spoken language production (noncommunicative repetitive tongue movements; green). The statistical threshold was set at $Z > 2.3$, cluster-corrected. Anterior is to the left. The MNI coordinates are along the x -axis, with negative being to the left. The greater the number, the more lateral the sagittal slice. Regions of activity were located in: 1, pre-SMA and dACC; 2, bilateral anterior insula; 3, bilateral superior temporal cortex including left and right medial planum temporale; 4, left posterior inferior frontal gyrus (incorporating Broca's area) and extending dorsally into posterior middle frontal gyrus; and 5, right inferior frontal gyrus.

subcomponents of the posterior DMN, apparent from the ICA analysis shown in [Figure 60.3](#), may have been responsible for the semantic demands of the task. The added advantage of the ICA analysis over and above the univariate analyses was demonstrating that subcomponents of left inferior parietal cortex and posterior temporal cortex were contributing to speech production, even though the overall effect size did not increase significantly.

Another study using very much the same experimental design and analyzed with 55-component ICA has demonstrated multiple overlapping networks, particularly in parietal cortex ([Geranmayeh, Wise, et al., 2014](#)). Although these many overlapping networks are a challenge to interpret, they confirm the left fronto-temporo-parietal network of the earlier study and the “deactivation” of much of the posterior DMN by the particular picture description task. This would seem to indicate that the activity in the angular gyri and the posterior midline cortex visualized in the earlier PET studies was predominantly related to the rich declarative memory recall associated with “storytelling” rather than a strict recall of factual knowledge about objects.

There are clearly other ways that can be used to elicit speech production from participants while they are encased in a scanner. An alternative method used picture description but put constraints on what words may be used to describe the scene ([Grande et al., 2012](#)). This inevitably led to periods when the participants formulated concepts to describe the scene, pauses as they searched for synonyms rather than uttering the “banned” words, and succeeded or failed at completing clause-like units. Analyzing the acquired data was performed in brief epochs so that signal could be related to particular episodes during speech production, such as successful lexical retrieval contrasted with a pause because of an initial failure of lexical retrieval. This required continuous data acquisition, which seems to have presented the authors with fewer problems with artifacts than has been our experience. Also, it has to be said that the task is quite unlike the seemingly effortless flow of normal conversational speech with no constraints (within the limits of polite discourse) on the vocabulary used.

Finally, it is apparent that we have made no mention of the functions of the left superior frontal gyrus,

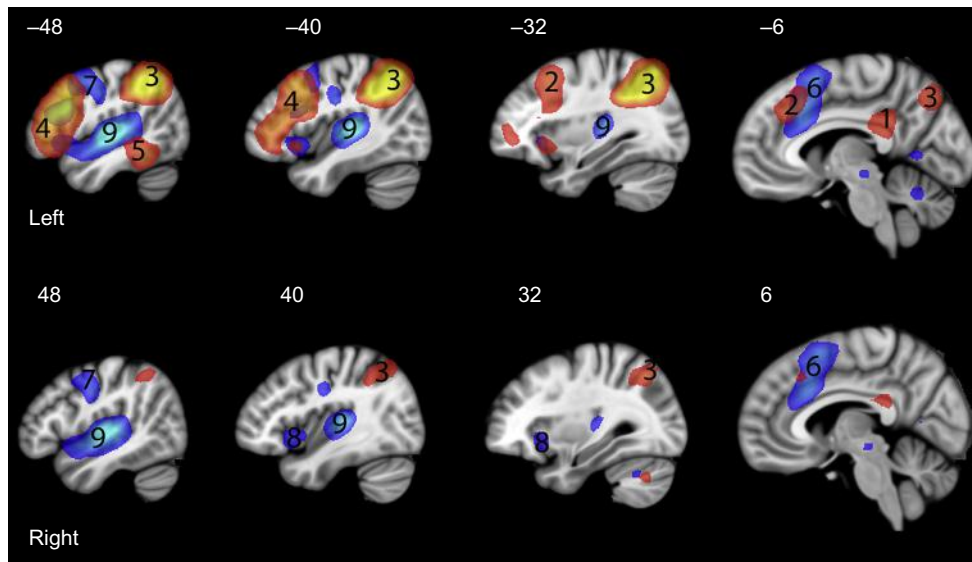

FIGURE 60.3 Standard T1-weighted anatomical slices overlaid with components from an ICA analysis of the study illustrated as univariate contrasts in Figure 60.2. Components 1 (shown in blue) and 24 (shown in red/yellow) demonstrated correlated activity for production of sentences that was significantly greater than for noncommunicative repetitive tongue movements. The statistical threshold was set at $Z > 4$. The images are sagittal views (MNI coordinates in the x -axis, with negative being to the left) with, in addition, one coronal slice (MNI coordinate in the y -axis) and one axial slice (MNI coordinate in the z -axis). The results from the ICA analysis demonstrated a widely distributed network for sentence production, including prominent left parietal activity not apparent in the univariate contrasts. The numbered regions show correlated activity for sentence production greater than for tongue moments in the following regions: 1, posterior cingulate cortex; 2, dACC; 3, left and right inferior parietal cortex; 4, left dorsolateral prefrontal cortex, including Broca's area; 5, left inferolateral temporal cortex; 6, pre-supplementary area and dACC; 7, lateral premotor cortex; 8, anterior insula; and 9, left and right superior temporal gyri.

FIGURE 60.4 Schematic drawing of activity observed during an fMRI study contrasting non-communicative repetitive tongue movements with spoken language production (Geranmayeh et al., 2012). In addition to sensory cortices (not shown), activity was predominantly distributed in the posterior half of the DMN in the posterior midline cortex and in the posterior lateral parietal lobe on the right.

rostral to the pre-SMA, and the right lateral cerebellum, apparent in most of the studies on sentence-level and narrative-level speech production. These regions are clearly involved, but their role in the higher-order cognitive processes involved in speech generation remains speculative. Further, the basal ganglia must be involved at the cognitive as well as the motor-sensory level of speech production, but these are difficult regions to image during speech production even with the benefit of "sparse" temporal sampling. However, one study has demonstrated anterior striatal activity in relation to sentence production, with posterior

striatal activity related to the articulatory processes (Argyropoulos et al., 2013). Future high-resolution scanning with meticulous attention to denoising the data is likely to be productive in revealing the roles of different corticostriatal loops during speech production.

60.5 CONCLUSION

This is an account of our views, limited though they are, on the functional anatomy and the neurobiology of sentence-level speech generation. The difficulties

associated with data acquisition during sentence and narrative production have made it an under-researched area in functional neuroimaging. Further attempts to relate measures of fluctuations in local cerebral blood flow with poor temporal resolution to refined linguistic theory (and even more to the creative narratives of playwrights and novelists) make the whole enterprise seem distinctly inadequate. The generation of speech is strongly dependent on context, and the repetition of a sentence to the generation of a description of an object through memory-related reminiscing add increasing complexity in terms of both domain-specific and domain-general processing being embedded within functional neuroimaging data. Nevertheless, the ability to speak and to be able to express one's needs, thoughts, and desires is pre-eminent in humans, and its loss is so devastating to patients with brain disease that, in many ways, it can be considered the most important area of systems neuroscience research. If we could find a way reliably to improve speech after aphasic stroke over and above what natural recovery can offer, then that would be a very important achievement. Whether functional neuroimaging research in normal participants and in patients with brain injury or neurodegeneration can contribute to this goal remains to be seen. However, it is a fascinating endeavor. Although some may wish to try and dissect out the detail or to differentiate processes according to theoretical constructs of linguistic hierarchies, we ultimately have to accept that language is an anatomically and functionally interconnected system that lesion-deficit analyses have long demonstrated to be a largely left-lateralized network and one that is not well-represented by a "language neophrenology." Its function in normal communication is dependent on interactions with representations of memories, both autobiographical and semantic, and, depending on goals and contexts, is controlled by systems that also exert control over other cognitive functions. Above all, the language system interacts with the auditory system (during speech comprehension), the visual system (during reading), and the motor system (during speech production). As we image adults, we have to accept that we are making observations of brains that have "hard-wired" these disparate processes together over decades. Visualizing the "big picture," which in its entirety supports our ability to put what is in our head into the head of another through the medium of standing airwaves, is something on which we and others have made a modest start.

61.1 INTRODUCTION

The quantity of, quality of, and speed of access to semantic knowledge in the human brain is astonishing. Given any fragment of information, such as the word “camel,” a healthy adult human can almost instantly generate a vast amount of other related information, such as the ways in which camels are and are not like other animals, how they look and move, where they live, how they interact with people, that it is the name of an American brand of cigarettes, that they are the subject of a famous story by Rudyard Kipling (*How the Camel Got His Hump*), and so forth. Curiously, this kind of conceptual knowledge—although often discussed by philosophers—did not become a major topic of research in cognitive science and neuroscience until relatively recently. Endel Tulving put it on the psychological map in 1972, when he proposed that semantic memory was a qualitatively different kind of knowledge from the episodic memory typically studied by experimental psychologists at that time. Elizabeth Warrington put it on the neuropsychological map in 1975, when she demonstrated that brain disease could selectively impair semantic memory. Now, approximately 40 years later, semantic memory is a commonplace object of behavioral study, brain research, and theorizing.

Over the past 15–20 years, we and our colleagues have been developing a story about the structure and neural basis of semantic memory that we call the hub-and-spoke hypothesis (Lambon Ralph, 2014; Lambon Ralph & Patterson, 2008; Lambon Ralph, Sage, Jones, & Mayberry, 2010; Patterson, Nestor, & Rogers, 2007; Rogers et al., 2004). The basic plot of this story comes in

two parts (Figure 61.1). First, many different modality-specific cortical regions represent the aspects of conceptual knowledge that *are* modality-specific: the color of a camel in color regions, its shape in visual-form regions, the way it moves in regions that code visual movement, its name in language-specific cortex, and so on. Second, all of these regions send information to and receive information from a hub component of the semantic network, which codes semantic similarity structure and represents concepts in a manner that abstracts away from the specific features of how they look or sound or move or what they are called. The links between each modality-specific region and the hub are called spokes. Because it is the hub part of this story that is (somewhat) novel, other semantic-memory researchers—especially those critical of this hypothesis—occasionally describe our theory as one in which concepts have a completely abstract form of representation and reside in the hub. For example, Gainotti (2014) included our work in a short list of models “that assume that semantic representations... are stored in an abstract and propositional format” (Gainotti, 2014, p. 7). We acknowledge that some earlier expositions of our incompletely formed view may have sounded a bit like this (Patterson & Hodges, 2000), but it is certainly not an accurate description of our current hub-and-spoke hypothesis about semantic memory. We therefore begin the account of our position with an explanation of the crucial spoke components of the theory, called “the importance of the spokes and the regions from which they emanate” (Sections 61.2). Section 61.3 argues that, although essential, the spokes and their modality-specific sources are insufficient and

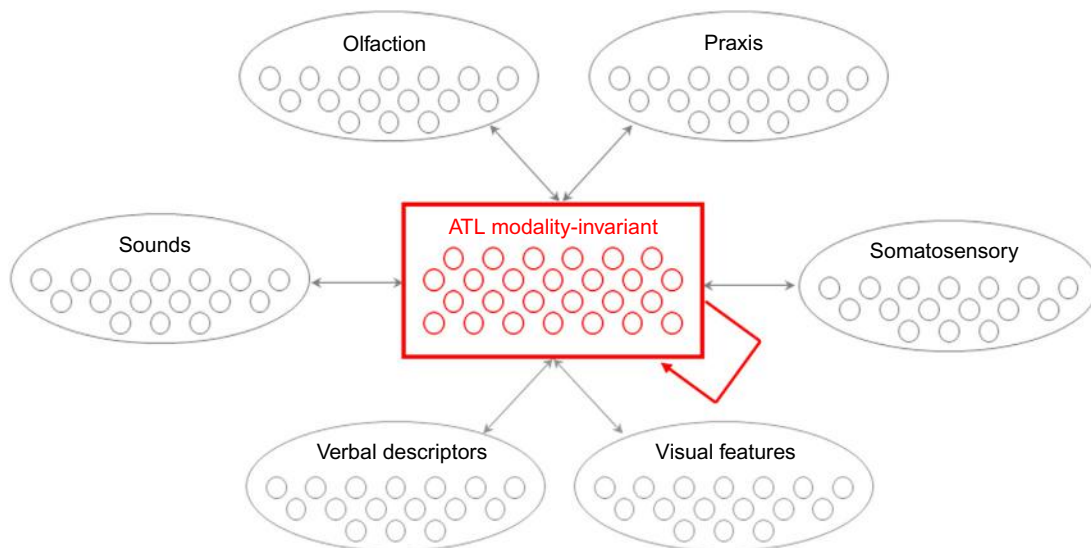

FIGURE 61.1 The “hub-and-spoke” model of conceptualization. Under this hypothesis, concepts are formed by the mutual interaction of modality-specific sources of information (the “spokes”) with a central representational hub (red) that provides additional modality-invariant representational resource. The spokes are assumed to rely on modality-specific secondary association cortical regions while regions within the anterior temporal region (and, perhaps, other tertiary association areas) underpin the transmodal hub. Conceptualization follows from the joint action of the hub and spokes (see text for further details). Various computational implementations of this framework have been described in detail and demonstrate how concepts can be coded in this framework and how data from SD and patients with unilateral temporal lobe damage can be mimicked. *From Rogers et al., 2004 and Schapiro et al., 2013.*

that a transmodal hub is also necessary. [Section 61.4](#) addresses reasons for locating the proposed hub in the anterior temporal lobe (ATL). [Section 61.5](#) offers evidence for the bilateral nature of the ATL hub. [Section 61.6](#), on the graded hub hypothesis, provides some more specific suggestions about different roles for various areas of the ATL.

61.2 THE IMPORTANCE OF THE SPOKES AND THE REGIONS FROM WHICH THEY EMANATE

It now seems almost incontrovertible that our knowledge about the modality-specific sensory and motor features of objects and other concepts is represented in or very near the same brain regions that process such information when it is encountered in the real world ([Barsalou, 2008](#)). This view, usually called either *grounded* or *embodied* cognition, is endorsed in one form or another by so many researchers that if we were to try to mention all of them, the rest of this section might consist of nothing but a list of references. Several different forms of evidence converge to support this idea, principally: (i) regionally specific patterns of brain activation, observed in healthy participants, that differ as a function of the modality or category of the stimulus and/or response; (ii) patterns of cognitive impairment, resulting from brain lesions in

different locations, that also differ in principled ways depending on the sensory or motor features of the stimulus or response; and (iii) data from transient disruption of neural function in different regions via transcranial magnetic stimulation in neurologically intact participants ([Pobric, Jefferies, & Lambon Ralph, 2010b](#)). To be sure, some specific claims about modality or category-specific effects are open to debate (see [Chen & Rogers, 2014](#), for a good discussion). To be even more sure, brain function is almost infinitely more subtle and complex than our limited ability to study it and think about it ([Patterson & Plaut, 2009](#)). This means that any claim for a simple relationship between a specific category and a specific brain region (e.g., “the fusiform face area [FFA] in the right posterior temporal lobe is completely and uniquely dedicated to processing faces”) is unlikely to characterize the true state of things in the brain. We already know that areas other than the FFA respond to faces ([Pitcher, Walsh, Yovel, & Duchaine, 2007](#)) and that damage to the FFA resulting in prosopagnosia typically disrupts some abilities beyond face processing ([Behrmann & Plaut, 2012](#)). Nevertheless, there is a considerable degree of sensory-feature and motor-feature specialization in both processing and representation of different kinds of things that no theory of semantic representation can ignore. And it is crucial to emphasize that, according to embodied/grounded theories, this specialization does not just reflect surface

features of stimuli: *words* referring to concepts of different types can also produce both brain activations in modality-relevant sensory or motor regions (Hauk, Shtyrov, & Pulvermüller, 2008; Pulvermüller, 2005; Simmons et al., 2007) (though see de Zubicaray, Arciuli, & McMahon, 2013 for an alternative interpretation of some results that might seem to support necessary activation in motor cortex when participants process action words) and distinctive patterns of impairment in patients with lesions in or near such sensory/motor areas (Boulenger et al., 2008; Pulvermüller et al., 2010). That is, a degree of specialization seems to apply to the concepts or mental representations of objects, not just objects in the real world.

In a useful review of “embodiment and the neuroscience of semantics,” Meteyard, Cuadrado, Bahrami, and Vigliocco (2012) placed various theories about conceptual knowledge on an embodiment continuum, from “strong” to “weak” to “secondary” to “absent.” The previous paragraph summarizes our reasons for rejecting theories that argue for purely abstract semantic representations with no element of embodiment. However, we also reject the most strongly embodied theories for reasons described in the next section. To summarize this first section, the hub-and-spoke hypothesis suggests that semantic knowledge is represented in a widely distributed brain network including modality-specific regions of cortex from which connections (spokes) emanate, sending activation to and receiving activation back from another essential component of the network: a transmodal semantic hub.

61.3 THE INSUFFICIENCY OF THE SPOKES AND THEIR SOURCES: WHY WE NEED A HUB

Strongly embodied theories of conceptual knowledge “effectively push semantics out into primary cortical areas and make it completely dependent on sensory and motor systems” (Meteyard et al., 2012, p. 793). In other words, according to such theories, the brain network for your knowledge of a concept such as *camel* consists only of the specific sensory/motor/linguistic features that you have experienced concerning camels. How do strongly embodied theories account for the fact that, on hearing the word “camel,” you can almost instantly generate all that other information mentioned in the introduction? They assume that all of the feature representations in the modality-specific regions of cortex are connected to one another. Hearing the word “camel” initially produces selective activation of an auditory/linguistic representation; then, in a pattern-completion fashion,

activation rapidly spreads via the inter-area connections to other modality-specific aspects of your camel knowledge. Straightforward enough, so why reject this hypothesis?

First, consider semantic dementia (SD), a neurodegenerative condition in the spectrum of frontotemporal dementia. The characteristics of SD especially germane to the current discussion—one neuroanatomical and four behavioral/cognitive—are as follows:

1. All clinical diagnoses of neurological origin are associated with a degree, larger or smaller, of variability across individual patients in “the three S’s”: site, size, and/or side of lesion. This fact, of course, makes it somewhat tricky to be confident about the precise neuroanatomical basis of the deficits. Such variability inevitably applies to SD, but it is widely agreed among researchers of neurodegenerative diseases that SD falls at the lower end of this spectrum of variability, especially in its early-middle phases (Acosta-Cabronero et al., 2011; Guo et al., 2013; Mion et al., 2010). To quote from Hodges and Patterson (2007), “Patients with even early-stage SD show bilateral, though typically asymmetrical, atrophy of the ATLs; as the disease progresses, the degeneration extends either caudally into the posterior temporal lobes or rostrally into the posterior, inferior frontal lobes, or both. Quantitative MRI studies... have refined these observations by showing consistent and extreme atrophy (commonly 50–80% gray matter loss) of the polar and perirhinal cortices and the anterior fusiform gyri (Davies, Graham, Xuereb, Williams, & Hodges, 2004; Du, Schuff, & Kramer, 2007; Gorno-Tempini, Dronkers, & Rankin, 2004)” (p. 1009). It should be noted that the hippocampus and entorhinal cortex are also substantially abnormal in SD (Chan, Fox, & Rossor, 2002; Williams, Nestor, & Hodges, 2005). Unlike the case of Alzheimer’s disease (AD), however, the medial temporal atrophy in SD is much more severe in the rostral than in the caudal region. Why SD patients, despite their hippocampal abnormality, do not have the profoundly impaired anterograde amnesia characteristic of AD is a fascinating and evolving story (Nestor, Fryer, & Hodges, 2006; Nestor, Fryer, Ikeda, & Hodges, 2003), but this is not especially germane to this chapter on semantic memory.

Results of the multimodal imaging study of SD patients and healthy controls by Guo et al. (2013), in agreement with many other investigations of SD, established that focal atrophy was confined to the ATL bilaterally. The critical finding of Guo et al., however, is that this focal structural damage was accompanied by reduced physiological integrity

- in many or all of the modality-specific regions demonstrated to be connected to the ATL in the control participants. Furthermore, the patients' semantic deficits correlated with both the ATL atrophy and the reduced connectivity to more specific regions. This one highly salient piece of research thus supports the existence and necessity of both the hub and the spokes. Guo et al. concluded that their evidence favors a model of the semantic network in which "a critical transmodal ATL semantic hub [is] positioned to integrate functionally relevant and topographically organized links to distributed modality-specific regions" (p. 2,988).
2. At least in the prefinal stages of the disease, the cognitive consequences of SD are largely confined to disruption of semantic knowledge per se (Guo et al., 2013; Hodges, Patterson, Oxbury, & Funnell, 1992; Snowden, Goulding, & Neary, 1989; Warrington, 1975) and of abilities in which semantic memory plays an important interactive role (Patterson et al., 2006).
 3. The deterioration of semantic memory in SD is pan-category and transmodal: different kinds of concepts (e.g., concrete/abstract; living/human-made) are all impaired, and the semantic deficits are apparent no matter what format of stimulus (object, picture, spoken word, written word, environmental sound, taste, touch, etc.) is used to probe for conceptual knowledge and no matter what modality of response (pointing, speaking, writing, drawing, etc.) is used to measure performance (Bozeat, Lambon Ralph, Patterson, Garrard, & Hodges, 2000; Rogers et al., 2004).
 4. The pattern of the cognitive deficits in SD invariably reflects an interactive impact of the familiarity or frequency of the stimulus concept (i.e., how often a concept is experienced) and the typicality of the stimulus in its domain (i.e., how similar each exemplar is to the category average or "prototype"). In many diverse tests and tasks that have manipulated the frequency and typicality of the stimuli, significantly impaired and poorest performance by SD patients is always observed for atypical and less familiar stimuli/concepts (Lambon Ralph et al., 2011; Patterson et al., 2006; Rogers et al., 2004; Woollams, Cooper-Pye, Hodges, & Patterson, 2008).
 5. The nature of the errors made by SD patients is anything but random and, in virtually any task, their errors can be described as resulting from failures of appropriate generalization and discrimination (see Lambon Ralph & Patterson, 2008, for an extended discussion of such errors in both receptive and expressive experimental tasks, as well as in everyday life, and in both verbal and

nonverbal contexts). In object naming, for example, instances of a category that are of moderate familiarity and typicality can no longer be discriminated correctly, resulting in errors such as naming a fox as "dog" or a zebra as "horse" or calling them both "animal." But less familiar and atypical animals such as a seahorse or a snail even fail to be generalized to the animal category: they usually result in content-less naming responses such as "a little thing" or "I don't know" or "what do you do with that?" (Patterson et al., 2007; Woollams et al., 2008). The same is true for object and word categorization: typical things are overgeneralized and atypical things are undergeneralized (Mayberry, Sage, & Lambon Ralph, 2011; Snowden, Griffiths, & Neary, 1996).

The first neuroanatomical characteristic indicates that the brain dysfunction in SD is typically centered on the ATL, with consequent disruption to the integrity of connections between the ATL and modality-specific primary and association cortices. The last four neuropsychological characteristics indicate that the cognitive abnormality is relatively restricted to semantic memory (and its impact on other tasks) and follows a highly consistent pattern. Given this set of well-established observations, it seems difficult to construct an account of SD that is compatible with a semantic network consisting only of modality-specific sensory, motor, and language regions of the brain. To our knowledge, there are no reports of significant structural degradation of modality-specific regions in SD. Furthermore, if SD did involve widespread degeneration of modality-specific regions, then it should yield cognitive deficits well beyond semantic memory, as seen in AD. For example, visuospatial processing depends substantially on parietal lobe regions; AD patients have parietal hypometabolism/atrophy with disrupted visuospatial ability; SD patients have neither (Pengas et al., 2010). Finally, if the transmodal semantic disorder in SD did arise from widespread abnormalities to modality-specific regions, then why would the pattern of disorder (the interaction between familiarity and typicality and the nature of the errors) be so consistent across all modalities and tasks? It seems much more plausible that the deficits in SD all emerge from disruption to a part of the semantic network that codes conceptual space independent of any modality-specific features of concepts in which the structure is defined by similarity of instances within domains and strongly influenced by familiar and typical instances (Rogers et al., 2004).

SD provides a clear, potentially definitive line of evidence against the strongest embodied theories of conceptualization, but it should also be noted that some researchers in related fields (such as philosophy,

e.g., Wittgenstein, 2001, and cognitive science, e.g., Rosch, 1975; Smith & Medin, 1981) have also argued that models based on modality-specific features alone might be inadequate for the formation of coherent concepts and categories. A full exposition of the various arguments is beyond the scope of this chapter (these can be found in Lambon Ralph, 2014; Lambon Ralph, Sage, et al., 2010; Patterson et al., 2007; Rogers & McClelland, 2004), but the kernel of the issue is that the relationship between the abundance of modality-specific information and the plethora of concepts that emerge from them is highly complex and nonlinear. Our key working hypothesis, implemented computationally (Rogers et al., 2004; Schapiro, McClelland, Welbourne, Rogers, & Lambon Ralph, 2013) and supported neuroanatomically (Binney, Parker, & Lambon Ralph, 2012; Guo et al., 2013), is that concepts represent the *joint* action of distributed modality-specific regions (the “spokes”) with an intermediate transmodal representational region (the “hub”). The hub provides the key additional computational capacity to draw the multiple and complex sources of information together, thereby deriving coherent and generalizable concepts.

61.4 WHY SHOULD THE HUB BE CENTERED ON THE ATL?

The principal argument here is, unsurprisingly, that the SD patients whose behavior strongly suggests the existence of a semantic hub have atrophy consistently centered on the ATL. It is worth noting that the best hypothesis about the location of a semantic hub in the ATL has changed somewhat since the earliest proposals. Because damage (e.g., as measured by VBM analyses on structural MR images in SD) appears to be maximal at the temporal pole (Brodmann area 38), that was the originally suggested hub region (Hodges et al., 1992; Patterson & Hodges, 2000). These earlier studies did not have sufficient power—because of relatively low patient numbers—to support correlations between lesion location and semantic performance. With improved diagnostic recognition of and further research on SD, however, that limitation has begun to recede, and the best evidence points to a region in the ATL posterior to the temporal pole, the anterior portion of the fusiform gyrus, which is subjacent to the head and body of the hippocampus (Brodmann areas 20 and 36). That is, atrophy and hypometabolism are severe across the entire anterior temporal region including both the temporal pole and this slightly more posterior and inferior region; however, the abnormality in the anterior fusiform correlates best with semantic scores (Libon et al., 2013; Mion et al., 2010).

Because no one is satisfied with scientific proposals/conclusions based on a single form of evidence, it is fortunate that there are populations other than SD patients and techniques other than the ones already mentioned that are compatible with a transmodal component of the semantic network located in the ATL. In this context, it is vital to note that standard fMRI—the source of most evidence concerning localization of function in the healthy brain—has been a rather inadequate source of evidence concerning the ATL because of various methodological limitations, including MRI field inhomogeneities, limited field-of-view, and the nature of the baseline task against which semantic task performance is compared (Devlin et al., 2000; Visser, Jefferies, & Lambon Ralph, 2010). Functional imaging studies using full field-of-view PET have often reported ATL activations when healthy participants perform semantic tasks (Sharp, Scott, & Wise, 2004; Vandenberghe, Price, Wise, Josephs, & Frackowiak, 1996). Furthermore, the relevance of the ATL to semantic knowledge is supported by recent results from: (i) distortion-corrected fMRI of this region (Visser, Jefferies, Embleton, & Lambon Ralph, 2012; Visser & Lambon Ralph, 2011); (ii) multivoxel pattern analyses of fMRI data (Peelen & Caramazza, 2012); (iii) the application of rTMS to the lateral part of this region (Lambon Ralph, Pobric, & Jefferies, 2009; Pobric, Jefferies, & Lambon Ralph, 2010a; Pobric et al., 2010b; Pobric, Jefferies, & Lambon Ralph, 2007); and (iv) source-based analyses of MEG signals (Marinkovic et al., 2003).

Three kinds of evidence combine to suggest that the ATL might constitute a reasonable location for a transmodal semantic hub. First, findings from nonhuman primate physiology (Gloor, 1997) and human functional and structural connectivity studies (Binney et al., 2012; Guo et al., 2013) indicate that a number of primary sensory and motor areas, along with their related association cortices, connect to and merge information in the ATL. Second, in addition to the rather factual nature of much conceptual information, semantic memory is often “flavored” by aspects of emotion and reward. Brain regions vital to these aspects of experience, including the amygdala and other limbic structures as well as the orbitofrontal cortex, are also close and well-connected to the ATL. Finally, the temporal lobe regions apparently important in semantic memory are immediately adjacent to the anterior parts of the medial temporal lobe memory system critical for rapid learning of new episodic information. Conceptual knowledge, although mostly, and for good reasons, acquired gradually (McClelland, McNaughton, & O’Reilly, 1995), is ultimately based on information experienced in episodes.

As a final note on this topic, it is potentially interesting and important that the center of the ATL

transmodal hub (anterior fusiform/ITG) aligns with previously separate literature on neurophysiological evidence from patients who have depth or grid electrodes surgically implanted as part of investigation and treatment for long-term epilepsy. Ventral ATL regions are often considered to be visually specific, reflecting the apex of a visual “ventral” stream of processing (Albright, 2012); however, the same area also apparently plays a role in language processing. In their seminal studies, Lüders et al. (1986, 1991) demonstrated that stimulation of this region gave rise to transient language impairment (of reading and naming) and, consequently, they coined the term “basal temporal language area.” Direct measurement of local field potentials confirmed its role in naming (Nobre, Allison, & McCarthy, 1994). More recent studies have demonstrated that these regions show sensitivity to semantic categories, but not low-level variations in visual characteristics (e.g., orientation and size). Strikingly, these semantic effects emerge very rapidly (~120 ms) after the onset of the stimulus (Chan et al., 2011; Liu, Agam, Madsen, & Kreiman, 2009). Although further direct comparisons with SD patients and functional neuroimaging are required, these data from the cognitive neurosurgery literature appear to support the hypothesis that this region is the centerpoint of a transmodal semantic hub.

61.5 EVIDENCE FOR AND POSSIBLE REASONS FOR A BILATERAL ATL HUB

So far, our attention has been on the ATL as a whole and in the singular. In the next two sections we consider emerging evidence for subdivisions both within the ATL in each hemisphere, from dorsal to ventral (see Section 61.6) and (in this section) across the two hemispheres. The ATL abnormality in SD patients is always bilateral (although often very asymmetrical, at least until late in the disease), suggesting that both left and right regions may contribute to conceptual knowledge. Other patient groups with clinically notable impairment of semantic memory typically have bilateral ATL damage [e.g., AD (Hodges & Patterson, 1995) and herpes simplex virus encephalitis (Lambon Ralph, Lowe, & Rogers, 2007; Noppeney et al., 2007)]. Likewise, formal meta-analyses of the functional neuroimaging literature indicate that both ATLs are implicated in semantic function in neurologically intact participants (Binder, Desai, Graves, & Conant, 2009; Visser et al., 2010). These neuropsychological and neuroimaging results prompt some obvious but important questions. First, does semantic impairment require bilateral ATL damage? And, if so, then what are the roles of the left versus right ATL?

Recent studies that have explored semantic function in patients with unilateral ATL damage indicate that semantic performance is generally much better than in patients with bilateral ATL diseases, especially SD. With more sensitive assessments, however, expressive and receptive semantic deficits can be observed after unilateral ATL lesions (Bi et al., 2011; Lambon Ralph, Cipolotti, Manes, & Patterson, 2010; Lambon Ralph, Ehsan, Baker, & Rogers, 2012). These contemporary studies fit with the older comparative neurology literature that consistently reported chronic multimodal (visual and auditory) “semantic” impairment in primates and monkeys after bilateral ATL resection, but only a milder and transient form of the same impairment after unilateral resection (Brown & Schafer, 1888; Klüver & Bucy, 1939). Intriguingly, and relevant to the cross-methodology data noted at the end of their seminal paper, Klüver and Bucy highlighted striking similarities between primates following bilateral ATL resection and the patients previously described by Pick with frontotemporal dementia. The same pattern as that observed in the primate studies was replicated in a rare human single-case neurosurgery study (Terzian & Dalle Ore, 1955). In an (ultimately unsuccessful) attempt to control the patient’s epilepsy, these investigators performed sequential full-depth ATL resections. As in the previous primate studies, after initial unilateral removal, the patient exhibited transient deficits of language, recognition and memory. However, after bilateral resection, a chronic and severe comprehension deficit emerged, along with other features of what is now referred to as Klüver-Bucy syndrome. Taken together, the full (although admittedly still rather limited) set of neuropsychological and neurosurgery findings can be summarized as follows: unilateral ATL damage generates semantic impairment in the acute stage that often diminishes rapidly, leaving patients in the chronic phase with a mild comprehension deficit. This impairment can be detected with sensitive neuropsychological assessments but is nothing like the level of semantic impairment found in SD and other bilateral ATL diseases.

Before considering the explanation for these findings in more detail, a brief aside to avoid potential confusion is merited. By far the most famous example of bilateral temporal resection is that of patient HM. After surgery, he and the other patients reported in the seminal case-series study of Scoville and Milner (Scoville & Milner, 1957) presented with profound anterograde amnesia but not with other impairments of higher cognition, including language and semantic memory. At face value, this might appear to contradict the hypothesis that semantic representation is reliant on a bilateral ATL system; in

fact, a closer consideration of the location of the resections adds further weight to our hypothesis that the ventrolateral aspects of the ATL are crucial to semantic memory. Because of the fact that Scoville used an orbital approach to the medial temporal regions when performing the bilateral selective hippocampectomy (rather than the lateral approach commonly used in most modern neurosurgical procedures), the ventral and lateral aspects of the ATL were preserved in patient HM and the other patients in the original case series.

The notion that both left and right ATL contribute to semantic representation is reinforced by recent studies applying rTMS to neurologically intact participants. The technique is complementary to neuropsychological studies in that one can assess performance before stimulation and then after it during the transient refractory period. Its advantage over lesion studies is that the location and timing of the stimulation are under experimental control; however, the behavioral effect of stimulation is (happily!) not only transient but also much smaller than that of neurological damage. Careful, sensitive assessment methods are thus required. As noted, SD patients always have bilateral temporal abnormalities, making it difficult in SD to separate and establish a selective role, if any, of left versus right ATL. It is possible, however, to contrast the effect of rTMS to left versus right ATL, and this has been done for verbal and nonverbal comprehension tasks in a series of studies (Lambon Ralph, Pobric, & Jefferies, 2009; Pobric et al., 2010a). In these studies, rTMS to either ATL generated an equivalent effect on both verbal and nonverbal semantic tasks, thus supporting our working hypothesis that both ATLs contribute to a transmodal semantic hub.

A potential explanatory framework for the patient (SD and unilateral resection) and rTMS results was explored in a recent computational model of bilateral ATL semantic representation (Schapiro et al., 2013). This was based on a direct extension of the original Rogers “hub-and-spoke” computational model (Rogers et al., 2004). Instead of a single transmodal representational hub, however, Schapiro and colleagues split it into two separate “demi-hubs” with only partial connectivity between them. The model, which was trained in exactly the same manner as the Rogers single-hub variant, was able to learn all of the training patterns despite having a lower number of connections overall. When considerable unilateral damage was applied to the simulation, a small semantic impairment resulted that could be reduced by allowing some postdamage weight adjustment (to mimic spontaneous recovery: Keidel, Welbourne, & Lambon Ralph, 2010; Welbourne & Lambon Ralph, 2007; Welbourne, Woollams, Crisp, & Lambon Ralph, 2011). In contrast, when the same total amount of damage

was distributed across both demi-hubs, a substantial and considerably greater semantic deficit emerged—replicating the difference between patients with unilateral versus bilateral ATL lesions. Detailed analysis and mathematical exploration demonstrated that the difference between unilateral and bilateral damage in the model was related to the differential propagation of noisy activation. Damage in any computational model not only diminishes the level of activation but also adds noise to its processing. When damage is focussed within one (only partly interconnected) demi-hub, the unaffected system generates strong and relatively noise-free activations that are able to dominate the response from the model; thus, it performs generally accurately (albeit slightly less efficiently than before). In contrast, bilateral damage across both demi-hubs results in weakened and noisy representations, leading to inaccurate responses.

Although it seems clear that both left and right ATLs are important to conceptual knowledge, the current literature contains mixed results and conclusions regarding the nature of the contribution from each side. Based on results from a variety of techniques, some researchers argue for a left–right dissociation in which the left ATL is primarily responsible for verbal semantic processing, whereas the right is much more important in processing faces, objects, and nonverbal sounds (Gainotti, 2012, 2014; Mesulam et al., 2013; Snowden, Thompson, & Neary, 2004; Thierry & Price, 2006). Other research groups report results more compatible with either similar contributions from the two ATL sides or at least only graded dissociations. Furthermore, even results indicating left–right dissociation are open to a different and more subtle interpretation than a categorical “left = verbal, right = nonverbal.” There is no doubt that cortical regions posterior to the ATL have significantly different involvement in the processing of verbal versus nonverbal information. Given that the great majority of corticocortical connections are very local and within rather than across hemisphere, this means that as information moves from caudal (sensory) regions to rostral (conceptual) regions, verbal input will activate the left ATL more than the right, and nonverbal input such as faces and objects will preferentially activate the right ATL. This account of left/right differences in semantic processing, including two implemented computational models, has been advanced by Ikeda, Patterson, Graham, Lambon Ralph, and Hodges (2006); Lambon Ralph, McClelland, Patterson, Galton, and Hodges (2001); Mion et al. (2010), and Schapiro et al. (2013).

In conclusion, the current literature provides only a partial answer to the nature of the contribution of left versus right ATL to semantic processing. There is broad agreement (across methods and patient groups)

that both left and right ATL contribute in some fashion and that the left ATL is more involved than the right in generating names and speech from semantic memory. The issues that are subject to considerable current research activity center around two alternative hypotheses: (i) graded connectivity-related differences in the contribution of each ATL to a primarily bilateral neural system or (ii) a more modular distinction in which each ATL is relatively specialized for discrete subdivisions of semantic processing.

61.6 THE GRADED HUB HYPOTHESIS

In this final section, we consider potential functional variations within each ATL. As noted, although the robust and consistent data from SD patients have been crucial in linking bilateral ATLs to semantic representation, these findings are a less powerful source of information regarding the contributions of left versus right ATL. In a similar vein, although the atrophy in SD is generally agreed to be more profound in the ventral than the dorsal ATL, most of the ATL is abnormal by the time that SD patients come to clinical attention, with the result that the condition of SD is insufficient to inform us about potential variations in representation of conceptual knowledge from dorsal to ventral regions. There is also the question of lateral versus medial aspects of the ATL. All of these “unknowns” constitute yet another reason for adopting multiple methods, because limitations in one approach can often be compensated by advantages conferred by other techniques.

Ever since the seminal work of Brodmann (1909), it has been known that there are variations in cytoarchitecture that, in turn, imply different types of neurocomputation. Two major distinctions in the ATL region noted by Brodmann were a shift from granular through dysgranular to agranular cortex in moving from lateral to medial structures around the temporal pole and a significant change in cytoarchitecture from BA22 (approximately equivalent to the superior temporal gyrus) to the neighboring areas (pole, BA38; middle and inferior temporal gyri, BA21 and BA20, respectively). Although noting that there were also differences between the other ATL regions (sufficient to give them different labels), Brodmann commented that they were graded rather than absolute differences; in fact, it is possible to consider them to be one single larger cytoarchitectural region as some of his contemporaries did. Modern, sophisticated studies (Ding, Van Hoesen, Cassell, & Poremba, 2009) have increased the number of cytoarchitectural divisions proposed for the ATL but, echoing Brodmann’s original observations, these divisions are thought to be graded rather than

absolute in nature. Although local cytoarchitecture is only one factor in neurocomputation (others—like connectivity—are also crucial), these classic and contemporary findings might lead us to expect some functional variations across the ATL, albeit they are probably graded in nature.

Recent (distortion-corrected) neuroimaging studies have provided new insights about white-matter connectivity within the ATL and also the location of semantically related functional activations. With regard to white-matter connectivity, Binney et al. (2012) observed connections both along gyri and between neighboring gyri, providing a neural basis for blending of information in a rostral and lateral direction along the temporal cortex. In addition, there is a more regionally specific pattern of connectivity from the temporal lobe to other areas: the temporopolar cortex is primarily connected via the uncinate fasciculus to orbitofrontal and ventral prefrontal regions; posterior temporal areas to inferior parietal regions; and superior temporal areas to inferior prefrontal regions. Very similar patterns of connectivity have been revealed by a recent analysis of resting-state functional connectivity seeded from different parts of the human temporopolar cortex (Pascual et al., 2013). These long-range connections are likely to be germane not only for considering how various forms of modality-specific information interact with a transmodal ATL hub but also for considering how semantic representations interface with other cognitive mechanisms, such as executive functions and working memory (Binney et al., 2012; Jefferies & Lambon Ralph, 2006).

With the benefit of methods and techniques to allow effective probing of activations across the entire ATL (including ventral regions), recent fMRI studies have started to reveal various graded patterns of semantic activation, which seem to fit with the graded differences in connectivity and cytoarchitecture in this area (Binney et al., 2012; Ding et al., 2009). These neuroimaging studies point to the bilateral ventrolateral subregion as the centerpoint of a graded ATL semantic hub. Across studies, this region is consistently activated, irrespective of task, input modality, or category of stimuli (Sharp et al., 2004; Vandenberghe et al., 1996; Visser et al., 2012; Visser & Lambon Ralph, 2011). Moving away from this neural location, there seem to be gradual shifts in the semantic function dependent on the proximity/connectivity to different primary inputs (Visser et al., 2012; Visser & Lambon Ralph, 2011). Thus, activation is more sensitive to auditory-related stimuli (verbal and nonverbal) in lateral superior regions and to visual inputs in posterior ventral temporal areas. These early explorations of the ATL region are consistent with variants of the hub-and-spoke model that include graded variations of connectivity (Plaut, 2002).

In summary, recent evidence has made it clear that the ATL does not function as one undifferentiated mass but rather with important graded variations of function across the region. Given the pattern of its structural and functional connectivity, these graded changes in ATL function appear to reflect the varying influence of different inputs and outputs on the processing in local ATL subregions.

61.7 CONCLUDING COMMENT

Semantic memory/conceptual knowledge is central to much of human life. It may not be involved when you walk into a room to sit down, but recognizing that an unfamiliar chair is something on which to sit requires semantic memory. It may not be involved when you move your tongue and lips, but it is the basis of every novel utterance that you make. A huge amount has been learned about this central aspect of human function in the relatively short time in which cognitive neuroscientists have been addressing it in their experimental work and theorizing, but there is so far to go that future models of the organization and neural basis of semantic memory may look like “objects” that we have never encountered before. It would be a foolhardy researcher who tries to predict which of the field’s current interpretations of data will still be alive one or several decades from now. Maybe the proposal of a semantic hub will be here today and gone tomorrow. All we can say is that today, we find it difficult to conceive of a hub-less framework that would account for existing data regarding semantic memory.

What Does It Mean? A Review of the Neuroscientific Evidence for Embodied Lexical Semantics

Olaf Hauk

MRC Cognition and Brain Sciences Unit, Cambridge, UK

62.1 INTRODUCTION

We often have the impression that we create a “mental image” of concepts when we refer to them in discourse, remember them, or reason about them. This seems to suggest that concepts can evoke similar processes as those engaged during the acquisition of this concept. Philosophers have entertained the idea of mental images, in the sense of re-experienced perceptions or actions, for a long time. David Hume stated that the idea of the color red and the actual perception of red differ only in degree and not in nature (Hume, 1985). Immanuel Kant claimed that we cannot think about a line without drawing it in our mind (Kant, 1995). However, the delineation of unconscious and possibly automatic semantic processing from more deliberate and effortful conceptual processing and mental imagery is still a major issue in cognitive science. In the neuroscience of language, the degree to which representations and processing of semantics relies on brain systems for perception and action is still a matter of great controversy.

Most authors will agree that lexical semantics is about the relationship between symbols and what they represent, as well as their relationship to other symbols and their meanings. Unfortunately, relating specific experimental results to such a general definition is not straightforward. Any single study will need to make a choice of particular symbols and particular things they stand for, modes of presentation, contexts, task instructions, and measurements. This chapter introduces the major theoretical approaches in research on embodied

semantics, describes the most popular neuroscientific methods used to test them, and provides a selective overview of the empirical literature. The main focus is on lexical semantics (i.e., the meaning of words and symbols), but references to other conceptual domains (e.g., sentence-level processing) will be made where appropriate.

62.2 MODELS OF EMBODIED SEMANTICS

Several authors have pointed out that a clear definition of “embodiment” or “grounding” is lacking (Chatterjee, 2010; Hauk & Tschentscher, 2013; Mahon & Caramazza, 2009; Meteyard, Cuadrado, Bahrami, & Vigliocco, 2012; Pulvermüller, 2013b; Wilson, 2002). Here, I review the literature in light of the empirically tractable question: which brain systems subserve specific perceptual and motor functions and contribute to semantic representations and processes? Answering this question requires researchers to define the brain systems that subserve specific perceptual and motor functions, as well as criteria for semantic representations and processes. Disentangling representations and processes may be impossible. Representations can be measured only if they affect the outcome of processes in both behavioral and neuroscientific studies (Anderson, 1978).

The “grounding problem,” for example, was formulated by Harnad (1990). In a system that only consists of symbols and relationships among symbols, no symbol can have “meaning,” because to get to the meaning of one symbol, one would have to follow a

path of relationships among symbols that do not have meaning either. Therefore, at least some concepts must be grounded in nonsymbolic representations. Harnad suggests a hybrid model of the conceptual system that contains symbolic and nonsymbolic representations. It is not obvious where these nonsymbolic representations should be located. The idea that semantics is widely distributed across the brain was articulated well before the neuroimaging days (Gage & Hickok, 2005). Does a concept have to reactivate the retina, LGN, V1, or higher visual association areas? Does it matter whether an action-word activates primary or premotor cortex or SMA? Unless we can specify a clear boundary of what is just periphery and preprocessing, and what is essential for the generation of meaning, we cannot come to a conclusion here—but this is exactly the question “what is meaning?”

Some of the major theoretical approaches dealing with the grounding problem are illustrated in Figure 62.1 and share some important features. They postulate that semantics emerges from an interplay of distributed sensory-motor areas that represent visual, auditory, and tactile information, and amodal or polymodal “core language areas,” “hubs,” or “higher-order association cortices” that bind these distributed areas together. These models have been developed for different purposes and on the basis of different types of empirical data, and it is unclear whether neuroscience can currently provide data that can clearly distinguish between these theories. In the following, the main features of these models are briefly highlighted.

Arguably the first empirical support for the view that semantic categories are differentially represented in the brain came from neuropsychological patients who were differentially impaired regarding concepts relating to living and nonliving things (Warrington & Shallice, 1984). This led to the “sensory-functional hypothesis” that semantic knowledge is structurally organized according to its reliance on perceptual (such as for animals) or functional (such as for tools) features (Martin, 2007).

The involvement of perceptual-motor systems is an essential part of Barsalou’s theory of “Perceptual Symbol Systems” (PSS; Figure 62.1A) (Barsalou, 1999). Association areas of the brain are formed during perceptual experience in a bottom-up manner and are sensitive to patterns in sensory-motor systems. These association areas have the capacity to reactivate sensory-motor areas to form modal and analogical perceptual symbols. PSS theory later led to the “Language and Situated Simulation” theory (Barsalou, 2009; Simmons, Hamann, Harenski, Hu, & Barsalou, 2008), which assumes that conceptual

processing can be broken down into two stages: an early “linguistic” stage, which comprises basic and possibly unconscious word recognition processes as well as retrieval of word associations, and a later “situated simulation” stage, which represents “deep conceptual information” that can be conscious and deliberate, which is the basis for “symbolic processes such as predication, conceptual combination, and recursion” (Barsalou, 2008).

The idea of hierarchically organized convergence zones is also a key part of Damasio’s framework of “convergence and divergence zones” (CDZs; Figure 62.1B) (Damasio, 1989; Meyer & Damasio, 2009). Convergence zones develop on the basis that “temporally coincident activity at the separate sites modifies the connectivity patterns to, from, and within a shared CDZ downstream” and, therefore, “CDZs register linkages among knowledge fragments” (Meyer & Damasio, 2009). The authors point out that CDZs are not the representations themselves, “but, rather, establish meaning via time-locked multiregional retro-activation of early cortices.”

The formation of connections between sensory-motor and perisylvian core language areas on the basis of associative learning is postulated in Pulvermüller’s theory of semantics (Pulvermüller, 1999, 2013a; Figure 62.1C). During language acquisition, the co-occurrence of word forms such as “kick” or “grass” with the execution of kicking movements or the perception of grass, respectively, forms automatic associations between core language areas in perisylvian brain regions and the corresponding sensory-motor regions. This theory has led to the specific “somatotopy of action-words” (SAW) model, which makes the specific prediction that different types of action-words (“pick, kick, lick”) should activate motor cortex in a somatotopic manner in accordance with the associated effectors (Pulvermüller, 2005).

Connectionist models of semantics attempt to model semantics as emerging from distributed neuronal networks, where semantic and word form features are represented as distributed activation patterns in different layers of a neuronal network. In a neuropsychologically inspired implementation, the connection between written and spoken word forms and distributed semantic features in sensory-motor areas are accomplished by a “semantic hub” in the anterior temporal lobes (Figure 62.1D; Patterson, Nestor, & Rogers, 2007; Rogers et al., 2004).

A number of authors have focused on amodal or polymodal brain areas involved in semantics but allow for the possibility that aspects of semantics may be distributed across larger brain systems (Binder & Desai, 2011; Poeppel & Hickok, 2004; Price, 2000). Some authors have concluded that

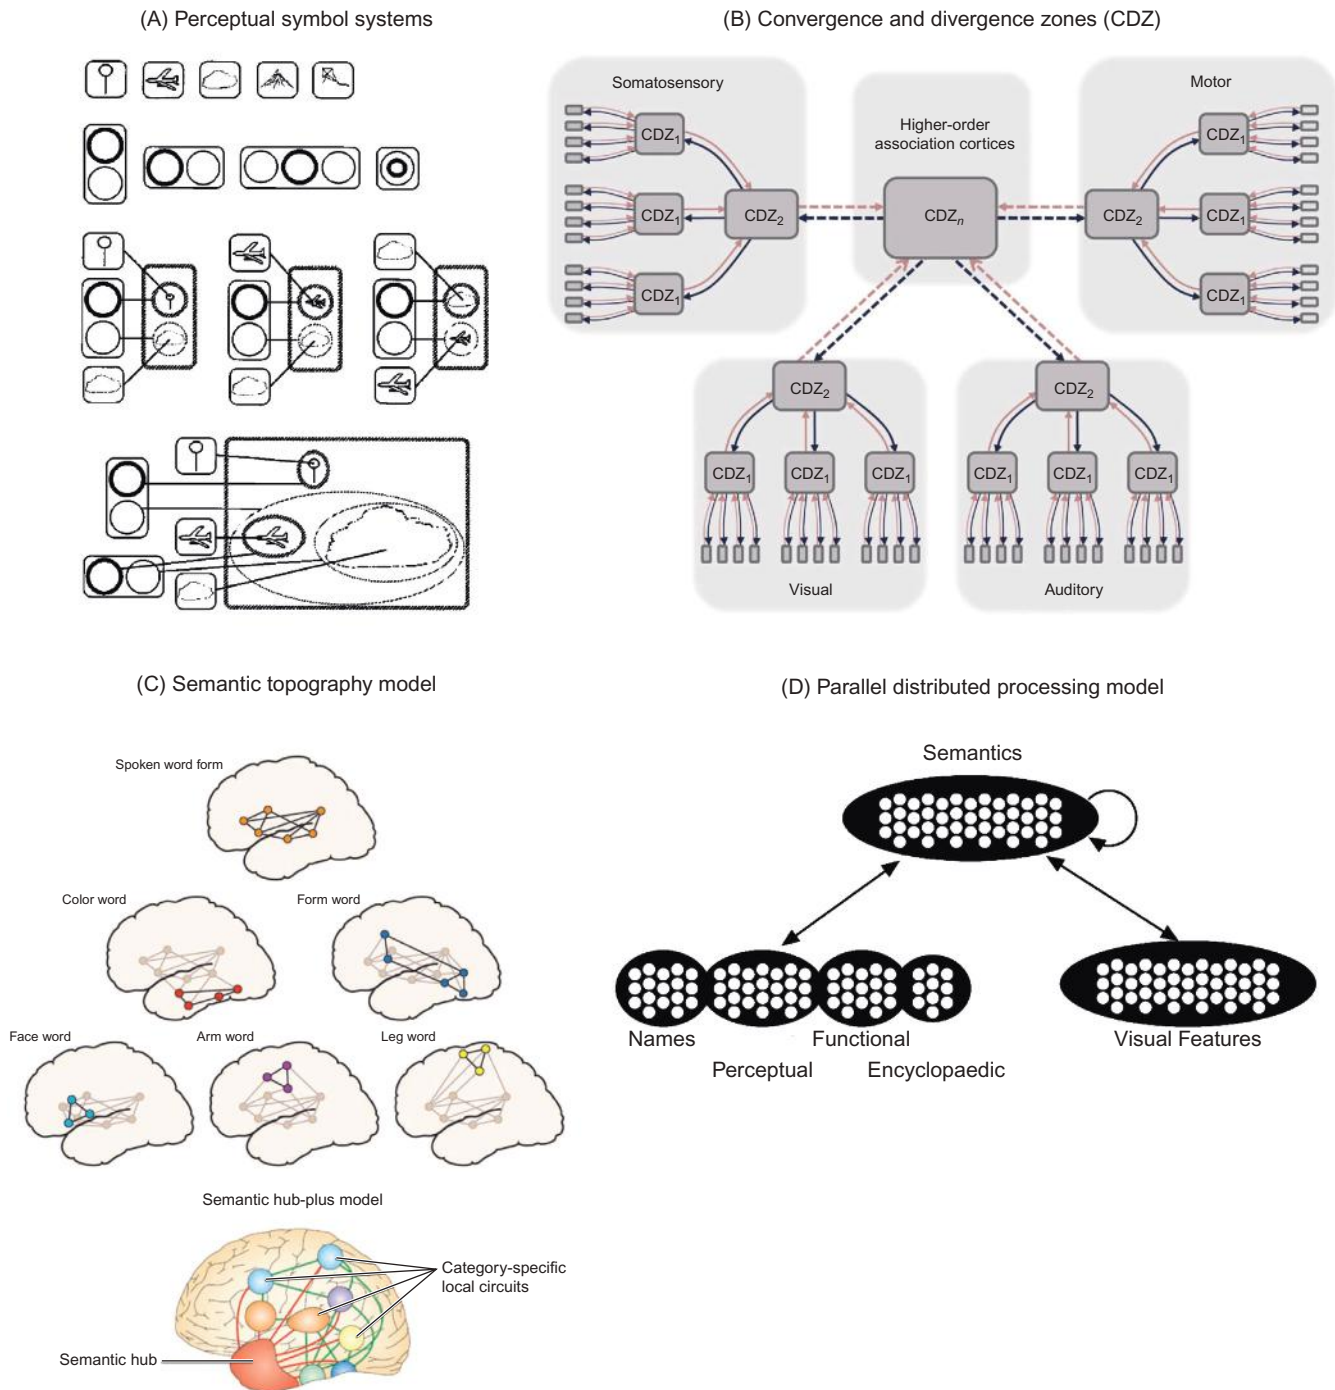

FIGURE 62.1 Illustration of models for conceptual-semantic representations that assume a link to sensory-motor systems. (A) Perceptual symbol systems and how they describe (i) object categorization, (ii) spatial relationships, (iii) combinatorial, and (iv) recursive processing. (B) Convergence and divergence zones. (C) Semantic topography model. (D) Parallel distributed processing model. (A) From *Meyer and Damasio (2009)*; (B) from *Barsalou (1999)*; (C) from *Pulvermuller et al. (2010)*; (D) modified from *Rogers et al. (2004)* with permission from the publisher.

“conceptual knowledge is represented within a non-differentiated distributed system” (Tyler et al., 2003). Others have argued against the idea of strong embodied semantics and argue that “concepts are, at

some level, ‘abstract’ and ‘symbolic,’ with the idea that sensory and motor information may ‘instantiate’ online conceptual processing” (Mahon & Caramazza, 2008).

62.3 METHODS FOR NEUROSCIENTIFIC RESEARCH ON EMBODIED SEMANTICS

A large number of behavioral studies have shown effects of congruency between semantic features of a stimulus (word, sentence, picture, etc.) and the type of response execution (finger response, foot response, pull versus push a lever, etc.). Results of this kind are interesting and useful because they demonstrate how task irrelevant semantic stimulus features can affect task performance. However, they are not direct evidence for the neuronal overlap of the representations and processes for action concepts and movements. Such interference could still occur at a higher level, where information from these two systems converges, or it could be caused by spreading activation (i.e., a passive “leakage” of activation from one brain system to another) without a functional contribution.

It is generally acknowledged that neuroimaging tools such as functional magnetic resonance imaging (fMRI), positron emission tomography (PET), electroencephalography (EEG), and magnetoencephalography (MEG) are correlational (Henson, 2005), that is, an effect obtained with either of these measures can be either cause or consequence of the perceptual or cognitive processes assumed to elicit it. Arguably the most extensively used method in the neuroscience of embodied semantics is fMRI, whose main appeal lies in its high anatomical precision in the millimeter range (Brett, Johnsrude, & Owen, 2002). Unfortunately, the BOLD response—which is the basis for most standard fMRI results—only provides snapshots of brain activity with an exposure duration of several seconds. Interpreting these data therefore requires a model for the relationship between stimulus and brain activity for at least 2 s or more.

One remedy for this problem is using the millisecond temporal resolution of EEG and MEG, which can provide upper limits for the earliest latency at which a stimulus feature affects brain responses. Psychophysiological measures such as EEG and MEG can be analyzed as event-related potentials or fields (ERPs and ERFs), often characterized in terms of “components” (P100, N400, etc.), or as time-frequency representations of the brain signal, which provide information about brain responses in specific frequency bands (such as alpha, beta, gamma, theta). However, a clear one-to-one relationship between components or frequency bands and brain processes cannot be assumed. The spatial resolution of EEG and MEG is limited (Hauk, Wakeman, & Henson, 2011), but it is reasonable to assume that high-density EEG and MEG recordings can distinguish different sensory-motor modalities and resolve the somatotopy of motor cortex. The most direct—although invasive—way to

obtain signals from specific brain areas is to measure the electrocorticogram (ECoG) from the cortical surface (Edwards et al., 2010) or to record from intracranial electrodes.

A method that has the potential to reveal causal involvement of brain areas in cognitive processes is transcranial magnetic stimulation (Devlin & Watkins, 2006). Brief magnetic pulses, either applied during stimulus processing (“single-pulse”) or as a sequence of pulses before testing for repetitive TMS (“rTMS”), are applied to specific brain sites. The effect of TMS is often described as “temporary lesions” but, depending on stimulus parameter and experimental paradigm, facilitatory effects can also be obtained. TMS can also be used to elicit motor-evoked potentials (MEPs), such as evoked electrical voltage deflections measured along a muscle (e.g., of the thumb). However, this method is also only correlational because it can detect an effect of stimulus or task features on motor cortex activity but not a causal role of motor cortex activity on behavioral performance.

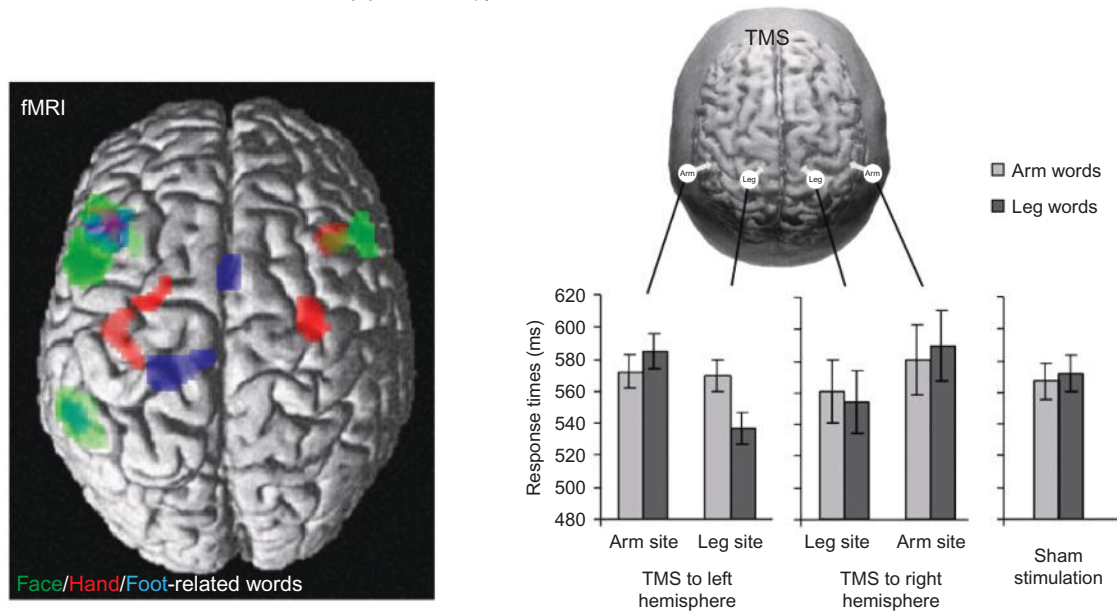

Lesion studies can also provide evidence for causal relationships between brain areas and cognitive processes. It is not straightforward to determine how secondary effects of brain lesions, such as inability to move specific effectors and neuronal plasticity, may affect performance in experimental paradigms. Nevertheless, a clear double dissociation in patient groups, for example, demonstrating impairment of action-knowledge after impairment of motor cortex in one group and impaired visual knowledge in patients with impaired visual cortices, would be strong evidence for involvement of sensory-motor brain areas in semantics.

As with all empirical studies, there are general methodological issues with respect to replicability and publication bias (Ioannidis, 2005; Vul, Harris, Winkielman, & Pashler, 2009). For example, for a given result, it is worth asking how many unpublished null effects there may be or whether the results were obtained using a prespecified analysis pathway (Wagenmakers, Wetzels, Borsboom, van der Maas, & Kievit, 2012).

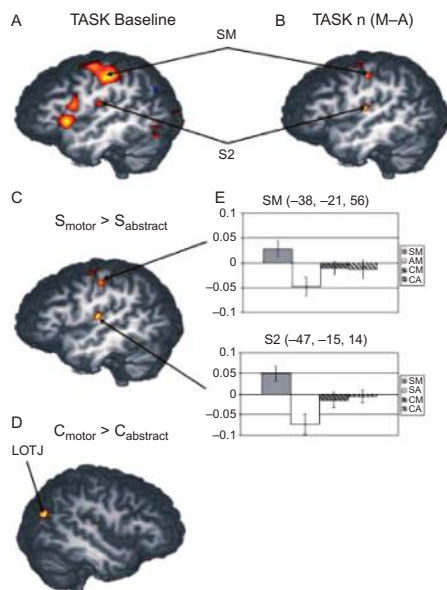

62.4 REVIEW OF THE EMPIRICAL LITERATURE

Some previous reviews of the empirical literature on embodied language have argued in favor of an embodied view on language and semantics (Fischer & Zwaan, 2008; Kiefer & Pulvermuller, 2011; Pulvermuller, 2013a). Others have focused on the difficulties in defining the concept of embodiment (Chatterjee, 2010; Hauk & Tschentscher, 2013;

(A) Somatotopy of action-words

(B) Concrete vs Abstract action verbs (fMRI)

(C) Action words in literal and idiomatic context (MEG)

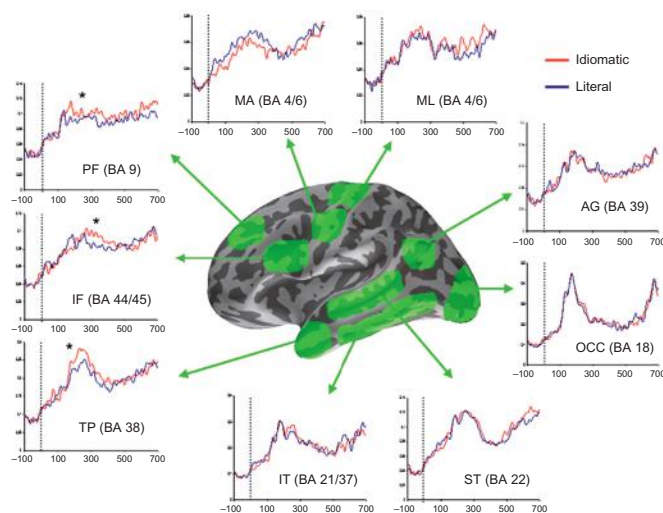

FIGURE 62.2 Examples of neuroscientific studies investigating the involvement of sensory-motor systems in action-word processing. (A) Left: fMRI results for somatotopic activation of cortical motor areas in response to face-, hand-, and foot-related words, respectively. Right: TMS evidence that stimulation of left-hemispheric hand-motor and foot-motor cortex facilitates hand-word and foot-word processing, respectively. (B) Results from an fMRI study that reported motor cortex activation to concrete action verbs, but not abstract verbs based on action concepts. SC/MA: simple/complex motor/abstract verbs. (C) Time course of brain activation for action-words in idiomatic and literal contexts as revealed by MEG source estimation. (A) Left: modified from *Hauk et al. (2004)*; right: from *Pulvermüller, Hauk, Nikulin, and Ilmoniemi (2005)*; (B) from *Ruschmeyer et al. (2007)*; (C) from *Boulinger et al. (2012)* with permission from the publisher.

Mahon & Caramazza, 2009; Meteyard et al., 2012), and some have adopted a critical stance and argue that embodiment plays a minor role in language processing (Mahon & Caramazza, 2008). This chapter presents

some typical studies that illustrate the experimental approaches (as shown in Figure 62.2), methodological challenges, and possible interpretations of the evidence as well as recent developments.

62.4.1 Concrete Lexical Semantics

A classic finding in support of embodied language processing is the Action-Sentence-Compatibility-Effect (ACE). Participants performed hand movements faster when the direction of movement was congruent with the direction of movement described in a preceding sentence compared with when it was incongruent (Glenberg & Kaschak, 2002; Zwaan, van der Stoep, Guadalupe, & Bouwmeester, 2012). Similar interference effects have been observed with visual and auditory motion paradigms, as well as in studies on movement kinematics (Boulenger et al., 2006; Kaschak, Zwaan, Aveyard, & Yaxley, 2006; Meteyard, Zokaei, Bahrami, & Vigliocco, 2008; Mirabella, Iaconelli, Spadacenta, Federico, & Gallese, 2012).

A number of fMRI and PET studies have shown that sensory-motor areas become active during language comprehension, mostly in the action domain (e.g., Hauk, Johnsrude, & Pulvermuller, 2004; for overviews see Kemmerer, Castillo, Talavage, Patterson, & Wiley, 2008; Postle, McMahan, Ashton, Meredith, & de Zubicaray, 2008; Pulvermüller, 2005), but also for auditory (Kiefer, Sim, Herrnberger, Grothe, & Hoenig, 2008) and visual concepts (Hauk, Davis, Kherif, & Pulvermuller, 2008; Pulvermuller & Hauk, 2006; Simmons et al., 2007), a mixture of those (Kiefer et al., 2012; Noppeney & Price, 2003), and other domains (Barros-Loscertales et al., 2012; van der Laan, de Ridder, Viergever, & Smeets, 2011). Although a number of studies have reported sensory-motor activation in language processing, null effects have been reported as well (Edwards et al., 2010; Postle et al., 2008), and some studies have illustrated significant variability of action-word activation across studies (Kemmerer et al., 2008) and across participants (Willems, Hagoort, & Casasanto, 2010).

Only a few fMRI studies have directly addressed the ambiguity of fMRI data with respect to semantic or postsemantic origins of the observed effects. Tomasino, Werner, Weiss, and Fink (2007) suggested that motor cortex activation for action-words is mainly caused by mental imagery processes. Willems, Hagoort, et al. (2010) reported that action-words in a lexical decision task produced activation patterns in motor areas that were nonoverlapping with activation patterns in a mental imagery task, suggesting that motor areas may play different roles in imagery and semantics. Wheatley, Weisberg, Beauchamp, and Martin (2005) concluded from priming effects in inferior temporal cortex that this area is involved in automatic object processing. Hauk et al. (2008) studied the effect of semantic category on the word frequency effect and provided evidence that differential effects for semantic

word categories in posterior middle temporal cortex occur at a semantic rather than imagery stage.

The exact time course of semantic word processing is still a matter of debate, but it is plausible to assume that effects within the first 400 ms after stimulus presentation do not reflect deliberate mental imagery processes (Hauk et al., 2008). With respect to the embodiment of action-word semantics, Pulvermüller, Härle, and Hummel (2001) and Hauk and Pulvermuller (2004) reported differences between action-word types in the ERP at approximately 200 ms that were consistent with somatotopy. Similarly, differences between words with and without acoustic features occurred in ERPs at approximately 200 ms. In a parallel fMRI study, activation to words with acoustic features overlapped with areas activated during listening to sounds (Kiefer et al., 2008). Around the same latency, Moscoso del Prado Martin, Hauk, and Pulvermuller (2006) observed differences between color-related and form-related words. For auditory stimuli, the brain responses measured by MEG at approximately 200 ms differed depending on the action-word category, even when participants were distracted by watching a silent movie, suggesting early automatic activation of semantic cell assemblies (Pulvermüller, Shtyrov, & Ilmoniemi, 2005). With respect to brain oscillations, van Elk, van Schie, Zwaan, and Bekkering (2010) compared action verbs presented in sentence context related to human or animal actions. They observed stronger desynchronization in beta as well as mu frequency bands, with mu effects starting at approximately 160 ms, and starting in the beta band at approximately 500 ms. The estimated neuronal sources were consistent with motor cortex activation. One study investigated time-frequency ECoG responses to auditorily presented hand-verbs and mouth-verbs in four patients but did not find evidence for a somatotopic activation pattern (Canolty et al., 2007). TMS studies using MEPs have also provided evidence that motor areas are modulated by action-semantics within a few hundred milliseconds of word presentation (Buccino et al., 2005; Labruna, Fernandez-del-Olmo, Landau, Duque, & Ivry, 2011).

The main advantage of TMS, compared with correlational neuroimaging, is that it allows interfering with activation in some brain areas and measurement of the effect of this interference on behavioral performance. Pulvermüller et al. (2005) investigated the effects of TMS pulses delivered at 150 ms after hand-word and leg-word presentation to hand and leg motor cortex on performance in a lexical decision task, and they found an interaction of stimulation site and word type (i.e., responses to arm-related words were faster when hand motor was stimulated) and vice

versa for leg-words after leg motor cortex stimulation. Similarly, [Willems, Labruna, D'Esposito, Ivry, and Casasanto \(2011\)](#) found facilitated action-word processing after premotor cortex rTMS. [Tomasino, Fink, Sparing, Dafotakis, and Weiss \(2008\)](#) studied effects of TMS on hand-action-verb processing at different stimulation latencies (150 and 750 ms after word presentation) and in different tasks. The main result was a facilitatory effect of hand motor cortex stimulation at all stimulation latencies, but only in the imagery task and not in lexical or silent reading tasks, suggesting a postsemantic origin of this effect. Interestingly, no disruption of action-word processing after (r)TMS to motor areas has been reported yet.

An interesting development in behavioral research is the use of motor or movement priming paradigms, where a particular movement type is used as a prime (presumably leading to preactivation of the corresponding brain system), and the effect on behavior is assessed. [Glenberg, Sato, and Cattaneo \(2008\)](#) asked their participants to move beans along a particular direction; they found an interference effect for this direction and the direction implied by concrete and abstract sentences. Hand and foot movements have also been reported to differentially affect working memory performance for action-word types ([Shebani & Pulvermuller, 2013](#)). Effects of motor priming on early brain responses have been reported in an EEG/MEG study ([Mollo, Pulvermuller, & Hauk, 2011](#)).

Evidence for impaired semantics after damage to sensory-motor brain systems from clinical populations has been provided from Parkinson's disease ([Boulenger et al., 2008](#); [Herrera, Rodriguez-Ferreiro, & Cuetos, 2012](#)), stroke patients ([Neininger & Pulvermüller, 2003](#); [Trumpp, Kliese, Hoenig, Haarmeier, & Kiefer, 2012](#)), and semantic dementia ([Pulvermuller et al., 2010](#)). [Kemmerer, Rudrauf, Manzel, and Tranel \(2010\)](#) reported that lesions in several brain areas including precentral gyrus, possibly extending into hand-related motor areas, as well as ventral postcentral gyrus, predicted performance in tasks such as word-picture matching or word comprehension for action verbs. However, using a similar approach but with smaller sample size, [Arevalo, Baldo, and Dronkers \(2012\)](#) did not find evidence for somatotopic effects of different action-word categories. Some authors have argued that neuropsychological studies so far have, at best, demonstrated subtle effects of deficits in patients with sensory-motor impairments on semantic processing ([Binder & Desai, 2011](#); [Mahon & Caramazza, 2009](#)).

62.4.2 Abstract Lexical Semantics

A particularly challenging case for theories of embodiment is abstract concepts, because they have

no obvious referents in sensory-motor experience. Possible approaches to the incorporation of abstract semantics in frameworks of embodiments are summarized by [Glenberg et al. \(2008\)](#) and [Pecher, Boot, and Van Dantzig \(2011\)](#). For example, it has been suggested that abstract semantics relies on concrete concepts by means of metaphor or image schemas ([Gibbs & Steen, 1999](#); [Lakoff, 1987](#)), that some abstract concepts can be based on generalizations from situated simulations ([Barsalou, 1999](#); [Wilson-Mendenhall, Barrett, Simmons, & Barsalou, 2011](#)), and that abstract concepts can be acquired as abstractions of concrete concepts ([Glenberg & Robertson, 1999](#)). It has also been pointed out that affective semantic features are important for abstract concepts ([Kousta, Vigliocco, Vinson, Andrews, & Del Campo, 2011](#)), and that abstract semantics cannot be explained within a single system ([Shallice & Cooper, 2013](#)).

Behavioral evidence for embodied semantics has mostly been provided by studies on sentence processing. For example, the action-sentence compatibility effect (ACE) has also been observed for abstract sentences, where direction of movement was implied by abstract sentence contents (e.g., "reading to" versus "being read to") ([Glenberg et al., 2008](#)). Similar effects have been observed with metaphors ([Santana & de Vega, 2011](#)).

Several fMRI studies have investigated the embodiment of abstract sentences. For example, [Boulenger, Hauk, and Pulvermuller \(2009\)](#) reported somatotopic activation for idiomatic sentences. Two studies failed to find such effects for abstract sentences ([Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni, 2006](#); [Raposo, Moss, Stamatakis, & Tyler, 2009](#)), whereas others found effects of metaphor familiarity and sentence type in motor, motion, or somatosensory regions ([Desai, Binder, Conant, Mano, & Seidenberg, 2011](#); [Desai, Conant, Binder, Park, & Seidenberg, 2013](#); [Lacey, Stilla, & Sathian, 2012](#)). [Citron and Goldberg \(2014\)](#) found more activation for metaphorical sentences related to taste compared with their literal counterparts in emotion-related areas amygdala and anterior hippocampus, as well as in gustatory areas, suggesting a role of emotion in metaphor comprehension.

Only few fMRI studies have investigated the embodiment of abstract words in isolation. [Ruschemeyer, Brass, and Friederici \(2007\)](#) did not find motor cortex activation for abstract words based on action concepts. [Moseley, Carota, Hauk, Mohr, and Pulvermuller \(2012\)](#) found stronger motor cortex activation to emotion words compared with nonaction-related words, which was interpreted as embodied abstract semantics. [Wilson-Mendenhall, Simmons, Martin, and Barsalou \(2013\)](#) found more activation in frontal and temporal cortex for social concepts, and more activation in intraparietal sulcus for arithmetic concepts, indicating that

even abstract concepts are represented in concept-specific distributed networks.

In a MEG version of their previous fMRI experiment, [Boulenger, Shtyrov, and Pulvermuller \(2012\)](#) presented literal and idiomatic sentences and analyzed the time course of brain responses after the critical word (e.g., “habit” in “she kicked the habit”). Literal and idiomatic sentences differed in their brain responses after approximately 200 ms, with some evidence for somatotopic activation for arm-related and leg-related idioms in this latency range.

Evidence on lexical embodied semantics from TMS studies is also scarce. [Glenberg et al. \(2008\)](#) measured TMS-induced MEPs in their study on the abstract ACE described and found that MEP amplitudes were greater in transfer sentences than in no-transfer sentences, and that there was little difference between concrete and abstract sentences. [Scorilli et al. \(2012\)](#) found MEP effects for both concrete and abstract words stimulating at 250 ms after word onset. [Fernandino et al. \(2013\)](#) reported differential processing of literal, idiomatic, metaphoric, and abstract action-related sentences in Parkinson’s patients.

Considering the scarcity of evidence and the variability in stimuli, tasks, contexts, and measurement techniques, it is currently impossible to come to firm conclusions about abstract lexical semantics. Most studies reviewed used sentence stimuli, raising the question as to what degree does lexical semantics interact with context.

62.5 THE INFLUENCE OF TASK, CONTEXT, AND INDIVIDUAL EXPERIENCE

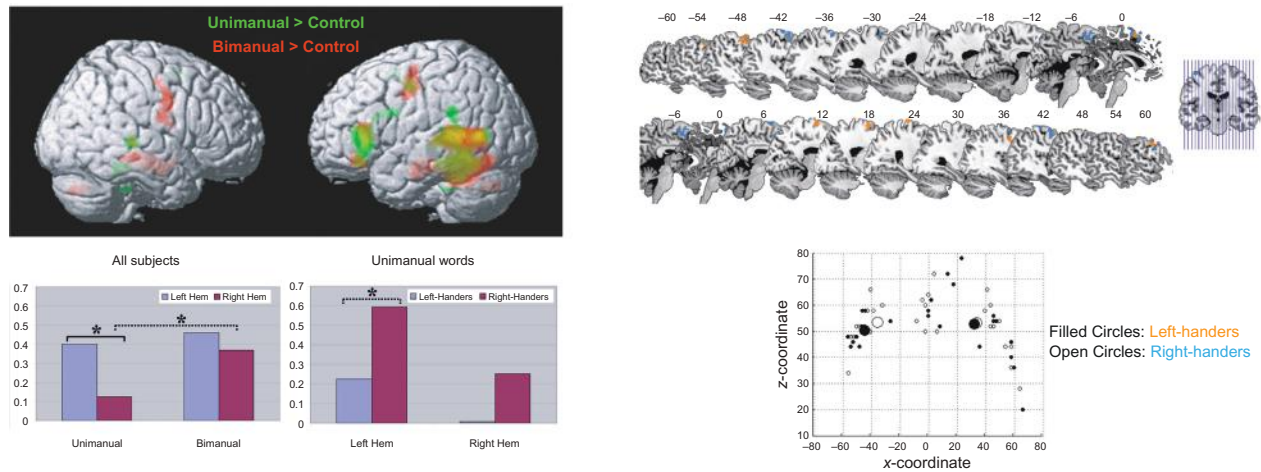

The proverb “If you have a hammer, everything looks like a nail” suggests that our environment and goals shape the way we assign meaning to objects around us. The way we use the meaning of words flexibly in different contexts and situations is a formidable challenge for theories of semantics. It is still unclear which levels of processing are affected by top-down processing, for example, depending on task and context. Some authors have pointed out that the field of word recognition suffers from the “curse of automaticity,” and that lexical processing should be considered as flexible ([Balota & Yap, 2006](#)). Even masked semantic priming effects on N400 amplitudes have been shown to depend on task context ([Kiefer & Martens, 2010](#)). However, it is still unclear whether top-down control affects information retrieval during word recognition, or only later selection and decision processes ([Chen, Davis, Pulvermuller, & Hauk, 2013](#)).

Surprisingly few neuroscientific studies have systematically investigated the effects of task modulation on embodied semantic word processing (some examples are shown in [Figure 62.3](#)). A recent study looked at the specific effect of different semantic tasks. In an fMRI study, [van Dam, van Dijk, Bekkering, and Rueschemeyer \(2012\)](#) investigated brain activation to words that had to be judged either for color or for action attributes. Areas in the left parietal lobes activated more for action-words than for abstract words, but only during action-related judgments. This was interpreted as evidence for flexible and context-dependent semantic processing.

The degree to which semantic representations are embodied may depend on the experience of the individual (e.g., the context and frequency with which a concept is encountered and processed). An interesting test case involves left- and right-handed individuals: does the way we usually perform an action shape the way we represent it semantically? Two studies on this issue have led to different results. [Willems, Toni, Hagoort, and Casasanto \(2010\)](#) reported more activation in left motor cortex when right-handed individuals read unimanual action-related words (e.g., “throw”), whereas left-handed individuals showed more activation in right motor areas. [Hauk and Pulvermuller \(2011\)](#) found that unimanual words (“throw”) activated left motor cortex in both left-handed and right-handed individuals, whereas bimanual words (“clap”) activated motor cortex bilaterally in both groups. These seemingly contradictory findings may be explained by the use of different tasks. [Willems, Toni, et al. \(2010\)](#) used a lexical decision task that engages motor areas and may shift participants’ attention to action-related aspects of the stimuli. [Hauk and Pulvermuller \(2011\)](#) used a silent reading task that did not require an explicit response. This highlights the importance of investigating effects of task demands on brain activation during semantic processing.

With respect to abstract concepts, it has been reported that brain responses to the same emotions differed depending on the situation in which they were situated ([Wilson-Mendenhall et al., 2011](#)). Recent studies have reported a “disembodiment effect of negation,” that is, less motor cortex activation to action-words in negated (“He doesn’t throw the ball”) compared with affirmative context, for example, measuring grip force ([Aravena et al., 2012](#)), movement kinematics ([Bartoli et al., 2013](#)), and fMRI ([Tettamanti et al., 2008](#)). This suggests that the involvement of sensory-motor systems may not be necessary for semantic processing in general, but rather are dependent on context and task demands. Future research should address the question whether task effects occur at early and possibly unconscious stages of semantic processing, or at later stages that require combinatorial processes or deliberate mental imagery.

(A) Action-word processing in left- and right-handers

(B) Modulation of action-word processing by context

FIGURE 62.3 Examples of neuroscientific studies that investigated the influence of experience and task demands on action-word processing. (A) Left: fMRI results that indicate different lateralization of brain activation in motor areas for unimanual and bimanual action-words (e.g., “throw” and “clap”), but independently of the handedness of the participants. Right: fMRI results suggesting different lateralization of brain activation between left-handed and right-handed individuals in response to hand-related action-words. (B) Grip force amplitude is larger after action-words in affirmative (dark blue) compared with negative (light blue) context as well as with a nonaction control condition. (A) Left: modified from *Hauk and Pulvermüller (2011)*; right: modified from *Willems, Hagoort, et al. (2010)*; (B) modified from *Aravena et al. (2012)* with permission from the publisher.

62.6 CONCLUSION

Although most authors—especially those behind the models illustrated in [Figure 62.1](#)—acknowledge that sensory-motor systems may contribute to semantic processing at some stage, the main controversy surrounds the issue about how relevant or essential these contributions really are, and whether the existing evidence tells us anything interesting about how we represent and process meaning ([Chatterjee, 2010](#); [Hauk & Tschentscher, 2013](#); [Mahon & Caramazza, 2008](#); [Meteyard et al., 2012](#); [Pulvermüller, 2013b](#)).

The reasons for the grounding of concepts in non-symbolic representations, such as those put forward

by [Harnad \(1990\)](#), do not constitute a compelling theoretical argument for the embodiment of semantics in sensory-motor brain systems: As long as we do not know how the patterns of trees on our retinas evoke the concept of a “forest” in us, we also do not understand how reactivation of early visual brain areas can do this. Independently of the theoretical standpoint, one can address empirical questions regarding which brain areas contribute to the processing of semantic feature x in task y in participant group z . Even with respect to this dry formulation of the problem, the evidence is not yet conclusive. Most evidence stems from correlational studies predominantly reporting behavioral interference effects (which do not allow direct

inferences about interaction at the neuronal level) and fMRI results (which are ambiguous with respect to semantic and postsemantic origins of effects). Time course information from EEG/MEG and TMS-MEP studies exists, but it is scarce and still susceptible to spreading-activation-criticism. The most direct evidence, that is, clearly replicable impaired performance in a semantic task after disruption of sensory-motor brain activity (using TMS or lesion data), has not yet been established. Studies investigating perceptual-motor priming on behavioral and brain responses in semantic tasks, possibly in combination with measures of brain connectivity, may be able to reveal links between specific perceptual-motor functions and brain systems in the future.

An inconclusive empirical basis is by no means specific to research on embodied semantics. Even the roles of the classical language areas, such as Broca's or Wernicke's, or the locations of semantic hubs, are still a matter of debate (Binder & Desai, 2011; Patterson et al., 2007; Pulvermuller, 2013a), and semantic effects in sensory-motor systems are unlikely to be more reliable. Clarifying this situation would be a prerequisite for the investigation of connectivity among the hubs and a distributed system, which is the logical next step in research of embodied semantics. A solid foundation in a "simple" field such as lexical semantics would also be beneficial for researchers attempting to address questions about polysemy or homonymy, combinatorial semantics, pragmatics, and others. In order to jump high, one should stand on firm ground. The empirical evidence base for embodied theories of semantics still needs solidification, and it is difficult to find neuroscientific benchmark data that all theorists agree have to be explained. Future research should attempt to make large-scale standardized data sets available and make use of the possibility to preregister acquisition and analysis parameters.

63.1 INTRODUCTION

Investigations of acquired dyslexia began in the late 19th century with Dejerine's report of two patients with quite different patterns of reading impairment. Dejerine's first patient (Dejerine, 1891) developed dyslexia and dysgraphia, (i.e., deficits in reading and spelling/writing respectively) after an infarction involving the left parietal lobe. Dejerine termed this disorder "alexia with agraphia"¹ and attributed the disturbance to a disruption of the "optical image for words," which he thought to be supported by the left angular gyrus. Anticipating some contemporary psychological accounts, Dejerine concluded that reading and writing required the activation of these "optical images" and that the loss of the images resulted in the inability to recognize or write even familiar words.

Dejerine's second patient (Dejerine, 1892) was quite different. This patient demonstrated a remarkable dissociation between reading and writing; he was unable to read aloud or for comprehension, yet he could write remarkably well. Like some subsequently reported patients, he was unable to read what he had written. Invoking a prominent theoretical construct of the time, "alexia without agraphia" was attributed to a disconnection between visual input regarding the letter string and the "optical images" for words supported by the left angular gyrus, the brain region he thought to be critical for word recognition.

After decades of relative obscurity, the study of acquired dyslexia was revitalized by the elegant and insightful analyses by Marshall and Newcombe (1966, 1973). These seminal studies were significant for at

least two reasons. First, they demonstrated that detailed assessment of multiple aspects of performance could provide crucial insights; they demonstrated, for example, that systematic analyses of the types of errors made by dyslexics were crucial in the assessment of performance. By scrutinizing the effects of variables (e.g., part of speech, imageability) that had been largely ignored in prior studies, Marshall and Newcombe contributed greatly to the emerging discipline of cognitive neuropsychology. Second, these investigators described novel reading disorders including "deep" and "surface" dyslexias.

On the basis of these data, Marshall and Newcombe (1973) concluded that the pronunciation of written words could be derived by two distinct procedures. The first was a direct procedure whereby familiar words activated the appropriate stored representation (or visual word form) that, in turn, activated meaning directly; reading in deep dyslexia was assumed to involve this procedure. The second procedure was assumed to be a phonologically based process in which "grapheme to phoneme" or "print-to-sound" correspondences were used to derive the appropriate phonology (i.e., "sound out" the word); the reading of surface dyslexics was assumed to be mediated by this nonlexical procedure.

The conceptual framework proposed by Marshall and Newcombe may be illustrated by the "box and arrow" model presented in Figure 63.1. Because this account provides the general framework with which the various acquired dyslexias will be discussed and motivated one of the leading computationally instantiated current models of reading (Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001; Rastle, Tyler, & Marslen-Wilson, 2006),

¹Acquired disorders of reading have been designated "dyslexia" and "alexia" by different authors; we use the terms interchangeably.

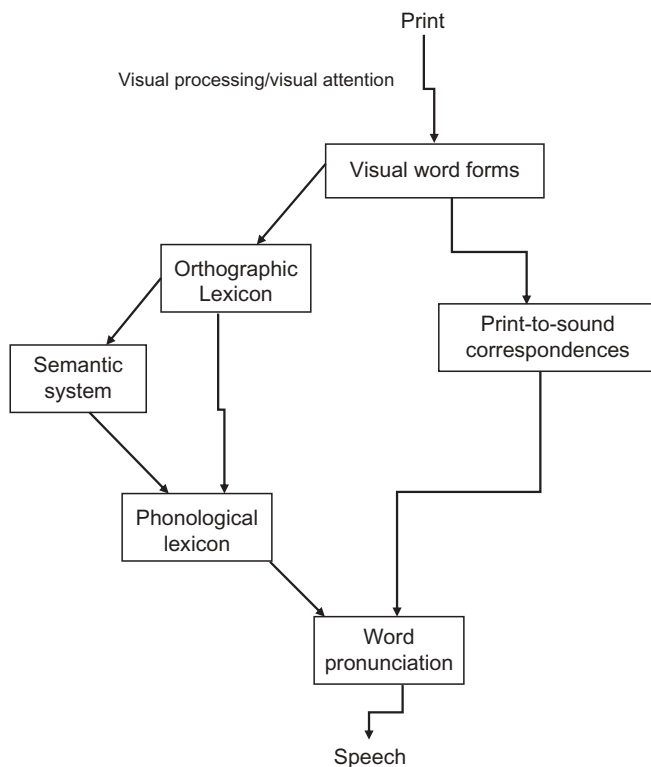

FIGURE 63.1 A simplified information-processing model of the procedures involved in reading provided for illustrative purposes.

we briefly describe it here. It should be emphasized that we use this model as a heuristic only; alternative accounts of reading such as the “triangle model” (Harm & Seidenberg, 2004; Plaut, McClelland, Seidenberg, & Patterson, 1996) that make very different assumptions about the mechanisms underlying reading are also discussed.

The information-processing model of reading depicted in Figure 63.1 provides three distinct procedures for oral reading. Two of these procedures correspond to those described by Marshall and Newcombe (1973). The first involves the activation of a stored entry in the visual word form system and the subsequent access to semantic information and, ultimately, activation of the stored sound of the word at the level of the phonologic output lexicon. The second involves the nonlexical grapheme-to-phoneme or print-to-sound translation process; this procedure does not entail access to any stored information about words, but rather is assumed to be mediated by access to a catalog of correspondences between letters or letter sequences and speech sounds. Some accounts of the language mechanisms subserving reading incorporate a third reading procedure. This mechanism is lexically based in that it is assumed to involve the activation of the visual word form system and the phonologic output lexicon. The procedure differs from the

lexical procedure described here, however, in that there is no intervening activation of semantic information. This procedure has been called the “direct” reading mechanism or route. Support for the direct lexical mechanism comes from a number of sources including observations that some subjects read aloud words that cannot be readily “sounded out” that they do not appear to comprehend (Coslett, 1991; Schwartz, Marin, & Saffran, 1979). More recently, Law, Wong, Sung, and Hon (2006) provided evidence for a lexical but nonsemantic route in reading. They reported data from two Chinese patients who had suffered strokes and whose performance on tests of phonology and access to semantics for verbal materials argued for independent lexical mechanisms.

This chapter focuses on disorders of reading rather than language more generally; it should be noted, however, that disorders of reading are rarely observed in isolation. In the large majority of instances, for example, phonologic dyslexia is associated with deficits in phonology that can be demonstrated on a range of nonreading tasks (Woollams, Hoffman, Roberts, Lambon Ralph, & Patterson, 2014; but see Cipolotti & Warrington, 1996). Similarly, even “pure alexia” is not pure in the sense that most patients with this disorder also exhibit deficits in other aspects of visual processing (Behrmann & Plaut, 2014). The association of reading with more basic cognitive and perceptual deficits is not surprising given that the first evidence of written language dates to approximately 4,000 years ago, whereas spoken language and the other perceptual and motor faculties that underpin reading evolved over a far greater amount of time. Although most investigators would likely agree that many of the processes involved in reading are “domain general” in that they are crucial for oral language or other faculties, the degree to which reading invokes reading-specific faculties remains a matter of significant debate (Rastle et al., 2006; Woollams et al., 2014).

63.2 PERIPHERAL DYSLEXIAS

A useful starting point in the discussion of the dyslexias is the distinction offered by Shallice and Warrington (1980) between “peripheral” and “central” dyslexias. We take the former to be conditions characterized by a deficit in the processing of visual aspects of the stimulus that prevent the patient from reliably matching a familiar word to its stored representation or “visual word form” (Shallice & Warrington, 1980). In contrast, central dyslexias reflect impairment procedures by which visual word forms gain access to meaning or speech production mechanisms. We start by considering the major types of peripheral dyslexia.

63.2.1 Alexia Without Agraphia or Pure Alexia

The classical syndrome of alexia without agraphia or pure alexia is perhaps the prototypical peripheral dyslexia. The traditional account (Dejerine, 1892; Geschwind & Fusillo, 1966) of this disorder attributes the syndrome to a “disconnection” of visual information; as conceptualized by Dejerine (1892), this syndrome is attributed to the combination of two impairments. First, the left hemisphere is deprived of visual input by a left posterior lesion. Second, visual information from the right hemisphere is disconnected from the left hemisphere structures mediating word recognition (the left angular gyrus on Dejerine’s account) by a lesion that involves the splenium of the corpus callosum or the extension of these fibers in the deep white matter of the occipital lobe (forceps major).

Although these patients do not appear to be able to read in the sense of fast, automatic word recognition, many are able to use a compensatory strategy that involves naming the letters of the word in serial fashion; they read, in effect, “letter-by-letter” (Patterson & Kay, 1982). Using the slow and inefficient letter-by-letter procedure, pure alexics typically exhibit significant effects of word length, requiring more time to read long words as compared to short words. Although patients with this disorder have demonstrated features of “surface” (Friedman & Hadley, 1992) or “deep” dyslexic phenomena (Buxbaum & Coslett, 1996), in most subjects performance is not influenced by factors such as part of speech (e.g., noun vs functor), the extent to which the referent of the word is concrete (e.g., “table”) or abstract (e.g., “destiny”), or whether the word is orthographically regular (i.e., can be “sounded out”). It should be noted that pure alexia may be differentiated from hemianopic dyslexia (see Schuett, Heywood, Kentridge, & Zihl, 2008 for review). The latter syndrome is associated with significant right or left visual field defects and is manifested primarily in text reading. Based on evidence demonstrating that subjects with the disorder have impaired saccadic eye movements as well as the observation that the disorder is observed in subjects with lesions that involve more than calcarine cortex (i.e., V1), hemianopic dyslexia is thought to be caused by a combination of reduced visual fields and impaired systems controlling eye movements and visual attention.

A number of alternative accounts of the processing deficit in pure alexia have been proposed. Thus, some investigators have proposed that the impairment is attributable to a limitation in the transmission of letter identity information to the visual word system (Patterson & Kay, 1982) or an inability to directly encode visual letters as abstract orthographic types

(Bub & Arguin, 1995). A number of investigators have proposed that pure alexia is attributable to a low-level visual impairment (Chialant & Caramazza, 1996; Farah & Wallace, 1991). Although many patients with the disorder have no clinically evident visual deficits, more careful assessments of vision have consistently demonstrated visual deficits. Mycroft, Behrmann, and Kay (2009), for example, they demonstrated that these subjects have difficulty processing letter-like stimuli as well as matching checkerboards. Additionally, Behrmann and Plaut (2014) demonstrated that these patients have difficulty with demanding facial recognition tasks. Finally, Roberts et al. (2013) demonstrated that pure alexics have difficulty processing complex visual stimuli and the degree of impairment roughly paralleled their word recognition deficits. It would seem that, at least in many instances, pure alexia is associated with a deficit in processing stimuli comprising easily confusable components that require high spatial frequency, the prototypical example of which is words.

Shallice and Warrington (1980) argued that the disorder is attributable to a disruption of the visual word form system. Subsequent work has supported their hypothesis. Numerous functional imaging studies have demonstrated that the posterior, inferior temporo-occipital cortex, particularly on the left, is activated in response to letter strings (Cohen & Dehaene, 2004; Cohen, Dehaene, Chochon, Lehéricy, & Naccache, 2000); it has been proposed that this region supports the visual word form area (VWFA). Several studies have suggested that damage to the VWFA itself can cause pure alexia (Gaillard et al., 2006; Tsapkini & Rapp, 2010; Turkeltaub et al., 2014). In most of these cases, the white matter pathways neighboring the VWFA may also have been damaged, although in our recent case the stroke was restricted to the cortex itself (Turkeltaub et al., 2014). This patient recovered quickly and was not available for extensive testing, limiting the value of this case. Based on these cases, a reasonable hypothesis is that different processing deficits associated with pure alexia may result from either disconnection of, or direct damage to, the text-sensitive areas of the left mid-fusiform cortex. For instance, damage to the VWFA itself may result in loss of orthographic representations, manifested by relatively greater impairment of spelling than is seen when an intact VWFA is disconnected from visual input (Rapcsak & Beeson, 2004).

The “disconnection” account originally offered by Dejerine has received support from an elegant neuroimaging study of a subject who was examined before and after a surgical procedure that resulted in dyslexia (Epelbaum et al., 2008). The surgical lesion was just posterior to the VWFA (localized using preoperative fMRI), sparing the cortex of the VWFA itself, but damaging inferior longitudinal fasciculus fibers connecting

it to more posterior areas of occipital cortex. This analysis supported the long hypothesized role of the inferior longitudinal fasciculus in normal reading.

An important contribution to the understanding of the anatomic basis of pure alexia has recently come from the comparison of eye movements during reading of subjects with pure alexia and subjects with right hemianopia who did not exhibit the full syndrome of pure alexia (Pflugshaupt et al., 2009). Whereas all subjects exhibited low-amplitude rightward saccades during text reading, the substantial increases in fixation frequency and viewing time were specific to subjects with pure alexia. Furthermore, supporting claims about the role of damage to the visual word form system in pure alexia, they found that the region corresponding to the visual word form system in the left fusiform gyrus was disrupted in pure alexia but not hemianopic subjects without dyslexia.

Similarly, in a prior lesion overlap comparison, individuals with hemianopic alexia had damage restricted to medial occipital lesions, whereas those with pure alexia had ventral occipital lesions extending more laterally into the fusiform gyrus and the neighboring white matter (Leff, Spitsyna, Plant, & Wise, 2006). This again implicates lateral ventral occipital pathways in reading, but these studies do not clarify whether pure alexia results from direct disruption of text-sensitive areas of cortex, such as the VWFA or from disconnection of these cortical areas from visual input.

We note that the different accounts of pure alexia are not mutually exclusive. As with many syndromes defined on the basis of a single, cardinal deficit, there is reason to believe that pure alexia may be attributable to different processing impairments in different individuals (see Rosazza, Appollonio, Isella, & Shallice, 2007).

Although most reports of pure alexia have emphasized the profound nature of the reading deficit, often stating that patients were utterly incapable of reading without recourse to a letter-by-letter procedure (Geschwind & Fusillo, 1966; Patterson & Kay, 1982), we and other investigators have reported data demonstrating that pure alexic patients are able to comprehend words that they are unable to explicitly identify (Coslett & Saffran, 1989a; Landis, Regard, & Serrat, 1980; Shallice & Saffran, 1986). The interpretation of these data remains controversial. Behrmann, Plaut, and Nelson (1998) have suggested that the preserved access to meaning in pure alexia is mediated by the (lesioned) normal reading system. By this account, the imageability and part of speech effects as well as the implicit nature of the reading performance are assumed to be attributable to weak activation of stored word forms by the visual input.

Alternatively, we (Coslett & Saffran, 1989a, p. 19; Saffran & Coslett, 1998) and others (Landis et al., 1980)

have argued that the implicit reading that emerges in pure alexia reflects the lexical processing of the right hemisphere. We reported data, for example, from four patients with pure alexia who performed well above chance on a number of lexical decision and semantic categorization tasks with briefly presented words that they could not explicitly identify (Coslett & Saffran, 1989b). Three of the patients who regained the ability to explicitly identify rapidly presented words exhibited a pattern of performance consistent with the right hemisphere reading hypothesis (Coltheart, 2000; Coltheart, Patterson, & Marshall, 1980; Saffran, Bogyo, Schwartz, & Marin, 1980) in that they read nouns better than functors and words of high imageability (e.g., *chair*) better than words of low imageability (e.g., *destiny*). Additionally, both patients for whom data are available demonstrated a deficit in the reading of suffixed (e.g., “flower”) as compared to pseudo-suffixed (e.g., “flowed”) words. We return to this issue of right hemisphere contributions to reading in a discussion of deep dyslexia.

Recent imaging studies provide a complex picture of the anatomic bases of reading in recovering pure alexics. In a case of an intracerebral hemorrhage in the area of the VWFA, brain activity during a text lexical decision task was observed in the right hemisphere homolog of the VWFA 7 days after stroke but shifted back to the left VWFA after 50 days (Ino et al., 2008). We recently reported a patient with chronic pure alexia in whom transcranial direct current stimulation was provided in combination with multiple oral rereading treatment. In this case, ventral occipito-temporal activity shifted from the right to the left hemisphere after only 5 days of treatment (Lacey et al., 2015). Other case reports have demonstrated posterior displacement of reading-related activity in the left fusiform cortex (Gaillard et al., 2006) and bilateral activity in posterior fusiform and anterior temporal areas after left focal left mid-fusiform resection (Tsapkini, Vindiola, & Rapp, 2011).

63.2.1.1 Neglect Dyslexia

Neglect dyslexia, first described by Brain in 1941, is characterized by a failure to explicitly identify the initial portion of a letter string. The disorder is most frequently encountered in subjects with the syndrome of left-sided spatial neglect. Interestingly, just as the recognition of objects may be influenced by “top-down” factors, the performance of patients with neglect dyslexia is often influenced by the lexical status of the letter string (Sieroff, Pollatsek, & Posner, 1988); thus, patients with this disorder may fail to report the “ti-” in nonwords such as “tigggle” but read the word “gigggle” correctly. The fact that performance is affected by the lexical status of the stimulus suggests that neglect dyslexia is not attributable to a failure to register letter information, but reflects an attentional

impairment at a higher level of representation (Behrmann, Moscovitch, Black, & Mozer, 1990; Ládavas, Shallice, & Zanella, 1997). Haywood and Coltheart (2000) suggested that neglect dyslexia can be caused by deficits at three types of spatial representations; alternatively, Mozer (2002) simulated in a connectionist model the error patterns reported in neglect dyslexia using an explicit attentional mechanism based on a single viewer-centered reference frame and implemented. It also should be noted that reading errors in neglect dyslexia cannot be taken as evidence that access to meaning is entirely abolished because Ládavas, Paladini, and Cubelli (1993, 1997) demonstrated that neglected words influenced performance (see also Lie & Coslett, 2006).

Finally, it should be noted that neglect dyslexia for the right side of letter strings is occasionally observed in subjects with left hemisphere lesions. As demonstrated by Petrich, Greenwald, and Berndt (2007), this deficit may be severe for written words but not evident for any other type of stimulus.

63.2.1.2 Attentional Dyslexia and Related Disorders

Perhaps the least studied of the acquired dyslexias, attentional dyslexia is characterized by the relative preservation of single-word reading in the context of a gross disruption of reading when words are presented as text or in the presence of other words or letters (Price & Humphreys, 1993; Saffran, 1996; Warrington, Cipolotti, & McNeil, 1993). Patients with this disorder may also exhibit difficulties identifying letters within words, even though the words themselves are read correctly (Saffran, 1996), and be impaired in identifying words flanked by extraneous letters (e.g., “lboat”). Finally, we (Warrington et al., 1993) reported a patient with attentional dyslexia secondary to autopsy-proven Alzheimer disease who produced frequent “blend” errors in which letters from one word of a two-word display intruded into the other word (e.g., “bake lime” read as “like”). A number of investigators have explored additional reading deficits in subjects with degenerative disorders such as the “visual variant” of Alzheimer disease (Price & Humphreys, 1995). Crutch and Warrington (2007) reported data from three subjects in whom the effects of visual “crowding” were systematically investigated. They found that the proximity (but not identity) of flanking letters significantly influenced the report of a target letter.

63.3 CENTRAL DYSLEXIAS

63.3.1 Phonological Dyslexia

First described in 1979 by Derouesne and Beauvois, phonologic dyslexia is attributable to a selective deficit

in the procedure translating between print and sound (see Coltheart, 1996; Nickels, Biedermann, Coltheart, Saunders, & Tree, 2008). In the context of the reading model depicted in Figure 63.1, the account of this disorder is relatively straightforward. Good performance with real words suggests that the processes involved in normal “lexical” reading—that is, visual analysis, the visual word form system, semantics, and the phonological output lexicon—are at least relatively preserved. The impairment in nonword reading suggests that the print-to-sound translation procedure is disrupted.

As the procedure by which stored representations of words contact semantics or output phonology are preserved, the cardinal deficit in phonologic dyslexia is impaired reading aloud of unfamiliar letter strings or nonwords. Thus, patients with this disorder correctly read 85–95% of real words (Bub, Black, Howell, & Kertesz, 1987; Funnell, 1983). Some patients with this disorder read all different types of words with equal facility (Bub et al., 1987), whereas other patients are relatively impaired in the reading of functors (or “little words”) (Glosser & Friedman, 1990). Because stored lexical representations for familiar words are available, the regularity of print-to-sound correspondences is not relevant to the performance of phonologic dyslexics; thus, these patients are as likely to correctly pronounce orthographically irregular words such as *colonel* as words with standard print-to-sound correspondences such as *administer*. Many errors in response to real words bear a visual similarity to the target word (e.g., *topple* read as “table”); errors with nonwords typically involve the incorrect application of print to sound correspondences (e.g., *stine* read as “stim” [to rhyme with “him”]) or the substitution of a visually similar real word (e.g., *flig* read as “flag”).

The cause of the impairment in translating between print and sound remains controversial. Some investigators have emphasized the role of a general phonologic deficit in the genesis of phonological dyslexia (e.g., Farah, 1996; Harm & Seidenberg, 1999; Woollams et al., 2014). Consistent with this claim, Patterson and Marcel (1977) and Crisp and Lambon Ralph (2006) demonstrated that the severity of the reading deficit in phonologic dyslexia is correlated with the degree of impairment on nonreading phonologic tasks. By this account, the disorder is attributable to a general phonologic impairment (see also Rapcsak et al., 2009). With other accounts (e.g., Castles, Bates, & Coltheart, 2006; Coltheart et al., 2001), phonologic dyslexia is attributable to impairment of a reading-specific processing module that translates between letters and sounds. Evidence in support of this comes from several reports of patients with phonologic dyslexia who do not demonstrate deficits on nonreading tasks (Coltheart, 2006; Tree & Kay, 2006). We return to this issue later.

Phonologic dyslexia has been observed in association with lesions in a number of sites in the dominant peri-Sylvian cortex (Rapcsak et al., 2009) and, on occasion, with lesions of the right hemisphere (e.g., Patterson, 1982). Damage to the superior temporal lobe and angular and supramarginal gyri in particular is found in many patients with this disorder, including those with logopenic progressive aphasia, which is commonly associated with phonological alexia (Brambati, Ogar, Neuhaus, Miller, & Gorno-Tempini, 2009). Damage to inferior frontal cortex, including the frontal operculum, has also been associated with phonological dyslexia (Fiez, Tranel, Seager-Frerichs, & Damasio, 2006; Rapcsak et al., 2009), as has the insula (Ripamonti et al., 2014). Although quantitative data are lacking, the lesions associated with phonological dyslexia appear, on average, to be smaller than those associated with deep dyslexia.

A few studies have examined imaging changes associated with rehabilitation of phonological dyslexia. In one case, semantic mediation treatment resulted in recruitment of right perisylvian areas, but subsequent over-training of items was associated with a shift in activity back to left perilesional areas (Kurland et al., 2008). Another study found increased right posterior perisylvian and bilateral inferior frontal activity during pseudoword reading after an auditory discrimination treatment for phonological dyslexia (Adair et al., 2000).

63.3.2 Surface Dyslexia
