Surface dyslexia, first described by Marshall and Newcombe (1973), is a disorder characterized by the inability to read words with “irregular” or exceptional print-to-sound correspondences. Languages differ with respect to the consistency with which letters are mapped to sounds; in some languages (e.g., Italian), letter-to-sound correspondences are predictable, whereas in other languages (e.g., English) rules govern the mapping between print and sound, but there are also numerous exceptions. Patients with surface dyslexia fail to read words such as *colonel*, *yacht*, *island*, *have*, and *borough*, for which the mapping between print and sound is not governed by rules. In contrast, these patients perform well with words containing regular correspondences (e.g., *state*, *hand*, *abdominal*) as well as nonwords (e.g., *blape*). A significant effect of word frequency is typically encountered such that regularization errors are far more common with low-frequency words. The great majority of patients with surface dyslexia also demonstrate semantic impairment on tasks that do not involve reading (Woollams, Ralph, Plaut, & Patterson, 2007; see Cipolotti & Warrington, 1996 for an exception).

The fact that the nature of the print-to-sound correspondences significantly influences performance in surface dyslexia demonstrates that the deficit in this syndrome is in the semantically mediated and “direct” reading mechanisms. Similarly, the preserved ability to read words and nonwords is taken as evidence that the procedures by which words are “sounded out” are at least relatively preserved.

In the context of the model depicted in Figure 63.1, surface dyslexia is attributed to disruption of the direct and semantically mediated mechanisms with a reliance on print-to-sound correspondences. In the context of dual-route models of reading, these disruptions may occur at different levels of representation within the lexical system. Thus, for example, surface dyslexia has been attributed to a disruption of semantics in conjunction with a deficit in the “direct” route (Schwartz et al., 1979; Shallice, Warrington, & McCarthy, 1983) or with a lesion involving the phonologic output lexicon (Howard & Franklin, 1987). On the “triangle” connectionist model, surface dyslexia is attributed to a disruption of semantics (Woollams et al., 2014).

Surface dyslexia is infrequently observed in patients with focal lesions. In a sample of 59 patients with dyslexia due to left hemisphere stroke, Ripamonti et al. (2014) identified five with surface dyslexia. These patients had lesions primarily involving the temporal lobe, including both posterior and anterior regions. Surface dyslexia is most often encountered in patients with progressive, degenerative dementias such as Alzheimer disease or fronto-temporal dementia. Surface dyslexia is characteristic of semantic dementia, a disorder associated with left temporal atrophy in which subjects slowly but inexorably lose knowledge of the world (Breedin, Saffran, & Coslett, 1994; Hodges, Patterson, Oxbury, & Funnell, 1992).

Few studies have explicitly examined the neuroanatomical basis of surface dyslexia in semantic dementia. One examined atrophy associated with exception word and pseudoword reading in a sample of patients with semantic dementia and the “logopenic” variant of primary progressive aphasia, and found that anterior temporal lobe atrophy was associated with exception word reading deficits (Brambati et al., 2009). Similarly, another recent study identified an area of left anterior middle temporal cortex that was active in control subjects during an exception versus pseudoword reading comparison, and it was also atrophied in a patient with surface dyslexia related to semantic dementia (Wilson et al., 2012). Another study examined the neural basis of over-regularization in surface dyslexia due to semantic dementia (Wilson et al., 2009). In control subjects, they identified an area of intraparietal sulcus that is active during pseudoword and low-frequency regular word reading, suggesting this area is involved

in grapheme-to-phoneme conversions. In patients with surface dyslexia, this area was activated in association with regularization errors on exception words.

63.3.3 Deep Dyslexia

Deep dyslexia, initially described by Marshall and Newcombe (1973), is an intriguing but complex acquired dyslexia, the hallmark of which is the production of semantic errors in which a word related in meaning is substituted for the target word. Thus, shown the word *castle*, a deep dyslexic may respond “knight”; presented with *bird*, the patient may respond “canary.” At least for some deep dyslexics, it is clear that these errors are not circumlocutions. Semantic errors may represent the most frequent error type in some deep dyslexics, whereas in other patients they comprise a small proportion of reading errors. Deep dyslexics also typically produce frequent “visual” errors (e.g., *skate* read as “scale”) and morphological errors in which a prefix or suffix is added, deleted, or substituted (e.g., *scolded* read as “scolds”; *governor* read as “government”).

In contrast to surface dyslexia and phonologic dyslexia that, on traditional accounts, appear to be largely attributable to disorders of print-to-sound correspondence and stored word representations, respectively, deep dyslexia has a number of deficits that, at least on some accounts, are attributed to multiple processing impairments. All deep dyslexics exhibit a severe impairment in phonologic processing. Reading of nonwords, for example, is typically profoundly impaired. Nonword letter strings such as *flig* or *churt* frequently elicit “lexicalization” errors (e.g., *flig* read as “flag”), perhaps reflecting a reliance on lexical reading in the absence of access to reliable print-to-sound correspondences. Performance is often poor on other phonologic tasks such as naming the sound associated with a letter or even rhyme judgments for auditory words.

Another consistent finding in deep dyslexia is that patients are typically far more successful reading words of high imageability as compared to low imageability. Thus, words such as *table*, *chair*, *ceiling*, and *buttercup*, the referent of which is concrete or imageable, are read more successfully than words such as *fate*, *destiny*, *wish*, and *universal*, which denote abstract concepts.

Another characteristic feature of deep dyslexia is a part of speech effect such that nouns are read more reliably than modifiers (adjectives and adverbs) that are, in turn, read more accurately than verbs. Deep dyslexics manifest particular difficulty in the reading of functors (a class of words that includes pronouns, prepositions, conjunctions, and interrogatives including *that*, *which*, *they*, *because*, *under*, etc.). The striking

part of speech effect may be illustrated by the patient reported by Saffran and Marin (1977) who correctly read the word *chrysanthemum* but was unable to read the word *the*. Many errors to functors involve the substitution of a different functor (*that* read as “which”) rather than the production of words of a different class such as nouns or verbs. As functors are, in general, less imageable than nouns, verbs, or adjectives, some investigators have claimed that the apparent effect of part of speech is in reality a manifestation of the pervasive imageability effect (Allport & Funnell, 1981). We (Coslett, 1991) have reported a patient, however, whose performance suggests that the part of speech effect is not simply a reflection of a more general deficit in the processing of low-imageability words.

Several alternative explanations have been proposed for deep dyslexia. Some investigators have argued that deep dyslexia is on a continuum with phonologic dyslexia (Crisp, Howard, & Lambon Ralph, 2011; Patterson & Lambon Ralph, 1999). With this account, the two disorders share as the primary disorder an impairment in phonologic processing, but the deficit is more severe in deep dyslexics. Friedman (1996) noted that as subjects with deep dyslexia recovered, they often stopped making semantic errors, thereby meeting criteria for phonologic dyslexia (see also Glosser & Friedman, 1990). On the basis of 12 subjects with acquired dyslexia, Crisp and Lambon Ralph (2006) argued that deep and phonologic dyslexia were distinguished by the severity of their semantic and phonologic impairments.

Other investigators believe that deep dyslexia reflects the effects of multiple deficits (Morton & Patterson, 1980; Shallice, 1988). First, the strikingly impaired performance in reading nonwords and other tasks assessing phonologic function suggest that the ability to translate between print and sound is severely disrupted. Second, the presence of semantic errors and the effects of imageability (a variable thought to influence processing at the level of semantics) is taken as evidence that these subjects also suffer from a semantic impairment. Finally, the production of visual errors suggests that these patients suffer from impairment in the visual word form system or in the processes mediating access of the stimulus to the visual word form system.

A third potential account is that deep dyslexia derives from a post-semantic impairment. Caramazza and Hillis (1990) reported two patients who made frequent semantic errors yet demonstrated intact comprehension of written and spoken words. They argued that semantic errors can arise after intact semantic information is contacted; they attribute the deficit to an output lexicon that specifies phonologic form. Buchanan and colleagues (Buchanan, McEwen, Westbury, & Libben, 2003; Caramazza & Hillis, 1990; Colangelo & Buchanan, 2007) have taken a similar position.

Finally, a number of investigators have argued that deep dyslexics' reading is mediated by a system not normally used in reading—the right hemisphere (Coltheart, 2000; Coltheart et al., 1980; Saffran et al., 1980). As articulated by Coltheart (2000), this account proposes that orthographic processing is mediated by the right hemisphere in deep dyslexics; semantic information is accessed in the right hemisphere as well. Speech production may depend on the left inferior frontal region or, in some individuals, the right inferior frontal region.

Although long considered to be “word blind” (Dejerine, 1892; Geschwind, 1965), several lines of evidence support the claim that the right hemisphere may possess some capacity to read (see Lindell, 2006 for review). One seemingly incontrovertible line of evidence comes from the performance of a patient who underwent a left hemispherectomy at age 15 for treatment of seizures caused by Rasmussen encephalitis (Patterson, Vargha-Khadem, & Polkey, 1989). After the hemispherectomy, the patient was able to read approximately 30% of single words and exhibited an effect of part of speech; she was also utterly unable to use a grapheme-to-phoneme conversion process. Thus, in many respects this patient's performance was similar to that of acquired deep dyslexia.

The performance of some patients with partial or complete hemispheric disconnection are also consistent with the claim that the right hemisphere is literate. These patients may, for example, be able to match printed words presented to the right hemisphere with an appropriate object (Zaidel, 1978; Zaidel & Peters, 1981). Interestingly, the patients are apparently unable to derive sound from the words presented to the right hemisphere; thus, they are unable to determine if a word presented to the right hemisphere rhymes with an auditorally presented word. Michel, Hénaff, and Inriligator (1996) also reported a patient with a lesion of the posterior portion of the corpus callosum whose reading of words presented to the right hemisphere was similar to that of deep dyslexics.

Finally, we reported data from an investigation with a patient with pure alexia whose recovered reading was disrupted by transcranial magnetic stimulation to the right, but not the left, hemisphere, suggesting that the right hemisphere mediated reading in this subject (Coslett & Monsul, 1994).

Although deep dyslexia has occasionally been associated with posterior lesions, the disorder is typically encountered in association with large peri-Sylvian lesions extending into the frontal lobe (Coltheart et al., 1980). As might be expected given the lesion data, deep dyslexia is usually associated with Global or Broca aphasia but may rarely be encountered in patients with fluent aphasia.

Several functional imaging studies have addressed the anatomic basis of deep dyslexia. Weekes, Carusi, and Zaidel (1997) reported measured regional blood flow with Xenon-133 in a deep dyslexic performing a variety of reading tasks. By subtracting blood flow related to viewing a false font from a condition involving lexical decision to visually presented words, they demonstrated that for the deep dyslexic subject, blood flow was greater in the right hemisphere as compared to the left, supporting the role of the right hemisphere in word recognition; additional comparisons suggested that word production in this subject was likely to be mediated by the left frontal lobe. Subsequently, Price et al. (1998) reported an fMRI investigation from which they concluded that reading in deep dyslexia was mediated by the left hemisphere. This interpretation was subsequently challenged by Coltheart (2000), who argued that their data, in fact, supported the right hemisphere account of deep dyslexia.

63.4 COMPUTATIONAL MODELS OF READING

For ease of exposition, the discussion to this point has been framed with reference to an information processing or “box and arrow” account of the processes involved in reading. In the past two decades, however, there have been substantial advances in the precision and specificity of theoretical accounts of reading; several computationally explicit models have been developed that not only account for normal reading but also can be “lesioned” in an effort to simulate patient data (e.g., Lambon Ralph, Patterson, & Plaut, 2011; Nickels et al., 2008; Patterson, Seidenberg, & McClelland, 1989). One model, originally developed by Seidenberg and McClelland (1989) and subsequently elaborated by a number of investigators (Harm & Seidenberg, 2004; Plaut et al., 1996; Woollams et al., 2014), belongs to the general class of parallel distributed processing or connectionist models. This model is often termed the “triangle model” because it incorporates three major types of representations—orthographic units, semantic units, and phonological units (see Figure 63.2). Crucially, this model does not incorporate word-specific representations; instead, “knowledge” is distributed across connections between units. In this account, there are two procedures by which subjects may learn to pronounce a word. First, by means of repeated exposure to letter strings, subjects learn to map letter sequences to phonology. The probabilistic mapping between letters and sounds is assumed to provide the means by which both familiar and unfamiliar words are pronounced. Second, the model incorporates a

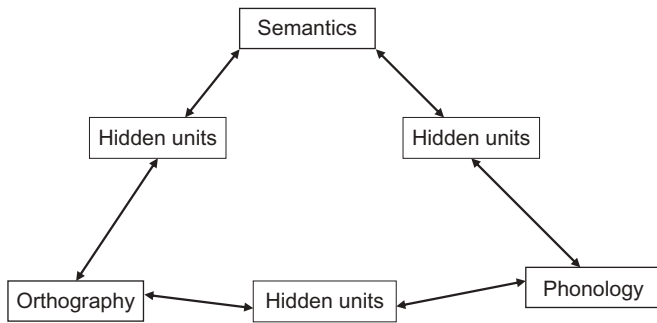

FIGURE 63.2 A simplified version of the “triangle model” of reading.

“semantic” reading procedure in which meaning is initially accessed; subsequently, patterns of activation across semantic and orthographic units are mapped onto phonology (Harm & Seidenberg, 2004). This model not only accommodates many of the classic findings in the literature on normal reading but also has been “lesioned” in an attempt to reproduce the patterns of reading impairment characteristic of different types of acquired dyslexia (Plaut & Shallice, 1993; Welbourne & Lambon Ralph, 2007; Woollams et al., 2007). Woollams et al. (2007) provide evidence that the triangle model accommodates many aspects of the performance of surface dyslexia exhibited by patients with semantic dementia. Welbourne and Lambon Ralph (2007) attempted to model phonological dyslexia with the “triangle” model. Reasoning that the performance of subjects with acquired dyslexia reflects not only the effect of the lesion but also the effects of recovery, they re-trained a lesioned version of the Plaut et al. (1996; simulation 4) connectionist model; they argue that if the network was permitted to “recover,” then a pattern of deficits characteristic of phonological dyslexia was observed. The adequacy of these simulations remains a topic of substantial debate. Coltheart (2006) has argued that “lesioned” versions of these models do not faithfully reproduce the pattern of deficits observed in phonological or surface dyslexia.

An alternative computational account of reading has been developed by Coltheart and colleagues (Castles et al., 2006; Coltheart & Rastle, 1994; Coltheart et al., 2001; Rastle & Coltheart, 1999). The “dual-route cascaded” or DRC model represents a computationally instantiated version of the dual-route theory presented in Figure 63.1. This “localist” account incorporates a “lexical” route that includes a listing of familiar orthographic and phonological word forms; in addition, the model incorporates a “nonlexical” route by which the pronunciation of letter strings is generated by the serial application of rules specifying position-specific grapheme-to-phoneme correspondences. Finally, like

the triangle model, the DRC model incorporates a semantic system that may mediate between orthography and phonologic output representations; to this point, semantic representations have not been implemented in the model. The model also assumes that both procedures operate in parallel and that there is interaction between the lexical and nonlexical procedures.

The DRC model accommodates a wide range of findings from the literature on normal reading. For example, Coltheart et al. (2001) demonstrated that the DRC model generates accounts for phenomena seen in normal reading, including effects of frequency, regularity, position, position of regularity, neighborhood size, pseudohomophony, lexicality, length, and a number of interactions of these variables. They developed an algorithm that yields quantitative predictions about reading of orthographically regular words from performance of orthographically irregular words and nonwords; they demonstrated that this equation accurately predicts performance of young normal readers, children with developmental dyslexia, and children with brain tumors (Castles et al., 2006). Rapcsak, Henry, Teague, Carnahan, and Beeson (2007) extended this work to a heterogeneous but well-studied group of 33 adults with acquired dyslexia from stroke. They demonstrated that the performance was well-predicted by the equation derived from dual-route theory. Finally, Nickels et al. (2008) reported simulations of the data from three subjects with phonological dyslexia with the DRC model. Interestingly, no single lesion generated adequate simulations for all three subjects; consistent with the basic principle that different sites of pathology are likely to generate different processing deficits, different “lesions” to the model were required to reproduce the pattern of deficits exhibited by the different patients.

Finally, a computationally instantiated model of reading aloud based on Glushko’s (1979) “reading by analogy” hypothesis has also been developed (Damber, Marchand, Adamson, & Gustafson, 1999). In this account, there is a single procedure for deriving the pronunciation of letter strings that is based on analogy to familiar words (Glushko, 1979; Kay & Marcel, 1981). This account proposes that when confronted with the nonword “paze,” subjects generate a response that rhymes with gaze, reflecting the fact that “-aze” has a single phonological instantiation in English; when presented the letter string “tave,” in contrast, subjects are both slower to respond and more variable as “-ave” has multiple phonological instantiations in English (e.g., have versus gave). Marchand and Friedman (2005) demonstrated that a computationally implemented version of the analogy account can be lesioned to account for the data of two dyslexic subjects with unusual patterns of performance.

Although the DRC and triangle models are based on fundamentally different perspectives regarding the brain basis of reading and are instantiated in very different computational architectures, both models accommodate a wide range of empirical data. Additional data will be required to adjudicate between the models and the theoretical perspectives that animate them.

63.5 ASSESSMENT OF READING

As previously noted, the specific types of dyslexia are distinguished on the basis of performance with different types of stimuli. For example, deep dyslexia is characterized by impaired performance on non-words, an effect of part of speech such that nouns are read better than modifiers or functors and an effect of imageability such that words denoting more abstract objects or concepts are read less well than words of high imageability. The assessment of patients with dyslexia should include stimuli varying along the dimensions discussed here.

The effect of imageability or concreteness should be assessed by presenting words of high (e.g., *desk, frog, mountain*) and low (e.g., *fate, universal, ambiguous*) imageability. Part of speech should be assessed by presenting nouns (e.g., *table, meatloaf*), modifiers (e.g., *beautiful, early*), verbs (e.g., *ambulate, thrive*), and functors (e.g., *because, their*). The effect of orthographic regularity should be assessed by presenting regular words that can be “sounded out” (e.g., *flame, target*) and irregular words that cannot (e.g., *come, tomb*). The ability to “sound out” words is also assessed by presenting nonword letter strings that may sound like a real word (e.g., *phish*) or may not (e.g., *blape*).

Because word frequency is typically an important determinant of performance, a wide range of word frequencies should also be used. To obtain a reliable assessment of performance, testing should include at least 10 words of each of the stimulus types noted in this chapter. The compilation of the appropriate lists of stimuli may be time-consuming; consequently, many investigators use published word lists, some of which are commercially available (Kay, Lesser, & Coltheart, 1996). Clinical assessments of acquired dyslexia should also include sentence and paragraph reading, because real-life reading requires reading words in context rather than in isolation. In the research setting, additional tools such as eye-tracking, neuroimaging, or electrophysiology can complement behavioral performance.

Finally, it should be noted that there is an emerging literature on the treatment of acquired reading disorders. Whereas there is no widely recognized and effective treatment for any of the acquired dyslexias, there have been a number of reports of theoretically

motivated interventions that appear to offer promise (see Leff & Behrmann, 2008 for a review).

Imaging Brain Networks for Language: Methodology and Examples from the Neurobiology of Reading

Anjali Raja Beharelle¹ and Steven L. Small²

¹Laboratory for Social and Neural Systems Research, University of Zurich, Zurich, Switzerland;

²Department of Neurology, University of California, Irvine, CA, USA

64.1 INTRODUCTION

Functional neuroimaging is a powerful tool for answering questions regarding how the brain implements language. Standard functional neuroimaging methods tend to treat the brain from a modular perspective, identifying sets of individual regions that are active during particular language tasks. The majority of studies examining the neurobiology of language have used standard functional neuroimaging methods that can help map out areas involved in reading and spoken language. Anatomically, the brain consists of dense and complex connections among these areas, suggesting that interregional communication plays a key role in cognitive function. More recent advances in neuroimaging methods have been developed that can be used to examine the interacting and overlapping networks of the brain regions that support reading. This permits the exploration of the functional properties of any single region with respect to the activity of the other regions within the network (neural context; McIntosh, 1998, 2000), which is essential for characterizing the integration of function among regions. In this chapter, we summarize some of the principal methods of assessing functional and effective brain connectivity and give examples of current studies using these approaches to investigate reading-related networks. We also discuss the advantage each method confers relative to the other methods.

Functional and effective connectivity can be assessed in the context of a particular behavior (task-dependent) or during rest (task-independent). Task-dependent

approaches detect synchronization of activity in neural regions in response to extrinsic stimulation. Approaches involving the absence of a task examine intrinsic functional connections that are formed via spontaneous activity arising during the “resting state” (Biswal, Yetkin, Haughton, & Hyde, 1995). Resting state functional connectivity is thought to reflect a history of coactivation among regions across a wide range of tasks and time (Fox & Raichle, 2007) and can be used to characterize regions across the whole brain into groupings that show high correlations of spontaneous activity (these groups have been referred to as communities, modules, subnetworks, or clusters in network analyses; Power et al., 2011).

Connectivity analyses require the selection of a set of relevant nodes within the network to focus the investigation. This is a nontrivial undertaking because there is a lack of consensus regarding how best to define fundamental neural elements (Craddock et al., 2013) and connectivity results can vary based on choices that are made regarding node definition. The specific brain subunits encompassed by the nodes can range from patches of cortex as small as one voxel in size to macroscopic brain regions (such as the pars opercularis of the inferior frontal gyrus). When macroscopic brain regions are used, parcellation schemes have varied widely and can be anatomically based (e.g., automated anatomic labeling (AAL), Tzourio-Mazoyer et al., 2002; the Talairach Daemon, Lancaster et al., 2000; or the “Destrieux” atlas, Fischl et al., 2004) or functionally based (e.g., the CC200 and CC400 atlases that are derived from 200- and 400-unit

functional parcellations, respectively; Craddock, James, Holtzheimer, Hu, & Mayberg, 2012). Although these atlases share some similarities macroscopically, the specific details of the parcellations can vary considerably. Meta-analyses can also be conducted to define nodes based on previous task-based neuroimaging studies (e.g., Vogel et al., 2013).

64.2 FUNCTIONAL CONNECTIVITY ANALYSES: A SET OF EXPLORATORY TECHNIQUES

64.2.1 Overview

Functional connectivity can be defined as the synchronization between spatially remote neurophysiological events (Friston, Frith, Liddle, & Frackowiak, 1993). First introduced via early electroencephalography (EEG) and multiunit recording studies, functional connectivity analyses were applied to positron emission tomography and functional magnetic resonance imaging (fMRI) in 1993. Analyses of functional connectivity identify reliable patterns of covarying brain signals that index neural activity. These techniques are exploratory in nature because they are mostly data-driven and are not based on an explicit hypothesis or model about the relationships among neural regions or the effects of task conditions or subject groups. Therefore, a functional connection does not necessarily arise from direct communication between the two regions, because their covariance (or correlation) could be due to input from a third region (or a variety of other inputs), and thus causal inferences cannot be made about the association.

64.2.2 Independent Components Analysis

64.2.2.1 ICA Method

Independent components analysis (ICA) is used to take a large data set consisting of many variables and reduce it into smaller number dimensions that can be understood as self-organized functional networks (Beckmann & Smith, 2004). Unlike principal components analysis (PCA), which assumes that the components are uncorrelated in both spatial and temporal domains, ICA components are maximally statistically independent in only one domain. The rationale for ICA is that blood-oxygen-dependent (BOLD) signal measured within the voxels can be regarded as a linear combination of a smaller number of independent component sources. The independent components are identified to be maximally statistically independent, but they are not necessarily uncorrelated as principal components are (McIntosh & Mišić, 2013).

For neuroimaging analyses, independence among components can be imposed in either the spatial (spatial ICA) or the temporal (temporal ICA) domain. Spatial ICA is used more often for fMRI analyses because neural activity is assumed to be sparse among a large number of voxels. Therefore, the independent components isolate coherent networks that overlap as little as possible. However, this assumption of sparseness in the brain can be problematic because spatial ICA will push each non-contiguous activity cluster into separate components. Temporal ICA is more often used for event-related potential (ERP) data because scalp recordings have distinct time courses; therefore, the underlying components are assumed to be temporally independent but may have overlapping spatial topographies.

To compare components across participants, the ICA can be performed on all participants as a group. Here, the data from all subjects are concatenated so that each subject is treated as an observation of the same underlying system (Calhoun, Adali, Pearlson, & Pekar, 2001; Kovacevic & McIntosh, 2007). If data are concatenated along the spatial dimension, subjects will have unique spatial maps but common time courses. The converse is true if data are concatenated along the temporal dimension. The concatenated group data are then decomposed into independent components. This puts all subjects in the same space and allows them to be directly compared. Statistical inference on the independent components is then possible.

This method is useful for extracting functionally segregated networks supporting a cognitive function. The independence of the regions identified as active during task performance relative to the rest of the brain cannot be inferred from the other connectivity methods.

64.2.2.2 ICA: Reading Network Example

In an fMRI study, Ye, Doñamayor, and Münte (2014) used ICA to examine connectivity across the whole brain underlying semantic integration during a sentence reading task with either semantically congruent or incongruent endings. The authors extracted a functional network consisting of the supplementary motor area, left basal ganglia, left inferior frontal gyrus, left middle temporal gyrus, and left angular gyrus that was modulated by the semantic manipulation in the semantic reading task. The time courses of these regions were highly correlated and their activity was greater for incongruent versus congruent sentence endings.

64.2.3 Seed Partial Least Squares (PLS)

64.2.3.1 PLS Method

In general, seed-based functional connectivity techniques examine the correlation with an *a priori* region

of interest (ROI) or “seed” region. In its most basic form, an averaged ROI time series is correlated with the time series of all other voxels in the brain or with the average time series of a set of ROIs. Determining the seed region can be done based on functional activity or anatomical parcellation.

A specific type of seed-based functional connectivity can be performed with partial least squares (PLS) (McIntosh, Bookstein, Haxby, & Grady, 1996). PLS is a multivariate analysis technique that can be used to identify a set of variables (called latent variables (LVs)) that optimally link spatiotemporal brain data to the task design or to behavioral measures, or, in the case of seed PLS, that link functional connectivity to other neural seed regions by extracting commonalities between them. PLS is similar to a PCA with several important differences: (i) PLS analysis is constrained to the part of the covariance matrix that is related to the time series of the given neural seed region that allows for interpretation of brain connectivity results as relating to each experimental condition; (ii) statistical inferences regarding the significance of the experimental manipulations are made using nonparametric permutation methods that allow one to select the LVs that significantly express task or behavioral effects on connectivity; and (iii) bootstrap resampling is used to retain only voxels that robustly express the task or the behavioral effects. Finally, PLS is specialized to handle larger data sets where the dependent measures are highly correlated; therefore, it is well-suited for the analysis of neuroimaging data (McIntosh & Lobaugh, 2004).

Brain activity data for PLS are organized into a 2D matrix where the rows contain scan data for each participant within each task condition and the columns consist of voxels \times time. A second matrix consisting of time series of the seed neural region is similarly stacked by participant within condition within participant group. The data from the seed region are then correlated with the overall brain data of the participants and subjected to singular value decomposition (SVD). From the input matrix, SVD creates a set of orthogonal singular vectors (the LVs), which represent the entire covariance of the mean-centered matrix in decreasing order of magnitude and whose number is equal to the total number of task conditions times groups. Thus, the LVs can be thought of as being similar to the eigenvectors generated by PCA. Each LV consists of a pair of left- and right-singular vectors that relate brain connectivity to the experimental design.

The weights within the LV at each voxel–time point combination are referred to as voxel saliences. The voxel saliences identify a collection of voxels that, as a group, have connectivity to the seed region most related to the task design. The task saliences indicate

the degree to which each task is related to the pattern BOLD connectivity differences. The saliences are similar to PCA eigenvector weights.

To determine how often the singular value matrix for an LV generated from the original analysis is larger than singular value matrices generated from random data, permutation testing is used. Permutation testing involves resampling *without* replacement, where data are shuffled to reassign the order of task conditions for each participant (Good, 2004). PLS is then re-run a certain number of times on each set of reordered data, and the number of times the permuted singular values exceed the original values is calculated and given a probability. The 95th percentile of the resulting probability distribution of singular values is used as the significance threshold. In this scenario, the assumption of a normal distribution is not required (McIntosh et al., 1996).

In a second step, one assesses the reliability of each voxel’s contribution to the LV by estimating the standard error of the voxel saliences using bootstrapping. Bootstrapping consists of resampling *with* replacement where participant data are shuffled while the experiment conditions remain fixed. SVD is then performed on the resampled matrix consisting of participant subsets of the original data set, and the standard error of the voxels contributing to the task effects are calculated (Efron & Tibshirani, 1993). The ratio of the salience to the standard error of the voxels is used to threshold the data and can be thought of as similar to a z-score if the data are normally distributed.

Although this method is quite data-driven, the advantage of seed PLS relative to the other methods is that it permits the testing of a hypothesis focused on a particular ROI.

64.2.3.2 PLS: Reading Network Example

Reinke, Fernandes, Schwindt, O’Craven, and Grady (2008) examined how whole brain functional connectivity changed with the visual word form area (VWFA) based on whether participants viewed English words, meaningful symbols such as \$ and %, digits, words in an unfamiliar language (Hebrew), and a control set of stimuli consisting of geometric shapes. They were able to show that while neural activity in the VWFA did not differ significantly for words and meaningful symbols, a specific functional network of regions including the left hippocampus, left lateral temporal, and left prefrontal cortices was specific to words. This study underscored the fact that the neural context of the VWFA, specifically the broader distributed brain activity that is correlated with the VWFA, is specific for visual word processing but not for activity in the focal brain region itself.

64.2.4 Synchronization of Neuronal Oscillations

64.2.4.1 SNO Method

Scalp recordings techniques such as magnetoencephalography (MEG) and EEG, which afford greater temporal resolution than fMRI, allow for real-time investigation of brain network dynamics during reading. Constituent neuronal populations involved in the same functional network are identifiable because of the fact that they fire in synchrony at a given frequency. The specificity of this frequency allows the neuronal population to participate in a variety of representations at different points in time. In addition, oscillatory synchrony can also serve to bind together information that is represented in the different neuronal populations (Gray, Konig, Engel, & Singer, 1989).

In its simplest form, one can investigate the linear interdependencies or correlations between the amplitudes of various EEG or MEG signals. This avoids the necessity to band-pass filter or extract instantaneous phase. One can also examine the cross-correlation, which includes further information about the systematic time shifts between the amplitudes of the two signals. However, studies often examine phase synchronization in frequency space. Cross-spectral density can be computed by multiplying the Fourier-transformed signals of the time series. Coherence is assessed by normalizing the cross-spectral density with the power spectral density of both time series. This value ranges from 0, if the signals have no similarity, to 1, if the signals are identical. It is critical for such a synchronization analysis to select the frequency bands of interest. Often, one can assess reliability via confidence levels by comparing to synthetic data, which are created by shuffling the time point of the original data while preserving spatial relationships (Gross et al., 2001).

The advantage of this method is that it allows the researcher to characterize dynamics among regions involved in reading on a faster temporal scale than the other methods.

64.2.4.2 SNO: Reading Network Example

Kujala et al. (2007) found the strongest synchronization among regions often implicated in reading (occipital temporal, medial, superior, and inferior temporal, prefrontal, and orbital cortices, face motor areas, insula, and cerebellum) at 8–13 Hz during a rapid reading task. Notably, regions such as the supramarginal gyrus or the posterior superior temporal cortex, which are thought to be involved in grapheme-to-phoneme conversion, were not a part of the network, potentially because the nature of the task required a more lexical-semantic than phonological reading strategy.

64.3 EFFECTIVE CONNECTIVITY ANALYSES: A SET OF CONFIRMATORY TECHNIQUES

64.3.1 Overview

Effective connectivity is defined as a directed causal influence of one region on another (Aertsens, Gerstein, Habib, & Palm, 1989). Analyses of effective connectivity involve confirmation of hypotheses. Unlike exploratory analyses, a confirmatory approach begins with the construction of an explicit model of interregional neural relationships. The model is then tested for goodness of fit with the observed data and/or whether it can fit the observed data better than an alternative model. Therefore, effective connectivity analyses test precise hypotheses that take into account external inputs and the neuroanatomical architecture rather than being data-driven like functional connectivity analyses (McIntosh & Mišić, 2013).

64.3.2 Psychophysiological Interactions (PPI)

64.3.2.1 PPI Method

If an experimental manipulation relates to significant changes in the correlation between a pair of brain regions, then this suggests an interaction between the psychological variable and the neural or physiological connectivity, termed a psychophysiological interaction (PPI) (Friston et al., 1997). In a typical functional connectivity analysis, regions may have some baseline correlations due to anatomical connections as in the case of resting state networks (Biswal et al., 1995), common sensory inputs, or neuromodulatory influences. Furthermore, if a change in correlation of activity in the seed is observed with another region, it could be caused by a change in another functional connection, a change in the level of observation noise, or a change in the amplitude of endogenous neuronal fluctuations (Friston, 2011). Therefore, a significant correlation or even a significant change in correlation cannot always be interpreted as a change in the underlying coupling between the two regions. PPI seeks to address this issue by moving beyond task-independent correlations and examining changes in correlations that occur as a result of an imposed task manipulation.

In PPI, the activity of the seed region is regressed onto the activity of another brain region across different experimental conditions and the change in slope is calculated. Just like seed PLS, the first step of PPI involves selecting a seed region and extracting its time course. The goal is to find regions with which the seed has a stronger relationship during a particular experimental condition than during the others (i.e., a task by seed region interaction). For this purpose, an

interaction (PPI) regressor is created by taking the scalar product of the mean-centered task time course with the mean-corrected seed region time course. Voxels whose activity correlates only with the seed region or that show an effect of task will have some correlation to the predictor. Therefore, it is necessary to include the experimental task design and the physiological time courses from which the interaction term was created as covariates of no interest in the model. This will ensure that the variance explained by the interaction term goes significantly beyond what can already be explained by the main effects of task and correlation to the seed.

The advantage of this method is that, much like seed PLS, it allows the researcher to test a hypothesis focused on a particular ROI or voxel. However, it specifically examines how the task modulates the network based on that ROI.

64.3.2.2 PPI: Reading Network Example

Callan, Callan, and Masaki (2005) trained native Japanese speakers to learn the character-to-sound associations of an unknown orthography (either Thai or Korean phonograms, i.e., a grapheme that represents a phoneme or a combination of phonemes) and examined changes in brain connectivity pre- and post-training with fMRI. They found significant changes in activation post-training relative to pre-training in the left angular gyrus, and then used this region as a seed for a PPI analysis. The authors then identified a network showing greater integration of left angular gyrus activity with activity in the primary visual cortex and superior temporal gyrus for the trained phonograms after training. This finding underscored the importance of the left angular gyrus in grapheme-to-phoneme conversion.

64.3.3 Structural Equation Modeling (SEM)

64.3.3.1 SEM Method

The purpose of structural equation modeling (SEM) is to define a theoretical causal model consisting of a set of predicted covariances between variables and then test whether it is plausible when compared to the observed data (Jöreskog, 1970; Wright, 1934). In neuroimaging, these causal models consist of the brain activity signal of interest in a subset of ROIs and the pattern of directional influences among them (McIntosh & Gonzalez-Lima, 1991, 1994). The influences are constrained anatomically so that a direct connection between two regions is only possible if there is a known white matter pathway between them.

The first step in defining an SEM is to specify the brain regions, which are treated as variables, and the causal influences between them in terms of linear

regression equations. There is always one equation for each dependent variable (activity in the ROI), and some variables can be included in more than one equation. This system of equations can be expressed in matrix notation as $\mathbf{Y} = \beta\mathbf{Y} + \psi$, where \mathbf{Y} contains the variances of the regional activity for the ROIs, β is a matrix of connection strengths that defines the anatomical network model, and ψ contains residual effects, which can be thought of as either the external influences from other brain regions that cannot be stipulated in the model or the influence of the brain region on itself. Because the model is underspecified, having more unknown than known parameters, it is not possible to construct the model in a completely data-driven manner, and thus some constraints are needed on the model parameters. The most common approach is to arbitrarily restrict some elements of the residual matrix ψ to a constant, usually 35–80% of the variance for a given brain region, and to set the covariances between residuals to zero (McIntosh & Gonzalez-Lima, 1994). It is also common in neuroimaging to keep the path coefficients in both directions equal for regions that have mutually coupled paths.

The main idea of SEM is that the system of equations takes on a specific causal order, which can be used to generate an implied covariance matrix (McArdle & McDonald, 1984). Unlike in multiple regression models, where the regression coefficients are derived from the minimization of the sum of squared differences from the observed and predicted dependent variables, SEM minimizes the difference between the observed covariance structure and the one implied by the structural or path model. This is done by modifying the path coefficients and residual variances iteratively until there is no further improvement in fit. In most cases, a method such as maximum likelihood estimation or weighted least-squares is used to establish a fit criterion that needs to be maximized. The identified best-fitting path coefficient has a meaning similar to a semipartial correlation in that it reflects the influence of one region onto a second region with the influences from all other regions to the second region held constant. SEM can be conceptualized as a method that uses patterns of functional connectivity (covariances) to derive information about effective connectivity (path coefficients) (McIntosh & Mišić, 2013).

Model inference is done in SEM by comparing the goodness-of-fit between the model implied covariance matrix and the empirical covariance matrix using a χ^2 test. It is also possible to compare model fits using a χ^2 difference test, and this can be done to examine whether one or more causal influences change as the result of a task or group effect. To this end, models are combined in a single multigroup or stacked run.

The null hypothesis is that the effective connections do not differ between groups or task conditions and the null model is constructed so that path coefficients are set to be equal across groups or task conditions. The alternative hypothesis is that the effective connections are significantly different between groups or task conditions. Implied covariance matrices are generated for each group- or task-specific model. An alternative χ^2 that is significantly lower (better fitting) than the null χ^2 implies a significant group or task effect on the effective connections that were specified differently in the models. It is possible that the omnibus test can indicate a poor overall fit, but the difference test shows a significant change from one task to another. SEM has been shown to be robust in these cases and is able to detect changes in effective connectivity, even if the absolute fit of the model is insufficient (Protzner & McIntosh, 2006). Finally, it is possible to use an alternative approach to model selection, where nodes of the network are selected *a priori*, but the paths are connected in a data-driven manner (see Bullmore et al., 2000).

The advantage of SEM is that one can identify directionality in the influence of activity from one region to that of another. In addition, SEM allows the researcher to test the validity of a theoretical model regarding network interactions among regions supporting the task under investigation.

64.3.3.2 SEM: Reading Network Example

Levy et al. (2009) used SEM to test neuroanatomical predictions made by the dual-route cascade reading model (Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001) on reading skill. Their effective connectivity models consisted of four left hemisphere ROIs: middle occipital gyrus (MOG); occipito-temporal junction (LOT); parietal cortex (LP); and inferior frontal gyrus (IFG). For reading words, MOG→LP, MOG→LOT, and LP→IFG pathways were significantly more involved than the LOT→LP path, suggesting that information traffics along both ventral and dorsal pathways during word reading. For pseudoword reading, MOG→LOT and LOT→LP were significantly more involved than MOG→LP, suggesting that information first flows to LOT before being transferred to the dorsal pathway. In addition, increased reliance on the “word pathway” (MOG→LP) positively correlated with reading skill and increased reliance on the “pseudoword pathway” (MOG→LOT) correlated with the pseudoword reading ability. Their findings are in agreement with the DRC model, suggesting that regular words can be read in two ways (via parallel dorsal and ventral stream processing); however, the dorsal pathway is selective for word stimuli and increased connectivity in this pathway is related to better word

reading. Pseudowords, however, undergo letter/sublexical analysis in the posterior ventral pathway before being fed to the dorsal path.

64.3.4 Dynamic Causal Modeling (DCM)

64.3.4.1 DCM Method

The key concept behind Dynamic Causal Modeling (DCM) is that brain networks comprise an input-state-output system, where causal interactions are mediated by unobservable neuronal dynamics (Friston, Harrison, & Penny, 2003). Referred to as a causal model, these “hidden” interactions are specified by coupling parameters, which denote the degree of synaptic coupling and model effective connectivity. The local neuronal dynamics underlying these interactions are defined by a set of differential equations. This causal model is then combined with a forward, or observation, model that relates the mapping from the neuronal activity to the observed responses (Friston, Moran, & Seth, 2013). It is important to note that causality is inferred at the neuronal population level and not at the level of the observed responses.

In the causal model, each ROI consists of neuronal populations that are intrinsically coupled to each other and extrinsically coupled to neuronal populations of the other regions in the network. Stochastic or ordinary differential equations relate the present state of a neuronal population to the future state of the same neuronal population and to the states of the other populations. The coupling parameters can be thought of as rate constants, which determine how rapidly one population affects another (McIntosh & Mišić, 2013). Experimental effects are modeled as external perturbations to the system, which can cause either a change in coupling or a change in neuronal activity of a population. The underlying causal model is represented as a system of coupled differential equations, where the rate of changes of state x is a function of the states of the other populations (x), the external inputs, and the coupling parameters, which are unknown and need to be inferred similarly to the path coefficients in SEM. DCMs do not stipulate any particular biophysical model of neuronal activity and only require the model to be biologically plausible and sufficiently able to explain the external perturbations and the interactions between neuronal populations.

In the second step of DCM, the forward model is used to map neuronal states into the observed signal measurements while incorporating unknown parameters. The form of the forward model depends on the imaging modality. For ERPs, for example, the mapping function is the lead field matrix that models the propagation and volume conduction of electromagnetic fields

through neural tissue, cerebrospinal fluid, skull, and skin. The unknown parameters that are introduced are the location and orientation of the source dipole (Kiebel, David, & Friston, 2006). If BOLD signal contrast is the observed measure, then the mapping function models how changes in neuronal activity engender changes in local blood flow, which result in an influx of oxygenated blood and a reduction in deoxygenated hemoglobin (Buxton, Wong, & Frank, 1998). Here, the unknown parameters can specify factors such as the rate constants of vasodilatory signal decay and capillary resting net oxygen extraction (Stephan, Weiskopf, Drysdale, Robinson, & Friston, 2007).

DCMs use a Bayesian approach (see Friston et al., 2002) for estimating the unknown parameters in the models. Essentially, a posterior distribution is estimated for each parameter using an optimization algorithm and taking into account prior beliefs about the value the parameter can realistically take on and the observed data. The observed data are used to update the model (i.e., estimate the parameters) to maximize model evidence in a procedure known as Bayesian model inversion. The model evidence accounts for the ability of the model to explain the data as accurately as possible and to have the fewest parameters (i.e., parsimonious models are rewarded). Models can be compared by taking the ratio of their respective model evidences or the difference in their respective log evidences, and model comparisons can be made to determine group or task effects on anatomical connections in a similar manner to SEMs; however, DCMs can also vary in the specification of their priors for different task or group treatments.

Model inversion is performed on each subject individually. Therefore, an experimenter must decide whether to keep the same model for all subjects in a between-subjects analysis. If experimenters choose this, then they can multiply the model evidences or add the log evidences across subjects to get the group model evidence, and this essentially represents a fixed-effects analysis. In this case, one approach to obtaining group-level estimates of the parameters is to compute a joint density for the subject-specific posterior distribution estimates. If the experimenters want to treat the subjects as heterogeneous, then they can take the ratio of the number of subjects who show positive model evidence for a given model to the number of subjects who show greater model evidence for another model (Stephan et al., 2007), and this is essentially a random-effects analysis. In this case, it is common to take a summary statistic of the subject-specific posterior distribution estimates (such as the median or mode of the distribution) as the parameter estimate and conduct traditional random-effects analyses comparing the group means of these summary statistics (e.g., *t*-test).

Like SEM, DCM can show the directional influences of regions on one another. Whereas SEM is used to test theoretical models of network interactions based on what is known about anatomical connections, DCM is meant to provide a more explanatory understanding of the relationships among regions identified to be active during task-based fMRI analyses.

64.3.4.2 DCM: Reading Network Example

The triangular part of the inferior frontal gyrus is thought to be particularly involved in semantic processing, and the opercular part is thought to have more of a role in phonological tasks (e.g., Poldrack et al., 1999). Mechelli et al. (2005) tested this theoretical framework using DCM. Effective connectivity from the anterior fusiform gyrus to the pars triangularis increased for exception words (e.g., PINT or STEAK), necessitating more lexical-semantic processing relative to pseudowords and between dorsal premotor cortex and posterior fusiform gyrus for pseudowords (e.g., RINT or MAVÉ) requiring more phonological mapping relative to exception words. This finding demonstrated distinct neuronal mechanisms for semantic and phonological processing and confirmed previous theories of dissociation of function in the inferior frontal gyrus.

64.4 TECHNIQUES SPANNING BOTH FUNCTIONAL AND EFFECTIVE DOMAINS

64.4.1 Granger Causality (GC)

64.4.1.1 GC Method

Granger causality (GC) does not fit easily into the functional or effective connectivity because it has both exploratory and confirmatory characteristics. The main idea behind GC is that B “Granger causes” A if B contains information that helps predict the future of A better than information in the past of A predicts or information in the past of other conditioning variables, C (Friston et al., 2013). The GC measure is based on the relative change in the model error when new time series are added to improve the prediction of the dependent signal (Granger, 1969). Essentially, GC is the ratio of the variance of the model before and after the addition of the new time series (time series “B”) in this case:

$$F_{y \rightarrow x} = \ln \frac{\text{Var}(ea||a)}{\text{Var}(ea||ab)}$$

In the context of brain networks, multiple predictors comprising the past time series of all ROIs can be specified to account for the present time series of all ROIs. If one assumes the effects to be linear, then the

relationships can be specified using multivariate linear regression (through what is termed multivariate vector autoregressive (MVAR) modeling; Goebel, Roebroeck, Kim, & Formisano, 2003). An MVAR model contains every possible connection in the network, and each connection is tested to determine which ones are non-zero. This allows subnetworks to be extracted without having to specify connectivity patterns *a priori*. For any given connection, the influence of all other nodes are partialled out, allowing one to obtain an estimate for whether the past time series of B helps predict the time series of A more than what is accounted for by all other variables combined, C. The coefficients in the MVAR can be estimated using ordinary least-squares (by minimizing the difference in the sum of squared errors between the predicted and observed values of the present times series).

The advantage of Granger causality is that it allows a researcher to pinpoint directional influences of regions on another without any *a priori* hypothesis regarding which regions are involved in particular subnetworks. This is the case because subnetworks are identified in a data-driven manner.

64.4.1.2 GC: Reading Network Example

In a MEG study, Frye, Liederman, McGraw Fisher, and Wu (2012) used GC to examine the connectivity of bilateral temporoparietal areas (TPAs) in dyslexic and typical readers during a nonword reading task. The important feature of this study is that GC allowed them to examine hierarchical network structure (i.e., which nodes show dominant influences of the other nodes) rather than connectivity alone. In the beta frequency band, those participants with greater connectivity from the left TPA to other regions (left TPA dominant) were more likely to show improved phonological decoding performance, and those with greater connectivity from other regions into the TPA were more likely to show poorer phonological decoding performance across both groups of participants. It may be the case that participants in which a hierarchical network topography is manifested (i.e., those with greater outward connectivity of TPA) also show more stable network processing, allowing them to optimally process stimuli, because neural networks with hierarchical structures have been shown to be more stable compared to neural networks with nonhierarchical topography. Second, greater relative outward connectivity of the right TPA to other brain areas was associated with worse performance in dyslexic readers. This finding extends previous studies of dyslexic readers that reported greater TPA activity by indicating that the direction of influence of the right TPA onto other brain regions may play a key role in dyslexia.

64.4.2 Graph Theory

64.4.2.1 Graph Theory Method

Graph theoretic measures can be applied to structural, functional, and effective connectivity matrices (Bullmore & Sporns, 2009). Unlike the metrics previously discussed, which are often limited by which seeds or subset of nodes are chosen *a priori*, graph theoretic measures provide information regarding changes in the topology of the whole brain as well as the role that the individual nodes play within that topology, thereby providing a comprehensive assessment of patterns of information flow. This approach allows for the investigation of functional integration and functional segregation within the global brain network architecture.

The first step of such an analysis is to construct a graph that consists of nodes (i.e., the neural elements of interest) and edges, representing the statistical dependencies or connections between the nodes. For structural connectivity graphs, the edges correspond to anatomical white matter pathways; for functional connectivity graphs, the edges are pairwise associations between the brain signals of the nodes; and for effective connectivity graphs, the edges consist of pairwise measures of the causal influence of one node onto another. Structural brain connectivity yields a sparse and directed (or asymmetric) graph. Functional and effective brain connectivity give rise to full undirected (or symmetric) or directed graphs, respectively, which can be further reduced by setting a threshold to control the degree of sparsity. All graphs may be weighted, with the weights representing connection densities or efficacies, or binary, indicating the presence or absence of a connection.

Once the graph is constructed, various graph theoretic measures can be computed (see Rubinov & Sporns, 2010). One can simply measure the connectedness of each node by counting its total number of connections (degree). To investigate integration, one can examine the least number of steps necessary to get from one node to another (shortest path length) as well as the characteristic path length for the entire network. The network's global efficiency is a related measure that is the average inverse shortest path length. To examine segregation, one can compute the clustering coefficient, which is the fraction of the node's neighbors that are also neighbors of each other. One can also partition the brain into subnetworks or communities within the whole brain and then examine their interactions by computing modularity, which is the ratio of the density of connections within specific subnetworks compared to the density of connections between subnetworks. Once the brain has been partitioned into subnetworks, it is possible to identify

which nodes act as connector hubs (the terminology for these nodes varies, but here we mean nodes that play a strong role in linking subnetworks to each other) by computing their participation coefficient and which nodes act as modular hubs (nodes that have greater connections within their own subnetwork) by computing their within-module degree z-score. Finally, it is possible to assess the frequency with which certain combinations of nodes or edges occur by looking at motifs. Some metrics, such as modularity or characteristic path length, produce one value per subject and can be submitted to standard between-subject univariate tests. The node-specific measures can be used to generate topological maps for each subject, and some correction for multiple comparisons must be performed for inferential analyses about robust effects.

The advantage of graph theory, unlike most of the other methods that require confining analyses to *a priori* regions thought to be involved in a functional network, is that we have the capability of examining and quantifying interactions among regions on a whole-brain level, thus giving us a comprehensive view of functional network architecture while still being able to assign specific connectivity roles within the network to certain nodes.

64.4.2.2 Graph Theory: Reading Network Example

Vogel et al. (2013) examined the functional subnetwork structure during resting state in an attempt to identify a reading-dedicated community. Unlike previous studies that have examined this, the authors only included prominent reading-related regions derived from a meta-analysis (including left supramarginal gyrus, angular gyrus, middle temporal gyrus, and inferior frontal gyrus) as nodes in the analysis. Rather than cluster into their own community, reading-related regions were assigned to other communities whose primary function is more general than reading (e.g., the VWFA was assigned to a visual community, and the angular gyrus was assigned to a default mode community), suggesting the lack of an intrinsic reading community in the brain. This was the case with mature as well as developmental subjects, suggesting that the regions implicated in reading are broadly used across many tasks, including reading. Because this study was undertaken during resting state, it does not rule out that there may be special relationships among some of these regions during task-based reading.

64.5 CONCLUSIONS

Connectivity analyses identifying neural networks move beyond isolating a collection of individual regions that are associated with reading and provide

an account of how neural regions interact with one another. Exploratory methods such as ICA and PLS aim to reduce the original data into interpretable functional networks. Effective connectivity analyses like SEM and DCM are useful, particularly when trying to test *a priori* anatomical or theoretical hypotheses about the neurobiology underlying reading (e.g., the DRC model). Graph theoretic measures take into account the global topology of neural networks while also specifying the role of individual regions within a network or subnetwork. These measures can identify the patterns of information flow among regions across the whole brain rather than examining interactions with a seed or within a subset of region, and they have been used to test whether reading-specific subnetworks exist in the brain.

Anthony J. Krafnick and Diana R. Alkire

Center for the Study of Learning, Georgetown University, Washington, DC, USA

65.1 INTRODUCTION

65.1.1 What Is Developmental Dyslexia?

Unlike spoken language, available to humans for many thousands of years, written language is a recent (less than 6,000 years) cultural invention and has not been subjected to evolutionary pressure. As such, existing brain regions that subservise other functions, such as spoken language and object recognition, are utilized for reading acquisition, which occurs over a protracted period of time with formal schooling. However, for some children, learning to read is especially difficult.

Developmental dyslexia is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede growth of vocabulary and background knowledge (Lyon, Shaywitz, & Shaywitz, 2003).

This is one of several research definitions of dyslexia and was developed by the International Dyslexia Association and endorsed by the US-based National Institute of Child Health and Human Development. Like most definitions, it emphasizes problems with decoding, a critical piece in research and diagnostic evaluation of dyslexia that is attributed to poor phonological awareness (PA). Comprehension of text can be impacted as a secondary consequence of poor decoding (this distinguishes dyslexia from specific language impairment, wherein poor language comprehension can directly lead to reading problems; see Nation, Cocksey, Taylor, & Bishop, 2010).

Dyslexia is the most prevalent learning disability. It affects 5–12% of the English-speaking population, and the incidence is two to three times higher in males than in females (Rutter et al., 2004). These rates are slightly lower for other languages and other writing systems (Brunswick, McDougall, & Davies, 2010), with reading being especially challenging in English, where the orthography is deep (the mapping between sound and print is not one-to-one; see Richlan, 2014). Dyslexia is highly heritable, with an estimated 30–50% chance of being passed from parent to child (Fisher & DeFries, 2002). Linkage and association studies have identified candidate genes and established relationships between genotypical variance and the dyslexia endophenotype (for review, see Scerri & Schulte-Körne, 2010). Because reading provides the key to learning almost all subject materials, reading failure can be a limiting factor in almost all of a child's academic learning experiences.

65.1.2 Skills That Support Typical Reading Acquisition are Impaired in Dyslexia

There is a rich behavioral literature describing normal reading acquisition (Ehri, 1999) and the skills that promote learning to read (Schatschneider, Fletcher, Francis, Carlson, & Foorman, 2004; Wagner & Torgesen, 1987). These include broad language skills such as expressive and receptive language, vocabulary, morphology, and syntax (Scarborough, 2005). Further, specific skills such as PA (Bradley & Bryant, 1983; Schatschneider et al., 2004) and orthographic awareness (Badian, 1994) have been shown to be critical to reading acquisition. Understanding the phonological code allows grapheme–phoneme mapping of unfamiliar words, and visual word form recognition aids in mapping orthography of familiar

words to the mental lexicon, together providing access to semantic representations. Good orthographic awareness, whereby words are recognized without decoding, leads to better reading fluency and, in turn, reading comprehension. PA refers to a “broad class of skills that involve attending to, thinking about, and intentionally manipulating the phonological aspects of spoken language” (Scarborough & Brady, 2002). PA, typically measured by sound manipulation at the phoneme level (e.g., phoneme deletion), predicts future reading acquisition in normal readers with a high degree of confidence (Schatschneider et al., 2004; Wagner & Torgesen, 1987) and is especially impaired in dyslexic readers (Lyon et al., 2003; Peterson & Pennington, 2012; Vellutino, Fletcher, Snowling, & Scanlon, 2004). These studies have also shown that two other measures of phonological processing, speeded lexical retrieval (rapid naming of letters and numbers) and verbal short-term memory, often have a moderating role in reading outcome in addition to PA.

It has become widely accepted that weak PA is the core deficit in dyslexia, causing reading impairment by interfering with the grapheme–phoneme mapping required for decoding. A causal role of poor PA in dyslexia has been demonstrated by a combination of evidence: (i) young children’s PA skills predict later reading outcome; (ii) poorly developed PA skills are found in children with dyslexia as early as kindergarten and often prevail into adulthood; (iii) reading level-match design studies demonstrate that children with dyslexia have weaker PA than younger children matched on reading level; and (iv) interventions addressing these weaknesses in PA are largely successful in bringing about gains in decoding in individuals with dyslexia. Together, these have led to the theory that a phonological core deficit best describes the condition of dyslexia (McCardle, Scarborough, & Catts, 2001; Stanovich & Siegel, 1994). Although this account is not likely to represent the entire explanation of this reading disability (Peterson & Pennington, 2012;

Scarborough, 2005), and although alternative theories exist, it is most relevant to the neurobiology of language and thus provides the framework for this chapter. For discussion of theoretical frameworks such as auditory temporal, motor timing, automaticity-based cerebellar, and visual magnocellular deficits, we refer the reader to other in-depth reviews (Ramus, 2004; Vellutino et al., 2004).

65.2 FUNCTIONAL ANATOMY OF READING

As described in detail in the present volume (Cathy Price and Karalyn Patterson) and elsewhere (Price, 2012), reading is supported by a network of regions in the left hemisphere, including ventral (occipitotemporal), dorsal (temporoparietal), and inferior frontal cortices (Figure 65.1). The occipitotemporal cortex (OTC) holds the so-called visual word form system (VWFS), specifically the “visual word form area” (VWFA), which is responsible for visual identification of words. Both the temporoparietal (TPC) and inferior frontal (IFC) cortices play a role in phonological and semantic processing of words, with IFC also involved in articulatory processes. These areas have all been shown to be altered in dyslexia (for review see Gabrieli, 2009; Pugh et al., 2001; Sandak, Mencl, Frost, & Pugh, 2004).

65.3 NEUROANATOMICAL BASES OF DYSLEXIA

A neuroanatomical basis of dyslexia was first discovered during postmortem examinations of gross anatomy of brains of adults who had dyslexia during their lifetime. Most notably, the asymmetry typically seen in the planum temporale, favoring the left

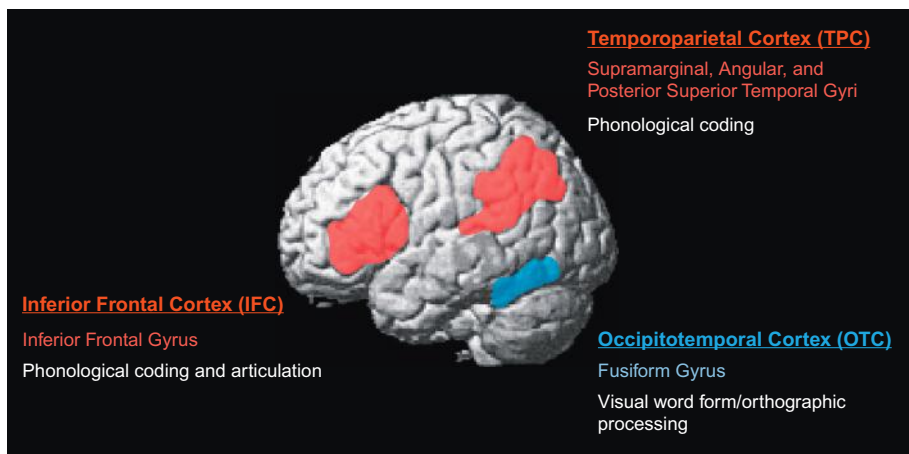

FIGURE 65.1 Schematic representation of brain regions involved in reading and reading-related processes.

hemisphere in size, was not found in the brains of these dyslexics (Galaburda & Kemper, 1979). The same investigators also discovered ectopias on the cortical surfaces of these brains, presumed to be a result of improper cortical migration (Galaburda, Sherman, Rosen, Aboitiz, & Geschwind, 1985), a finding that has received renewed interest in the context of dyslexia-associated genes involved in axonal guidance during development (Galaburda, LoTurco, Ramus, Fitch, & Rosen, 2006).

Manual tracing of magnetic resonance imaging (MRI) structural images later allowed for the replication of differences in the planum temporale *in vivo*, along with more general differences in TPC (Hynd, Semrud-Clikeman, Lorys, Novey, & Eliopoulos, 1990; Larsen, Høien, Lundberg, & Ødegaard, 1990; Leonard et al., 2001). New observations were reported for the cerebellum (Eckert et al., 2003; Leonard et al., 2001) and inferior frontal gyrus (IFG) (Robichon, Levrier, Farnarier, & Habib, 2000). Not surprisingly, given the variability in measurement techniques, some reports conflicted. The advent of automated image processing techniques has enabled more quantitative and investigator-independent examinations of brain differences in dyslexia. Notably, voxel-based morphometry (VBM), using fully or semiautomated algorithms, has now been used in several studies of whole-brain gray matter volume (GMV) in adults and children (for recent review of details see Evans, Flowers, Napoliello, & Eden, 2014). These studies suggest that the most reliable differences in dyslexia are located in bilateral temporal lobe structures (inferior, middle, and superior gyri), inferior parietal lobes, and cerebellum. This has been confirmed by meta-analyses of existing VBM studies of GMV in dyslexia (Linkersdörfer, Lonnemann, Lindberg, Hasselhorn, & Fiebach, 2012; Richlan, Kronbichler, & Wimmer, 2013). For example, Richlan and colleagues (2013) found, as shown in Figure 65.2A, less GMV in right superior temporal gyrus (STG) and left superior temporal sulcus (STS).

VBM has also been used to examine white matter volume (WMV) anomalies in dyslexia, and less WMV has been found within left temporoparietal regions in dyslexic children (Eckert et al., 2005). Diffusion tensor imaging (DTI) studies have shown results of lesser fractional anisotropy (FA) in dyslexic individuals compared with controls, indicating differences in white matter integrity primarily in temporoparietal and frontal areas (Klingberg et al., 2000; for review see Vandermosten, Boets, Wouters, & Ghesquière, 2012). A meta-analysis of DTI studies in dyslexia localized the most common finding to a left temporoparietal region (Figure 65.2B) and used tractography to demonstrate that this region hosts the arcuate fasciculus (also referred to as superior longitudinal fasciculus) and the

corona radiata (Vandermosten et al., 2012). Combined with related observations of correlations between FA values and reading skill in left temporoparietal tracts (Odegard, Farris, Ring, McColl, & Black, 2009), these findings suggest a loss of connections between temporoparietal and frontal areas and interruption of networks that subserve phonological processing (Boets, 2014).

65.4 NEUROFUNCTIONAL BASES OF DYSLEXIA

Early functional studies were limited to adults because they used xenon (Flowers, Wood, & Naylor, 1991) and positron emission tomography (PET) techniques (Gross-Glenn et al., 1991; Paulesu et al., 1996; Rumsey et al., 1992). Then, magnetoencephalography (MEG) and functional magnetic resonance imaging (fMRI) became available in the 1990s and provided better temporal and spatial resolution, respectively, without the concern of radioactive tracers. Reading and its constituent components (phonology, orthography, and semantics) were examined using a range of overt and covert tasks, mostly using single word presentation. Despite variations in tasks and participants, a substantial corpus of publications from different countries achieved convergence in their findings of left hemisphere areas, including: (i) the inferior ventral visual stream, broadly referred to here as OTC; (ii) posterior dorsal TPC, including the posterior superior temporal gyrus (pSTG: within Wernicke's area), the angular gyrus (AG), supramarginal gyrus (SMG), and the inferior parietal lobule (IPL); and (iii) IFC, including IFG within Broca's area. For example, lower signals in dyslexic compared with control groups have been demonstrated in the left OTC (Cao, Bitan, Chou, Burman, & Booth, 2006; Georgiewa et al., 1999; Hu et al., 2010; Paulesu, 2001; Richlan et al., 2010; Shaywitz et al., 1998; Siok, Niu, Jin, Perfetti, & Tan, 2008; Van der Mark et al., 2009; Wimmer et al., 2010; see also Salmelin, Service, Kiesilä, Uutela, & Salonen, 1996) and the left TPC (Brunswick, McCrory, Price, Frith, & Frith, 1999; Cao et al., 2006; Eden et al., 2004; Georgiewa et al., 1999; Paulesu, 2001; Richlan et al., 2010; Shaywitz et al., 1998, 2003; Wimmer et al., 2010). OTC dysfunction has been interpreted in terms of problems with word form processing, whereas less TPC activity has been attributed to poor phonological processing (Pugh et al., 2001; Shaywitz et al., 1998). Findings in the IFG have conflicting results, with some studies reporting hypoactivation in dyslexics relative to controls (Eden et al., 2004; Siok et al., 2008) and others reporting hyperactivation (Shaywitz et al., 1998) or no differences (Paulesu, 2001; Paulesu et al., 1996).

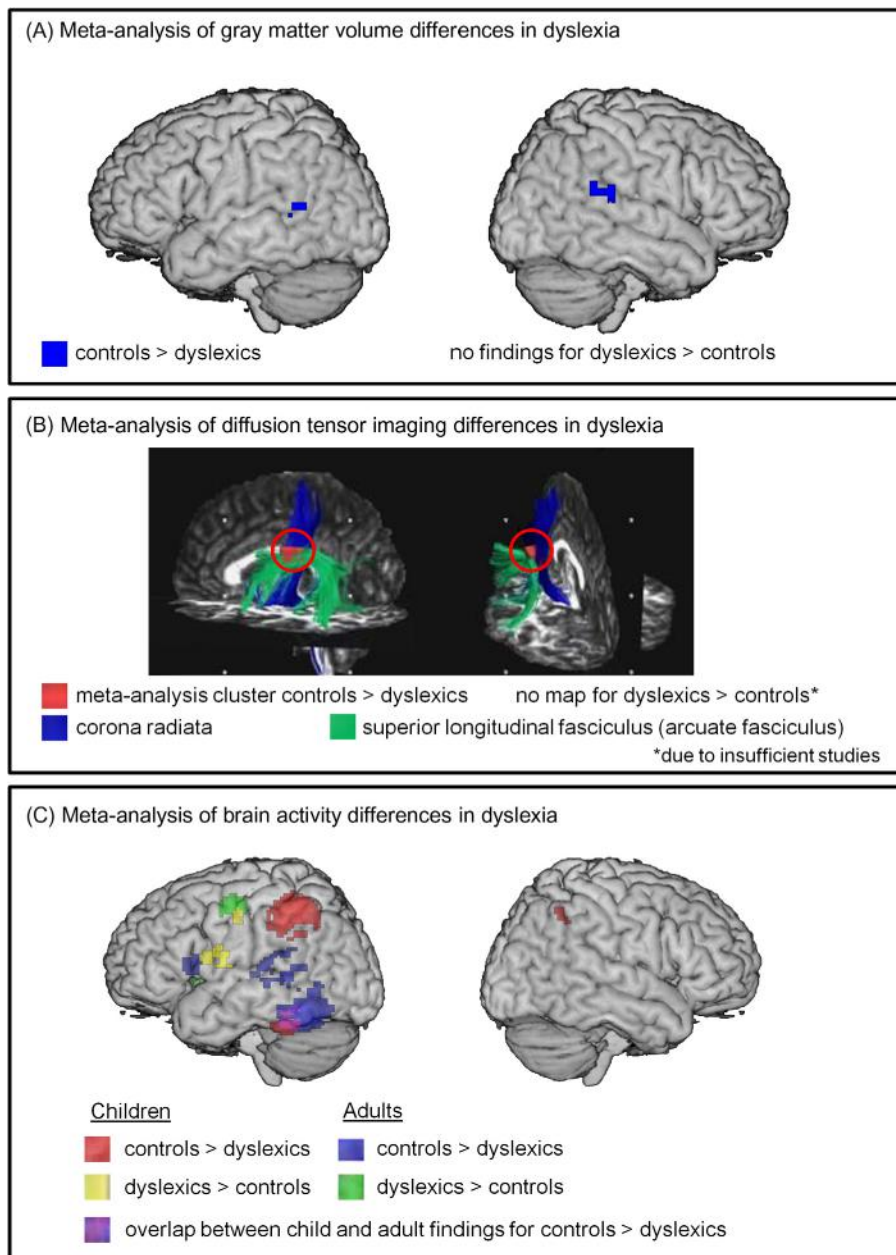

FIGURE 65.2 (A) Surface rendering of meta-analysis results for GMV differences in dyslexics versus controls (children and adults combined). Areas of less GMV in dyslexics are shown in blue; there were no findings for the reverse comparison. (B) Two angles of the same sagittal/horizontal view of an anatomical scan with superimposed three-dimensional fibretracking data (obtained from one representative adult control subject) through the left temporoparietal cluster identified in a meta-analysis (depicted in red: controls more than dyslexics; reverse comparison not conducted). The cluster contained fibers belonging to the corona radiata (blue) and to the superior longitudinal fasciculus/arcuate fasciculus (green). (C) Surface rendering of two meta-analyses results for brain activity differences in dyslexics versus controls (children and adults analyzed separately). Areas of less activity in children with dyslexia are shown in red, and areas of more activity are shown in yellow. Areas of less activity in adults with dyslexia are shown in blue, and areas of more activity are shown in green. The overlap between children and adults in areas of relatively less activity in dyslexics is shown in violet. Adapted from (A) Richlan et al. (2013); (B) Vandermosten et al. (2012); (C) Richlan et al. (2011) with permission from the publisher.

Meta-analyses have again captured the most salient observations (Linkersdörfer et al., 2012; Maisog, Einbinder, Flowers, Turkeltaub, & Eden, 2008; Richlan, Kronbichler, & Wimmer, 2011). Richlan and colleagues (2011) performed separate meta-analyses of dyslexic children and adults (Figure 65.2C). They found left IFG hypoactivation in adults but not in children with dyslexia (and hyperactivation in precentral/premotor regions for both children and adults) and TPC hypoactivation in pSTG in adults and in IPL in children, together suggesting a dynamic developmental course of dyslexia. Notably, hypoactivation of the left OTC was found in both children and adults, suggesting early alteration in this region.

Significant interest in the VWFS has influenced studies of dyslexia. This region is not only underactivated in dyslexia; specific patterns have also been uncovered using a region-of-interest (ROI) approach: whereas typically reading children and adults demonstrate a posterior-to-anterior gradient of increasing word selectivity in medial left OTC (i.e., relative signal increase for words compared with false font/symbol string stimuli along the posterior-to-anterior axis; Brem et al., 2006; Olulade, Flowers, Napoliello, & Eden, 2013; Van der Mark et al., 2009; Vinckier et al., 2007), this gradient is disrupted (Van der Mark et al., 2009) and fails to become tuned in the early phases of learning (Maurer et al., 2007) in children with dyslexia.

Functional connectivity has been used to better assess interregional correlations or cooperation between different brain areas in typical and dyslexic readers. Using PET and fMRI, respectively, two early investigations reported reduced connectivity between the AG and several sites, including the pSTG, ventral OTC, and early visual areas in dyslexics during phonological tasks (Horwitz, Rumsey, & Donohue, 1998; Pugh et al., 2000). Horwitz et al. (1998) also reported reduced AG connectivity with the IFG and cerebellum. There are several similar seed-based studies in adults, and disruption of connectivity has also been observed in children, with some (Cao, Bitan, & Booth, 2008) noting reduced connectivity between the ventral OTC and the IPL and others (Richards & Berninger, 2008) reporting abnormal connectivity between the left IFG and multiple bilateral brain regions. These studies and others (Van der Mark et al., 2011; Vourkas et al., 2011; see also Koyama et al., 2011, for resting-state connectivity) illustrate the complex nature of the reading process and the fact that dyslexia is associated with focal differences as well as disruptions of connections among regions.

The origin of these differences remains unknown. Several theories on the etiology and processes by which the phonological deficit might be operating have been put forward; these range from low-level perceptual problems to higher meta-cognitive dysfunction and are beyond the scope of this chapter (we refer the reader to specific studies and comprehensive reviews, e.g., Ahissar, 2007; Boets, 2014; Giraud & Ramus, 2013; Goswami, 2011, 2015; McArthur & Bishop, 2001; McNorgan, Randazzo-Wagner, & Booth, 2013). Multimodal brain imaging is proving a valuable tool for testing these theoretical frameworks. For example, using a multivoxel pattern analysis of fMRI data in adult dyslexics, Boets and colleagues (2013) found intact phonetic representations in bilateral auditory cortices but disrupted functional and anatomical connections between these regions and the left IFG, suggesting a problem of access. These findings echo earlier brain imaging reports of “disconnection” in dyslexia (Paulesu et al., 1996). As such, the search for the neurobiological basis for the phonological core deficit in dyslexia has expanded beyond the left TPC regions known to be engaged in phonological processing in typical readers to tracts that connect posterior to frontal brain regions.

Specifically, the developmental trajectory of the neural basis of dyslexia is still poorly understood. Given that reading is acquired over a protracted period of time and during development, it is likely that brain-based findings are going to be dynamic, sometimes presenting proximally and other times distally to the point of origin. For example, if normal reading acquisition is achieved by phonological assembly of novel words in left dorsal regions, with a shift to more

automatic word recognition in OTC with increasing reading expertise, then dyslexia might represent failure to advance to the use of OTC due to disruption of dorsal TPC for phonological assembly (Pugh et al., 2001; Sandak et al., 2004). It could be that the OTC underactivity represents a primary deficit, as suggested by impaired OTC function in both children and adults (Richlan et al., 2011). However, the problem may not originate in cortex *per se*, but rather in abnormal connecting fibers preventing the normal development of skills subserved by the cortex that feeds into them (Boets, 2014). Hyperactivations (e.g., in left frontal as well as right hemisphere regions) have been interpreted as compensatory mechanisms to offset underactivity elsewhere (Pugh et al., 2001), but their role is not clear. Many of the findings depend on the age of participants, and together these factors indicate the need for longitudinal studies of dyslexia to shed light on the timing and etiology of these differences.

65.5 GENETIC AND PHYSIOLOGICAL MECHANISMS IN DYSLEXIA

Genetic linkage studies have found several loci that may be involved in dyslexia, and at some of these loci genetic variants associated with disease risk have been identified (Scerri & Schulte-Körne, 2010). Several genes in the *DYX2* (dyslexia susceptibility-2) locus on chromosome 6p22 have been associated with dyslexia (Eicher & Gruen, 2013), including *KIAA0319*, *TTRAP*, and *DCDC2*.

Some of these dyslexia-associated genes have been studied in knockout mice and have been found to be implicated in abnormal neuronal migration (Galaburda et al., 2006). A recent study suggests increased excitability and decreased temporal precision in action potential firing in neocortex of *DCDC2* knockout mice, implicating the *N*-methyl-D-aspartate (NMDA) receptor (Che, Girenti, & Loturco, 2014).

In humans, magnetic resonance spectroscopy (MRS) has been used to identify which neurometabolites might be altered in dyslexia. *N*-acetyl-aspartate and choline were found to be abnormal in adults with dyslexia (Bruno, Lu, & Manis, 2013), and choline and glutamate were abnormal in children with dyslexia (Pugh et al., 2014). These reports highlight the connections between choline levels and abnormal white matter (dove-tailing with the described WMV and FA studies), as well as between increased glutamate and hyperexcitability at the level of the synapse (Pugh et al., 2014). More direct connections have been made between brain anatomy and dyslexia-associated genes. For example, Meda et al. (2008) investigated associations between *DCDC2* and GMV in typical readers and found that individuals heterozygous for the deletion,

compared with those homozygous for no deletion, had significantly higher GMV in brain regions related to reading/language and symbol decoding. Looking at white matter integrity, Darki, Peyrard-Janvid, Matsson, Kere, and Klingberg (2012) found that *DYX1C1*, *DCDC2*, and *KIAA0319* were significantly associated with WMV in the left temporoparietal region and that WMV was positively correlated with reading ability. In functional studies, participants with the *KIAA0319/TTRAP/THEM2* variants showed a reduced left-hemispheric asymmetry of the STS (Pinel et al., 2012), and Cope et al. (2012) found activity in several brain areas to be influenced by variants in the *DYX2* locus. Together these studies are beginning to reveal the possible connections between molecular mechanisms and behavior in dyslexia, as well as the brain's mediating role.

65.6 NEUROBIOLOGY OF READING INTERVENTIONS

Understanding the brain-based changes underlying successful reading intervention demonstrated by behavioral studies (Alexander & Slinger-Constant, 2004; Bradley & Bryant, 1983) provides insights into treatment mechanisms of dyslexia and, potentially, its etiology. Functional neuroimaging studies in children and adults have reported several regions of increased activation after reading intervention. These have often been discussed in terms of "compensation" versus "normalization" processes and in the context of language function, with some discussion on skills outside of language that might support reading. As summarized by Barquero, Davis, and Cutting (2014), areas of postintervention increases include bilateral inferior frontal, superior temporal, middle temporal, middle frontal, superior frontal, and postcentral gyri, as well as bilateral occipital cortex, IPL, thalami, and insulae. A meta-analysis of fMRI studies (also reported by Barquero et al. (2014)) sheds light on the most salient postintervention increases, namely left thalamus, right insula/IFG, left IFG, left middle occipital gyri, and right posterior cingulate (Figure 65.3). There are also studies examining anatomical changes after reading intervention in dyslexia, demonstrating GMV increases in children in left anterior fusiform gyrus/hippocampus and precuneus and right hemisphere hippocampus and cerebellum (Krafnick, Flowers, Napoliello, & Eden, 2011), and increased FA in left anterior centrum semiovale in adults (Keller & Just, 2009). These anatomical changes do not directly colocalize to the functional changes described, suggesting that the neurobiological mechanisms of reading remediation are complex. For example, even if the intervention involves training of phonological skills, the brain mechanisms underlying successful reading gains may

FIGURE 65.3 Axial view of meta-analysis results for brain activity increases in dyslexics after reading intervention: left middle occipital gyrus, thalamus, inferior frontal gyrus; right posterior cingulate and insula/inferior frontal gyrus. From Barquero et al. (2014) with permission from the publisher.

rely on memory and other learning mechanisms. Further, the roles of participant age and the method of treatment in the neural correlates of reading intervention have yet to be fully explored.

There is increasing interest in correlating success of reading acquisition with neurobiological measures. For example, adult compensated dyslexics followed from childhood were shown to have more activation in right superior frontal and middle temporal gyri and left anterior cingulate gyrus compared with persistently poor readers (Shaywitz et al., 2003). Some studies have compared postintervention brain activity in dyslexic children who showed a favorable behavioral response to intervention with activity in children who did not benefit from treatment (Davis et al., 2011; Odegard, Ring, Smith, Biggan, & Black, 2008). More activity in responders than in nonresponders was found by Odegard et al. (2008) in left IPL and in left STG by Davis et al. (2011).

Furthermore, neuroimaging data have been used to predict long-term outcomes of reading in typically reading (McNorgan, Alvarez, Bhullar, Gayda, & Booth, 2011) and dyslexic children (Hoeft et al., 2011). The latter study found that right IFG activation and right superior longitudinal fasciculus integrity at the beginning of the study predicted reading scores in dyslexics 2.5 years later. As such, brain-based predictive studies

bear important information on the mechanisms of successful treatment of dyslexia and also hold potential for contributing to the decision for a specific intervention strategy.

65.7 CAUSE VERSUS CONSEQUENCE?

A pressing question for the neurobiological bases of dyslexia is in regard to whether the findings that distinguish dyslexics from nondyslexics represent a cause or consequence of the disorder. Literate and illiterate adults differ in brain function (Dehaene et al., 2010) and anatomy, including brain regions known to be involved in dyslexia, such as the arcuate fasciculus (Thiebaut de Schotten, Cohen, Amemiya, Braga, & Dehaene, 2014), suggesting that reading acquisition results in significant learning-induced plasticity. Adults who were illiterate but then learned to read exhibit greater GMV in TPC compared with illiterate adults (Carreiras et al., 2009). Longitudinal studies of typical readers reveal widespread decrease in cortical thickness with age (Giedd et al., 1999), yet language regions in perisylvian cortex thicken (Sowell et al., 2004) in correlation with improvements in phonological skills (Lu et al., 2007). As such, it is possible that typical readers, as a consequence of learning to read, experience changes in brain anatomy and function that are not realized in dyslexic readers (who read less), leading to a relative difference that is the consequence, and not the cause, of dyslexia.

Therefore, brain imaging studies have implemented experimental designs that disambiguate those characteristics causal to dyslexia from those that are secondary or, in fact, the consequence of experience (or lack of experience). This question can be addressed by: (i) longitudinal studies of typical readers and children at risk for dyslexia (based on a family history or early signs of weaknesses in skills that support reading) and (ii) studies using the reading level-match design, where children with dyslexia are compared with younger typical readers who are matched on reading level (Goswami & Bryant, 1989). The noninvasive nature of fMRI and event-related potential (ERP) techniques has allowed pediatric studies to flourish, and brain imaging studies on the causal nature of dyslexia have begun to emerge. For example, Raschle, Chang, and Gaab (2011) report reduced GMV in left OTC, bilateral TPC, left fusiform gyrus, and right lingual regions in prereading children with, compared with children without, a family history of dyslexia (see Hosseini and colleagues, 2013, for similar work measuring network differences in surface area). The same group of children also showed less brain activity in bilateral OTC and left TPC (Raschle, Zuk, & Gaab, 2012).

Interestingly, maternal history of reading disability is associated with smaller bilateral prefrontal and TPC GMV of 5- to 6-year-olds, and because these replicate for the left IPL on a measure of surface area but not cortical thickness, they are likely due to prenatal influences (Black et al., 2012). In studies of white matter structure, it has been shown that the volume and FA of the arcuate fasciculus is positively correlated with PA in children before they learn how to read (Saygin et al., 2013). The reading level-match design has also been applied: Hoeft et al. (2007) found left IPL GMV differences in dyslexia for both control group comparisons (age-matched and reading level-matched) in a study that used fMRI data to determine the ROIs for GMV analyses. However, using a whole-brain approach (as well as a follow-up analysis using ROIs), Krafnick, Flowers, Luetje, Napoliello, and Eden (2014) found that few GMV and none of the WMV differences identified between dyslexics and age-matched controls emerged when dyslexics were compared with controls matched on reading abilities. Also, the older controls (age-matched to the dyslexics) had more GMV than the younger controls in several of the areas identified as variant in the dyslexics when compared with age-matched controls, raising the possibility that not all differences can be attributed to dyslexia *per se*. Interestingly, in a sample of children eventually diagnosed with dyslexia, the structural abnormalities that preceded learning to read were found in early visual and auditory cortical areas and not in regions associated with reading (Clark et al., 2014). As such, the question remains whether anomalies in neural migration or synaptic activity affect brain anatomy and function directly or via reading experience.

65.8 IMPORTANT VARIABLES IN STUDIES OF DYSLEXIA

Due to the heterogeneity in dyslexia, researchers have attempted to identify subgroups. For example, Jednoróg, Gawron, Marchewka, Heim, and Grabowska (2014) have shown that cognitive subtypes of dyslexia are characterized by distinct patterns of GMV. This concept is also being applied to functional neuroimaging studies of reading intervention based on subtypes (Heim, Pape-Neumann, van Ermingen-Marbach, Brinkhaus, & Grande, 2014). Although the phonological deficit theory also dominates such studies, it must be noted again that there are criticisms of and theoretical alternatives to the phonological deficit theory, and careful consideration must be given to dyslexia in languages other than English (Brunswick et al., 2010), particularly those in which grapheme-phoneme mapping is more direct (orthographically transparent). A behavioral study of dyslexia in six

languages revealed that high orthographic complexity of a language exacerbates phoneme deletion and rapid naming problems in dyslexia (Landerl et al., 2013). In the case of German, where mapping between graphemes and phonemes is highly consistent, dyslexia is associated with poor reading speed and spelling, whereas phonological deficits have a lesser role (Wimmer & Schurz, 2010). It is also debated whether the demands of a logographic writing system such as Chinese result in brain-based differences that are specific to dyslexia in that orthography (Siok, Perfetti, Jin, & Tan, 2004) or not (Hu et al., 2010).

Because of higher prevalence of dyslexia in males, some studies are based on samples that are dominated by males, yet the results are generalized to both sexes with dyslexia. For example, less than 20% of the participants in the studies included in the meta-analysis by Linkersdörfer et al. (2012) were female. However, there is evidence to suggest sex-specific differences in brain anatomy in dyslexia, as illustrated by GMV differences in dyslexic females (children and adults) compared with controls that reside outside of the language regions typically reported in males with dyslexia (Evans et al., 2014). Differences in cortical thickness have been reported for girls but not boys in ventral OTC (Altarelli et al., 2013), and altered asymmetry (rightward) of the planum temporale surface area in dyslexic boys but not girls (Altarelli et al., 2014). Given the sexual dimorphism in the general population for brain anatomy (Good et al., 2001) and brain function underlying language, including phonological processing (Shaywitz et al., 1995), these findings may call for sex-specific models of dyslexia and, at least, highlight the need to include more females in dyslexia research.

Another understudied group includes those of low socioeconomic status (SES). This has recently been addressed in a study showing that the differences observed in both OTC and STG in dyslexia exist independently of SES (Monzalvo, Fluss, Billard, Dehaene, & Dehaene-Lambertz, 2012), even though SES is associated with differences in GMV (but not WMV) in areas relevant to language (Jednoróg et al., 2012). Together, these and other variables will continue to play an increasingly important role in studies of the brain bases of dyslexia.

65.9 CONCLUSION

Building on decades of behavioral work, brain imaging has provided a neurobiological basis for understanding reading and dyslexia. Consistent with the predominant phonological core deficit theory of dyslexia, anatomical and functional studies have revealed differences in left temporoparietal, inferior frontal, and ventral occipitotemporal cortices, together

with disruptions of their connections. This work has been integrated with efforts in reading intervention, predictors of reading outcome, dyslexia-associated genes, and neurometabolites. Studies conducted at different ages suggest an age-dependent neurobiological profile of dyslexia. Although this is captured by current putative neurocognitive developmental models of dyslexia, longitudinal investigations in young children are ultimately needed to ascertain how these differences behave over time (e.g., a given anomaly may be a different manifestation of an earlier anomaly) and to determine which differences are attributed to dyslexia *per se* (rather than altered reading experience) using methods that capture the neurodevelopmental origin of these. Further, diversity of writing systems and orthographic depth is likely to play a modulating role, suggesting that beyond the universal aspects of dyslexia, orthography-specific aspects of reading disability will need to be integrated into neurobiological models (Richlan, 2014).

Rodent Models of Speech Sound Processing

Crystal T. Engineer, Tracy M. Centanni and Michael P. Kilgard

School of Behavioral and Brain Sciences, The University of Texas at Dallas, Richardson, TX, USA

66.1 RODENT MODELS ARE IMPORTANT FOR STUDYING NEURAL CORRELATES OF SPEECH PERCEPTION

Numerous studies have documented the ability of rodents to perform complex speech discrimination tasks as accurately as humans. The observation that rodents exhibit categorical perception of speech sounds indicates that the basic neural mechanisms used to distinguish speech sounds are present in rodents. Speech sounds evoke unique spatiotemporal response patterns in both human and rodent auditory cortex. Rodent models of speech sound processing provide the opportunity to precisely control the genetic and environmental factors that can impair speech sound processing in humans.

66.2 SPEECH SOUND DISCRIMINATION BY RODENTS

66.2.1 Consonants

Numerous studies of speech sound processing in rodents have shown that humans and rodents discriminate speech sounds similarly. Kuhl and Miller (1975) performed one of the most well-known studies of rodent speech perception, which went against the theories of the time that speech perception was unique to humans. Chinchillas were trained to categorize /d/ and /t/ syllables in multiple vowel and talker contexts. The acoustic cue voice onset time (VOT), which is the time between the onset of the consonant and the onset of voicing, can be used by humans and rodents to categorize stop consonants. The voiced consonants (/b/, /d/, /g/) have a short VOT, whereas the voiceless consonants (/p/, /t/, /k/) have a long VOT. Chinchillas were trained on an avoidance conditioning

task during which they had to cross a barrier when presented with a target sound and refrain from crossing when presented with a nontarget sound. The chinchillas could accurately categorize voiced *versus* voiceless sounds, and they were even able to generalize when presented with synthetic syllables, syllables spoken by novel talkers, and syllables with novel vowels. The chinchillas were then tested using synthetic /d/ and /t/ syllables with VOTs ranging from 0 to 80 ms to determine their phonetic boundary, the VOT where they were unable to distinguish the voicing category. Chinchillas and humans had a nearly identical phonetic boundary (33.5 ms for chinchillas and 35.2 ms for humans). A follow-up study determined the phonetic boundary for chinchillas using a /b/-/p/ continuum and a /g/-/k/ continuum, and found that chinchillas and humans have equivalent boundaries for these sounds as well (Kuhl & Miller, 1978). These findings support the idea that speech categories make use of natural boundaries in the auditory system that are present in rodents and are not unique to humans.

Studies testing the phonetic boundaries of synthetic speech sound continuums in gerbils provided additional evidence that rodents and humans discriminate speech sounds similarly. Gerbils were trained to categorize vowel, liquid, and stop consonant speech sounds (Sinnott & Mosteller, 2001). The gerbils listened to a repeating background speech sound and had to jump off a platform when the repeating background sound changed into a target speech sound to receive a food pellet reward. The phonetic boundaries in gerbils were similar to the boundaries using the same sounds in humans, particularly for the stop consonant task (on a continuum of 8 stimuli: stimulus 4.7 boundary for gerbils and stimulus 4.5 boundary for humans).

In addition to stop consonants, speech sound continuums can also be made for affricate and fricative

speech sounds by altering the rise time and duration of the sounds. The affricate “ch” has a shorter duration and faster rise time compared with the fricative “sh.” Rats were trained to press a left lever for one sound (e.g., “ch”) and a right lever for the other sound (“sh”), and they were tested on their ability to generalize to sounds midway along the continuum (Reed, Howell, Sackin, Pizzimenti, & Rosen, 2003). The investigators concluded that rats, like humans, appear to use the rise time cue to accurately categorize these sounds.

As in humans, speech sound discrimination by rats can be affected by previous exposure to speech sounds. Infants who were exposed to a unimodal distribution of sounds at the midpoint of a /d/-/t/ continuum are less able to discriminate the endpoints of the continuum compared with infants who were exposed to a bimodal distribution of sounds near the edges of the /d/-/t/ continuum (Maye, Werker, & Gerken, 2002). After the same exposure, rats, like infants, were able to discriminate the sounds more accurately when exposed to a bimodal distribution compared with a unimodal distribution (Pons, 2006).

While operant speech discrimination training in rodents can be time-consuming, rats can rapidly learn to discriminate between consonant sounds using a prepulse inhibition (PPI) task (Floody & Kilgard, 2007). During the PPI task, a standard speech sound is played (“pa”) in the background, and this sound rarely predicts a loud startle stimulus (a 102-dB burst of white noise). A second oddball speech sound (“ba”) occurs rarely, but it is always followed by the startle stimulus. After just a few minutes of training, rats startled less to the startle stimulus when it was preceded by the oddball sound compared with trials in which the startle stimulus was preceded by the standard sound. These results suggest that rats could reliably detect the change from the standard speech sound to the oddball speech sound.

Rats have also been tested on consonant discrimination using pairs of sounds that differ in one articulatory feature (place of articulation, voicing, or manner of articulation). Studies of speech sound processing in rats often use speech sounds that have been shifted higher by one octave to better match the rat hearing range. Rats were trained to press the lever in response to a target consonant (“d”), and to refrain from pressing the lever in response to a nontarget sound (“t”). As seen in previous studies, rats could easily discriminate most consonant contrasts, such as “d” versus “t” or “sh” versus “ch” (Engineer et al., 2008). Rats were also able to accurately categorize the sounds when additional temporal or speaker variation was introduced (Engineer et al., 2013). Rats can discriminate consonant sounds in the presence of background noise or after spectral and temporal degradation (Ranasinghe,

Vrana, Matney, & Kilgard, 2012; Shetake et al., 2011). However, rats were unable to discriminate consonant contrasts that are difficult for individuals learning English as a second language (Engineer et al., 2008), such as “r” versus “l” (Logan, Lively, & Pisoni, 1991), suggesting that rodents are a good animal model of speech perception.

66.2.2 Vowels

Rats are also able to discriminate between vowel sounds. Rats were trained to discriminate between two vowel categories, and were able to generalize to novel vowel sounds (Eriksson & Villa, 2006; Perez et al., 2013). Next, novel vowels were introduced where the formant frequency correlation to the fundamental frequency was reversed, altering the normal relationship between the formant and fundamental frequencies. The results showed that rats, like humans, use the fundamental frequency as a cue in vowel discrimination (Eriksson & Villa, 2006).

Chinchillas are also able to discriminate between vowel sounds with a high degree of accuracy. Similar to the Kuhl consonant discrimination study, chinchillas were trained to categorize /a/ and /i/ vowels (Burdick & Miller, 1975). There was no decrement in performance when /a/ and /i/ vowels in multiple pitch (low, natural, and high) and multiple talker contexts (two male, two female) were introduced. The chinchillas were able to generalize to vowels produced by novel talkers (12 male, 12 female), as well as synthetic vowels. This extensive set of experiments demonstrated that rodents, like humans, are able to accurately categorize vowels while ignoring large amounts of irrelevant variability in the sounds.

66.2.3 Complex Tasks

Rodents not only are able to discriminate between individual consonant and vowel sounds but also are able to perform complex speech sound discrimination tasks. Toro and colleagues found that rats were able to discriminate between sentences spoken in Dutch and sentences spoken in Japanese, but were unable to discriminate sentences in the two languages when the sentences were presented backwards (Toro, Trobalon, & Sebastián-Gallés, 2003, 2005). The same observation has also been reported in infants and monkeys (Ramus, Hauser, Miller, Morris, & Mehler, 2000).

Toro and colleagues also examined the ability of rats to segment a speech stream using statistical regularities (Toro & Trobalón, 2005). After being passively exposed to words from an artificial language (e.g., “tupiro” or “pigola”), rats were tested using words

they had been exposed to, part-words that were composed of the last syllable of one word with the first two syllables of another word, or nonwords that were composed of syllables in a different order than the order the rats had previously heard. Rats pressed the lever more often during the test phase in response to a word that they had been exposed to compared with part-words or nonwords, suggesting that the rats were able to detect syllable regularities in the speech stream.

Rats are also able to learn rules involving repeating consonants and vowels, and they can generalize the rule to novel words (de la Mora & Toro, 2013). In the first experiment, rats were trained on CVCVCV words (“C,” consonant; “V,” vowel) and learned to press the lever for words that had repeating vowels (AAB structure, “bakasi”), but not for words with three different vowels (ABC structure, “bakisœ”). The rats were then able to generalize to new words composed of novel consonants and vowels (e.g., lever press for “felepu,” but not for “felopu”). The second experiment focused on consonants instead of vowels, and rats learned to press the lever for words that had repeating consonants (AAB structure, “sasœki”), but not for words that did not have repeating consonants (ABC structure, “sikabœ”). Rats were then able to generalize the repeating consonant rule to new words composed of novel consonants and vowels (press for “fefulo” but not “fepulo”). The same set of experiments was performed in humans, and although humans could accurately generalize the repeating vowel rule, they were unable to generalize the repeating consonant rule, suggesting that humans process consonants and vowels differently because of their experience with language. This study replicates the findings of a previous study showing that rats can learn rules for sequences of auditory (3.2 or 9 kHz tone) or visual stimuli (light or darkness) and transfer the learned rule to novel sequences (Murphy, Mondragon, & Murphy, 2008).

66.3 SPEECH SOUND NEURAL CODING

The early stages of speech sound processing in rodents closely parallel early speech processing in humans (Johnson, Nicol, & Kraus, 2005). Responses to speech sounds in both humans and animals closely resemble the physical characteristics of the sound early in the auditory system (e.g., in the auditory nerve or inferior colliculus [IC]), and they grow more abstract to better represent the perceptual characteristics of the sound at higher levels of the auditory system (e.g., in secondary auditory cortex or prefrontal cortex).

Responses in the auditory nerve of chinchillas were recorded in response to synthetic speech sounds differing in VOT (Sinex & McDonald, 1988). As in previous

studies, a /ga/–/ka/ or /da/–/ta/ continuum of speech sounds with VOTs ranging from 0 to 80 ms in 10 ms steps was presented. Neurons with a low characteristic frequency (CF) near the first formant of the speech sounds increased their firing rate in response to the onset of voicing, and the strength of this onset response can be used to accurately predict the onset of voicing when compared with baseline. Neurons with higher frequency tuning, however, did not reliably change their firing rate and were not good predictors of the onset of voicing. A second study of auditory nerve responses to sounds differing in VOT in chinchillas found differing results (Stevens & Wickesberg, 1999). This study used the naturally spoken syllables /da/ and /ta/ and found that both low- and high-frequency neurons accurately encode the onset of voicing. This finding that naturally spoken speech and synthetic speech produce different results in the same area of the same species suggests that auditory nerve responses are highly dependent on the acoustics of the sound.

Slightly higher along the auditory pathway, in the ventral cochlear nucleus, responses were recorded in anesthetized rats in response to six naturally spoken consonants differing in VOT (/bot/, /dot/, /got/, /pot/, /tot/, and /kot/) (Clarey, Paolini, Grayden, Burkitt, & Clark, 2004). Responses recorded in three ventral cochlear nucleus cell types (primary-like, chopper, and onset) were similar to auditory nerve responses. The consonant release evoked a peak of activity followed by a second peak of activity in response to voicing onset.

Responses in the IC to speech sounds differing in VOT also accurately encode the onset of voicing. However, IC neurons have less sustained responses through both the consonant and vowel portions of the sound compared with auditory nerve responses (Portfors & Sinex, 2005). A separate study recorded IC responses to 28 CVC (consonant–vowel–consonant) speech sounds differing in either the vowel or the initial consonant (Perez et al., 2013). IC response patterns predicted both consonant and vowel discrimination performance. Speech sounds that evoke similar IC response patterns (“rad” versus “lad” or “dad” versus “dead”) are more difficult for rats to discriminate than speech sounds that evoke distinct IC response patterns (“dad” versus “bad” or “dad” versus “deed”). Consonant discrimination was well-predicted by IC response pattern similarity when spike timing information was preserved, whereas vowel discrimination was well-predicted by IC response pattern similarity when spike timing information was eliminated. The observation that consonants and vowels are processed differently parallels similar findings in humans (Caramazza, Chialant, Capasso, & Miceli, 2000; Poeppel, 2003).

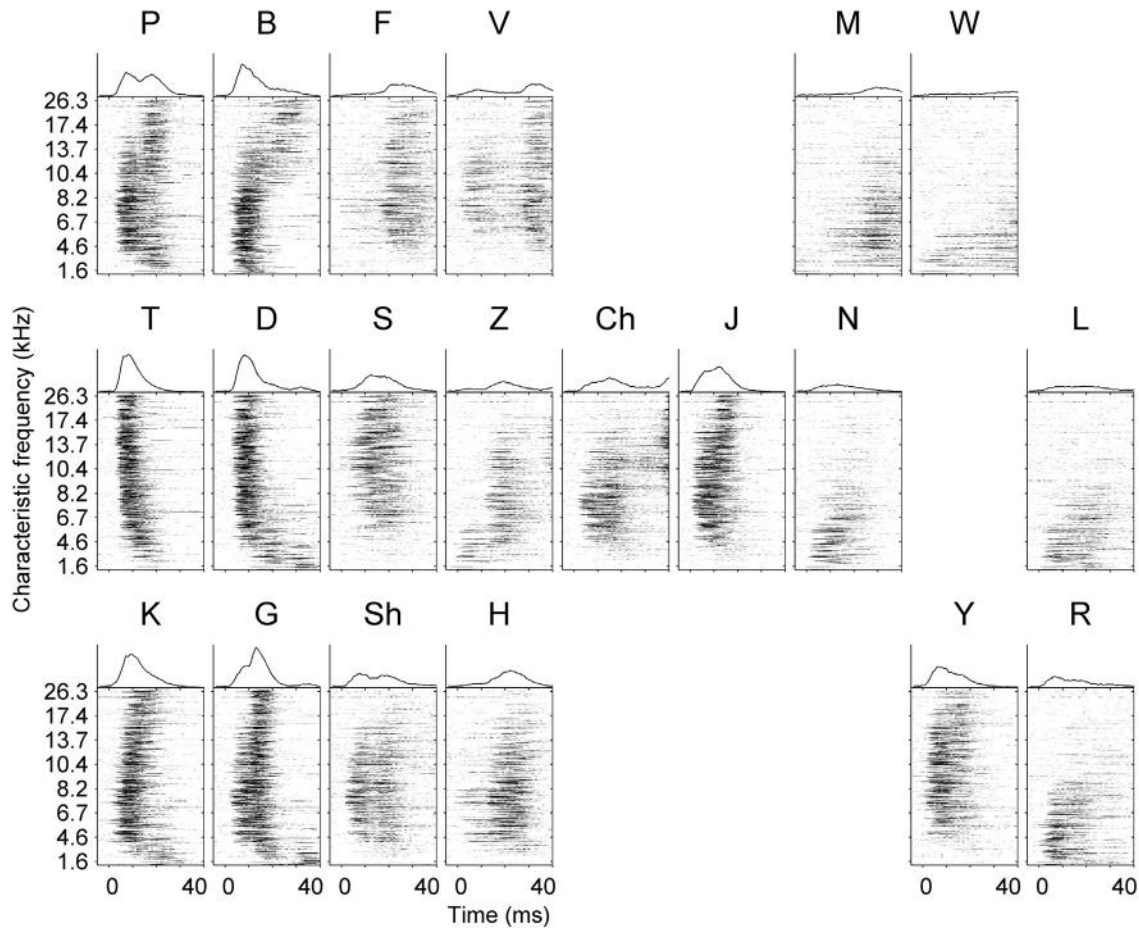

FIGURE 66.1 Primary auditory cortex responds uniquely to individual consonant sounds. The y-axis orders A1 sites by CF (kHz), and the x-axis is time (ms). The average population response is plotted above each neurogram. From *Engineer et al. (2008, Figure 2)* with permission from the publisher.

Although auditory nerve and IC neurons respond throughout a speech sound, primary auditory cortex (A1) neurons more strongly represent the onset and transition parts of speech sounds. The A1 response pattern evoked by each consonant and vowel sound is unique (*Engineer et al., 2008; Perez et al., 2013*). For example, the stop consonants /b/, /d/, and /g/ differ in their place of articulation, and A1 neurons respond distinctly to each of the consonants. For the consonant /b/, A1 low-frequency neurons respond first, followed by high-frequency neurons; for the consonant /d/, A1 high-frequency neurons respond first, followed by low-frequency neurons; for the consonant /g/, A1 mid-frequency neurons respond first, followed by high- and low-frequency neurons (*Figure 66.1*). As in IC, A1 neural response patterns accurately predict speech sound discrimination accuracy ($R^2 = 0.75$; *Figure 66.2*).

A recent study compared the amount of redundancy in the responses to speech sounds in IC neurons compared with A1 neurons (*Ranasinghe, Vrana, Matney, & Kilgard, 2013*). The firing rate evoked by each speech

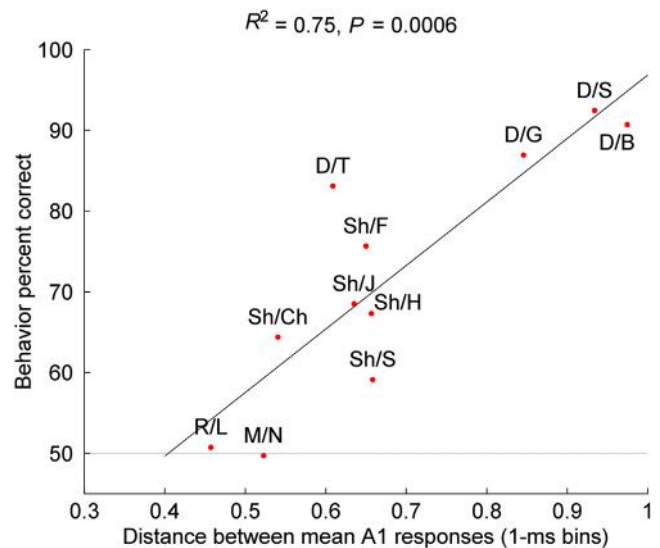

FIGURE 66.2 Neural similarity predicts consonant discrimination ability. The dotted line indicates chance performance (50%). From *Engineer et al. (2008, Figure 5a)* with permission from the publisher.

sound was compared in pairs of IC neurons that were tuned to the same CF. The response strength to a speech sound was nearly identical in pairs of IC neurons tuned to the same frequency. The same comparison was made using pairs of A1 neurons tuned to the same frequency, but the response strength to a speech sound in one A1 neuron could not be predicted by the response strength to a speech sound in a similarly tuned A1 neuron. This finding indicates that A1 neurons evoke response patterns that are more diverse than the patterns evoked by IC neurons. The result that IC neurons tuned to the same frequency evoke identical response patterns while A1 neurons tuned to the same frequency evoke distinct response patterns supports the finding that responses in A1 and higher auditory areas are more abstract and do not just represent the physical characteristics of the sound (Chechik et al., 2006).

The various auditory cortical fields in the rat brain respond differently to speech sounds (Centanni, Engineer, & Kilgard, 2013). The cortical response patterns in A1, anterior auditory field (AAF), ventral auditory field (VAF), and posterior auditory field (PAF) are correlated with behavioral discrimination ability. As shown previously in IC and A1, the firing rate evoked by each speech sound in pairs of neurons tuned to the same CF was compared across the four auditory cortex fields. A1 and AAF neurons tuned to the same frequency evoked more similar response patterns than neurons in PAF and VAF, suggesting that PAF and VAF are higher along the auditory hierarchy and represent speech sounds in a more abstract manner.

The similarity of the basic behavioral and neural responses to speech in rodents and humans can be explained by the conservation of basic auditory coding principles across mammals. There is evidence that humans process speech sounds differently than animals at later stages, but processing at earlier stages is remarkably well-conserved (Davis, Ford, Kherif, & Johnsrude, 2011; Obleser, Wise, Dresner, & Scott, 2007). This fact provides an opportunity to use animal models to better understand speech processing under difficult conditions such as background noise, hearing loss, central nervous system damage, and genetic disorders.

66.4 SPEECH SOUND PROCESSING PROBLEMS

66.4.1 Acoustic Degradation

Human and animal communication requires spectrotemporal precision in auditory cortex (Ranasinghe et al., 2013; Sinex & McDonald, 1988; Steinschneider, Fishman, & Arezzo, 2003; Steinschneider, Volkov, Noh, Garell, & Howard, 1999). Auditory-evoked responses in A1 of

gerbils were recorded using gerbil vocalizations that were spectrally degraded to 16, 8, or 4 bands using a noise vocoder or temporally degraded by reversing the sound using a variety of bin sizes (5, 10, 20, 30, 50, 100, 150, 200, 250 ms, or the entire sound). Spike rate could not be used to identify stimulus condition, but a Euclidean distance measure comparing pairs of spike trains (Victor & Purpura, 1997) was able to identify the calls with a high degree of accuracy. This method was more accurate on the spectrally degraded calls than the temporally degraded calls (Ter-Mikaelian, Semple, & Sanes, 2013). These results demonstrate that the timing of evoked action potentials contains more information about gerbil call identity than the number of action potentials that occur over the same period of time, and they suggest that A1 spike timing could also be used to accurately identify spectrally and temporally degraded speech sounds.

As discussed, chinchillas are able to discriminate between human consonant sounds and could be a useful model to understand neural correlates of speech sound discrimination in humans. The initial consonant from the words “ball,” “dirty,” “persons,” and “today” were degraded into one, two, three, or four spectral bands, and recordings were acquired from individual auditory nerve fibers. Responses to one- and two-band spectrally degraded stimuli were significantly different than responses to sounds with greater spectral information (Loebach & Wickesberg, 2006). Because rodents are highly accurate at discriminating human speech sounds (Ranasinghe et al., 2012), these results suggest that a rodent would be able to accurately discriminate human speech sounds with more than two spectral bands.

Rats are able to behaviorally discriminate human speech sounds after significant spectral or temporal degradation. Ranasinghe et al. (2012) demonstrated that rats discriminate human speech sounds even when only four bands of spectral information are preserved, as is seen in human participants (Figure 66.3). The Euclidean distance between pairs of auditory cortical responses to the degraded sounds was able to predict the accuracy of the rats when discriminating the same sounds (Ranasinghe et al., 2012).

Rats are also able to accurately discriminate speech sounds in high levels of white and speech-shaped background noise with thresholds that are comparable with those of humans (Shetake et al., 2011). Like humans, rats are more impaired both neurally and behaviorally at discriminating sounds in speech-shaped noise compared with white noise (Busch & Eldredge, 1967). Both humans and rats are able to discriminate some speech sound contrasts even when the background noise is 12 dB louder than the speech signal (Miller & Nicely, 1955; Shetake et al., 2011). The observation that rodents are able to discriminate human speech sounds in a variety of difficult listening

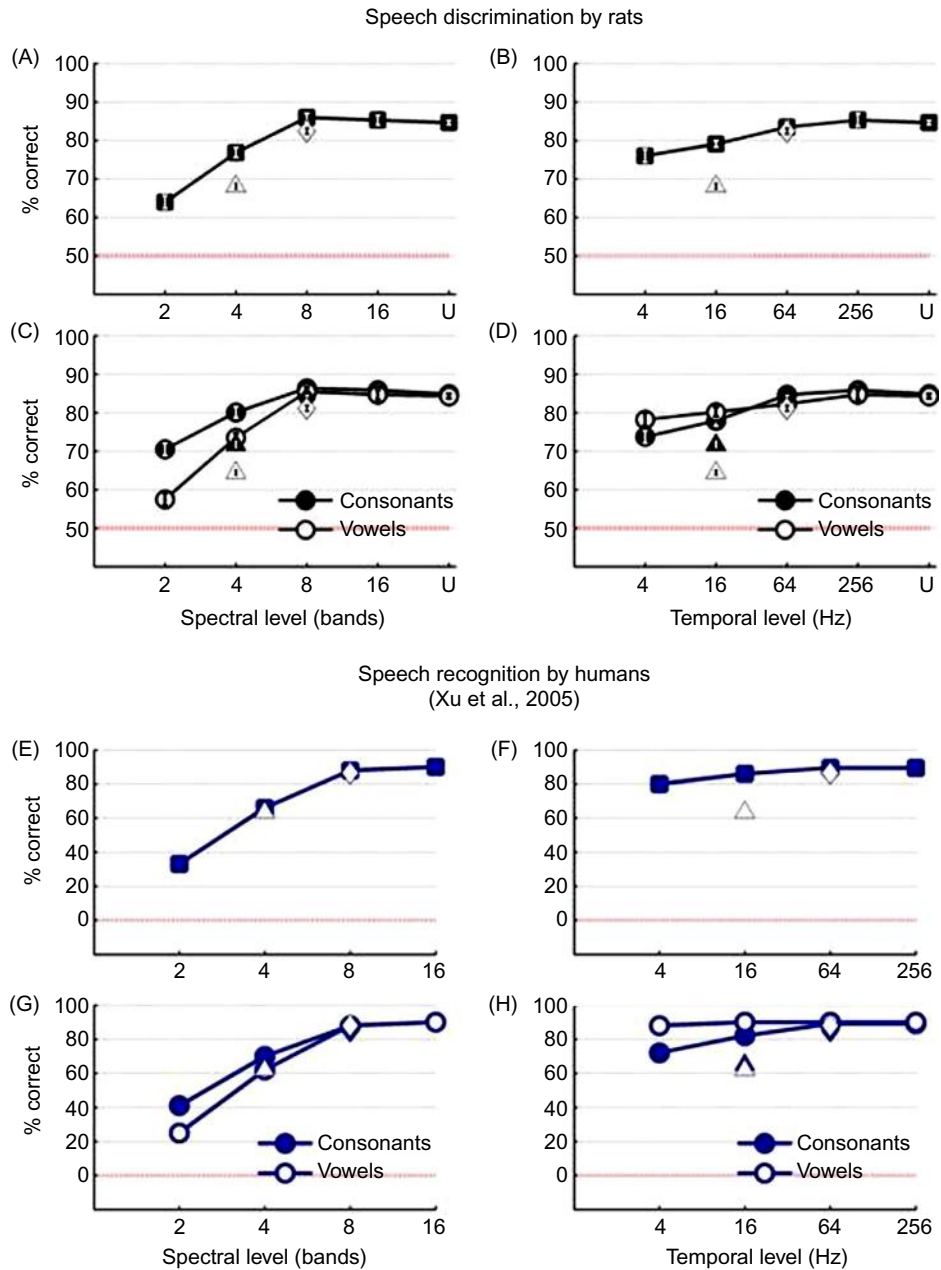

FIGURE 66.3 Rats and humans can discriminate consonant and vowel sounds even after significant stimulus degradation. Rats are able to discriminate a target sound from several distractors when spectral information is reduced to only two bands of spectral information (top left) or when the temporal information is reduced by low pass filtering of the speech envelope at 4 Hz (top right). The human pattern of speech discrimination performance after spectral degradation (bottom left) and temporal degradation (bottom right) was similar to rat performance, which suggests that rats are a good model for speech sound processing. Data from *Ranasinghe et al. (2012, Figure 3)* and *(Xu, Thompson, & Pfingst, 2005, Figures 1 and 2)* with permission from the publisher.

situations with thresholds that mimic those seen in humans suggests that rodents are good animal models of speech sound processing.

66.4.2 Cortical Lesions

Damage to auditory cortex has been a useful tool in rats to investigate the role of specific auditory areas.

Removal or inactivation of auditory cortex causes deficits specific to the affected region. Aspiration lesions involve physically removing the gray matter section of cortex while leaving the white matter underneath intact. Bilateral removal of auditory cortex by this method does not impair rats' ability to reflexively discriminate consonant–vowel–consonant speech sounds (*Floody, Ouda, Porter, & Kilgard, 2010*), as measured

with a gap-detection startle task. Gap detection is a task that relies on the rat's reflexive startle response rather than an operant go/no-go task. When tested on the operant task described, rats with auditory cortex lesions were unable to discriminate between consonant onsets when tested using an operant go/no-go task (Porter, Rosenthal, Ranasinghe, & Kilgard, 2011). These results suggest that auditory cortex is important for categorization of consonant sounds, but it is not required for reflexive responses to a change in consonant acoustics. Vowel discrimination ability is not impaired by the removal of A1 through electrolytic lesions, but it is impaired by removal of dorsal and rostral auditory areas (Kudoh, Nakayama, Hishida, & Shibuki, 2006). These results suggest that the different auditory areas in rodents may extract different information from speech, similar to humans (Obleser, Leaver, VanMeter, & Rauschecker, 2010).

66.4.3 Rodent Models of Speech Processing Impairments

Exposure to loud, repetitive stimuli during the early postnatal period is known to cause changes in the structure and function of auditory cortex. A1 in rats is organized from neurons tuned to low frequencies at the posterior end to neurons tuned to high frequencies at the anterior end (Centanni et al., 2013; Polley, Read, Storace, & Merzenich, 2007). When young rat pups were raised in an environment with constant exposure to pulsed noise, A1 developed with a significantly different tonotopic organization (Chang & Merzenich, 2003; Ranasinghe et al., 2012). However, despite significant degradation of tone response in A1, neural and behavioral discrimination of speech sounds remained highly accurate in these rats (Ranasinghe et al., 2012).

As discussed thus far, rodents have become a useful model for studying perception and discrimination of human speech sounds in a variety of contexts. Rodent models also have the advantage that environmental and genetic conditions can be strictly controlled to a level not possible in human participants. Many researchers have used such models to make progress in understanding the biology and function of many human speech sound processing impairments. In addition to the cortical and stimulus degradation conditions already discussed, rodents exposed to high doses of valproic acid *in utero* have been used to study autism and valproate syndrome (Engineer et al., 2014; Markram & Markram, 2010). A recent study used rodents to evaluate the neural and behavioral effects of temporary or permanent hearing loss on speech processing (Reed et al., 2014). Many other environmental insults, including perinatal anoxia (Strata et al., 2005), and prenatal

exposure to antidepressants (Simpson et al., 2011) or pollutants (Kenet, Froemke, Schreiner, Pessah, & Merzenich, 2007) are known to impair auditory system function in rats, but the impact of these insults on speech processing have not been evaluated. Rodent models are likely to aid in understanding the neural mechanisms responsible for a variety of communication disorders.

66.4.4 Genetic Manipulation

Rodents may prove to be particularly useful for understanding communication disorders with a genetic etiology. Rodents have a homolog for the majority of the genes that cause communication disorders in humans (Kere, 2011; Polleux & Lauder, 2004; Shearer & Smith, 2012). Genetic disruption is now routinely performed in rodents. The genes *FMR1*, *MeCP2*, and *KIAA0319* have been the focus of intense study in rodent models in recent years, because disruption of these genes can cause Fragile X syndrome, Rett syndrome, and dyslexia, respectively. Rats with reduced expression of *Kiaa0319* (the rat homolog of *KIAA0319*) have cortical abnormalities similar to those seen in dyslexia, including microgyria and heterotopia (Szalkowski et al., 2013). Neural responses in the auditory brainstem to speech sounds in dyslexic individuals exhibit much more trial-by-trial variability (Figure 66.4A) than in control subjects (Hornickel & Kraus, 2013). It has been proposed that the inefficient mapping from phonemes (sounds) to graphemes (letters) is a major cause of reading problems. The recent demonstration that the dyslexia gene *Kiaa0319* can increase trial-by-trial variability in rats provides the first direct link between the genetics of dyslexia and a potential mechanistic explanation (Centanni et al., 2014). Reduced expression of *Kiaa0319* reduced the amplitude of the average neural response to speech and delayed the time to peak response, which is consistent with human studies. Use of the rodent model made it possible to demonstrate that these differences in the average response are caused by elevated variability and not by a reduction in the neural response (Figure 66.4B). The total number of cortical action potentials evoked in response to speech sounds in rats with reduced *Kiaa0319* expression was not significantly different from that of control rats. This important experiment confirms that rodent models of speech sound processing are well-suited for evaluating critical and long-standing hypotheses regarding the neural basis of speech sound processing disorders.

It was not initially expected that rodents would provide a valuable animal model of speech sound processing because rodents do not use language. However, the body of experimental evidence described suggests that rodents are an appropriate model of

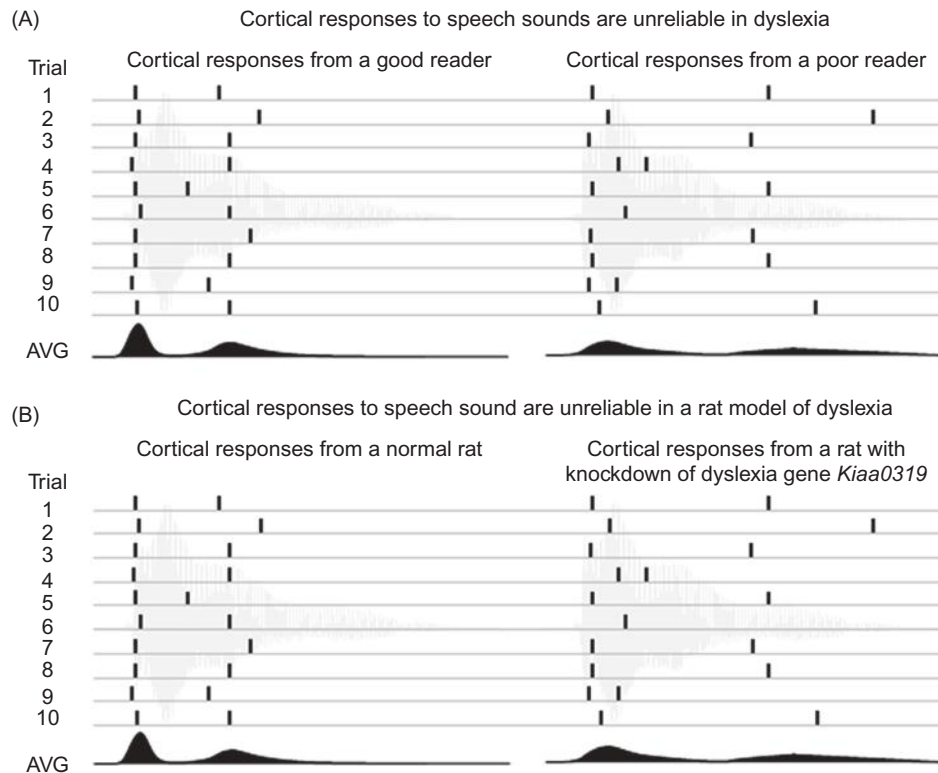

FIGURE 66.4 Schematic of increased neural variability in dyslexia and in a rat model of dyslexia. (A) In normal readers, neural responses to speech sounds (gray) are consistently timed across multiple presentations of the same stimulus. In individuals with dyslexia, the average neural response is significantly delayed and weaker due to greater trial-by-trial variability (Hornickel & Kraus, 2013). (B) In control rats, neural responses to speech sounds are consistently timed across multiple presentations of the same stimulus. In rats with reduced expression of the dyslexia gene *Kiaa0319* (caused by *in utero* RNA interference), neural responses to speech sounds were more variable, which caused the average neural response to be delayed and reduced in amplitude, even though the number of evoked action potentials (black tick marks) was the same as in control rats (Centanni et al., 2014).

human speech sound processing. The early stages of speech sound processing (e.g., the spatiotemporal response patterns evoked by human consonant and vowel sounds) in humans and rodents rely on conserved neural mechanisms that are shared by all mammals. Additionally, the shared behavioral discrimination thresholds between rats and humans allow researchers to investigate neural correlates of behavioral ability while maintaining strict control of genetic and environmental variables that cannot be controlled in human participants.

Future research should take advantage of this model, especially as candidate genes for a variety of disorders are identified. Genetic knockdown models, such as the one described, will be useful in disorders where a specific protein is produced in lower quantities than in typically developing individuals. Knockout models, such as the fragile X model described, will be useful in evaluating the neural and behavioral impairments of disorders in which the protein is not translated at all (Engineer et al., 2014). Both models will provide the opportunity to not only elucidate the

neural mechanisms behind these disorders but also help evaluate the effectiveness of behavioral and pharmacological interventions. Future work in rodent models may also make valuable predictions about ways to predict response to treatment in humans with the same conditions.

Introduction to Memory

Shauna M. Stark and Craig E.L. Stark

Department of Neurobiology and Behavior, University of California, Irvine, CA, USA

67.1 INTRODUCTION: AMNESIA AND PATIENT H.M.

Amnesic patients gave us the first insight into the role of the hippocampus and surrounding medial temporal lobe cortex in the formation of long-term memory (Penfield & Milner, 1958; Ribot, 1882). Most notably, in the 1950s, the hippocampus and most of the surrounding medial temporal cortex were surgically removed in epileptic patient H.M. in an attempt to cure his seizures (Scoville & Milner, 1957). His resulting profound amnesia and inability to learn new things and recall them at a later time emphasized the importance of these brain regions for memory encoding and retrieval. The following decades of research in humans, nonhuman primates, and rodents have contributed to a model of the medial temporal lobe memory system, which includes the hippocampal region, perirhinal, entorhinal, and parahippocampal cortices (Cohen & Eichenbaum, 1993; Squire, 1992; Squire, Stark, & Clark, 2004).

After his surgery, H.M. suffered from both anterograde and retrograde amnesia. Anterograde amnesia refers to an inability to learn new information and retrieve it later as part of a long-term memory trace (Scoville & Milner, 1957). H.M. was unable to learn the names of the hospital staff, even years after his surgery and after repeated exposure to these individuals (Milner, Corkin, & Teuber, 1968). He was severely impaired regarding episodic memory, or memory for autobiographical events that are associated with a specific time, place, and emotion (Tulving, 1984), and semantic memory, consisting of general knowledge about the world (Tulving & Schacter, 1990). He was also unable to learn new vocabulary or apply new meanings to existing words (such as the computer-related meaning for Windows[®]) (Gabrieli, Cohen, & Corkin, 1988). In contrast, retrograde amnesia refers to

memory loss extending back in time from the surgery or accident that caused the amnesia (Ribot, 1882; Squire, Clark, & Knowlton, 2001). For example, H.M. could recall early childhood memories, but not events that happened in the years immediately prior to his surgery.

Although H.M. was severely impaired on most tests of memory (including, but not limited to, verbal, spatial, and object-base stimuli presented in visual and auditory domains), he was able to learn some new information (Corkin, 2002). He could acquire tasks that tapped skill or habit learning, demonstrating decreased reaction times and increased accuracy on a mirror-tracing task over repeated sessions. Although he could not explicitly recall the task from one session to the next, his performance improved with practice (Milner, 1962). The dichotomy between these two types of memory prompted the hypothesis that there are multiple forms of memory supported by multiple memory systems in the brain, broadly divided into declarative memories (both episodic and semantic information), which rely on the medial temporal lobes, and nondeclarative or procedural memories, which rely on an array of other brain structures outside the medial temporal lobe system (Squire, 1992). In this chapter, we review these types of memory and the brain regions that support them. In addition, we discuss how these learning systems might be relevant for language learning, such as vocabulary acquisition, and the flexible and creative expression of language.

67.2 MEDIAL TEMPORAL LOBE MEMORY SYSTEM

Squire and Zola-Morgan (1991) proposed the “medial temporal lobe memory system” to describe the network of brain structures critically involved in

long-term memory formation. This neural system consists of the hippocampus and the adjacent entorhinal, perirhinal, and parahippocampal cortices (which together form the parahippocampal gyrus). These structures form a loose hierarchy such that hippocampus receives projections from entorhinal cortex, which in turn receives projections from the perirhinal and parahippocampal cortices. These connections are bidirectional, feeding information forward into the hippocampus and returning it back through the cortices. In addition, heavy projections run between the perirhinal and parahippocampal cortices that, in turn, receive widespread projections from unimodal and polymodal areas in the frontal, temporal, and parietal lobes (Amaral, 1999).

Although these medial temporal structures are all involved in declarative memory, some specificity has been assigned to individual structures; however, it remains a matter of debate how exclusive that specificity is for each region. The parahippocampal cortex receives input from the dorsal visual stream, often dubbed the “where” visual stream because it is involved in the spatial relationships of visual stimuli. Thus, this region (or a portion of this region) has been coined the parahippocampal place area (Kanwisher, McDermott, & Chun, 1997) and is often associated with memory tasks that involve a spatial component. In contrast, the perirhinal cortex receives input from the ventral visual stream, or the “what” visual stream, which has been associated with object-based representations. Lesion studies have identified a double dissociation between these two regions on spatial and object-based memory tasks (see Malkova & Mishkin, 2003 for a review). In addition, neuroimaging studies have reported activation in the parahippocampal cortex when participants view scenes (Davachi, Mitchell, & Wagner, 2003; Epstein, Harris, Stanley, & Kanwisher, 1999) or when scene representations are evoked (Buffalo, Bellgowan, & Martin, 2006) and there is preferential activity in the perirhinal cortex for objects (Awipi & Davachi, 2008). However, this dichotomy may be oversimplified and dependent on task demands. Some studies have reported comparable imaging-related activity for objects in both the parahippocampal and perirhinal cortices (Litman, Awipi, & Davachi, 2009), whereas others have reported parahippocampal activation for associations that are not restricted to spatial information (Aminoff, Gronau, & Bar, 2007). An alternative view is that the perirhinal cortices and parahippocampal cortices are preferentially involved in item-based and contextual information, respectively (Aggleton & Brown, 1999; Cohen & Eichenbaum, 1993; Ranganath, 2010; Wang, Yonelinas, & Ranganath, 2013).

The entorhinal cortex is the main interface between the hippocampus and rest of the neocortex. It consists of six layers that contain different types of cells and

innervate the various subfields of the hippocampus. Most notably, the entorhinal cortex contains “grid cells.” These cells code for spatial locations in an environment by responding to a grid of locations oriented at a specific angle and with specific spacing (Hafting, Fyhn, Molden, Moser, & Moser, 2005). The universal spatial representation of these grid cells may reflect a context-specific code within the hippocampal network that is crucial for successful storage of episodic memories (Fyhn, Molden, Witter, Moser, & Moser, 2004). The entorhinal cortex can also be divided into the lateral and medial portions, which may be involved in differential processing (Kerr, Agster, Furtak, & Burwell, 2007). The medial entorhinal cortex, the primary location of the grid cells (and “head direction cells”), has been heavily associated with spatial processing (Hafting et al., 2005; McNaughton, Battaglia, Jenson, Moser, & Moser, 2006). In contrast, the lateral entorhinal cortex exhibits little spatial modulation (Hargreaves, Rao, Lee, & Knierim, 2005; Yoganarasimha, Rao, & Knierim, 2010) and may be more involved in object-based processing (Hunsaker, Mooy, Swift, & Kesner, 2007).

The hippocampus sits at the end of the medial temporal lobe network, sharing reciprocal connections with the entorhinal cortex. It is shaped somewhat like a seahorse (*hippocampus* is the Greek term for seahorse) and comprises the subfields CA1-CA4, the dentate gyrus, and the subiculum (Cajal, 1911). These subfields interact with each other in two primary loops, often referred to as the direct and indirect pathways. In the direct pathway, projections from the entorhinal cortex feed forward to the CA1, onto the subiculum, and return back to the entorhinal cortex. In the indirect pathway, the entorhinal cortex feeds forward to the dentate gyrus and then onto the CA3. The CA3 has strong recurrent connections and also projects to CA1 (which then completes the cycle projecting to the subiculum, and then back to the entorhinal cortex). The various layers of the entorhinal cortex interact differentially with these subfields and the various subfields also share reciprocal connections with one another, but these two pathways represent the primary flow of information through the hippocampus (Amaral & Lavenex, 2007; Duvernoy et al., 2005).

Some of these subfields exhibit unique properties that contribute to memory formation and retrieval. Computational models have proposed pattern separation and pattern completion as primary mechanisms of the hippocampus (Marr, 1971; Treves & Rolls, 1994). Pattern separation refers to the process whereby similar representations are transformed into distinct, nonoverlapping representations. Pattern completion, in contrast, refers to transforming incomplete or degraded representations into previously stored representations by filling in the missing information. Both mechanisms are critical in

forming new associative memories, storing memories independently of each other, retrieving memories from partial cues, and flexibly applying stored memories to novel situations (Yassa & Stark, 2011).

The dentate gyrus has been associated with pattern separation in rodents (Leutgeb, Leutgeb, Treves, Moser, & Moser, 2004; Vazdarjanova & Guzowski, 2004) and humans (Bakker, Kirwan, Miller, & Stark, 2008; Lacy, Yassa, Stark, Muftuler, & Stark, 2011). The dentate gyrus receives input from the entorhinal cortex via the perforant path (Witter, 1993). Activity in the dentate gyrus is markedly sparse, with very few neurons firing at any given time (Jung & McNaughton, 1993), leading to a strong reduction in potential overlap between patterns (i.e., pattern separation). It has sparse and powerful projections to the CA3 (Blackstad, Brink, Hem, & Jeune, 1970; Swanson, Wyss, & Cowan, 1978) that give it the potential to strongly drive representations in the CA3 (McNaughton & Morris, 1987). These properties make the dentate gyrus optimal for coding unique representations and sensitive to small changes in input. The CA3 contains an extensive recurrent collateral network of neurons postulated to act as an auto-associative pattern completion network (Marr, 1971; Treves & Rolls, 1992). These recurrent collaterals may be involved in matching the input from the dentate gyrus with other stored representations (Rolls, 2007). The winner of the competition between the information sent from the dentate gyrus and the stored representation from the CA3 is then fed onto the CA1, which does not appear to perform either pattern separation or completion. One theory suggests that the CA1 plays a role in matching sensory input with an existing memory trace, whereas the CA3 and dentate gyrus are involved in the detection of a mismatch with a stored representation (Duncan, Ketz, Inati, & Davachi, 2011; Hasselmo, 2005; Kumaran & Maguire, 2007).

These subfields may be specialized in other ways as well. The CA1 and CA3 subfields both exhibit place fields in rats, such that these neurons exhibit a higher rate of firing when an animal is in a specific location in the environment (O'Keefe & Dostrosky, 1971). These place cells are thought to help form a map of the environment (O'Keefe & Nadel, 1978). There is evidence that CA3 may also be involved in learning the sequence of events over time (Lisman, 1999), and possibly more involved in tasks involving spatial locations (Hunsaker, Rosenberg, & Kesner, 2008). CA1 may also be involved in sequence learning, although to a lesser extent (Farovik, Dupont, & Eichenbaum, 2010), and possibly more so for object-based learning (Hoge & Kesner, 2007; Manns, Howard, & Eichenbaum, 2007). There is conflicting evidence for these theories partly because of the interconnections between regions, which makes it difficult to isolate the functioning of any one region. Nevertheless, the subfields contain

unique properties that support the optimal functioning of the hippocampus as a unit in memory encoding and retrieval.

67.3 EPISODIC MEMORY

Episodic memory (and the related notion of autobiographical memory) refers to memory for specific experiences, usually associated with a time, place, and emotion (Tulving, 1984). Tulving (2002) likened the capacity of remembering specific episodes to "mental time travel," as if the individual is able to re-experience individual events. This type of memory is commonly associated with the subjective mental experience that requires a sense of self and an awareness that this event happened in the past. For example, recalling a birthday party that you attended, who was there, where it occurred, and your own personal interactions there, reflects your episodic memory of that event. In this way, episodic memories represent one-time episodes (i.e., one-trial learning) and rely heavily on the hippocampus. Similarly, the first exposure to a new vocabulary word will be encoded as an episodic memory and be associated with the context in which it was learned.

Episodic memory impairment is the hallmark symptom of amnesic patients. For example, patient H. M. was unable to recall any events from his daily life after his hippocampal resection (Corkin, 2002). Although the formation and retention of new episodic memories is clearly impaired in amnesia, the preservation of older episodic memories is less clear. It is clear that even in cases of extensive medial temporal lobe damage including the hippocampus, old autobiographical memories are typically still present. For example, H.M. was able to produce well-formed autobiographical memories from ages 16 years and younger (Corkin, 1984). Other amnesic patients have also produced rich autobiographical memories from earlier years prior to their amnesic episodes (Bayley, Hopkins, & Squire, 2006; Kirwan, Bayley, Galvan, & Squire, 2008). However, there is still debate regarding whether these memories are truly episodic and contain the same recollective detail found in healthy individuals (Gilboa et al., 2006; Moscovitch, Nadel, Winocur, Gilboa, & Rosenbaum, 2006). Whether the hippocampus is required to truly reexperience an event retrieved from memory (as suggested by Multiple Trace Theory, see below), it is clear that damage to this system would have profound effects on the learning and memory processes used in language (which need not be truly episodic).

There is debate in the literature regarding whether animals also possess episodic memory. Because

episodic memory is defined as having insight into the memory, to travel back in time and re-experience a memory, it is nearly impossible to test in animals. Therefore, based on this definition, [Tulving \(2002\)](#) argues that episodic memory is unique to humans and may be one of the factors that make humans unique from other animals. However, an alternative theory of episodic memory proposes that there is shared neural history between animals and humans, focusing on memory for events in context ([Allen & Fortin, 2013](#)). Episodic memories can instead be defined by the unique characteristics of their what, where, and when components. Utilizing this definition, [Clayton and Dickinson \(1998\)](#) demonstrated that scrub jays could remember what food they stored (worms or peanuts), as well as where (the location of the cage) and when (4 or 124 h ago) it was cached. This information can be updated and used flexibly ([Clayton & Dickinson, 1999](#); [Clayton, Yu, & Dickinson, 2003](#)) and expressed spontaneously ([Singer & Zentall, 2007](#)), and it has been demonstrated in other species, such as rats ([Eacott, Easton, & Zinkivskay, 2005](#); [Ergorul & Eichenbaum, 2004](#)), mice ([Dere, Huston, & De Souza Silva, 2005](#)), and nonhuman primates ([Hoffman, Beran, & Washburn, 2009](#)), much like the definition applied to episodic memories.

67.4 SEMANTIC MEMORY

The counterpart to episodic memory is semantic memory, which is defined as the recollection of facts and generalized knowledge about the world ([Squire, 1992](#); [Tulving, 1983](#)). Semantic memories reflect the information that remains after the details of the learning experience has been lost. Like autobiographical memories, the acquisition of semantic memories is impaired in amnesia ([Gabrieli et al., 1988](#); [Hamann & Squire, 1995](#)). Amnesic patients are impaired in learning new vocabulary words ([Verfaellie, Croce, & Milberg, 1995](#)), recognizing famous faces ([Smith et al., 2014](#)), and recalling current public events ([Reed & Squire, 1998](#)). Although this learning does not emphasize the source details of the learning event (the what-where-when context of the learning), the semantic knowledge is still not retained.

Most memories begin as relatively specific, episodic memories and gradually become more general or semantic over time ([Cermak, 1984](#)). The loss of source details may be the result of some form of averaging of learning experiences, where many details of the learning experience are irrelevant to the learned information. For example, most people know that George Washington was the first president of the United

States, or the meaning of the word “retribution.” However, most of us do not recall the details regarding when or where we first learned that information. As we encounter information over multiple learning episodes, in different contexts, those details are lost, perhaps during the process of systems consolidation. Systems consolidation refers to the process by which memories are transferred from the hippocampus to areas of the cortex as part of long-term retention ([McClelland, McNaughton, & O’Reilly, 1995](#)). Through this mechanism, most declarative memories are acquired through episodic learning but become semanticized over time.

Although this mechanism is generally accepted, there is some debate regarding the role of the hippocampus in retrieving semantic and episodic memories over time. The Standard Model of Systems Consolidation ([Squire & Alvarez, 1995](#)) asserts that the initial memory trace is critical in the early encoding of the memory; however, as that memory is transferred to the cortex, the hippocampus is no longer required for retrieval. In contrast, the Multiple Trace Theory ([Nadel, Samsonovich, Ryan, & Moscovitch, 2000](#)) proposes that the hippocampus is involved in the retrieval of all episodic memories, including remote ones. The hippocampal traces are presumed to be contextually rich in spatial and temporal details, critical for episodic memories, whereas the cortical traces are presumed to be semantic and largely context-free. In this framework, the hippocampus acts as an index to retrieve older episodic memories, along with their contextual details.

There is support for both these models in the amnesia literature (in many domains both make the same predictions) with no clear consensus regarding which is more accurate. The key test of these models relies on the nature of retrograde amnesia. If the hippocampus is required for the retrieval of all episodic memories, regardless of age, then there should not be evidence for a temporally graded retrograde amnesia for episodic memory. In other words, without a hippocampus, all memories should be semanticized, with no qualitative difference as a function of the age of the memory. Although early reports on H.M. indicated that he demonstrated temporally graded retrograde amnesia ([Scoville & Milner, 1957](#)), more refined testing later revealed that much of H.M.’s memories had become semanticized. For example, [Corkin \(2002\)](#) asserted that “H.M. was unable to supply an episodic memory of his mother or his father—he could not narrate even one event that occurred in a specific time and place.” Studies of other amnesic patients, however, have revealed older episodic memories that appear to be qualitatively intact and demonstrate a temporal gradient such that older memories are intact,

whereas more recent memories are impaired (Bayley et al., 2006; Kirwan et al., 2008). The discrepancies in these findings are sometimes attributed to variability in the etiology and location of the brain damage reported in various amnesic patients. Partial hippocampal damage is not uncommon, and there is considerable variability in the condition of the surrounding medial temporal cortex and lateral temporal cortex. However, even in lesions of the hippocampus in rodents, where the extent and location of the hippocampal damage can be better controlled and quantified, the evidence is mixed for temporally graded amnesia (Frankland & Bontempi, 2005; Sutherland, Sparks, & Lehmann, 2010). Recently, the Competitive Trace Theory has been proposed to account for these disparate data that combine aspects of both of them (Yassa & Reagh, 2013). Future studies are necessary to settle the debate regarding the role of the hippocampus in episodic memory retrieval.

Regardless of the differences between these models, it is clear that the hippocampus and surrounding medial temporal cortices are critical for the encoding of new information and then transferring this information into the cortex over time. These episodic experiences are thought to become semanticized over time through a process of “replay” in which the hippocampus trains the cortex directly (McClelland et al., 1995). There is also evidence, however, that the cortex can learn directly, without relying on the hippocampus to relay the information first. Although H.M. performed poorly on tests of current events or naming people who had become famous after his surgery, he was able to identify some of them, indicating some new learning (Corkin, 2002; Mayes et al., 1994). Furthermore, he was also able to draw an accurate and detailed map of his home, which he lived in only after his hippocampal resection (Corkin, 2002).

There are two main theories regarding how this new learning was accomplished. The first is that this learning was supported by residual medial temporal lobe structures that are still intact. In H.M., for example, the posterior parahippocampal gyrus was largely spared (Corkin, Amaral, Gonzales, Johnson, & Hyman, 1997; Salat et al., 2006). Another well-characterized amnesic patient, E.P., had a more complete medial temporal lesion (resulting from herpes simplex encephalitis) (Insausti, Annese, Amaral, & Squire, 2013; Stefanacci, Buffalo, Schmolck, & Squire, 2000), with very little residual functional tissue. Yet, he was able to identify some household items that had been acquired after the onset of his amnesia (Bayley, O'Reilly, Curran, & Squire, 2008). In this case, the medial temporal lobe is unlikely to have contributed to this new learning, leading to the second theory of how this learning was accomplished, which is by the neocortex directly.

Complimentary Learning Systems models of memory have proposed two learning systems in the brain: the hippocampal system (encompassing the hippocampus and surrounding medial temporal lobe regions) and the neocortical learning system (McClelland et al., 1995). As mentioned, the hippocampal system is responsible for episodic and semantic learning, rapidly acquiring information in a single episode and gradually transferring this information to the cortex over time for permanent storage. This process involves gradual, interleaved learning, possibly involving replay of events during wakefulness (Karlsson & Frank, 2009) and sleep (Frankland & Bontempi, 2005). In the absence of an intact hippocampal memory system, the cortex may be able to learn the statistical regularities or “similarity structure” in the environment through repeated exposure, mimicking the interleaved training normally provided by the hippocampus.

One could imagine that through repeated exposure via television and magazines, how a severely amnesic patient like H.M. could learn the names of presidents and other major events that occurred after his surgery by utilizing such a mechanism. A more rigorous demonstration of this learning comes from the training of vocabulary words to memory-impaired patients. Using a technique called “errorless learning” in which a new vocabulary word and its definition are presented repeatedly and without an opportunity for incorrect associations, amnesic patients have demonstrated new learning of vocabulary words (Glisky, Schacter, & Tulving, 1986). However, this learning is hyper-specific, such that performance plummets with any variation from the original training in the context in which the word is presented or any rewording of the definition (Baddeley & Wilson, 1994; Glisky et al., 1986). Nevertheless, these studies provide evidence that some new learning can be acquired outside of the medial temporal lobes and can be applied for rehabilitation (Clare, Wilson, Breen, & Hodges, 1999; Wilson, Baddeley, & Evans, 1994), particularly if specific training techniques are utilized to increase the generalization of the information (Stark & Gordon, 2008; Stark, Stark, & Gordon, 2005).

67.5 PROCEDURAL MEMORY

Learning mechanisms that operate outside the medial temporal lobe represent a diverse array of other types of learning, beyond the semantic learning noted. Procedural memory refers to several forms of learning that occurs during the performance of various tasks, which is typically expressed in enhanced or speeded performance (Squire, 2004). For example, learning a sequence of movements, such as swinging a golf club

or riding a bike, is expressed as a gradual improvement in speed and accuracy. Patients with amnesia perform normally on these procedural learning tasks because they do not rely on the medial temporal lobes, but instead they involve a variety of other structures. For example, patient H.M. was able to improve his accuracy on a mirror-tracing task over the course of several trials and several days, despite having no memory for the learning events themselves (Milner, 1962).

Procedural memory can take many different forms, sometimes called “habit learning.” Importantly, it operates outside of conscious awareness and typically requires several learning trials, in contrast to the hippocampal memory system, which requires only one exposure to acquire new information and involves conscious information processing. Procedural memory includes skills and habits, largely dependent on the striatum and basal ganglia, and refers to those tasks that involve a series of motor movements, such as riding a bike or playing the piano (Seger & Spiering, 2011). Priming and perceptual learning occur in the neo-cortex and are reflected in faster reaction times in responding to a repeated word or picture. The initial presentation “primes” the memory trace such that it is more accessible during a second presentation (Hamann & Squire, 1997; Levy, Stark, & Squire, 2004; Stark & Squire, 2000). Simple classical conditioning operates in the amygdala, such as fear conditioning in which an animal can learn to associate a painful shock with a particular context in one exposure and without the use of the hippocampus (Fanselow, 1994; Phillips & LeDoux, 1992), and the cerebellum, such as eye-blink conditioning (Steinmetz, Lavond, Ivkovich, Logan, & Thompson, 1992). Additionally, some tasks that require gradually acquiring the statistical regularities of a stimulus set can operate outside of the medial temporal lobe. For example, amnesic patients are able to learn new cognitive skills (Dienes, Baddeley, & Jansari, 2012; Squire & Frambach, 1990), artificial grammar (Knowlton & Squire, 1996), and categorical assignment (Hopkins, Myers, Shohamy, Grossman, & Gluck, 2004; Knowlton & Squire, 1993). This same network of brain regions also serves to support the rules associated with the sequential order of lexical items, the structure of phrases and sentences (syntax), and the morphology of complex words (Ullman, 2004).

67.6 MEMORY CONSOLIDATION AND SLEEP

As discussed, the process of memory consolidation at a systems level involves the transfer of memories from the hippocampus and medial temporal lobe structures to the cortex for long-term storage. There is

considerable debate regarding the role of the hippocampus in the retrieval of old episodic memories, but it is widely accepted that the final storage site of much of declarative memory is in the cortex. However, it is unclear how long it takes for a memory to be fully transferred to the cortex. Studies of retrograde amnesia indicate that it may take 10 or 20 years for memories to be fully consolidated and stable, such that they are resilient in the face of damage to the hippocampus (Bayley, Hopkins, & Squire, 2003; Cipolotti et al., 2001; Manns, Hopkins, & Squire, 2003; Nadel et al., 2000). This consolidation process occurs without intent or awareness, and it does not refer to conscious or behavioral rehearsal.

Systems consolidation is only one form of memory consolidation, however. At a cellular level, learning initially leads to an “early” form of Long-Term Potentiation (LTP) of synapses that will decay within hours unless specific forms of protein synthesis occur that stabilize or consolidate the memory at a cellular level within the hippocampus (Nicoll & Roche, 2013). Retrieval and replay of a memory can also “consolidate” or stabilize a memory, perhaps explaining at least some of why memory consolidation is facilitated by sleep (Stickgold & Walker, 2007).

Memory consolidation serves to stabilize the memory in the initial phase and then to enhance and integrate the memory at later stages. Motor skill memories have been shown to be disrupted by training on an alternate task within the first hours after training on the initial task, indicating the importance of the stabilization phase in reducing interference (Brashers-Krug, Shadmehr, & Bizzi, 1996; Walker, Brakefield, Hobson, & Stickgold, 2003). Memory consolidation may also serve to enhance memories, improving behavioral performance independent of further practice (Walker, Liston, Hobson, & Stickgold, 2002). Additionally, the memories gradually become integrated into existing memory networks (Dumay & Gaskell, 2005; Dumay & Gaskell, 2007; Stickgold, 2002). There is also evidence that the mere act of recalling a memory can destabilize it, making it vulnerable to interference and degradation, in a process called reconsolidation (Nader, 2003).

The stabilization phase of memory consolidation appears to occur largely during wakefulness (Brashers-Krug et al., 1996; Walker et al., 2003). The enhancement stage appears to occur primarily during sleep, either restoring previously lost memories (Fenn, Nusbaum, & Margoliash, 2003) or producing additional learning (Walker et al., 2003, 2002), both without need for additional practice. Although many of these studies involve a motor-learning task, such as finger tapping, and assess the improvement in performance over time, similar benefits have been reported for the learning of word pairs

after sleep (Gais, Molle, Helms, & Born, 2002). The “slow wave sleep” (SWS) phase of the rapid eye movement (REM) cycle of sleep seems to be particularly important (Gais & Born, 2004; Gais, Plihal, Wagner, & Born, 2000), with sleep deprivation resulting in learning impairments (Zimmerman, Stoyva, & Metcalf, 1970; Zimmerman, Stoyva, & Reite, 1978). Neuroimaging studies have revealed reactivation during sleep of regions active during learning of a task (Peigneux et al., 2003). This sleep reactivation, or replay, has also been observed in neural firing rates in rodent studies, particularly in the hippocampus, but also in other cortical regions (Euston, Tatsuno, & McNaughton, 2007; Ji & Wilson, 2007; Wilson & McNaughton, 1994). The process of sleep reactivation is thought to strengthen the cortical memory trace, thereby allowing memories to become independent of the hippocampus (Frankland & Bontempi, 2005). There is also evidence for replay during wakefulness that may play a similar role in consolidation (Karlsson & Frank, 2009).

67.7 NEUROGENESIS

Neurogenesis refers to the birth of new neurons in the brain and occurs primarily in the dentate gyrus of the hippocampus and the olfactory bulb (Altman, 1962, 1963). Recent estimates indicate that one-third of the neurons in the hippocampus are regularly renewed in the hippocampus throughout life, amounting to approximately 700 new neurons added to the hippocampus per day (Spalding et al., 2013). Adult-born hippocampal neurons have enhanced synaptic plasticity for a period of time (Ge, Yang, Hsu, Ming, & Song, 2007; Schmidt-Hieber, Jonas, & Bischofberger, 2004), indicating that they may provide an optimal mechanism for encoding new memories. The long-term storage capacity of the human brain is unknown, but the process of neurogenesis may provide an explanation for how a relatively small brain structure can continuously encode new experiences and integrate them into long-term storage.

There is some evidence for the functional significance of these newborn neurons for efficient pattern separation and the ability to distinguish and store similar experiences as distinct memories (Clelland et al., 2009; Sahay et al., 2011). These new neurons have been directly associated with spatial pattern separation (Clelland et al., 2009) and in the encoding of time in new memories (Aimone, Wiles, & Gage, 2006). In contrast, there is some evidence to suggest that older granule cells in the dentate gyrus are necessary for pattern completion, which serves to generalize similar memories with each other (Nakashiba et al., 2012). Computational models of neurogenesis in

hippocampal learning also propose that this mechanism can increase memory capacity (Becker, 2005). Taken together, neurogenesis provides a mechanism for encoding new memories over the course of the lifespan.

Neurogenesis also provides a mechanism to explain memory deficits and a target for improving memory performance. A decrease in adult-born neurons has been observed in cases of severe depression and is associated with an increased stress response (Sahay & Hen, 2007; Schloesser, Lehmann, Martinowich, Manji, & Herkenham, 2010; Snyder, Soumier, Brewer, Pickel, & Cameron, 2011). A neurogenesis deficit could bias hippocampal encoding and retrieval toward a narrow, predominately negative representation of context, generalizing across all positive or negative experiences (Becker & Wojtowicz, 2006). In addition, a decrease in neurogenesis may be linked to age-related declines in hippocampal function and associated memory performance (Kuhn, Dickinson-Anson, & Gage, 1996; Spalding et al., 2013; Zitnik & Martin, 2002).

The potential for rescue of neurogenesis is an important target for improving memory performance. Antidepressants have been shown to increase neurogenesis and rescue memory deficits (Dranovsky & Hen, 2006; Surget et al., 2011). Interestingly, environmental enrichment and physical exercise have proven to be extremely beneficial in increasing the production of newborn neurons and in their long-term integration in the brain. Environmental enrichment in animals involving larger cages with exposure to balls, tunnels, and other novelties, have resulted in greater neurogenesis (Kempermann, Kuhn, & Gage, 1997; Leal-Galicia, Castaneda-Bueno, Quiroz-Baez, & Arias, 2008). Likewise, voluntary wheel-running in rodents has been shown to increase neurogenesis and enhance learning (van Praag, 2008; van Praag, Shubert, Zhao, & Gage, 2005). These findings have been extended to humans, such that physical exercise has been associated with improved memory performance in healthy adults (Hertzog, Kramer, Wilson, & Lindenberger, 2009) and has been shown to offset some of the memory declines associated with aging (Erickson et al., 2011; Kramer, Erickson, & Colcombe, 2006) and Alzheimer’s disease (Cotman, Berchtold, & Christie, 2007; Lautenschlager et al., 2008).

67.8 AGING AND MEMORY

One of the key concerns of older adults is the experience of memory loss, both in the normal course of aging and as it is associated with Alzheimer’s disease and other forms of dementia. Age-related memory impairment affects various types of memory, including source memory (i.e., the knowledge of where or

when information was encoded) (Johnson, Hashtroudi, & Lindsay, 1993; Schacter, Koutstaal, Johnson, Gross, & Angell, 1997). Older adults are also more prone to false recollections (i.e., miscombining features of different events that are confidently held as true) (Koutstaal, Schacter, & Brenner, 2001; Lyle, Bloise, & Johnson, 2006). Changes in the hippocampus may be responsible for these errors in binding in older adults (Kessels, Hobbel, & Postma, 2007). It is worth noting that some domains of memory remain unchanged with age, such as procedural memory (Fleischman, Wilson, Gabrieli, Bienias, & Bennett, 2004) and working memory (Nilsson, 2003), whereas semantic knowledge (e.g., vocabulary) actually improves (Verhaeghen, 2003).

Although several brain regions undergo changes associated with aging, such as the frontal and temporal cortices (Fjell & Walhovd, 2005), changes in the hippocampus may be particularly relevant for memory-related declines. Hippocampal volume is reduced in older adults (Raz, Rodrigue, Head, Kennedy, & Acker, 2004), but there is no evidence that this volume loss is due to fewer neurons (Burke & Barnes, 2006). Instead, there may be synaptic loss, although only in selective regions. For example, the synapses in the CA3 subfield of the hippocampus that form the recurrent collaterals in the auto-associative network are not reduced in aging (Smith, Adams, Gallagher, Morrison, & Rapp, 2000). In contrast, the number of synapses from the entorhinal cortex into the dentate gyrus via the perforant path is reduced (Scheff, Price, Schmitt, & Mufson, 2006). This pattern was also observed in the integrity of the perforant path in humans using neuroimaging and was tied to memory performance, such that reduced perforant path integrity in older adults was correlated with worse memory performance (Yassa, Mattfeld, Stark, & Stark, 2011). In addition to this reduction in input, there is also reduced activity in the dentate gyrus, resulting in weak pattern separation processes (Wilson, Gallagher, Eichenbaum, & Tanila, 2006; Yassa et al., 2011; Yassa & Stark, 2011). In contrast, neuroimaging of the CA1 subfield of the hippocampus appears unaffected and is consistent with robust pattern completion performance (Stark, Yassa, Lacy, & Stark, 2013; Yassa et al., 2011).

In addition to age-related memory changes associated with normal aging, there are memory deficits and brain changes associated with Alzheimer's disease. The earliest brain changes in Alzheimer's disease appear to be targeted in the entorhinal cortex, demonstrating neuronal loss (Gomez-Isla et al., 1996) and an increase in neurofibrillary tangles associated with the disease (Braak, Alafuzoff, Arzberger, Kretschmar, & Del Tredici, 2006). Whereas memory-related changes associated with aging appear to be somewhat confined (with

preserved performance on most tests of recognition memory), Alzheimer's disease results in fairly general memory deficits (McKhann et al., 1984) that progress over the course of the disease and extend to other cognitive domains (Bowen et al., 1997). Discriminating between those individuals with healthy aging and those with early Alzheimer's disease remains a target of vigorous research (Bauer, Cabral, Greve, & Killiany, 2013; Colliot et al., 2008; Morris et al., 1991), particularly that aiming for earlier detection and, ultimately, earlier intervention and treatment.

67.9 LANGUAGE LEARNING AND THE MEDIAL TEMPORAL LOBE

The hippocampus and surrounding medial temporal cortices are involved in the acquisition of new facts and events, so it serves to reason that damage to these regions would impair the learning of language as well. Amnesic patient H.M. demonstrated the relative integrity of his expressive and comprehensive language capacity (Kensinger, Ullman, & Corkin, 2001). However, more detailed investigations revealed impairments in sentence ambiguity (MacKay, James, Taylor, & Marian, 2007; Schmolck, Stefanacci, & Squire, 2000) and increases in grammatical errors (MacKay et al., 2007; MacKay, James, Hadley, & Fogler, 2011). Studies of patients with damage limited to just the hippocampus perform much like healthy controls (Schmolck et al., 2000), indicating that other medial temporal structures or lateral temporal lobe structures, such as the anterolateral cortex (often also damaged in these patients), may be more involved (Schmolck, Kensinger, Corkin, & Squire, 2002). Consistent with this interpretation, patients with semantic dementia, a progressive neurodegenerative disorder characterized by loss of semantic memory in both verbal and nonverbal domains, have atrophy in the lateral temporal cortex (Bozeat, Lambon Ralph, Patterson, Garrard, & Hodges, 2000; Hodges, Patterson, Oxbury, & Funnell, 1992). These patients act as a counterpart to amnesia in that they have semantic learning impairments, whereas their episodic memory for recent events remains intact. In terms of consolidation, the anterolateral cortex may be critical as the long-term repository of perceptual and semantic categorical knowledge that is transferred from the hippocampus (Murre, Graham, & Hodges, 2001). Damage to the hippocampal memory system prevents the learning of new vocabulary, whereas damage to the anterolateral cortex impairs the semantic knowledge for previously acquired words and concepts.

The procedural memory system, composed of a large network of brain structures, including the basal ganglia, frontal cortex, parietal cortex, and the cerebellum, may subserve the rule-based structure underlying grammar. These regions may play a role in the maintenance in working memory for linguistic elements and in learning of grammatical rules underlying the regularities of complex structures (Ullman, 2004). This system is largely spared in amnesia, yet there has been mixed evidence regarding the integrity of grammar in these patients. Amnesic patient H.M. displayed normal syntactic processing and morphological production of irregular and plural words (Kensinger et al., 2001). Further investigation revealed that H.M. produced fewer grammatical sentences and described pictures less completely and accurately than controls, particularly for unfamiliar stimuli, challenging the conclusion that his language production is intact (MacKay, James, & Hadley, 2008). However, similar investigations of other amnesic patients have not replicated this deficit in grammar, identifying cerebellar (or other) degeneration in H.M. that may account for these impairments (Schmolck et al., 2002). The interaction between these two memory systems likely accounts for some of the deficits observed in H.M., particularly because his errors are more pronounced in reference to novel stimuli.

The hippocampus and surrounding medial temporal lobe may be critical for the acquisition of language and the ability to use it creatively and flexibly in novel ways. Certainly, the medial temporal lobe is necessary for the acquisition of new vocabulary words, including the meaning, lexical status, and pronunciation of the words (Gabrieli et al., 1988). In addition, the medial temporal lobe memory system may be critical for relational binding (Shimamura, 2010) and representational flexibility (Bunsey, 2002). Duff and Brown-Schmidt (2012) have made a strong argument for the necessity of the medial temporal lobe memory system in online language processing. They argue that language is a system of arbitrary associations arranged in a temporal pattern, consistent with the ample evidence that the hippocampus is critical for the learning of temporal sequences of events (Fortin, Agster, & Eichenbaum, 2002). Without a medial temporal lobe memory system, individuals with amnesia exhibit rigidity in their referential expressions, with a lack of communal knowledge during discourse (Duff et al., 2008). However, language is flexible and creative, allowing for a nearly unlimited combination of words in novel constructions and contexts. Combined, these data support the theory that the medial temporal lobe memory system contains unique properties, making it a key contributor to language learning and production.

Neural Basis of Phonological Short-Term Memory

Julie A. Fiez

Department of Psychology, Department of Neuroscience, Department of Communication Science and Disorders,
Center for Learning Research and Development and Center for the Neural Basis of Cognition,
University of Pittsburgh, PA, USA

The short-term maintenance of phonological (speech-related) information is crucial to the performance of many tasks. These include acts of communication, such as formulating and producing a spoken sentence (Acheson & McDonald, 2009), and acts of cognition, such as using inner speech to help mentally solve an arithmetic problem (Frank, Fedorenko, Lai, Saxe, & Gibson, 2012). Thus, understanding how phonological content is dynamically stored (i.e., understanding *short-term phonological memory*) is central to understanding how language is used for communication and verbally mediated cognition.

This chapter provides an overview of phonological memory that draws on cognitive psychological and cognitive neuroscience theories, methods, and results. Cognitive psychology, which emerged in the mid-1900s, marked a shift from behaviorist approaches that treated the mind as a “black box” to cognitive approaches that focused on internal representations and processes that underlie observable human behavior. The increase of cognitive neuroscience in the late 1900s provided the opportunity to look inside the “black box” through neuropsychological studies that examined the effects of brain damage on cognitive performance and neuroimaging studies that examined local changes in brain activity associated with the performance of cognitive tasks. As these two disciplines have continued to mature and interact, so has our understanding of phonological memory and its neural basis. The chapter begins by describing different theoretical perspectives on phonological memory. It then reviews how theoretical aspects of phonological memory have been mapped onto particular brain regions and considers how the

functions of implicated brain regions can be further contextualized by looking outside of the verbal working memory literature.

68.1 THEORETICAL PERSPECTIVES ON PHONOLOGICAL SHORT-TERM MEMORY

68.1.1 Phonological Memory as a Passive Process

Early research on phonological memory tackled basic questions, including how much verbal information can be stored in short-term memory (i.e., its capacity), how long it can be stored before the content is forgotten (i.e., its duration), and whether the loss of information is due to the decay of a memory trace or interference between similar traces. These questions can be posed for situations in which short-term memory storage is passive and when it occurs as part of a deliberate and effortful strategy to maintain presented information (Crowder, 1982; Jones, Macken, & Nicholls, 2004). In this first section, the passive storage of auditory and phonological content is discussed.

The Brown–Petersen task provides a classic example of how passive short-term phonological memory can be probed. In this task, subjects view three letters in each trial while at the same time performing a demanding concurrent task (e.g., mental arithmetic). The secondary task is designed to prevent (or minimize) active efforts to remember the presented letter trigram. After a short delay, subjects respond to a probe letter by indicating whether it was or was not presented in

the previously viewed trigram. Findings from the Brown–Peterson task indicate that verbal content is rapidly forgotten unless active measures are taken to prevent forgetting, which can occur due to both trace decay and item interference effects (Crowder, 1982).

One important twist is that there are modality effects in the passive storage of verbal content. Specifically, recall is typically better when list items are spoken rather than written. The benefit of auditory presentation is particularly pronounced for the final one or two items on a list. This enhanced recency effect can be observed even when subjects are required to perform a concurrent task that reduces their overall memory performance (Penney, 1989). Moreover, the size of an observed recency effect depends on whether an auditory stimulus is perceived as speech, as opposed to a nonspeech sound (Neath, Surprenant, & Crowder, 1993). Together, these findings suggest that passive phonological memory mechanisms may differ across sensory systems, such that there may be an “echoic store” that specifically supports the passive, short-term storage of spoken input (Crowder & Morton, 1969). This idea would be consistent with computational models of speech perception that emphasize the importance of temporal integration in the linguistic perception of an evolving acoustic signal (McClelland & Elman, 1986).

68.1.2 Phonological Memory as a Dedicated Repository That Can Be “Refreshed” via Inner Speech

Short-term phonological memory can also be investigated under conditions that allow the use of volitional processes, such as executive control and inner speech, as a way to mitigate information loss. Baddeley and Hitch (1974) used the term *working memory* to distinguish this more active type of short-term memory. Their seminal work popularized the use of serial recall tasks as a tool for studying the short-term maintenance of verbal information. For the prototypical immediate serial recall (ISR) task, subjects are given a short list of verbal items (e.g., a list of nine or fewer letters, digits, or words) that are presented one at a time (usually 1 every 1–2 s). After presentation of the list, subjects are prompted to immediately recall the items in the order they were presented through spoken, written, or pointed responses.

Baddeley and Hitch proposed the Multicomponent Model of Working Memory as a way to account for a body of experimental results obtained using the ISR task (Baddeley, 1986; Baddeley & Hitch, 1974). With nearly 10,000 citations to date, this model continues to be a highly influential conceptualization of

phonological memory. The original model contains a central executive component and two “slave” systems: a phonological loop for the maintenance of verbal content and a visuospatial sketchpad for the maintenance of nonverbal content. The phonological loop comprises a phonological store that is dedicated to working memory and that serves to temporarily hold verbal information, and an articulatory loop, through which inner speech is used to reactivate, or “refresh,” the representations in the phonological store. The store can be directly accessed by spoken stimuli, whereas written stimuli must be recoded into the store using the articulatory loop. Items in the phonological store are subject to decay unless they are refreshed by the articulatory loop. As a consequence, the number of items that can be maintained in phonological short-term memory will reflect how well the items can gain access to the phonological store, how well items represented within the store can resist interference and decay, and how quickly and effectively they can be reactivated by articulatory rehearsal.

68.1.3 Short-Term Phonological Memory as Attention-Based Activation

The Baddeley and Hitch model treats phonological memory as a process distinct from language processing. However, other theoretical models have regarded it as an emergent product of phonological knowledge stored in long-term memory and general attention mechanisms. For example, in the Embedded Processes model developed by Cowan (1999), there is a main memory repository that can be approximately equated with the long-term memory system and a very brief sensory store. Information in the long-term memory system can be brought into working memory, which occurs when an “embedded” subset of information in the long-term store takes on a temporarily heightened state of activation. A further embedded subset of the activated information can be made particularly salient when it falls under the *focus of attention*. Working memory is assumed to comprise all information in a readily accessible state by virtue of its activation, including information within the focus of attention and also information in an activated state outside of attention.

68.1.4 Short-Term Phonological Memory via Speech Planning and Efferent Reactivation

A third perspective on phonological memory regards it as the natural by-product of an interactive neural architecture for speech perception and production (for review, see Acheson & McDonald, 2009). In this view, degradation within the speech architecture

not only will affect linguistic performance but also will imperil the maintenance of phonological information as an emergent by-product of processing. This perspective is consistent with the fact that ISR and repetition deficits are pervasive in individuals with an acquired central disorder of language (e.g., some form of aphasia), and these deficits can be related to aspects of word and sentence-level performance (Martin, Saffran, & Dell, 1996; Martin, 2005).

The model proposed by Gupta and MacWhinney (1997) illustrates an integrated model of phonological memory and speech perception and production. In this model, phoneme-level representations are interconnected with lexical-phonology representations, which are interconnected with semantic representations. Speech input automatically activates phonemic and lexical representations of the spoken input, and then connections between the phoneme representations and an optional speech planning pathway allow the encoded phonological information to guide spoken output. Rehearsal is conceptualized as the volitional activation of lexical-phonological representations, which then activate phonemic representations and output planning. The engagement of output planning yields an efference copy of the planned production or, in other words, an internal representation of the planned articulation. The efference copy is processed in the same way that would occur if the planned output were presented as spoken input. Thus, verbal rehearsal yields automatic reactivation of the lexical-phonological and phoneme representations by using the internal outputs of speech planning to mimic the repeated presentation of the list items.

68.2 NEURAL PERSPECTIVES ON SHORT-TERM PHONOLOGICAL MEMORY

68.2.1 Passive Phonological Memory

The neural underpinnings of passive short-term phonological storage remain unclear, in part because they have received little direct investigation. One possibility is that the neurons involved in representing the experienced content (e.g., representing the phonological forms of spoken stimuli) exhibit persistent activity across a delay interval. There are neural mechanisms that could produce such persistent activity, such as top-down signals from prefrontal cortex or dynamically assembled oscillatory networks (Benchenane, Tiesinga, & Battaglia, 2011; Gazzaley & Nobre, 2012). However, such mechanisms are generally regarded as attention demanding, and therefore they would be difficult to sustain in combination with the types of effortful concurrent tasks that have been used to reveal passive short-term

phonological memory. Another possibility is that neurons involved in representing phonological content can undergo a form of short-term synaptic plasticity, leaving them more easily reactivated in response to a subsequent probe stimulus or internal recall attempt. This type of mechanism would be consistent with cellular and molecular studies of memory formation, which have shown that changes in neural connection strengths involve a variety of mechanisms that occur across different time scales (milliseconds to days). Thus, passive phonological memory could reflect intrinsic cellular processes that occur after a period of active neuronal firing (Nee & Jonides, 2013).

The neural basis of echoic memory has also received relatively little attention. The neuropsychological literature provides examples of patients with brain injury who did not show modality and auditory recency effects, suggesting that their brain injury disrupted the functions of an echoic store (Vallar & Papagno, 1986). However, the lesion sites of such patients have not been systematically investigated and, moreover, the impairments of these patients have not generally been interpreted from an echoic memory perspective. Neuroimaging studies have examined the short-term retention of spoken information but have generally used active conditions (e.g., repetition tasks) that do not specifically probe the passive storage of speech content (Hickok & Poeppel, 2004). Studies involving the auditory short-term memory abilities of nonhuman primates are similarly limited, but intriguing: results from neurophysiological recordings of single auditory cortex neurons indicate that a prior sound can influence the neural processing of a subsequent sound for at least 5 s, irrespective of whether an auditory stimulus sequence is presented within an active or passive behavioral context (Werner-Reiss, Porter, Underhill, & Groh, 2006).

68.2.2 Active Short-Term Phonological Memory: Differing Perspectives

The differing theoretical perspectives on active phonological memory lead to different proposed structure–function mappings in the brain. Much of the early research on this topic used the Baddeley and Hitch model to motivate experimental designs and explain observed findings. For instance, early neurobiological support for the phonological loop sub-component came from case studies of patients with brain injury, typically due to stroke. These studies provided evidence of dissociations in the behavioral profile of ISR performance across different patients, lending support to the idea that different components of verbal working memory could be dissociated from each other (Baddeley, 1986).

As neuroimaging became available in the 1980s and 1990s, it offered a new tool for investigating verbal working memory. Early work tested various aspects of the Baddeley and Hitch model, such as the assumption of a central executive processor that mediates the behavior of the subsidiary maintenance subsystems, the existence of dissociable verbal and visuospatial maintenance subsystems, and the dissociability of storage and rehearsal processes within a phonological loop. The results from such efforts generally placed the phonological storage component of the verbal maintenance subsystem into the left inferior parietal cortex, the speech-based rehearsal process into the inferior frontal gyrus (with possible additional contributions from the premotor, supplementary motor, and cerebellar areas), and the executive control system into the dorsolateral prefrontal cortex (D'Esposito et al., 1995; Paulesu, Frith, & Frackowiak, 1993; Smith & Jonides, 1998). Overall, this body of work provided convergent support for the general tenets of the Baddeley and Hitch model.

However, arguments have also been made against simple mappings of the Baddeley and Hitch model onto a corresponding set of brain regions. For instance, Chein and Fiez (2010) used neuroimaging and behavioral approaches to investigate the effects of three different manipulations on ISR performance and brain activation: irrelevant speech presentation, irrelevant nonspeech presentation, and concurrent articulation. These effects were chosen because different models of working memory posit unique patterns of association and dissociation between them. By gathering empirical evidence for how the effects patterned together, they tested which theory best predicted the observed data. The results indicated that the Embedded Process model (Cowan, 1999) provided the most straightforward fit to the data. Chein and Fiez combined key components of the Embedded Process model with their information about the neural locus of the different manipulations to assign functions to the brain regions that are active during verbal working memory tasks. They proposed that dorsolateral prefrontal cortex supports executive control, the dorsal sector of the inferior parietal cortex supports attentional scanning, the inferior frontal gyrus supports the activation of phonological information from long-term memory, and motor-related regions (e.g., premotor cortex, supplementary motor cortex, and the cerebellum) are specifically used when a volitional rehearsal-based strategy is used. One appealing aspect of this structure–function mapping is its closer alignment to the concept of working memory in the basic neuroscience literature, which has focused on the role of a frontoparietal attention system in maintaining the active neuronal firing that is necessary to keep information in conscious awareness (Goldman-Rakic, 1995).

Other investigators have approached the neuropsychological and neuroimaging literature on phonological memory from a psycholinguistic perspective (for reviews, see Buchsbaum & D'Esposito, 2008; Gupta & MacWhinney, 1997; Hickok & Poeppel, 2004; Jacquemot & Scott, 2006; Martin, 2005). All of these reviews present a cogent analysis of the overlap between brain regions involved in speech perception and production, leading them to argue against the idea of a dedicated phonological store. Instead, they posit that the speech perception and production system has an intrinsic ability to support the sustained activation of phonological information, and they share the view that the brain regions involved in phonological memory are highly interactive but at the same time tuned to different types of phonological representation. A psycholinguistic perspective on phonological memory motivates the following sections, which draw on results from outside the verbal working memory literature to further contextualize the neural basis of phonological memory.

68.2.3 A Core Phonological System

Although differing theoretical perspectives on phonological memory give rise to differing structure–function mappings, there is a high level of agreement on the set of involved brain regions (Figure 68.1). Anteriorly, the critical tissue can be broadly labeled as the left frontal operculum (L-FO) and considered to include the inferior frontal gyrus, the ventral portions of the precentral gyrus, and the anterior portions of the insula. Posteriorly, the critical tissue can be broadly labeled as the left temporoparietal junction (L-TPJ) and considered to include the posterior superior temporal gyrus and sulcus, the posterior sector of the insula, and the ventral portions of the supramarginal gyrus. Together, the L-FO and L-TPJ territories can be regarded as constituents of a core phonological system for language, which can be complemented by non-linguistic areas that have been associated with inner speech (e.g., the supplementary motor area, the premotor cortex, and the cerebellum) and brain regions involved in attentional control (e.g., dorsolateral prefrontal cortex).

Turning first to the frontal portion of the core phonological system, the L-FO territory is generally thought to be involved in output-based phonological processing (i.e., processing that is weighted toward supporting speech production) (Benson, 1979; Gupta & MacWhinney, 1997; Hickok & Poeppel, 2007; Martin, 2005). A variety of evidence suggests that the L-FO supports phonological representation at the level of articulatory gestures and that it is particularly important for

FIGURE 68.1 Neural regions associated with active short-term phonological memory. A variety of evidence indicates that tissue within the L-FO and the L-TPJ contributes to core phonological processing across a variety of language tasks, including verbal ISR tasks. It is thought that the dorsal L-TPJ territory is weighted toward representations and processes associated with speech perception (input-based phonological processing), the ventral L-TPJ territory is weighted toward representations and processes associated with lexical-level phonology and semantics, and the L-FO territory is weighted toward representations and processes associated with speech production. Phonological memory may also involve the use of motor-related regions (such as premotor cortex and the cerebellum) to take advantage of speech production mechanisms for reactivating input-based phonological representations and providing efferent-based signals that can be used to detect and correct errors in a rehearsed sequence. Not shown are regions thought to contribute to domain-general aspects of active phonological memory, such as parietal and dorsolateral prefrontal regions associated with attention and executive control. Abbreviations: artic reh, articulatory rehearsal; phon, phonology; lex, lexical; cbm, cerebellum; FO, frontal operculum; TPJ, temporoparietal junction.

tasks that require sublexical phonetic analysis (Hickok & Poeppel, 2007; Indefrey & Levelt, 2004). Although the L-FO is usually linked to rehearsal-related processing in verbal working (Paulesu et al., 1993; Smith, Jonides, Marshuetz, & Koeppe, 1998), there are reasons to believe that it may automatically support the output-based coding of visual and auditory stimuli in phonological memory even when rehearsal is not used. For instance, *Chein and Fiez (2010)* found that this region was affected differently by a concurrent articulation task than other motor speech areas in the frontal lobe.

There is less agreement about the role of posterior components of the core phonological system (Becker, MacAndrew, & Fiez, 1999; Buchsbaum & D'Esposito, 2008), most likely because specific areas within the L-TPJ territory make distinct contributions that require further delineation (Buchsbaum & D'Esposito, 2008; Jacquemot & Scott, 2006; Martin, 2005). Setting aside the issue of precise localization, the L-TPJ territory is commonly associated with input-based phonological processing (i.e., processing that is weighted toward

supporting speech perception) (Gupta & MacWhinney, 1997; Hickok & Poeppel, 2007; Jacquemot & Scott, 2006; Martin, 2005). Neuropsychological and neuroimaging studies provide compelling, although not completely consistent, evidence that the L-TPJ territory is active during the maintenance of phonological information and that it is crucial for normal ISR task performance (for review, see Buchsbaum & D'Esposito, 2008). It has often been proposed as the site of a phonological store: either one that is dedicated to verbal working memory (Paulesu et al., 1993; Vigneau et al., 2006) or one that reflects demands for the buffering of phonological and order information associated not only with verbal working memory but also with speech planning and production (Buchsbaum & D'Esposito, 2008; Gupta & MacWhinney, 1997; Jacquemot & Scott, 2006; Martin, 2005).

Anatomically, the dorsal sector of the L-TPJ is interconnected with regions associated with auditory, motor, and speech processing (Guenther, 2006; Petrides & Pandya, 1988; Rauschecker, 2011; Simonyan & Jurgens, 2002; Yeterian & Pandya, 1998); furthermore, neuroimaging studies have demonstrated that both sensory and motor-related responses can be found within this region (for review, see Guenther, 2006; Hickok, Houde, & Rong, 2011; Rauschecker, 2011). These and other findings suggest that this dorsal territory functions as a sensorimotor bridge between frontal tissue associated with speech production and temporal tissue associated with speech recognition and semantic analysis (Acheson, Hamidi, Binder, & Postle, 2011; Buchsbaum & D'Esposito, 2008; Hickok & Poeppel, 2007; Rauschecker, 2011). In the context of an ISR task, the dorsal L-TPJ may be weighted toward phonological encoding and the maintenance of order information, whereas the ventral L-TPJ may be weighted toward lexical-level coding (Acheson et al., 2011; Buchsbaum & D'Esposito, 2008; Gupta & MacWhinney, 1997; Jacquemot & Scott, 2006; Martin, 2005). Engagement of the ventral L-TPJ could provide a pathway that accounts for lexical and semantic influences on ISR task performance and speech production (Corley, Brockehurst, & Moat, 2011; Martin, 2008; Roelofs, 2004).

68.2.4 Neural Mechanisms for Articulatory Rehearsal

Moving outside the core phonological network, areas implicated in motor processing may be used to strategically implement verbal rehearsal. The motoric coding that is associated with intentional rehearsal could provide an efferent-based mechanism by which phonological information can be reactivated (Guenther, 1995; Gupta & MacWhinney, 1997; Jacquemot & Scott, 2006; Rauschecker, 2011). This is a conceptually simple

and compelling idea, but there is surprisingly little neural data to support it. One idea might be that premotor or motor association areas would be a source of excitatory input into one or more areas within the L-TPJ territory. Cortical surface electrode recordings from individuals undergoing presurgical planning for epilepsy treatment provide intriguing evidence for motor-related changes in L-TPJ tissue (Edwards et al., 2010). However, fMRI studies have not consistently revealed increased L-TPJ activation associated with verbal rehearsal and silent speech; if anything, there appears to be a suppression of activity within the superior temporal gyrus during speech production (Curio, Neuloh, Numminen, Jousmaki, & Hari, 2000; Paus, Marrett, Worsley, & Evans, 1996; Yinen et al., 2014). The disparate results may reflect the fact that speech production leads to highly focal regions of activation that can become obscured by surrounding areas of suppression and individual neuroanatomical variability (Buchsbaum, Olsen, Koch, & Berman, 2005; Flinker, Chang, Barbaro, Berger, & Knight, 2011).

A related idea is that efferent-based information may be used to monitor and correct for errors that occur during either overt speech production or internal speech. Theories of motor control and motor learning emphasize the need for neural mechanisms that allow motor representations to be derived from sensory goals (inverse models) and for sensory consequences to be predicted based on actual or planned actions (forward models); inverse and forward models are thought to play a critical role in detecting and correcting breakdowns in performance that occur when there are mismatches between sensory and motor representational spaces (Kawato & Wolpert, 1998; Wolpert & Ghahramani, 2000). A relatively large amount of data provide evidence that the L-TPJ territory plays a critical role in the monitoring of internal speech, most likely as recipient of information about the planned utterance (for review, see Guenther, 2006; Hickok et al., 2011; Rauschecker, 2011). The cerebellum is also likely to be important, given that this brain structure features prominently in many models of motor control and learning (Doya, 2000). Particularly relevant is the model of verbal rehearsal proposed by Desmond and collaborators (Desmond, Gabrieli, Wagner, Ginier, & Glover, 1997). This model proposes a cerebro-cerebellar loop involving frontal motor areas, which provides the superior cerebellum with information about the actual contents of the rehearsal loop, whereas a second loop involving the L-TPJ provides the inferior cerebellum with information about the intended contents. Circuitry within the cerebellum is used to compare the two pieces of information and to create an error correction signal (when there is a discrepancy) that is relayed to frontal motor areas to

adaptively modify the contents of the rehearsal loop. Neuropsychological studies have shown that individuals with cerebellar damage exhibit modest decrements in ISR performance, as would be expected if core phonological processing was left intact but the capacity for error correction was impaired (Justus, Ravizza, Fiez, & Ivry, 2005; Ravizza et al., 2006).

68.3 SUMMARY

Language and verbally mediated cognition involve short-term phonological storage in the form of passive and active mechanisms for maintaining phonological content. Three general classes of models provide differing theoretical perspectives on how short-term phonological memories are actively stored and maintained, and how different functional aspects of phonological memory map onto specific brain regions. In general, however, phonological memory is thought to rely on a core phonological network that includes the tissue surrounding the L-TPJ and the L-FO, brain territories that are also associated with speech perception and production, respectively. In addition, brain regions associated with motor aspects of speech production (e.g., premotor cortex, the cerebellum) may contribute to phonological memory, most likely by providing the neural substrates for inner speech. The volitional use of inner speech may mitigate memory loss by reactivating phonological content and providing the information needed to monitor and correct degraded representations in phonological memory.

Working Memory and Language

Bradley R. Buchsbaum

Rotman Research Institute, Baycrest, University of Toronto, Toronto, ON, Canada

69.1 INTRODUCTION

In human verbal communication there is frequently some period of time that intervenes between the sensory perception of a speech message and an appropriate response to that message. Consider the plight of the Starbucks *barista*: a fastidious customer makes his way to the front of the line and orders a rather complex espresso concoction. The cashier rings up the order and repeats it aloud: “double decaf lightly foamed soy milk cappucino”—a verbal message containing all of 7 words and 13 syllables. The *barista*, meanwhile busy preparing a *peppermint caramel machiatto* for the previous customer, must mentally record and retain in memory the content of the new request. Although the spoken message describing an elaborate coffee drink has only a brief existence as a stream of acoustic vibrations in the physical world, it must nevertheless be transmitted and stably represented in the minds of three successive people. The customer *produces* the message, the cashier *repeats* the message, and the *barista* must *maintain* the message “in mind” until he or she has completed the order. When the drink arrives at the counter with a cheerful: “Sir, your double decaf lightly foamed soy milk capuccino is ready!” a bystander, uninitiated to this routine modern coffee-ordering spectacle, might be forgiven for considering the fulfillment of the customer’s request to be something of a miracle. From the standpoint of the study of human cognition, the success of this commercial exchange depends critically not only on language competence (i.e., the ability to perceive and produce speech) but also on the ability to consciously hold onto a sequence of verbal information over a short period of time. In the parlance of modern cognitive psychology and neuroscience, we refer to this ability to retain information in an accessible state over short periods of

time as “working memory,” a cognitive faculty that enables humans and other complex animals to temporarily store, process, and manipulate important pieces of information that are no longer readily available in the sensory environment.

In this chapter, I first review how working memory emerged as a concept in cognitive psychology. I then describe the preeminent cognitive model of verbal working memory, the phonological loop, and the logic by which it explains critical laboratory phenomena associated with memory for verbal material. I then discuss the attempts and associated difficulties in mapping and otherwise situating the phonological loop in the brain. Finally, I cover the recent movement in the cognitive neuroscience of language to view verbal working memory as emerging from the language circuitry that underpins core language functions such as the perception and production on speech.

69.2 THE EMERGENCE OF THE CONCEPT OF SHORT-TERM MEMORY

The idea of memory as consisting of two main compartments, one for the current contents of consciousness and another for a permanent record of experience, has gone in and out of fashion in the past century. James (2011) coined the terms “primary memory” and “secondary memory” to refer to these two basic concepts, setting off a long-standing debate in the psychological sciences as to whether memory is best viewed as a unitary or mechanistically divisible phenomenon. In the middle part of the 20th century, most theorists viewed memory as a unitary system governed by a single set of principles that were largely invariant over time (Melton, 1963; Underwood, 1957). However, in the 1960s, evidence from cognitive

psychology began to point to the existence of two memory systems, one for very recent events (short-term memory) and one for events that occurred in the more distant past (long-term memory).

A critical piece of evidence supporting the “dual-store” view of memory came from studies of free recall. It was shown that when subjects are presented a list of words and must recall them in any order (free recall), performance is best for the first few items (the *primacy* effect) and for the last few items (the *recency* effect). When accuracy is plotted as a function of input order, it reveals a characteristic U-shaped (Davelaar, Goshen-Gottstein, Ashkenazi, Haarmann, & Usher, 2005; Glanzer & Cunitz, 1966; Waugh & Norman, 1965) pattern, which is referred to as the serial position curve. However, if a short delay (e.g., 10 s) is placed between stimulus presentation and recall during which subjects are required to engage in some distracting activity, the shape of the serial position curve changed. Performance on early items (primacy) is relatively unaffected, but the recency effect is abolished (Glanzer & Cunitz, 1966; Postman & Phillips, 1965). Recency effects are attributed to the readout of the last few items in a list from short-term memory (STM), and primacy effects are reflected in the long-term memory (LTM) advantage for the first few items in a list due to the greater rehearsal devoted to those items. Moreover, recall from the long-term store requires a more effortful and slow probabilistic form of retrieval that largely depends on associative, semantic, and contextual retrieval cues than is retrieval from the short-term store. It would be remiss not to mention that this interpretation of patterns of recency effects in immediate and delayed recall as reflected in the operation of two stores has long been disputed and is complicated by the demonstration of recency effects that can span across minutes or even days (Bjork & Whitten, 1974; Crowder, 1982), although it has yet to be shown that these “long-term recency effects” have the same underlying mechanism as standard recency effects.

In summary, short-term memory is essentially a limitation of the online capacity of an information processing system. Thus, short-term memory can be viewed as a cup into which sensory information flows. The capacity of the cup is fixed and is prone to overflowing. The precise capacity of the cup varies across individuals (Unsworth & Engle, 2007), although as Miller (1956) memorably pointed out, it tends to hover around a “magical number” of 7 plus or minus 2 (but see also Cowan, 2001). When incoming information exceeds the capacity of the cup, the spillover may still be recorded in a secondary container, that is, long-term memory.

69.3 NEUROLOGICAL EVIDENCE FOR A SEPARATION OF SHORT-TERM AND LONG-TERM MEMORY

One of the critical pieces of evidence supporting the existence of separable systems for short-term and long-term memory was the discovery of patients with brain damage that appeared to have selective deficits affecting only long-term or only short-term memory. The most famous example of such dissociation was the case of the patient H.M., whose medial temporal lobes were famously removed as a treatment of intractable epilepsy. The surgery resulted in nearly complete loss in the ability to form new long-term declarative memories (Corkin, 2002; Scoville & Milner, 1957). H.M. and other patients with bilateral medial temporal lobe lesions that have subsequently been described (Squire, Stark, & Clark, 2004) live in a kind of “permanent present tense” (Corkin, 2013), unable to consciously recall events that occurred even a few minutes ago. Notwithstanding this severe impairment in the ability to form new long-term declarative memories, such patients appear to have little or no deficit on tests of short-term memory such as repeating back short strings of digits (Baddeley & Warrington, 1970; Wickelgren, 1968), although deficits in short-term memory have been sometimes observed in these patients in tests using novel visual objects (Ranganath & Blumenfeld, 2005) or in tests of short-term associative memory (Olson, Page, Moore, Chatterjee, & Verfaellie, 2006; Ryan & Cohen, 2004; Yee, Hannula, Tranel, & Cohen, 2014).

Further bolstering support for the idea of a neurobiological distinction between short-term and long-term memory was the discovery of patients with severely impaired short-term memory for numbers and words together with a preserved ability to learn supra-span (e.g., more than 10 items) word lists with repeated study (Baddeley, Papagno, & Vallar, 1988; Basso, Spinnler, Vallar, & Zanobio, 1982; Shallice & Warrington, 1970; Warrington & Shallice, 1969). Thus, the behavioral pattern evidenced in these subjects contrasted with that of H.M. in that they could form new long-term (verbal) memories but had little or no verbal short-term memory. However, whereas H.M.’s memory deficit was a general memory impairment that applied to all forms of declarative information (e.g., verbal, visual, and spatial), these particular “short-term memory patients,” as they would later be called, had deficits that were confined to the auditory-verbal modality. It is also important to emphasize that the short-term memory deficits by these patients, in the purest cases (Shallice & Butterworth, 1977; Shallice & Vallar, 1990; Shallice & Warrington, 1977; Takayama,

Kinomoto, & Nakamura, 2004; Vallar & Baddeley, 1984; Vallar, Di Betta, & Silveri, 1997), are not accompanied by severe deficits in language comprehension and production. Thus, patient J.B. (Shallice & Butterworth, 1977) was able to have conversations normally and to speak fluently without abnormal pauses, errors, or other aphasic symptoms. What this seemed to show was that verbal storage is not “built in” to the language processing system but is an independent entity in its own right, an informational buffer that exists not to support language *per se*, but rather as a passive “holding place” where recently encountered linguistic information can be temporarily stored. Thus, the discovery of “short-term memory patients,” as they were to be called (Vallar, 2006), established a double dissociation both in brain localization (LTM, medial temporal lobe; verbal STM, temporoparietal cortex) and patterns of performance, between short-term and long-term memory systems. In addition, the short-term memory disorder could be distinguished from severe disorders of language production and comprehension such as Broca’s aphasia, Wernicke’s aphasia, and other classic neurological language impairments.

69.4 THE EMERGENCE OF THE CONCEPT OF WORKING MEMORY

The Working Memory model of Baddeley and colleagues (Baddeley, 1986, 2000; Baddeley & Hitch, 1974) was developed with the aim of explaining the relevant behavioral findings in the memory literature while also taking into account important neuropsychological case study reports such as those reviewed here. In addition, whereas prior models of short-term memory tended to emphasize storage buffers as the receptacles for information arriving from the senses, Baddeley and Hitch (1974) focused on rehearsal processes, that is, strategic mechanisms for the maintenance of items in memory. Baddeley and Hitch (1974) attempted to account for a system that could simultaneously manipulate the current contents of memory and update information in working memory in the service of task goals. Such a system is especially important when one needs to maintain information over short periods in many complex cognitive activities such as reading, mental calculation, spatial reasoning, and so forth.

In the canonical “real world” example, when one is trying to keep a telephone number in mind, one will often mentally rehearse the contents of the numeric sequence. Research has shown that in tests of serial recall, when subjects are prevented from engaging in subvocal rehearsal during a delay period that is inserted between stimulus presentation and recall,

overall performance suffers (Baddeley, Thomson, & Buchanan, 1975). In the case of verbal material, then, this suggested that the ability to keep verbal sequences in working memory depends on covert articulatory processes. This insight was central to the development of the verbal component of Working Memory, the “phonological loop,” and led to a broader conceptualization of short-term memory that sought to explain not only how and why information enters and exits awareness but also how resources are deployed in a strategic effort to capture and maintain the objects of memory in conscious awareness.

The key tenets of the Working Memory model are as follows: (i) it is a limited capacity system; at any moment in time, there is only a finite amount of information directly available for processing in memory; (ii) specialized subsystems devoted to the representation of information of a particular type, for instance, verbal or visuospatial, are structurally independent of one another (i.e., the integrity of information represented in one domain is protected from the interfering effects of information that may be arriving to another domain); and (iii) storage of information in memory is distinct from the processes that underlie sensory perception; instead, there is two-stage process whereby sensory information is first analyzed by perceptual modules and then transferred into specialized storage buffers that have no other role but to temporarily “hold” preprocessed units of information. Moreover, the pieces of information that reside in these specialized buffers are subject to passive, time-based decay as well as inter-item interference (e.g., similar sounding words like “man, mad, map, cap, mad” can lead to interference within a specialized phonological storage structure). Finally, the storage buffers have no built-in or internal mechanism for maintaining or otherwise refreshing their contents, rather, this must occur from without, through the process of rehearsal, which might be a motor or top-down control mechanism that can sequentially access and refresh the contents that remain active within the store.

The Working Memory model, first proposed by Baddeley and Hitch (1974) and later refined (Baddeley, 1986, 2000; Salame & Baddeley, 1982), argued for the existence of three functional components of working memory. The “central executive” was envisioned as a control system of limited attentional capacity responsible for coordinating and controlling two subsidiary slave systems, a *phonological loop* and a *visuospatial sketchpad*. The phonological loop was responsible for the storage and maintenance of information in a verbal form, and the visuospatial sketchpad was dedicated to the storage and maintenance of visuospatial information. In the past decade, a fourth component, the

“episodic buffer,” has been added to the model to capture a number of phenomena related to interactions between short-term and long-term memory that could not be readily explained within the original framework. In the next section, the phonological loop is described in more detail because it is the central component underlying working memory for verbal material.

69.5 THE PHONOLOGICAL LOOP

As noted, the Working Memory model entails a separation of domain-specific mechanisms of memory maintenance and domain-general mechanisms of executive control (Figure 69.1). Thus, the verbal component of working memory, or the phonological loop, is regarded as a “slave” system that is under the supervisory control of the central executive component. Within the phonological loop, two interacting components—the phonological store and the articulatory rehearsal process—enable verbal representations to be maintained in an active state.

The phonological store is a passive buffer wherein verbal information can be stored for brief (approximately 2 s) periods. The articulatory control process serves to refresh the contents of the store, thereby allowing the system to maintain sequences of verbal items in memory over some interval of time. This division of labor between two interlocking components, one an active *process* and the other a *passive* store, is crucial to the model’s explanatory power. For instance, when the articulatory control process is interfered with through the method of articulatory suppression (e.g., by requiring subjects to say “hiya” over and over again), items in the store rapidly decay and recall

performance suffers greatly. The phonological store, then, lacks a mechanism of reactivating its own contents but possesses memory capacity, whereas the articulatory rehearsal process lacks an intrinsic memory capacity of its own but can exert its effect indirectly by refreshing the contents of the store.

The phonological loop model of verbal working memory has stood the test of time, largely because it explains many of the behavioral phenomena associated with verbal memory performance in a simple and intuitive way. It is important to briefly note what these core behavioral phenomena are and how the phonological loop model accounts for them. The appeal of the model comes partly from its parsimony—with only a very minimal set of functional specifications, it is able to account for a large number of behavioral findings. It therefore provides a benchmark that any competing model, whether neural or purely cognitive, must be able to match. An overview of how the phonological loop explains certain well-established behavioral phenomena associated with verbal working memory, namely, the *phonological similarity effect*, the *word-length effect*, the effect of *articulatory suppression*, and the *irrelevant sound effect* (Repovs & Baddeley, 2006) is provided here. The phonological similarity effect refers to the finding that similar sounding sets of words are more difficult to retain in memory than sets of phonologically dissimilar words (Conrad & Hull, 1964). The locus of this effect is the phonological store, and it results from the increased amount of interference that occurs between memory traces that share overlapping representational (e.g., phonemic) features, relative to those that do not.

The word-length effect simply refers to the fact that lists of words that take more time to articulate—longer words—are more poorly remembered than words that take less time to articulate (Baddeley et al., 1975; Mueller, Seymour, Kieras, & Meyer, 2003). This occurs not only between sets of words that have different numbers of syllables but also in sets of words that are equated for number of syllables but are, nevertheless, unequal in absolute articulatory duration. The effect is explained by assuming that items in the phonological store suffer time-based decay that can only be reversed by way of articulation. Thus, as the articulatory loop cycles through a set of long words, the overall time elapsed between successive iterations will be greater and, therefore, the probability that one of the several items in the store may have (irretrievably) decayed will be consequently increased. This effect, then, is jointly determined by the properties of the rehearsal process (rate of articulation) and that of the phonological store (rate of decay).

The negative effect of articulatory suppression on recall performance is observed when subjects are

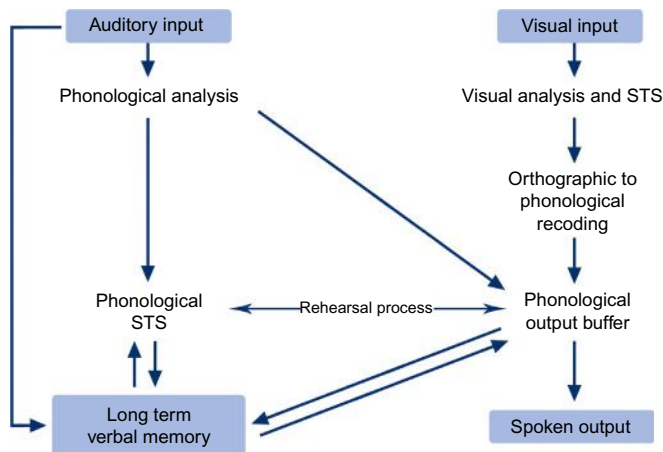

FIGURE 69.1 An anatomico-functional model of phonological short-term memory based on Vallar et al. (1997) and Baddeley, Gathercole, and Papagno (1998).

prevented from using inner speech either during presentation or during a delay inserted before recall. Thus, as articulatory suppression interferes with the articulatory rehearsal process, the mechanisms that are ordinarily used to refresh the items in the phonological store and the system are therefore unable to counteract trace decay, thus leading to a decline in recall performance.

The irrelevant sound effect occurs when the to-be-remembered verbal stimuli are accompanied by a stream of unattended auditory information (Macken, Mosdell, & Jones, 1999; Salame & Baddeley, 1982; Tremblay, Nicholls, Alford, & Jones, 2000). These “irrelevant sounds” need not be in the speaker’s native language or even phonemic to be disruptive, provided there is some degree of variation in the sound stream. For instance, a single tone or even white noise does not have an effect, although a changing sequence of tones does cause impairment (Jones, Madden, & Miles, 1992). The locus of the irrelevant sound effect is in the phonological store, where the incoming acoustic information interferes with the to-be-remembered items in the store. Because the presentation of irrelevant visual–verbal information does not have an effect on recall, it is assumed that auditory information has obligatory access to the store, whereas visual–verbal information does not. How, then, does visual–verbal information enter the phonological store? The answer, supported by several lines of evidence (Baddeley, Lewis, & Vallar, 1984; Levy, 1971), is that textual information must first be recoded phonologically before it can enter the store. This recoding process requires the involvement of the articulatory rehearsal process, because subvocalization is necessary to reroute visually derived verbal information into the phonological store. In support of this contention is the finding that articulatory suppression abolishes the phonological similarity effect for visual, but not auditory, presentation. Because auditory information has obligatory access to the store, articulatory suppression has no effect on its deposition within the store. For visual presentation, however, articulatory suppression ties up the rehearsal system, preventing phonological recoding of visual–verbal material and, consequently, blocking subvocally mediated access to the store. The main components of the phonological loop, as well as the manner in which its architecture and functional characteristics account for certain reliable effects observed in studies of verbal STM, have been briefly outlined. It should be made clear that it is not universally accepted that every detail of the phonological loop is perfectly supported by available evidence. For instance, there is a great deal of debate about whether the word-length effect is actually caused by an increase in the absolute spoken duration of the items, or whether it is better

explained by, for instance, the phonological complexity of the items (Caplan, Rochon, & Waters, 1992; Mueller et al., 2003).

In summary, the Working Memory model of Baddeley and colleagues describes a system for the maintenance and manipulation of information that is stored in domain-specific memory buffers. Separate cognitive components are dedicated to the functions of storage, rehearsal, and executive control. Informational encapsulation and domain segregation dictates that auditory-verbal and visual information is kept in separate storage subsystems—the phonological loop and the visuospatial sketchpad, respectively. These storage subsystems themselves comprise specialized components for the passive storage of memory traces, which are subject to time and interference-based decay, and for the reactivation of these memory traces by way of simulation, or rehearsal. Thus, storage components represent memory traces but have no internal means of refreshing them, whereas rehearsal processes (e.g., articulatory) have no mnemonic capacity of their own but can reactivate the decaying traces held in temporary stores. How neuroscience has built on the cognitive foundation of the Working Memory model of Baddeley and colleagues to refine our understanding of how information is maintained and manipulated in the brain is discussed here. We see that, in some cases, neuroscientific evidence has bolstered and reinforced aspects of the Working Memory model, whereas in other cases neuroscience has compelled a departure from certain core principles of the Baddeleyan concept.

69.6 NEURAL BASIS OF VERBAL WORKING MEMORY

Research on the neural basis verbal working memory has some unique challenges and is in several ways more difficult to study than, for example, visual or spatial working memory. For example, whereas in visual working memory many of the most influential ideas and concepts have derived from work in non-human primates and other animals, verbal working memory is a uniquely human phenomenon; therefore, it has benefited from animal research only in terms of broad neuroscience principles.

Even research on the primary modality relevant to verbal working memory, that of audition, is surprisingly scarce in the monkey literature because of the difficulty in training nonhuman primates to perform delayed response tasks with auditory stimuli, which can take upwards of 15,000 learning trials (Fritz, Mishkin, & Saunders, 2005). Because of the lack of animal work on verbal working memory, neuroscience has often looked to cognitive psychological models,

such as the Working Memory model of Baddeley colleagues, for a sensible framework for interpreting neuroscientific evidence about verbal working memory. Of course, many of the classic neurological studies of language were performed before “working memory” existed as a concept, let alone an object of avid neuroscience enquiry. Nevertheless, the core idea of Baddeley and colleagues phonological loop, namely, that verbal information can be reciprocally transferred between auditory and motor components, has a clear cognate in the Wernicke–Lichtheim–Geschwind model of language organization, the core of which originated in Carl Wernicke’s 1874 monograph on the aphasias (Geschwind, 1965b; Wernicke, 1874). A fundamental challenge to the cognitive neuroscience of verbal working memory has been to integrate both empirical data and theoretical constructs that have emerged from different subfields—cognitive, neurological, neuropsychological—of enquiry in the brain and behavioral sciences.

69.7 NEUROLOGICAL STUDIES OF LANGUAGE AND VERBAL SHORT-TERM MEMORY

Early neurological investigations of patients with language disturbances, or aphasia, revealed that lesions to specific parts of the cerebral cortex could cause selective deficits in language abilities (Goodglass, 1993). Thus, lesions to the inferior frontal gyrus and surrounding cortex are associated with Broca’s aphasia, a disorder that causes severe impairments in speech production. Broca’s aphasia is not, however, a disorder of peripheral motor coordination, such as the ability to move and control the tongue and mouth, but rather is a disorder of the ability to plan, program, and access the motor codes required for the production of speech (Goodglass, 1993; Mohr et al., 1978). Lesions to the posterior superior temporal gyrus and surrounding cortex, however, are associated with Wernicke’s aphasia, a complex syndrome that is characterized by fluent, but error-filled production, and poor comprehension and perception of speech. A third, less common, syndrome called conduction aphasia, typically caused by lesions in the auditory cortex and posterior Sylvian region (generally less extensive and relatively superior to lesions causing Wernicke’s aphasia), is associated with relatively preserved speech perception and comprehension, occasional errors in otherwise fluent spontaneous speech (e.g., phoneme substitutions), and severe difficulties with verbatim repetition of words and sentences (Axer, Keyserlingk, Berks, & Keyserlingk, 2001; Baldo & Dronkers, 2006; Damasio & Damasio, 1980).

From the standpoint of verbal short-term memory, there are a number of important points to be drawn from these three classic aphasic syndromes. First, the neural structures that underlie the perception and production of speech are partly dissociable. Although it is tempting to postulate that posterior temporal lesions primarily affect receptive language functions and anterior lesions affect productive language functions, this is not quite true. Both Wernicke’s aphasia and conduction aphasia are caused by posterior lesions, yet only the former is associated with a receptive language disturbance, whereas both syndromes involve a deficit in speech production. Moreover, lesions in and around the inferior frontal gyrus (Broca’s area), although normally associated with deficits in speech production (labored, nonfluent speech), can also lead to deficits in the comprehension of grammatically complex sentences and subtle deficits in speech perception (Berndt, Mitchum, & Wayland, 1997; Caplan, Baker, & Dehaut, 1985). Second, the aforementioned disorders affect basic aspects of language processing, such as the comprehension, production, and perception of speech. Third, the classical Wernicke–Lichtheim–Geschwind (Geschwind, 1965a) model of language explains each of these three syndromes as disruptions to components of a neuroanatomical network of areas in the inferior frontal and superior temporal cortices that subserve language function. Finally, it should not be surprising that aphasic syndromes associated with poor language performance have also been shown to affect verbal working memory (Burgio & Basso, 1997; De Renzi & Nichelli, 1975). This cannot be taken to necessarily imply that verbal working memory is a function of the core language network. For example, as noted, input to the storage component of the phonological loop theoretically depends on a functioning language system while not participating in core language processes such as speech perception and speech production. Thus, the association between language disturbances and verbal working memory impairment does not prove that the two systems are functionally equivalent.

This is especially true in light of evidence from neuropsychology showing that verbal short-term memory impairment need not accompany a basic impairment to the language faculty. An interpretation consistent with the phonological loop model of verbal working memory is that a selective deficit to verbal short-term memory is caused by lesions that have damaged the phonological store while leaving language perception and production centers intact. Moreover, these patients offer credence to the conceptualization of memory, exemplified by the phonological loop, as a distinct entity in its own right, whose functional purpose is to store and maintain information in mind, rather than to analyze and process incoming sensory input. Although

the evidence for such a functional dissociation on the basis of these “short-term memory patients” is intriguing and compelling, the anatomical localization of these lesions presents cognitive neuroscience with a difficult puzzle.

With respect to the “short-term memory patient,” the critical question from the standpoint of cognitive neuroscience is how a lesion in the middle of the perisylvian speech center encompassing the temporoparietal area could produce such a pure short-term memory deficit without any collateral impairment in basic online language functioning. One possibility is that the precise location of the brain injury is determinative, so that a particularly focal and well-placed lesion in temporoparietal cortex might spare cortex critical for speech perception and speech production while damaging a region dedicated to the temporary storage of auditory-verbal information. The number of patients described with a selective impairment to auditory-verbal short-term memory is small, however, and the lesion locations that have been reported are not clearly distinguishable from those that might, in another patient, have led to conduction or Wernicke’s aphasia (Baldo & Dronkers, 2006; Damasio, 1992; Goodglass, 1993). This would seem to be a question particularly well-suited for high-resolution functional neuroimaging.

69.8 FUNCTIONAL NEUROIMAGING INVESTIGATIONS OF VERBAL WORKING MEMORY

The first study that attempted to localize the components of phonological loop in the brain was that of Paulesu and colleagues (1993). In one task, English letters were visually presented on a monitor and subjects were asked to remember them. In a second task, letters were presented and rhyming judgments were made about them (press a button if letter rhymes with “B”). In a baseline condition, Korean letters were visually presented and subjects were asked to remember them using a visual code. According to the authors’ logic, the first task would require the contribution of all the components of the phonological loop—subvocal rehearsal, phonological storage, and executive processes—whereas the second (rhyming) task would only require subvocal rehearsal and executive processes. This reasoning was based on previous research showing that when letters are presented visually (Vallar & Baddeley, 1984), rhyming decisions engage the subvocal rehearsal system, but not the phonological store. Thus, a subtraction of the rhyming condition from the letter-rehearsal condition should isolate the neural locus of the phonological store. First,

results were presented for the two tasks requiring phonological processing with the baseline tasks (viewing Korean letters) that did not. Several areas were shown to be significantly more active in the “phonological” tasks, including (in all cases, bilaterally) Broca’s area (BA 44/45), the supplementary motor cortex (SMA), the insula, the cerebellum, Brodmann area 22/42, and Brodmann area 40. Subtracting the rhyming condition from the phonological short-term memory condition left a single brain area, Brodmann area 40, which is the neural correlate of the phonological store.

The articulatory rehearsal process recruited a distributed neural circuit that included the inferior frontal gyrus, cerebellum, supplementary motor area, and premotor cortex. Activation of multiple brain regions during articulatory rehearsal is not surprising given the complexity of the process and the variety of lesion sites associated with a speech production deficit. However, the localization of the phonological store in a single brain region, BA 40 (or the supramarginal gyrus of the parietal lobe), fit well with the idea of a “receptacle” where phonological information is temporarily stored. A number of follow-up positron emission tomography (PET) studies using various tasks and design logic generally replicated the basic finding of the Paulesu et al. study, namely, a fronto-insular-cerebellar network associated with rehearsal processes and a parietal locus for the phonological store (Awh et al., 1996; Jonides et al., 1998; Salmon et al., 1996; Schumacher et al., 1996; Smith & Jonides, 1999). Early PET studies of verbal working memory were interpreted as broadly supporting the architecture of the phonological loop, with storage being subserved by a left parietal lobe structure outside the core language network and articulatory rehearsal associated with regions known to be involved in motor speech planning.

In a trenchant review of these initial PET investigations of verbal working memory work, however, Becker, MacAndrew, and Fiez (1999) questioned whether the localization of the phonological store in the left parietal cortex could be reconciled with the logical architecture of the phonological loop. For instance, as reviewed, a key element of the phonological loop model is that auditory information (whether it be speech, tones, music, or white noise), but not visual information, has *obligatory access* to the phonological store. The reason for this difference is to account for dissociations in memory performance that depend on the modality in which information is presented. For instance, the presentation of distracting auditory information while subjects attempt to retain a list of verbal items in memory impairs performance on tests of recall. In contrast, the presentation of distracting visual information during verbal memory retention has no impact on verbal recall.

This phenomenon—the irrelevant sound effect—is explained by assuming that auditory information always enters the phonological store, but that visual–verbal information only enters the store when it is explicitly subvocalized. Becker et al., however, argued that if auditory information has automatic access to the phonological store, then its “neural correlate” should be active even during *passive auditory perception*. Functional neuroimaging studies of passive auditory listening (e.g., with no memory component), however, do not show activity in the region of the parietal that had been associated in previous studies with phonological storage, but rather show activation that is largely confined to the superior temporal lobe (Binder et al., 2000).

A second difficulty with a parietal locus of the phonological store is that efforts to show verbal mnemonic specificity to maintenance-related activity in the parietal lobe have not been successful (Chein, Ravizza, & Fiez, 2003). Instead, it has been shown that working memory for words, visual objects, and spatial locations all activate the area (Badre, Poldrack, Pare-Blagoev, Insler, & Wagner, 2005; Niendam et al., 2012; Nystrom et al., 2000; Zurowski et al., 2002). Thus, if there were a perfect “neural correlate” of the phonological store, then it must reside within the confines of the auditory cortical zone of the superior temporal cortex.

69.9 EVENT-RELATED fMRI STUDIES OF VERBAL AND AUDITORY WORKING MEMORY

Studies using event-related functional magnetic resonance imaging (fMRI), with its ability to isolate delay-period activity during working memory, have greatly improved our understanding of the neural circuitry associated with verbal working memory maintenance. Postle, Berger, and D’Esposito (1999) showed, with visual–verbal presentation of letter stimuli, that delay-period activity in single subjects was often localized in the posterior superior temporal cortex rather than the parietal lobe that was typically identified in the early PET studies reviewed here. Buchsbaum, Hickok, and Humphries (2001) also used an event-related fMRI paradigm in which, during each trial, subjects were presented with acoustic speech information that they then rehearsed subvocally for 27 s, followed by a rest period. Analysis focused on identifying regions that were responsive *both* during the perceptual phase and the rehearsal phase of the trial. Activation occurred in two regions in the posterior superior temporal cortex, one in the posterior superior temporal sulcus (STS) bilaterally and one along the dorsal surface of the left posterior planum temporale, that is, in the Sylvian fissure at the parietal-temporal boundary (area “Spt”). Notably, whereas the parietal lobe did

show delay-period activity, it was unresponsive during auditory stimulus presentation. In a follow-up study, Hickok, Buchsbaum, Humphries, and Muftuler (2003) showed that the same superior temporal regions (posterior STS and Spt) were active both during the perception and delay-period maintenance of short (5 s) musical melodies, suggesting that these posterior temporal storage sites are not restricted to speech-based, or “phonological,” information (Figure 69.2).

Several subsequent studies have confirmed the role of Spt in internal rehearsal of musical and speech sequences (Hashimoto, Lee, Preus, McCarley, & Wible, 2010; Hickok, Okada, & Serences, 2009; Koelsch et al., 2009). Acheson, Hamidi, Binder, and Postle (2011) used fMRI to identify posterior temporal regions activated during verbal working memory maintenance, and then used repetitive transcranial magnetic stimulation (TMS) to these sites while subjects performed a rapid paced reading task that involved language production but no memory load. TMS applied to the posterior temporal area significantly interfered with paced reading, arguing for common neural substrate for language production and verbal working memory.

Stevens (2004) and Rama et al. (2004) have shown that memory for voice identity, independent of phonological content (i.e., matching speaker identity as opposed to word identity), selectively activates the mid-STS and the anterior STG of the superior temporal region, but not the more posterior and dorsally situated Spt region. Buchsbaum, Olsen, Koch, and Berman (2005) have further shown that the mid-STS is more active when subjects recall verbal information that is acoustically presented than when the information is visually presented, whereas area Spt shows equally strong delay-period activity for both auditory and visual forms of input (Hashimoto et al., 2010). This finding is supported by regional analyses of structural magnetic resonance imaging (MRI) in large groups of patients with brain lesions that have showed that damage to the STG is most predictive of auditory short-term memory impairment (Koenigs et al., 2011; Leff et al., 2009). Leung and Alain (2011) have also shown dissociation between auditory object and spatial working memory, with the former activating more ventral stream auditory areas and the latter activating the dorsal parietal lobe. Thus, it appears that different regions in the temporoparietal area are attuned to different qualities or features of a verbal stimulus, such as voice information, input modality, phonological content, spatial location, and lexical status (Martin & Freedman, 2001); all of these codes may play a role in the short-term maintenance of verbal information.

Additional support for a feature-based topography of auditory association cortex comes from neuroanatomical tract-tracing studies in both monkeys and

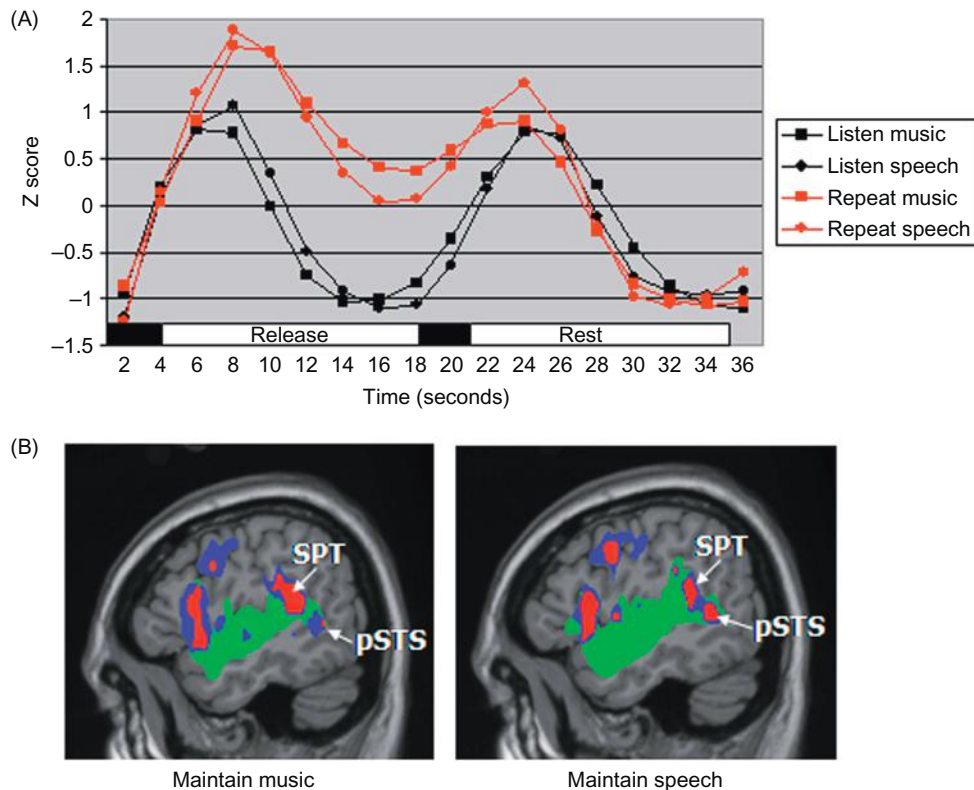

FIGURE 69.2 Main results from the Hickok et al. (2003) study of verbal and musical working memory maintenance. (A) Averaged time-course of activation over the course of a trial in area Spt for speech and music conditions. Timeline at the bottom shows the structure of each trial; black bars indicate auditory stimulus presentation. Red traces indicate activation during rehearsal trials, and black traces indicate activity during listen-only trials in which subjects did not rehearse stimuli at all. (B) Activation maps of the left hemisphere (sagittal slices) showing three response patterns for both music rehearsal (left) and speech rehearsal trials (right): auditory-only responses shown in green; delay-period responses shown in blue; and auditory + rehearsal responses shown in red. Arrows indicate the location of area Spt.

humans that have revealed separate temporo-prefrontal pathways arising along the anterior-posterior axis of the superior temporal region (Bavelier et al., 1998; Rauschecker, 2011; Romanski, 2004; Romanski et al., 1999; Saur et al., 2008). The posterior part of the STG projects to dorsolateral PFC (BA 46, 8), whereas neurons in the anterior STG are more strongly connected to the ventral PFC, including BA 12 and 47. Several authors have suggested, similar to the visual system, a dichotomy between ventral-going auditory-object and a dorsal-going auditory-spatial processing streams (Arnott, Binns, Grady, & Alain, 2004; Rauschecker & Tian, 2000; Tian, Reser, Durham, Kustov, & Rauschecker, 2001). Thus, studies have shown that the neurons in the rostral STG show more selective responses to classes of complex sounds, such as vocalizations, whereas more caudally located regions show more spatial selectivity (Chevillet, Riesenhuber, & Rauschecker, 2011; Rauschecker & Tian, 2000; Tian et al., 2001).

Hickok and Poeppel (2007) have proposed that human speech processing also proceeds along diverging auditory dorsal and ventral streams, although they

emphasize the distinction between perception for action, or auditory-motor integration, in the dorsal stream and perception for comprehension in the ventral stream. Buchsbaum et al. (2005) has shown with fMRI time series data that, consistent with the monkey connectivity patterns, the most posterior and dorsal part of the superior temporal cortex, area Spt, shows the strongest functional connectivity with dorsolateral and posterior (premotor) parts of the PFC, whereas the mid portion of the STS is most tightly coupled with BA 12 and BA 47 of the ventrolateral PFC (Figure 69.3). Moreover, gross distinctions between anterior (BA 47) and posterior (BA 44/6), parts of the PFC have been associated with conceptual-semantic and phonological-articulatory aspects of verbal processing (Poldrack et al., 1999; Wagner, Pare-Blagoev, Clark, & Poldrack, 2001). The fMRI studies have also shown that maintenance of verbal-semantic information relies to a greater extent on the anteroventral aspects of the temporal lobe than does maintenance of phonological information (e.g., nonword sequences; Fiebach, Rissman, & D'Esposito, 2006; Shivde & Thompson-Schill, 2004).

FIGURE 69.3 Map of functional connectivity delay period maintenance of verbal stimuli from Buchsbaum et al. (2005). Seed regions for correlation analysis are denoted by stars located in area Spt and the middle part of the STS. Warm (red, orange, and yellow) colors show areas more strongly correlated with Spt than with STS; cold (blue and green) colors show areas more strongly correlated with STS than Spt. Inset shows temporal-prefrontal connectivity in the monkey (Romanski et al., 1999).

Taken together, findings from functional neuroimaging have shown that the maintenance of verbal information in working memory relies on a distributed network of primarily frontal, temporal, and parietal brain regions. The particular topography of activation depends on the content matter of the to-be-remembered stimuli and/or current task goals. Moreover, activation patterns during memory for musical or tonal sequences overlap considerably with that for phonological sequences. There does not appear to be a single brain region where verbal information is passively stored, as would be predicted by the phonological loop model. Rather, it seems that short-term mnemonic storage is embedded in the very neural structures that support the auditory-verbal perception and production, and that these areas comprise a distributed fronto-temporo-parietal network.

69.10 RECONCILING NEUROPSYCHOLOGICAL AND FUNCTIONAL NEUROIMAGING DATA

The question regarding how a lesion in posterior Sylvian cortex, an area of known importance for online language processing, could occasionally produce an impairment restricted to phonological short-term memory has been posed previously. One solution to this puzzle is that subjects with selective verbal short-term memory deficits from temporo-parietal lesions

retain their perceptual and comprehension abilities due to the sparing of the ventral stream pathways in the lateral temporal cortex, whereas the preservation of speech production is due to an unusual capacity in these subjects for right-hemisphere control of speech (Buchsbaum & D'Esposito, 2008; Hickok & Poeppel, 2004; Nadeau, 2001). The short-term memory deficit arises from a selective deficit in auditory-motor integration—or the ability to translate between acoustic and articulatory speech codes—a function that is especially taxed during tests of repetition and short-term memory (Buchsbaum & D'Esposito, 2008). Conduction aphasia, the aphasic syndrome most often associated with a deficit in auditory repetition and verbal short-term memory in the absence of any difficulty with speech perception, may reflect a disorder of auditory-motor integration. It has recently been shown that the lesion site most often implicated in conduction aphasia circumscribes area Spt in the posteriormost portion of the superior temporal lobe, and is a link between a disorder of verbal repetition and a region in the brain often implicated in tasks of verbal working memory (Buchsbaum et al., 2011; see Figure 69.4). Thus, impairment in the ability to temporarily store verbal information, as occurs in conduction aphasia, may result from damage to a system, area Spt, which is critical for the interfacing of auditory and motor representations of sound.

69.11 SUMMARY AND CONCLUSION

Elucidation of the cognitive and neural architectures underlying verbal working memory has been an important focus of neuroscience research for much of the past two decades. The emergence of the concept of working memory, with its emphasis on the utilization of the information stored in memory in the service of behavioral goals, has enlarged our understanding and broadened the scope of neuroscience research of short-term memory. Data from numerous studies have been reviewed and have demonstrated that a network of brain regions, principally in the temporal and frontal lobes, is critical for the active maintenance of internal verbal representations. It is clear from these investigations that verbal memory cannot be localized to a single brain region, but rather it is an emergent property of the functional interactions between the frontal and posterior neocortical regions. Numerous questions remain about the neural basis of this complex cognitive system, but studies such as those reviewed in this chapter should continue to provide converging evidence that may provide answers to the many residual questions.

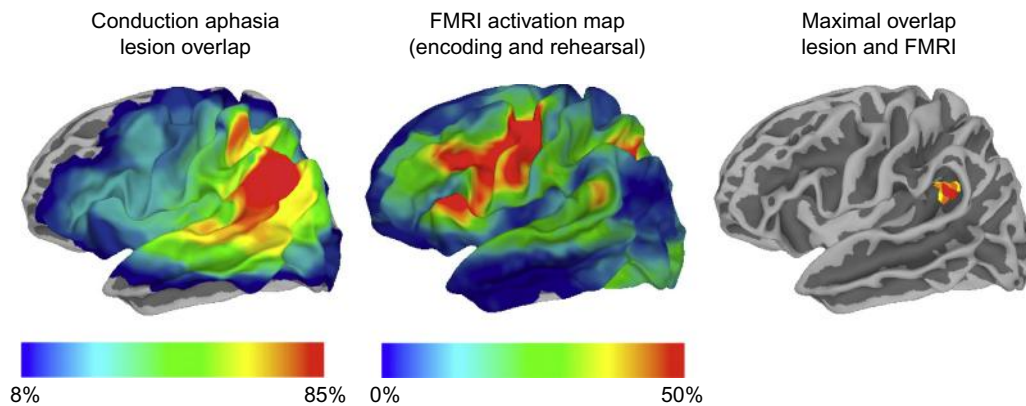

FIGURE 69.4 A comparison of conduction aphasia, phonological working memory in fMRI, and their overlap. The leftmost panel surface shows the regional distribution lesion overlap in patients with conduction aphasia (max is 12/14 or 85% overlap). Middle panel shows the percentage of subjects showing maintenance-related activity in a phonological working memory task. The right panel shows the area of maximal overlap between the lesion and fMRI surfaces (lesion >85% overlap and significant fMRI activity for conjunction of encoding and rehearsal).

Language Development in Autism

Morton Ann Gernsbacher¹, Emily M. Morson² and Elizabeth J. Grace³

¹Psychology, University of Wisconsin-Madison, Madison, WI, USA; ²Psychology and Neuroscience, Indiana University, Bloomington, IN, USA; ³Special Education, National Louis University, Chicago, IL, USA

The diagnostic criteria for autism in the American Psychiatric Association's (APA) most recent *Diagnostic and Statistical Manual* (APA, 2013) are mute regarding language development. Instead, the most recent diagnostic criteria mention only aspects of sociocultural communication, such as eye contact, facial expressions, or hand gestures. Language itself—the perception and production of speech or writing—is not referenced, and neither is language development.

In contrast, more than 30 years ago, when autism first appeared in the *Diagnostic and Statistical Manual* (APA, 1980), “gross deficits in language development” were considered so dispositive of the autistic phenotype that this diagnostic criterion not only was required but also was one of only a few criteria (Gernsbacher, Dawson, & Goldsmith, 2005; Gernsbacher, Geye, & Ellis Weismer, 2005). Seven years later, the focus moved away from how language developed to how language was produced. “Marked abnormalities in the production of speech, including volume, pitch, stress, rate, rhythm, and intonation” and “marked abnormalities in the form or content of speech, including stereotyped and repetitive use of speech” appeared as diagnostic criteria. However, these two criteria were among more than a dozen other criteria, and they need not be met to warrant a diagnosis (APA, 1987).

Another 7 years passed, and language development recurred in the diagnostic criteria (“delay in, or total lack of, the development of spoken language”), but again as only one of numerous criteria for which only a subset needed to be met (APA, 1994, 2000). Thus, abnormal language development at one time defined autism and then became an optional means for making a diagnosis. Now, it no longer figures into contemporary diagnostic criteria.

In this chapter, we review recent empirical research on language development in autism. To paint a

contemporary picture, we restrict our review to studies published in the twenty-first century. We conclude that language development in autism is often delayed, but not deviant; that a delay in language development is not unique to autism; and that language development in autism is remarkably heterogeneous and variable.

70.1 DELAY IN AUTISTIC LANGUAGE DEVELOPMENT

Many studies that have measured language abilities at one discrete point in time have suggested that autistic language development is delayed compared with typical language development. The most consistently reported delays are in producing and expressing language, what is often referred to as productive or expressive language. For example, autistic children have been reported to be delayed in speaking their first words (Charman, Drew, Baird, & Baird, 2003; Matson, Mahan, Kozlowski, & Shoemaker, 2010), speaking their first phrases (e.g., *blue car*, Grandgeorge et al., 2009; Kenworthy et al., 2012; Pry, Peterson, & Baghdadli, 2011), and speaking their first grammatical utterances (e.g., *go bye-bye*) or sentences (Anderson et al., 2007; Wodka, Mathy, & Kalb, 2013).

Therefore, studies that have measured the size of young, autistic children's expressive vocabularies at specific points during development have often reported that young, autistic children have smaller expressive vocabularies than typically developing children of the same age (Charman et al., 2003; Fulton & D'Entremont, 2013; Kover, McDuffie, Hagerman, & Abbeduto, 2013; Luyster, Kadlec, Carter, & Tager-Flusberg, 2008; Luyster, Lopez, & Lord, 2007; Miniscalco, Fränberg, Schachinger-Lorentzon, & Gillberg, 2012; Sandercock, 2013; Stone & Yoder, 2001).

Other studies that have examined other expressive language skills, for instance, expressing relations such as big and little, correctly producing grammatical morphemes for plurals and verb tenses, and using rising intonation when asking questions, have also reported that autistic children are less skilled than typically developing children (Fulton & D'Entremont, 2013; Hudry et al., 2010; Sigman & McGovern, 2005; Sutura et al., 2007; Vanvuchelen, Roeyers, & DeWeerd, 2011; Walton & Ingersoll, 2013).

That young, autistic children are often characterized by smaller expressive vocabularies should be of little surprise given that delays in the number of words and phrases children are saying are some of the most notable 'red flags' for autism (Baird, Cass, & Slonims, 2003; Filipek et al., 1999). Delays in early expressive language are also the primary concern that motivates parents to seek diagnostic evaluation of their children (Agin, 2004).

Regarding receptive language (the ability to understand language rather than produce it), reliable measurements are more difficult to obtain, particularly for very young children. Consequently, valid conclusions are more difficult to draw. One problem is that measuring receptive language in young children often relies heavily on parent report measures, such as the MacArthur-Bates Communicative Development Inventory (Fenson et al., 1993, 2007), which asks parents to check-off which of a list of words or phrases the parents believe their children can understand.

There are multiple reasons why parents might misestimate the number of words that their children understand (Feldman et al., 2000); for children who respond atypically, such misestimates are more likely (Akhtar & Gernsbacher, 2007, 2008; Bruckner, Yoder, Stone, & Saylor, 2007). Nonetheless, many studies using the MacArthur-Bates Communicative Development Inventory have reported that young, autistic children are delayed in their receptive language development (Charman et al., 2003; Fulton & D'Entremont, 2013; Luyster et al., 2008, 2007; Maljaars, Noens, Scholte, & Van Berckelaer-Onnes, 2012; Miniscalco et al., 2012; Paul, Chawarska, Cicchetti, & Volkmar, 2008; Paul, Chawarska, Fowler, Cicchetti, & Volkmar, 2007; Vanvuchelen et al., 2011).

Using more objective measures, other studies have also reported that autistic children are delayed in their receptive language development. These studies have used standardized assessments, such as the Reynell Language Development scale (RLDS: Miniscalco et al., 2012; Reynell & Gruber, 1990; Vanvuchelen et al., 2011), the Peabody Picture Vocabulary Test or British Picture Vocabulary Scale (PPVT: Dunn & Dunn, 1997; BPVS: Dunn, Dunn, Whetton, & Burley, 1997; Grigorenko et al., 2002; Howlin, 2003; Kover et al., 2013), the Clinical Evaluations of

Language Fundamentals (Aman et al., 2004; CELF: Semel, Wiig, & Secord, 1992, 1995, 2000, 2006; Sigman & McGovern, 2005; Wisdom, Dyck, Piek, Hay, & Hallmayer, 2007), the Mullen Scale of Early Learning (Luyster et al., 2008; MSEL: Mullen, 1995; Sutura et al., 2007; Swensen, Kelley, Fein, & Naigles, 2007), the Preschool Language Scale (Hudry et al., 2010; Jasmin et al., 2009; Walton & Ingersoll, 2013; PLS: Zimmerman, Steiner, & Pond, 1992, 2002), or the Psychoeducational Profile-3 (Fulton & D'Entremont, 2013; PEP-3: Schopler, Lansing, Reichler, & Marcus, 2005).

However, other studies that have also measured language abilities at one discrete point in time have not shown that autistic language development differed from typical language development. For example, autistic toddlers were not reported to differ from typically developing toddlers in the number of words that they produced (Goodwin, Fein, & Naigles, 2012); autistic teenagers did not differ from typically developing teenagers in the number of words that they understood (Åsberg, 2010; Henderson, Clarke, & Snowling, 2011; Paul, Augustyn, Klin, & Volkmar, 2005); and autistic children, teens, and adults did not differ from typically developing participants in the quality or quantity of their written language production, be it number of words, length of words, length of sentences, or complexity of sentences (Troyb, 2011).

To summarize, several contemporary studies have suggested that autistic language development is delayed compared with typical language development. These studies have suggested delays in both expressive (producing) language and receptive (understanding) language. However, other studies have not shown that autistic language development is delayed compared with typical language development. Thus, delayed language development is a common, but not a universal, characteristic of autism. In fact, there is good evidence that language develops independently from autistic traits. For example, in a recent large-scale study involving 3,000 pairs of twins, amount of language development was both phenotypically and genetically unrelated to degree of autistic traits (so-called severity; Taylor et al., 2014). The empirically demonstrated independence between language and autism underlies not only the variability in research findings but also the variability in autistic language development.

70.2 HETEROGENEITY AND VARIABILITY IN AUTISTIC LANGUAGE DEVELOPMENT

Several studies have reported observing language delays in some subgroups of autistic participants but not in others (Kjelgaard & Tager-Flusberg, 2001).

For example, the majority of a sample of autistic children achieved normative size expressive vocabularies, but 15% of that sample were delayed between one and two standard deviations below normal (Jones & Schwartz, 2009). Most of a sample of autistic teenagers did not differ from a sample of typically developing teenagers in their ability to read, but one-third of the sample did (Åsberg & Dahlgren Sandberg, 2012). Half of a sample of autistic children and teenagers produced scores on the BPVS in the average range, but one-quarter of the sample performed one to two standard deviations below average, and another one-quarter of the sample performed more than two standard deviations above average (McCann, Peppé, Gibbon, O'Hare, & Rutherford, 2005).

Autistic language development often demonstrates extreme variability. For example, in a large sample of autistic toddlers with a wide range of reported IQ scores, more than three-fourths of the sample had spoken their first words before 18 months, which is within the range of typical development. However, a bit more than 5% of the sample had still not spoken their first words at 6 years of age (Wilson et al., 2003), which is far beyond the range of typical development. In two large samples of autistic preschool-age children, some children scored 2 years below age level on measures of expressive and receptive language, whereas other children scored nearly 2 years above age level (Fulton & D'Entremont, 2013; Hudry et al., 2010).

In a sample of autistic children and teenagers whose receptive vocabulary was, on average, in the normal range, some autistic children scored as low as four standard deviations below normal, whereas other autistic children scored as high as two standard deviations above normal (Nation, Clarke, Wright, & Williams, 2006). Similarly, in a sample of autistic preschool-age children, their receptive vocabulary ranged from four standard deviations below normal to two standard deviations above normal (Jasmin et al., 2009). In a sample of autistic school-age children, their expressive vocabulary also ranged from four standard deviations below normal to two standard deviations above normal (Joseph, McGrath, & Tager-Flusberg, 2005). In a sample of autistic teens, their reading vocabulary ranged from three standard deviations below normal to one standard deviation above normal (Ricketts, Jones, Happé, & Charman, 2013).

To summarize, several studies have reported observing language delays in some subgroups of autistic participants but not others; autistic language development often demonstrates extreme variability. In large samples of autistic participants, it is not unusual to find scores on various language measures that range from as low as two standard deviations below the norm to as high as two standard deviations above the norm.

70.3 TRAJECTORIES OF LANGUAGE DEVELOPMENT

Within the first few years of life, autistic children's language development trajectories have been reported to be flatter than that of typically developing children (or children with other developmental disabilities; Landa & Garrett-Mayer, 2006). However, examining development over a longer period of time sometimes shows that autistic language development trajectories can subsequently become steeper. After an initial delay, there was accelerated growth.

For example, autistic boys of grade-school age began with lower receptive, expressive, and overall language skills than typically developing boys. However, over a 9-year period, the autistic boys' language skills improved, on average, by 10% per year, whereas the typically developing boys' language skills improved by only 1.6% per year (Cariello et al., 2011). Autistic children's language development continued on an upward trajectory at age 9, whereas nonautistic children, who were characterized by other types of atypical development, began to plateau (Anderson et al., 2007).

Vocabulary development continued to improve through adulthood for a sample of autistic adults first studied during grade school and followed-up in their early 20s; however, for a comparable sample of adults with language impairment, vocabulary development stagnated (Mawhood, Howlin, & Rutter, 2000). A steeper trajectory of language development is, of course, expected if the starting point is low—but only if the final measurement point also indicates improvement.

Figure 70.1 (modified from data reported by Dockrell, Ricketts, Palikara, Charman, & Lindsay, 2010) illustrates the growth of expressive language (Figure 70.1A) and receptive language (Figure 70.1B) during a 4-year period for a sample of more than 100 autistic children of grade-school age. Illustrated along with the autistic grade-school children is a matched sample of more than 200 grade-school children who were not autistic but had language disabilities. The data presented are the two groups' performances on expressive and receptive measures from the Clinical Evaluation of Language Fundamentals (Semel et al., 2006), presented in z-scores, based on a norms-based mean of zero and a norms-based standard deviation of one.

As Figure 70.1 illustrates, the older the autistic grade-school children, the better their expressive and receptive language skills. In contrast, for the language-disabled children who were not autistic, neither their expressive nor their receptive language skills improved with age. Although these data are cross-sectional, they represent a steep trajectory of increasing language development for the autistic children, such

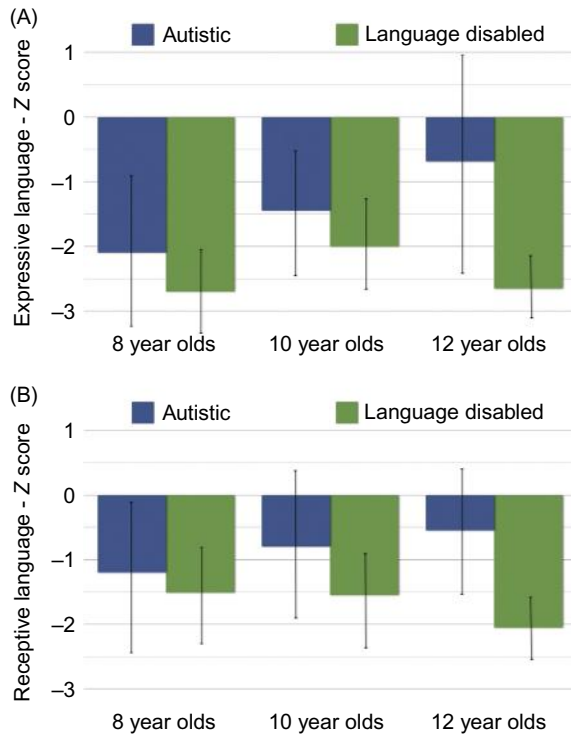

FIGURE 70.1 Growth of expressive language (A) and receptive language (B) during a 4-year period for a sample of more than 100 autistic children of grade-school age. Modified from data reported by Dockrell et al. (2010) with permission from the publisher.

that by the end point of measurement the autistic children's language skills did not differ from normal.

However, trajectories of language development in autism, similar to static measures of language ability in autism, show great individual variability. Figure 70.2 (modified from data reported by Smith, Mirenda, & Zaidman-Zait, 2007) illustrates individual trajectories in expressive vocabulary development for 35 autistic preschool-age children. Each child was assessed (by the MacArthur-Bates Communicative Development Inventory, Fenson et al., 1993) at four time points over a 24-month period. Although children were enrolled into the study only if their expressive vocabulary was less than 60 words, the children showed a wide range of vocabulary growth over the subsequent 2-year period, as Figure 70.2 demonstrates.

Some children, indicated by blue lines in Figure 70.2, showed a steep rate of expressive vocabulary development, with expressive vocabularies of nearly 700 words at the last time point. Other children, indicated by green lines in Figure 70.2, showed a steady increase in vocabulary development, with expressive vocabularies of 400 to a bit more than 600 words at the last time point. Still other children, indicated by gold lines in Figure 70.2, showed a slow increase in vocabulary development. The remaining children,

FIGURE 70.2 Individual trajectories in expressive vocabulary development for 35 autistic preschool-age children. Modified from data reported by Smith et al. (2007) with permission from the publisher.

indicated by red lines, showed a flat rate of vocabulary development, with little change in the number of words they produced over the 2-year period.

The four color-coded clusters illustrated in Figure 70.2 were produced via statistical cluster analysis (Smith et al., 2007) based on the trajectory of the individual children's vocabulary development. However, the average age of the children within each of the four clusters did not differ; neither did their level of cognitive development nor their degree of autistic traits. Most markedly, all children were undergoing the same therapy. Therefore, these data show just how variable the course of language development can be for autistic children, even when the children are all receiving 15–20 h per week of early behavioral intervention, including speech-language therapy.

Very few studies of autistic language development have followed participants through adulthood; indeed, very few studies have followed autistic participants into adulthood at all regarding any type of development (Dawson, Mottron, & Gernsbacher, 2008). However, one of the few longitudinal studies that has extended through adulthood followed 29 autistic adults who had marked language delays in childhood and 35 autistic adults who did not. In adulthood, the two groups did not differ in either their expressive or their receptive vocabulary (Howlin, 2003).

To summarize, within the first few years of life, autistic children's language development trajectories have been reported to be flatter than that of typically developing children (or children with other developmental disabilities); however, examining development over a longer period of time sometimes shows that autistic language development trajectories can also be steeper. After an initial delay, there is accelerated growth. However, trajectories of language development in autism, similar to static measures of language ability in autism, show great individual variability.

70.4 LANGUAGE DELAY VERSUS LANGUAGE DEVIANCE

Evidence suggests that language development can be delayed in autism, but is it deviant? Does it proceed in the same general sequence? Are there qualitative differences? Most studies that have investigated specific nuances of language development, rather than gross measures on standardized tests, have suggested that autistic children's language development proceeds in the same order and is qualitatively similar in its developmental course to the language development of nonautistic children at the same stages of development.

For example, although autistic toddlers and preschool-age children might understand fewer words than age-matched typically developing children, when compared with younger, typically developing children with the same size vocabulary, autistic children's receptive vocabularies contain the same relative proportion of words from different grammatical categories (e.g., nouns, verbs, pronouns, and the like) and the same relative proportion of words from various semantic categories (e.g., people, games and routines, body parts, sound effects, and the like; [Charman et al., 2003](#)).

Similarly, although autistic toddlers and preschool-age children might produce fewer words than age-matched typically developing children, when compared with younger, typically developing children with the same vocabulary size, there is substantial overlap in autistic and typically developing children's most frequently spoken words ([Wicklund, 2012](#)). When autistic toddlers are compared with nonautistic toddlers with delays in their language development ("late talkers"), the two groups are just as likely to produce words from a range of grammatical and semantic categories, including emotion terms, and the autistic toddlers do not differ from the nonautistic late talkers in the complexity of their grammatical utterances ([Ellis Weismer et al., 2011](#)).

When autistic preschool-age children are compared with nonautistic preschool-age children who have other developmental disabilities, the autistic children do not differ from the nonautistic children in their correct production of noun phrases, sentence structures, plurals, singulars, or past-tense inflections ([Park, Yelland, Taffe, & Gray, 2012](#)).

Norbury and colleagues have demonstrated in several studies that when compared with nonautistic children of grade-school age, autistic children do not differ from nonautistic children in their sequential achievement of a variety of language comprehension processes. For instance, autistic children of grade-school age acquire the understanding of idioms (e.g., "it's raining cats and dogs") at the same time as language

ability-matched nonautistic children do ([Norbury, 2004](#); see also [Gernsbacher & Pripas-Kapit, 2012](#)).

Autistic children acquire the understanding of metaphors (e.g., "[Because] John spent too long in the swimming pool, he was a prune") at the same time as language ability-matched nonautistic children ([Norbury, 2005b](#)). Autistic children acquire the ability to draw inferences from stories ([Norbury & Bishop, 2002](#); see also [Young, Diehl, Morris, Hyman, & Bennetto, 2005](#)), negotiate ambiguities in language ([Norbury, 2005a](#)), and structure the stories that they tell ([Norbury & Bishop, 2003](#)) at the same time as language-ability matched nonautistic children.

Norbury's studies also illustrate the independence between language development and autistic traits. In these studies, Norbury and colleagues typically assemble four participant groups: autistic children with language impairment; autistic children without language impairment; nonautistic children with language impairment; and nonautistic children without language impairment. By definition, the autistic participants differ from the nonautistic participants in their degree of autistic traits. For instance, in [Norbury's \(2005a\)](#) study, the difference in degree of autistic traits between the autistic and nonautistic participants is more than two standard deviations (which is beyond the effect size of the difference between average height of men versus women). Thus, the autistic children in these studies clearly have more autistic traits than the nonautistic children and most likely are "autistic enough."

However, in each of Norbury and colleagues' studies, it is the participants' degree of language impairment, not their degree of autistic traits, that predicts their ability to understand idioms ([Norbury, 2004](#)), understand metaphors ([Norbury, 2005b](#)), draw inferences from stories ([Norbury & Bishop, 2002](#)), negotiate ambiguities in language ([Norbury, 2005a](#)), and structure stories that they tell ([Norbury & Bishop, 2003](#)). Thus, autistic children do not differ from language-matched nonautistic children in their sequential achievement of important language comprehension processes.

Historically it was assumed that unusual, perhaps aberrant, features of language development characterized autism, such as echolalia (repeating words and expressions verbatim) and pronoun reversal (using *you* when *I* is intended). More recently, some researchers have suggested another aberrant feature might characterize autistic language development. Expressive language might proceed abnormally ahead of receptive language (i.e., autistic children say more than they understand). However, none of these putatively aberrant characteristics are empirically reliable or universal among autistic children, as [Gernsbacher, Morson, and Grace \(in press\)](#) recently argued.

Another characteristic of autistic language development that is sometimes assumed to be specific to autism is regression, or loss, of language skills. Unfortunately, codifying language loss is complicated (is it a consistent loss or a fluctuating loss?), and measuring language loss is difficult, particularly if measurements are not taken prospectively (Lord, Shulman, & DiLavore, 2004). Despite classification and measurement difficulties, two patterns appear to be consistent in the data on autistic language loss.

First, autistic children who seemed to lose language are those whose early language was developing on time or with little delay (Baird et al., 2008; Pickles et al., 2009). For example, autistic toddlers who were coded as having lost language had produced their first words at approximately 1 year of age, whereas autistic toddlers who were not coded as having lost language had not produced their first words until 2 years of age (Pickles et al., 2009).

Second, autistic children who seemed to lose language do not progress as quickly in subsequent language development as autistic children who do not seem to lose language. For example, at age 6, many of the autistic children who seemed to lose language earlier were still using single words, whereas other autistic children had advanced to producing sentences (Bernabei, Cerquiglini, Cortesi, & D'Ardia, 2007).

To summarize, most studies that have investigated specific nuances of language development, rather than gross measures on standardized tests, have suggested that autistic children's language development proceeds in the same order and is qualitatively similar in its developmental course to the language development of nonautistic children at the same stages of development. Although it has been assumed that aberrant features of language development characterize autism, such as echolalia and pronoun reversal, neither these features nor language loss is unique to autism.

Symptoms and Neurobiological Models of Language in Schizophrenia

Arne Nagels and Tilo Kircher

Department of Psychiatry and Psychotherapy, Philipps University Marburg, Marburg, Germany

71.1 INTRODUCTION

Schizophrenia is a common, severe, and complex mental disorder that affects approximately 1% of the population worldwide (Sawa & Snyder, 2002), irrespective of cultural background. The course of disease differs among patients; however, symptoms usually first occur in young adulthood (20–30 years). Before the acute onset of the disorder, patients experience a subclinical prodromal phase, lasting from weeks to years, comprising cognitive impairments, depression, subclinical psychotic symptoms, and psychosocial impairments. The diagnosis is made from interview-based clinical observations—the way in which patients communicate thoughts and emotions via language—often supplemented by third party reports. Overt organic causes, determined by physical examination, CT/MRI, blood and cerebrospinal fluid tests, or drug intoxication have to be absent. The course of illness varies widely between individuals, ranging from one single episode lasting a couple of weeks to episodic (e.g., a few episodes in a lifetime with symptoms present for several weeks with complete or partial remission) and severe, primary chronic, detrimental courses (patient lives in supported housing and work, dependent on social welfare). Treatment consists of antipsychotic medication, psychoeducation, cognitive behavioral psychotherapy, and social support, tailored to the individual needs of the patient.

Schizophrenia psychopathology can be subdivided into positive (e.g., delusions, hallucinations), negative (e.g., affective blunting, social withdrawal, anergia, laconic speech) and disorganized symptoms. The latter are reflected in disorganized behavior and/or incoherent, disorganized, or dysfluent speech patterns (e.g., thought interference, derailment), referred to as (positive)

formal thought disorder (FTD). Other language-related symptoms are auditory hallucinations—usually hearing the voices of other people—that are not covered in this chapter. Not all symptoms are present in all patients and the expression of a specific symptom in an individual also varies over time. FTD represents a *hallmark syndrome* playing a crucial role in the diagnosis of schizophrenia (DSM V, ICD 10). It is therefore not surprising that researchers with different backgrounds such as linguists, speech scientists, (neuro-)psychologists, psychiatrists, neuroscientists, and others are interested in the description and pathophysiology of the wide variety of language and speech impairments in these patients.

After more than a century of schizophrenia research, it has become clear that the interplay between genetic vulnerability and environmental risk factors contributes to the etiology of the disorder. The concordance rate of monozygotic twins, for instance, is approximately 50–80%, indicating a considerable influence of genetic predisposition. A number of risk genes have been identified, such as CACNA1C, NRG1, or MHC regions (each with a low odds ratio [OR] of approximately 1.2–1.6). Environmental risk factors further include high paternal age, pregnancy and birth complications, childhood maltreatment, urban upbringing, migration, and cannabis abuse. These risk factors lead—among others—to synaptic rarefaction and dysconnectivity, as well as to a neurotransmitter imbalance (particularly in the dopaminergic and glutamatergic system), giving rise to a vulnerable brain system. MRI brain volumetric investigations found reduced gray matter, most prominently in the frontal operculae, anterior cingulate cortex (ACC), and middle/superior lateral as well as medial temporal lobes. In addition, ventricular enlargements (Huber, 1955, 1961) as well as a dysconnection between brain areas—already

hypothetically postulated by Carl Wernicke (Wernicke, 1906)—are observed (Friston & Frith, 1995). These points are addressed in detail in the following sections.

Language-related dysfunctions in patients with schizophrenia can be observed throughout the different, multi-faceted domains of speech production and perception, ranging from basic auditory perception mechanisms (such as mismatch negativity [MMN]) to complex pragmatic information processing deficits (such as metaphors, jokes, irony, or Theory of Mind). Thus, relating language deficits to neural dysfunctions in a heterogeneous disorder is challenging and requires both reduction and abstraction. We therefore restrict our framework to the following premises. If available, we will focus on patients with (versus without) FTD. This approach controls for confounding factors such as general aspects of disease pathology and medication. Due to the complexity of the neural architecture of the language system, we will restrict ourselves primarily to “traditional” language-related brain regions (e.g., DLPFC, VLPFC, MTG, STG) and their connections, being aware that the neural network underlying human speech comprises multiple and widespread regions throughout the brain (e.g., corpus callosum, IPL, hippocampus, cerebellum, motor areas, subcortical loops). We further conceptualize schizophrenia—besides localized (focal) structural alterations—as a brain disconnection syndrome from synaptic to gross white matter levels.

Regarding specific linguistic domains, special consideration is given to neurobiological correlates of semantics and pragmatics while only briefly touching on the other domains such as acoustic perception, phonological processing, and syntax. First, we focus on the descriptive phenomenology of FTDs as well as on their structural and functional correlates (see Sections 71.2–71.4). Thereafter, results of a representative sample of studies on semantic impairments are discussed (see Section 71.5), whereupon we move to the superordinate level of pragmatic deficits (see Section 71.6). Dysfunctions on the phonological level as well as on the syntactic level are briefly referred to in Sections 71.7 and 71.8. Subsequently, we review neurobiological and molecular models of schizophrenia, relating them to language deficits and touching briefly on imaging genetics and pharmacological imaging approaches (Sections 71.9 and 71.10). Inversed language lateralization and functional asymmetries are summarized separately (Section 71.11).

71.2 PHENOMENOLOGY, ASSESSMENT, AND COURSE OF FORMAL THOUGHT AND LANGUAGE DISORDER

In patients with schizophrenia, impairments in the *production* of language and subjective alterations in the

thinking process are clinically referred to as FTD—a disorder in the *form* of thought and not the *content* (i.e., delusions). On a phenomenological level, severe positive FTD in schizophrenia is very similar to the speech of neurologically impaired patients with Wernicke’s aphasia (Faber et al., 1983) (e.g., *vagueness, looseness of associations, neologisms*, etc.) (Gerson, Benson, & Frazier, 1977).

One can distinguish positive from negative FTD. The latter mostly reflects a quantitative deficit in speech production (*poverty of speech, laconic speech, slowed thinking*) or a lack of ideas. Negative FTD, particularly *alogia*, are often seen in patients with chronic schizophrenia (McKenna & Oh, 2005). In contrast, positive FTD usually refers to a larger amount of produced speech (*logorrhea, pressure of speech*), loosening of associations, the use of new words (*neologisms*), or stilted speech (*manneristic speech*) phenomena. The total breakdown of language, referred to as *schizophrenia* or *word salad* typically occurs in acute states of the disease. In extremely rare cases, patients even use their own terminology, invented words, and novel morpho-syntactic constructions (new, private language), resulting in a largely or even entirely unintelligible speech.

FTD symptoms may vary markedly between patients and also during the individual course of illness, yet moderate consistency of FTD over time was also reported (Docherty, Cohen, Nienow, Dinzeo, & Dangelmaier, 2003). The presence of negative FTD may be predictive of a poor outcome (Andreasen & Grove, 1986).

Along with the introduction of operationalized diagnostic systems (the DSM III and ICD 10), the development of validated clinical rating scales for FTD took hold (Andreasen, 1986; Liddle et al., 2002; Parnas et al., 2005). An example is the Scale for the Assessment of Thought, Language, and Communication (Andreasen, 1986), translated and validated for German (Nagels et al., 2013), French (Bazin, Lefrere, Passerieux, Sarfati, & Hardy-Bayle, 2002), and Greek (Andreou et al., 2008). The existing rating instruments, however, did not consider subjectively reported FTD in patients that is the self-reported dysfunction in the production and perception of language and speech. For this purpose, a new comprehensive and nosologically open clinical rating scale for the comprehensive assessment of formal Thought and Language Dysfunctions (TALD), available in English and German, has been developed and validated (Kircher et al., 2014). The 30-item TALD scale, based on a clinical interview, has good psychometric properties and a four-dimensional structure of FTD symptoms, reflecting a positive and a negative factor as well as an objective and subjective dimension.

71.3 STRUCTURAL BRAIN CHANGES AND FTD

Regional cortical thinning in the frontal operculum and lateral temporal (language-related) cortices in patients with schizophrenia versus healthy subjects are consistent findings from structural MRI meta- and mega-analyses (Fusar-Poli, Radua, McGuire, & Borgwardt, 2012; Shepherd, Laurens, Matheson, Carr, & Green, 2012). Shenton et al. (1992) reported for the first time a relation between FTD and a reduction in grey matter volume of the posterior superior temporal region in schizophrenia patients with FTD. This finding has been replicated in other independent samples (Horn et al., 2010; Horn et al., 2009; Shenton, Dickey, Frumin, & McCarley, 2001). For example, Sans-Sansa et al. (2013) found correlations between volume reductions in Broca's and Wernicke's areas and *fluent disorganization* phenomena, whereas *poverty of content of speech* was related to reductions in bilateral medial frontal and orbito-frontal cortical regions, respectively. Altogether, these results show that volumetric structural aberrations in language related areas (superior temporal, lateral prefrontal) are the most consistent structural findings in schizophrenia and are correlated with the presence of FTD.

Besides cortical grey matter thinning in the superior temporal gyrus (STG), the integrity of the left white matter fiber bundle (fractional anisotropy measured with MRI Diffusion Tensor Imaging) of the left middle longitudinal fascicle—a long association fiber connecting the STG and temporal pole with the angular gyrus through the white matter of the STG—demonstrated a negative association with disorganized thoughts (Asami et al., 2013). Thus, the connection within the left STG and to the angular gyrus is correlated with the amount of FTD in patients, providing further evidence for the disconnection hypothesis previously mentioned.

71.4 NEURAL CORRELATES OF FTD (SYMPTOM CATCHING)

To date, very few studies have investigated the neural substrates of naturally produced speech in FTD patients, and brain activation using H₃O-PET or fMRI is measured at the same time (symptom catching approach). In these rare but revealing studies, patients were asked to speak about pictures in the scanner and their verbal output was recorded online and transcribed subsequently so that psychopathological phenomena could be assessed, evaluated, and precisely time-locked with the brain signal changes. Accordingly, in one study the amount of FTD as

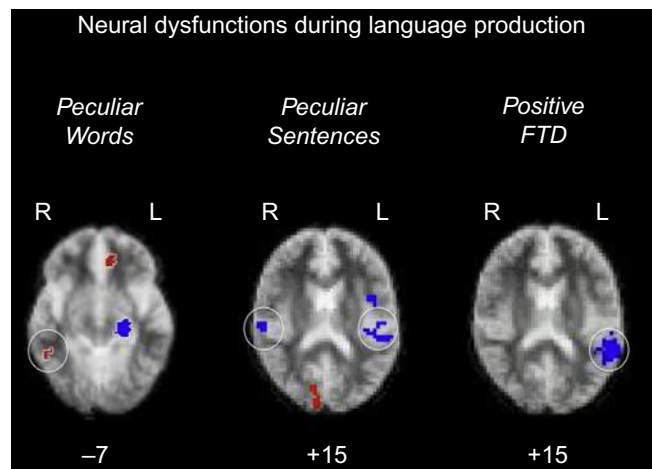

FIGURE 71.1 The “symptom catching” approach in schizophrenia patients during natural speech production. Brain signal changes were correlated with the production of “peculiar words” (left), “peculiar sentences” (middle), and “positive FTD” (right). Red voxels indicate positive correlations; blue voxels refer to negative correlations. Note that according to the neuroradiological convention, the left hemisphere (L) is presented on the right side (R) of the brain image. Based on Kircher (2003) and Kircher et al. (2001).

measured with a clinical rating scale (Thought and Language Index) (Liddle et al., 2002) was correlated with brain activation during 20-s epochs. The expression of positive FTD was found to be negatively correlated with activation in the left STG, part of Wernicke's area (Figure 71.1) (Kircher et al., 2001). Thus, during the production of positive FTD, brain activation in the STG fluctuated and was reduced during those short time intervals when language dysfunction (i.e., positive FTD) was maximal (Kircher et al., 2001; McGuire et al., 1998).

Using an fMRI event-related approach, the occurrence of particular FTD symptoms, recorded in continuously speaking patients, has been correlated with brain activation (see Figure 71.1). Here, a correlation was found between semantic paraphasias (“peculiar words”) and BOLD enhancements in the left anterior cingulate (ACC) and the right middle temporal gyrus (MTG) (Kircher, 2003). The ACC is associated with decision processes or error monitoring, as well as with the detection of paraphasias in this study. The retrieval of semantic information in the RH, in particular in the right MTG, was found to be related to the processing of wide associative semantic fields, giving rise to the selection of “unintended” but semantically related peculiar notions (Beeman, 1993). During the articulation of peculiar sentences (Liddle et al., 2002) as opposed to morpho-syntactically correct lexical sentences, the left and right STG were deactivated (Kircher, 2003) (for further details, see Section 71.8).

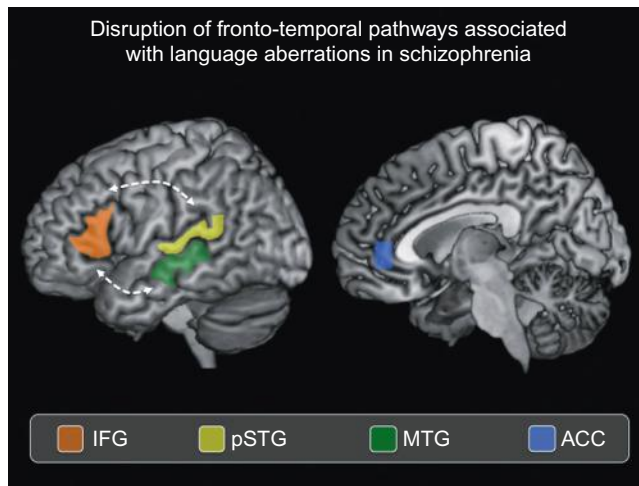

FIGURE 71.2 Brain regions (orange, inferior frontal gyrus [IFG]; yellow, superior temporal gyrus [STG]/inferior parietal lobe [IPL]; green, middle temporal gyrus [MTG]; blue, anterior cingulate cortex [ACC]) being associated with functional and anatomical aberrations in schizophrenia patients related to language impairments. Arrows depict fronto-temporal dysconnections (arcuate fasciculus, uncinate fasciculus, superior longitudinal fasciculus), particularly between the IFG and the pSTG/MTG. Note that brain regions are schematically depicted.

These areas are generally involved in both language production and perception, however deactivated, during aberrant, nonlexical speech production in patients.

The same approach has also been applied for negative FTD (poverty of speech), detecting positive correlations in the right inferior parietal lobe, middle frontal gyrus, cuneus, and the left posterior cingulate. Inverse correlations were found in the left hippocampal and fusiform region. Results were interpreted in terms of rich memories and associations being experienced subjectively by the patient, but not verbalized (Kircher, Liddle, Brammer, Murray, & McGuire, 2003). A recent investigation examined the neural activity associated with pauses that occurred between clauses and with pauses that were filled (Matsumoto et al., 2013). An attenuated involvement of the STG during between-clause pauses indicates defective speech planning and monitoring mechanisms being related to FTD symptomatology (Matsumoto et al., 2013). In summary, structural and functional imaging investigations point to an involvement of IFG and, in particular, STG structures in the pathophysiology of FTD (Figure 71.2).

71.5 SEMANTICS

Dysfunctions in semantic associations—measured behaviorally (Ketteler, Theodoridou, Ketteler, & Jager, 2012)—and semantic memory (Rossell & David, 2006) are frequently reported and account for some of the

language impairments. One way to access the functionality of the associative semantic network connections is realized by behavioral semantic priming tasks. Here, the participants decide whether a presented letter string is a word or a nonword and indicate their decision via button press. Beforehand, a prime word is briefly presented (e.g., 150 ms), which is either semantically related to the target word or not. The dependent variable is the reaction time that is significantly shorter when the priming word is semantically related to the target. Patients with positive FTD (versus non-TD patients) show a shorter reaction time during short Stimulus Onset Asynchrony (SOA) (<250 ms automatic processing versus more controlled processing with SOA >500 ms) for semantically indirectly (versus directly) related words. Indirectly related words are, for instance, *anvil–nail*, directly related words are *picture–frame*. Based on the assumptions of the spreading semantic activation model (Collins & Loftus, 1975), it has been shown in these semantic priming studies that altered associative processes within the semantic network or, in other words, decreases in inhibition in the spreading and associational activation are related to positive FTD in schizophrenia patients (Manschreck et al., 1988; Spitzer, Braun, Maier, Hermle, & Maher, 1993). It is important to note that this hyperpriming only occurs under the conditions that patients display positive FTD, there is automatic processing, and the semantic relation of words is indirect. In FTD patients, the automatic spread of activation happens faster and more widely in the semantic network (most likely related to the right lateral temporal lobe, see parts 4 and 11).

Brain imaging studies investigated the neural correlates of semantic association (priming) tasks in moderately thought-disordered patients with schizophrenia and healthy controls (Sass et al., 2014). Here, an effect of semantic relation was found within the right angular gyrus and precuneus. Moreover, semantic distance (direct as opposed to indirect semantic association of the prime target relation) revealed distinct patterns of activations encompassing the left middle temporal and right precuneus, among others. Here, direct relations induced higher activations in controls. Results were interpreted in terms of aberrant priming-related brain responses in schizophrenia patients. Both delayed and enhanced spreading activations within the semantic framework may influence semantic processing impairments. Kuperberg and colleagues took a similar approach using a semantic priming paradigm with directly related, indirectly related, and unrelated word pairs in schizophrenia patients (Kuperberg, Deckersbach, Holt, Goff, & West, 2007). They revealed hemodynamic dysactivation in inferior prefrontal and temporal regions in connection with direct and indirect (relative to unrelated) word pairs in chronic schizophrenia.

Speech does not consist of single, isolated semantic units, but rather of coherent discourse (i.e., several words in context). Concerning language comprehension on the sentence level, a recent review of fMRI studies revealed activation changes in the IFG as well as in the STG (left “fronto-temporal network”) in FTD versus non-FTD patients with schizophrenia (Rapp & Steinhauser, 2013). Weinstein and colleagues investigated a receptive language processing task, asking patients as well as healthy controls to listen to 30-s speech samples. Only FTD was reported to correlate positively with BOLD response in the left pSTG, indicating that compensatory mechanisms are involved to allow for normal performance (Weinstein, Werker, Vouloumanos, Woodward & Ngan, 2006). An association between fronto-temporal network dysfunctions and the presence of FTD was also found in the context of semantic decision tasks (Arcuri et al., 2012), so that a fronto-temporal dysconnection in the semantic network is suggested to be involved in FTD (Horn et al., 2012).

On a speech production level, lexico-semantic deficits are often investigated in highly controlled word generation tasks. A frequently used approach for assessing the functionality of word retrieval according to given stimuli (e.g., semantic categories such as “animals” = semantic verbal fluency; words to a given initial letter such as “P” = lexical verbal fluency) and rules (e.g., no word stem repetitions) within a predetermined time window is referred to as verbal fluency task (Nagels, Kircher, et al., 2012). In schizophrenia patients, deficits in semantic verbal fluency performance represent the most consistent neuropsychological finding (Henry & Crawford, 2005; Szoke et al., 2008). Larger deficits for semantic relative to lexical fluency performance suggest that, in addition to generalized retrieval difficulties of verbal information, schizophrenia is associated with particular impairments in the semantic store (Henry & Crawford, 2005). Neural evidence for impaired relational memory processes was derived from impaired semantic verbal fluency performance (Kircher, Whitney, Krings, Huber, & Weis, 2008). Here, patients revealed attenuated hippocampal activity indicating dysfunctions in the retrieval of semantic verbal knowledge. In general, neural dysfunctions—hypoactivations as well as hyperactivations, particularly in left prefrontal regions—during verbal fluency performance were reported (Broome et al., 2009; Curtis et al., 1998, 1999, 2001; Fu, Suckling, et al., 2005; Ragland et al., 2008), depending on the investigated task (e.g., semantic versus lexical fluency, continuous versus single word production, silent versus overt) and the specific cognitive demands (Curtis et al., 1999). In one study, the severity of psychotic symptoms was associated with the recruitment of the anterior cingulate (Fu, Suckling, et al., 2005).

Dysfunctions in the latter region as well as in the right prefrontal cortex for patients as compared with controls were interpreted in terms of compensatory mechanisms (Schaufelberger et al., 2005). According to this model, additional neural resources are recruited to counteract cognitive deficits. The inverted U-shaped model—originally introduced to explain task-related hypoactivations and hyperactivations in working memory paradigms (Manoach, 2003)—suggests that with increasing cognitive demand, frontal neural responses increase. In the case of schizophrenia patients, however, the U-shaped curve is shifted to the left, resulting in temporarily earlier activations as observed in healthy controls.

On the whole, behavioral study results point to impairments in retrieval and inhibition of contextually irrelevant semantic information in schizophrenia, particularly in patients with positive FTD. Neural aberrations were mainly reported in left frontal as well as in temporal brain regions. However, different experimental approaches (indirect versus direct priming, semantic decision, verbal fluency), varying semantic task demand (single word production versus continuous generation), production versus perception tasks, and FTD symptom severity all contribute to different neural responses and must be meticulously taken into consideration when interpreting the results.

71.6 PRAGMATICS

Apart from dysfunctions on the semantic level, contextual information processing in schizophrenia patients is impaired as well. In everyday communication, pragmatic aspects of communication such as interpretations in situations and conversational implicatures play an important role. Here, the intended meaning is often conveyed in an indirect way inasmuch as information exchange may comprise indirect meanings (“Could you open the window?”), abstract figurative expressions (proverbs), and nonliteral meanings (irony, sarcasm) asking the interlocutor to read the intended message between the lines (Rapp et al., 2013). In schizophrenia patients, the ability to transfer the abstract semantic content of a metaphoric expression (“Life is a journey.”) or a proverb (“You can lead a horse to water, but you can’t make him drink.”) to the intended concrete meaning is impaired. As a result, affected patients tend to interpret the figurative meaning literally, which is clinically referred to as *concretism*, a commonly observed phenomenon in schizophrenia.

Nevertheless, imaging studies on the neural basis of metaphor processing dysfunctions in schizophrenia are still rare, because many potentially confounding factors need to be controlled for (word frequency,

syntactic complexity, familiarity, etc.). The few studies available report the left IFG to be dysactivated during metaphor processing in patients (Kircher, Leube, Erb, Grodd, & Rapp, 2007; Mashal, Vishne, Laor, & Titone, 2013) (Figure 71.3).

Further evidence for neural dysfunctions in metaphor processing in schizophrenia was found in an fMRI study on abstract gesture processing (e.g., hearing “The

talk was on a high level” while watching the actor lift his hand to indicate the “high level”) (Straube, Green, Sass, Kirner-Veselinovic, & Kircher, 2013). Patients and a healthy control group were presented with either concrete iconic (form-descriptive) gestures or abstract metaphoric gesture material, as described. Imaging results indicate that the neural integration of gesture and speech is not impaired *per se*, because the processing of concrete iconic co-speech gesture was intact. However, patients failed to recruit the fronto-temporal neural network in the metaphoric gesture context, which leads to the assumption that the multi-modal integration of audio-visual language material is specifically impaired with respect to the abstract figurative domain. Evidence for a functional fronto-temporal dysconnectivity in patients was found in a subsequent investigation of metaphoric gesture processing (Straube, Green, Sass, & Kircher, 2014) (Figure 71.4). Here, the left superior temporal sulcus was misconnected to the IFG, supporting the view of a dysfunctional integration of abstract language material.

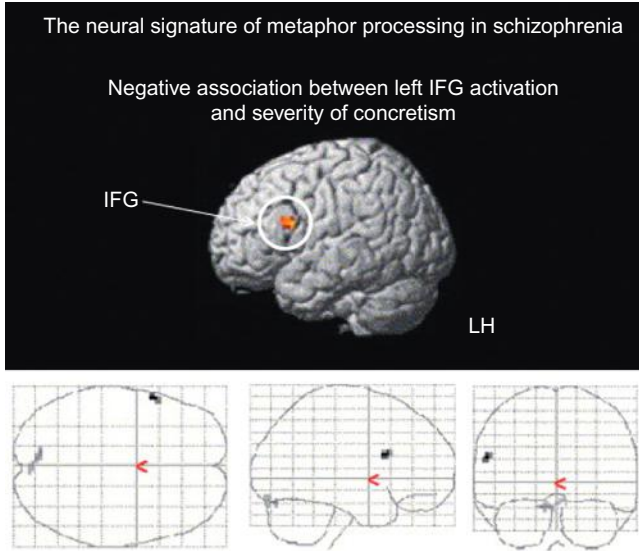

FIGURE 71.3 A negative association between left IFG recruitment and the severity of concretistic thinking in schizophrenia patients was found in the left hemisphere (LH). Based on Kircher et al. (2007).

71.7 AUDITORY SENSORY, PHONOLOGICAL, AND PROSODIC PROCESSING

Patients with schizophrenia exhibit aberrations in the most basic, early stages of auditory signal processing such as mere tone perception, distinction, and

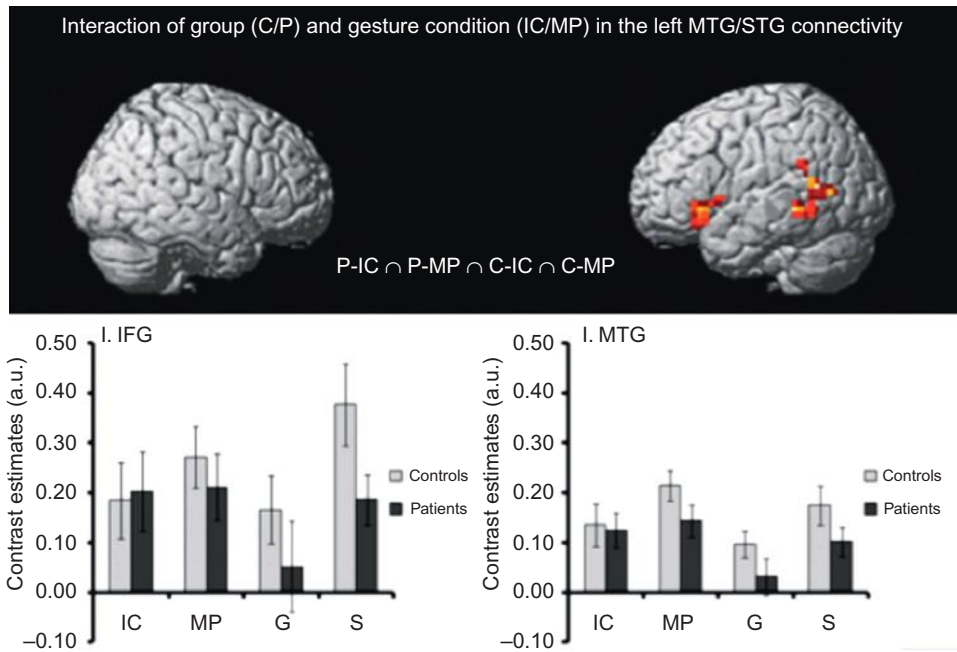

FIGURE 71.4 Dysconnectivity between the left IFG and the left MTG/STG region during metaphoric co-speech gesture processing (MP) in patients with schizophrenia (P) as compared with healthy controls (C). Apart from the metaphoric (MP) co-speech gesture video clips, an iconic (IC) condition was also presented. Based on Straube et al. (2014).

discrimination. This has been widely demonstrated using event-related potentials. For instance, “MMN” deficits represent an often replicated finding in schizophrenia patients (Kircher et al., 2004; Umbricht & Krljes, 2005). MMN is a correlate of auditory (sensory) memory and has been linked to coordinated neural mass synchronization (several thousands of neurons firing coordinated when a deviant tone occurs). MMN is generated in the posterior portion of the STG, as demonstrated in a combined MEG and fMRI study (Kircher et al., 2004) in healthy subjects, with a dysregulation in patients in this area. Further, the glutamate system, particularly the *N*-methyl-D-aspartate (NMDA) receptor (see Section 71.9), is fundamentally involved in the generation of MMN (Javitt, 2009). We therefore propose NMDA receptor dysfunction and synaptic rarefaction in the STG including the primary (sensory) auditory circuits as the origin of altered tone processing, giving rise to difficulties in acoustic discrimination (e.g., phones) and phonological working memory capacities. Note that this is the key area of dysfunction in auditory hallucinations and positive FTD (see Sections 71.3 and 71.4). Further auditory deficits such as prosody discrimination and detection impairments (Leitman et al., 2007) together with a reduced sensitivity to alterations in pitch processing (Kantrowitz, Hoptman, Leitman, Silipo, & Javitt, 2013), correlated with dysactivations in the STG in patients, also indicate impairments in the primary auditory cortex (Leitman et al., 2007). Taken together, it can be assumed that dysactivations in the left STG particularly contribute to phonological aspects of aberrant speech processing.

71.8 SYNTAX

More complex syntactic processing is impaired in some patients; in others, reduced syntactic complexity of spoken language is observed (Morice & McNicol, 1985). The articulation of grammatically more simple speech patterns in patients versus healthy control subjects was found to be associated with an absence of activation in the right posterior temporal as well as in the left superior frontal cortex in the patients only (Kircher, Oh, Brammer, & McGuire, 2005).

Neural dysfunctions underlying impaired syntactic processing may potentially be associated with impaired verbal working memory capacities as well as with aberrations in the online processing of morpho-syntactic relationships between words. Apart from these impairments, aberrations in the complex interaction between semantic memory and the build-up of sentence and discourse (Kuperberg, 2008) may play an influential role leading to dysfunctions on the syntactic level within a sentence (“Who does what to whom”)

(Kuperberg, 2008). These different cognitive, hierarchically organized, and serially linked processes cannot be easily disentangled and controlled for in an experimental setting. Thus, imaging studies investigating this particular field are still rare, so that the validity of obtained results is still limited to date.

71.9 NEUROTRANSMITTER DYSFUNCTION

So far, patient studies have been discussed focusing on different levels of language impairments in connection with the neural dysfunctions. To further probe particular neurotransmitter systems, pharmacological model psychoses have been tested with psychoactive substances administered to healthy volunteers. Schizophrenia-like symptoms such as hallucinations or FTD can be elicited in healthy subjects in a controlled experimental context by administering substances such as LSD, PCP, psilocybin, or ketamine (for review see Gouzoulis-Mayfrank, Hermle, Thelen, & Sass, 1998; Vollenweider & Kometer, 2010). The main neurotransmitter systems implicated in schizophrenia are dopamine, glutamate, and acetylcholine, which of course interact in a complex way.

Ketamine, a glutamatergic NMDA receptor antagonist, was used to test the hypothesis that an imbalance in the glutamatergic system is associated with the presence of psychotic symptoms. Thus, a number of PET (Vernaleken et al., 2012; Vollenweider, Leenders, Oye, Hell, & Angst, 1997; Vollenweider, Leenders, Scharfetter, et al., 1997; Vollenweider, Vontobel, Oye, Hell, & Leenders, 2000) and fMRI studies (Abel, Allin, Kucharska-Pietura, Andrew, et al., 2003; Abel, Allin, Kucharska-Pietura, David, et al., 2003; Fu, Abel, et al., 2005; Musso et al., 2011) investigated the effects of an experimentally controlled NMDA receptor blockade on the psychopathological, behavioral, and neural level. Ketamine administration particularly elicited FTD symptoms, largely resembling those observed in schizophrenia patients (Nagels, Kirner-Veselinovic, et al., 2012). Language-related fMRI ketamine studies used overt verbal fluency tasks (Fu, Abel, et al., 2005; Nagels, Kirner-Veselinovic, Krach, & Kircher, 2011), revealing quantitative impairments in verbal fluency performance on the behavioral performance level (Krystal et al., 1994; Nagels et al., 2011). In addition, positive correlations were found between left STG activations and ketamine-induced FTD symptoms during an overt verbal fluency task. Altogether, effects on the neural and behavioral level for visual field (VF) were comparable with those observed in patients with schizophrenia (e.g., fronto-temporal dysfunctions, impaired VF performance), strengthening the hypothesis of a glutamatergic

NMDA receptor dysfunction being involved in the pathophysiology of schizophrenia. However, more pharmacological imaging studies are needed to elucidate the connection between NMDA receptor dysfunction, symptom formation, and language impairments, particularly using multi-modal imaging approaches such as combined EEG-fMRI (Musso et al., 2011).

71.10 GENETIC INFLUENCE ON SPEECH AND LANGUAGE DYSFUNCTIONS IN SCHIZOPHRENIA

Alterations in language use are the only symptoms in schizophrenia that are genetically inherited (Arboleda & Holzman, 1985; Cardno, Sham, Murray, & McGuffin, 2001; Kinney et al., 1997). Research has recently focused on genetic variations of candidate genes for schizophrenia and their effects on brain structure and function. The majority of these common risk variants are found in the general population (>10%), and each conveys only very little increase in risk (OR 1.2–1.6). For many risk variants, their effects on the brain are unknown; therefore, imaging genetics studies comprise healthy subjects carrying a genetic risk single nucleotide polymorphism tagging marker for schizophrenia. This approach allows for an assessment of behavioral and imaging data in the absence of potentially confounding effects due to medication, duration of illness, or psychopathological differences between subjects.

Functional imaging tasks often investigate paradigms that are known to be sensitive for cognitive impairments in schizophrenia, such as semantic verbal fluency tasks. Thus, in the context of a genetic risk variant in CACNA1c, Krug et al. (2010) reported dysfunctions in the left IFG. Another susceptibility gene, NRG1, was also found to modulate VF performance as well as neural activations (Kircher et al., 2009). The authors report decreased activation encompassing the left IFG, right middle temporal gyri, and the anterior cingulate being correlated with the number of risk alleles in an overt semantic verbal fluency task. In this study, an association was found for both neural activation patterns and VF impairments similar to schizophrenia patients—but to a lesser degree—leading to the assumption that NRG1 has an impact on semantic language capacities.

Further imaging genetics investigations are needed to confirm the obtained results. Moreover, future studies should investigate follow-up, longitudinal designs to further elucidate the influence of candidate risk variants, as well as environmental effects on functional, structural, and behavioral aberrations over time.

71.11 LATERALIZATION ASYMMETRY IN SCHIZOPHRENIA

A well-replicated finding is the functional asymmetry or decreased language lateralization in schizophrenia (Bleich-Cohen, Hendlar, Kotler, & Strous, 2009; Bleich-Cohen et al., 2012) that is already present in patients with a first episode. In healthy subjects, the left STG as opposed to its contralateral homologue in the right hemisphere is comparatively thicker. However, in patients with schizophrenia this distribution is symmetrical or even reversed (Ratnanather et al., 2013). These structural asymmetry deficits as well as the cortical gray matter volume deficits in the STG region may contribute to FTD symptom formation (Horn et al., 2010; Sans-Sansa et al., 2013; Subotnik, Bartzokis, Green, & Nuechterlein, 2003). Diminished functional trans-hemispheric connectivity, due to structural and functional abnormalities in the corpus callosum, for example, between the VLPFC or lateral temporal lobes (Curcic-Blake et al., 2013), are other potential reasons for language impairments, particularly with respect to higher-order contextual discourse processing. Likely, the interaction deficit between hemispheres results in these language impairments (Strelnikov, 2010).

71.12 CONCLUSIONS AND FUTURE PERSPECTIVES

Language-related dysfunctions in patients with schizophrenia can be observed throughout all the multi-layered domains of speech production and perception. Structural, functional, and pharmacological imaging investigations mostly found aberrations in fronto-temporal neural circuits, particularly encompassing the left IFG and portions of the left STG, together with their interhemispheric and transhemispheric connections. Other areas, such as the hippocampi, precuneus, anterior cingulate, cerebellar, and motor areas, as well as subcortical structures are further involved in this language pathology.

With the exception of a few imaging studies, the majority of studies used highly controlled experimental perception/processing (rather than production) paradigms eliminating the “natural” complex context (Andric & Small, 2012). Imaging genetics approaches may play a role in relating genetic with neurophysiological and anatomical findings. Follow-up study designs are needed to illuminate the longitudinal progression of neural changes as well as its influencing factors.

Considering that the complex and multi-faceted human speech capacity and its neurobiological foundations are not yet fully understood in healthy participants,

it is not surprising that there is no single unified explanatory model for speech and language deficits in schizophrenia patients available yet. Further multi-modal and translational approaches—combining results from different scientific fields—are needed to explore the nature of the underlying pathophysiological mechanisms resulting in language aberrations in schizophrenia.

72.1 INTRODUCTION

Specific language impairment (SLI) is a developmental language disorder characterized by the inability to master spoken and written language expression and comprehension, despite normal nonverbal intelligence, hearing acuity, and speech motor skills, and no overt physical disability, recognized syndrome, or other mitigating medical factors known to cause language disorders in children (Tager-Flusberg & Cooper, 1999). Although numbers vary slightly across countries, in the United States SLI is estimated to occur in ~7% of English-speaking 5-year-old children (Tomblin, Smith, & Zhang, 1997). It persists, fully or partially, into adulthood, placing individuals with SLI at risk for poor academic performance, difficulty developing and maintaining friendships and significant relationships, difficulty in the work environment, and reduced earning potential and standard of living. The stress that accompanies coping with the disorder also places both individuals with SLI and their families at risk for secondary stress-related physical, social, and emotional problems (Catts, Bridges, Little, & Tomblin, 2008; Conti-Ramsden, 2013; Durkin & Conti-Ramsden, 2007; Tomblin, Freese, & Records, 1992).

SLI has been described in the literature for more than a century; however, despite decades of study, the cause of the disorder is still unknown (Leonard, 2014). Historically, hypothesized accounts of SLI have been based predominantly on experimental data and behavioral observations. Taking advantage of advances in noninvasive brain imaging techniques that allow for increased spatial and temporal resolution, a growing

number of SLI researchers have begun to focus on brain structure and brain function in this population. From these studies of the neurobiology of SLI, a richer understanding of the nature of brain–language relationships is beginning to develop.

Some of the techniques that have been used in these investigations of the neurobiology of SLI include structural magnetic resonance imaging (sMRI), functional magnetic resonance imaging (fMRI), diffusion tensor imaging (DTI), functional transcranial Doppler ultrasound (fTCD), single-photon emission computed tomography (SPECT), event-related potentials (ERPs), magnetoencephalography (MEG), and anatomically constrained magnetoencephalography (aMEG). Although each of these techniques has limitations, when taken together a profile emerges for SLI that is characterized not by a single pattern of gross abnormality but also by patterns of atypical brain morphology and tissue properties for some brain regions but not others, coupled with atypical patterns of neural activity mediating some aspects of language but not others.

72.2 NEUROPSYCHOLOGICAL PROFILE

There is no universally agreed on set of diagnostic criteria or terminology for SLI; however, there is general agreement among clinicians and researchers that these are children who have notable language disabilities that are below age-level expectations and are significantly out of line with other aspects of the child's development (for detailed discussion see Bishop, 2014; Reilly, Bishop, & Tomblin, 2014).¹ As with any clinical disorder,

¹In this chapter, we use the term “specific” to denote “ideiopathic” or “functional” language impairment—of unknown cause—as recently proposed by Bishop (2014).

there are individual differences in severity and symptomatology of SLI, yet despite this heterogeneity, there are some common deficit profiles. The most common profile is delayed onset and slower acquisition of the lexical, syntax, and grammatical morphological aspects of spoken and written language coupled with nonlinguistic cognitive processing, learning, and memory impairments (Leonard, 2000). These nonlinguistic deficits typically include slower speed of processing, poor phonological and verbal working memory, poor auditory processing, and slow and inefficient sequential procedural learning and memory (Leonard & Weber-Fox, 2012).

72.3 STRUCTURAL IMAGING OF SLI

Although the anatomical correlates of acquired language disorders in other clinical populations have received considerable attention over the past century (Geschwind, 1970, 1979), studies of brain morphology in SLI began in earnest in the early 1990s. In unimpaired populations, asymmetries in brain morphology within left hemisphere perisylvian areas are the norm, most notably expressed as relatively greater volumetric measures as compared with homologous right hemisphere regions, and they have been viewed as support for a left hemisphere dominance model of language (Dorsaint-Pierre et al., 2006; Szaflarski et al., 2012). Guided by Orton's proposal that a lack of left hemisphere dominance for language could result in the failure to develop language (Molfese & Segalowitz, 1988; Orton, 1937; Vallortigara, Rogers, & Bisazza, 1999), these initial studies focused on reversed or a lack of hemispheric asymmetry in SLI. Early studies used MRI and manual slice-wise tracing to investigate left–right hemisphere (a)symmetry in those regions specifically hypothesized to support language (Clark & Plante, 1998; Jernigan, Hesselink, Sowell, & Tallal, 1991; Plante, Swisher, Vance, & Rapcsak, 1991). These studies found a higher prevalence of “atypical” cerebral asymmetry (i.e., $R > L$) in the language-impaired participants as compared with normal language controls. Follow-up studies continue to report lacking or rightward asymmetry, as well as abnormal patterning, shape, and volume of brain morphology for SLI, most notably in anterior and posterior perisylvian areas such as pars triangularis, planum temporale, and the posterior ascending ramus in individuals with SLI (De Fossé et al., 2004; Gauger, Lombardino, & Leonard, 1997; Soriano-Mas et al., 2009).

With advances in imaging technologies, automated postprocessing, and statistical and modeling approaches to the analysis of brain imaging data, researchers are now able to quantify anatomical features of the brain in more nuanced units. Recent automated techniques can reliably separate cerebral and cerebellar gray and white matter

into cortical and subcortical compartments, measure the volumes of deep nuclei and cerebrospinal fluid (CSF) compartments, accurately reconstruct the cortex and subdivide its volume into measures of surface area and thickness at every region, and map the tissue properties and volumes of white matter connections across different cortical and subcortical regions. These morphological approaches all begin with noninvasive neuroimaging data, typically from MRI data—with one of the most common methods being voxel-based morphometry (VBM).

Using largely VBM-based processing and analysis techniques, data from studies of brain morphology in SLI consistently show atypical gray and white matter volumes in some brain regions but not in all brain regions (Badcock, Bishop, Hardiman, Barry, & Watkins, 2012; Girbau-Massana, Garcia-Marti, Marti-Bonmati, & Schwartz, 2014; Lee, Nopoulos, & Tomblin, 2013; Mayes, Reilly, & Morgan, 2015; Soriano-Mas et al., 2009). For instance, Badcock et al. (2012) observed that although total gray matter volume was no different for SLI and normal controls, gray matter volume was significantly different in some regions for SLI as compared with normal controls. Specifically, Badcock and colleagues observed that their SLI group had significantly *more* gray matter than controls in the left inferior gyrus (IFG), right insula, and left intraparietal sulcus, but significantly *less* gray matter in medial frontal pole, medial superior parietal cortex, posterior superior temporal sulcus (STS), superior temporal gyrus (STG), and subcortical regions such as the caudate nucleus and in the midbrain at the level of the substantia nigra.

One advantage of the VBM approach over previously common manual tracing methods is that researchers can more readily attempt to control for individual differences in intracranial and/or intrahemisphere volume by norm-referencing the morphology of specific regions of interest to individual intracranial and/or intrahemisphere volumes. For instance, Lee et al. (2013) controlled for differences in intracranial volume (ICV) in their SLI and normal control groups. They observed absolute volume of the bilateral caudate nucleus, left globus pallidus, bilateral thalamus, and cerebral lobes to be *less* for SLI as compared with normal controls. However, ICV was also significantly *less* for the SLI as compared with normal controls. To address this potential confound of differences in ICV between the two groups, Lee and colleagues adjusted region-wise measures based on each participant's total ICV. Using regional measures as a proportion of total volume, Lee and colleagues instead found that the putamen, right globus pallidus, nucleus accumbens, and hippocampus adjusted volumes were significantly *greater* for the SLI group as compared with normal controls, whereas adjusted volume of the cerebral lobes were now no longer different for SLI and normal controls.

A small number of researchers are beginning to examine the CSF volume in SLI; however, findings from these studies are somewhat inconsistent (Soriano-Mas et al., 2009). Comparing absolute values, Soriano-Mas et al. (2009) observed CSF volumes to be normal for children with SLI. However, using VBM and controlling for individual differences in ICV, Girbau-Massana et al. (2014) found a different pattern. They examined CSF volumes in a group of children with SLI, a group with SLI and reading disabilities, and a group of normal controls and found *greater* CSF volume for both SLI groups as compared with normal controls. Although the possible cognitive implications of greater CSF volume are not clear, similar effects in age-matched comparisons have been associated with a variety of clinical groups and may reflect relatively decreased total gray matter.

In addition to investigating cortical and subcortical structural volumes in SLI, researchers have also examined white matter in SLI using DTI measures. Based on anisotropic water movement within fibrous tissue, DTI measures provide indices of the overall *magnitude* of diffusion within a given white matter tract regardless of direction and indices of the *directionality* of diffusion (Basser, Mattiello, & LeBihan, 1994; Lim, Han, Uhlhaas, & Kaiser, 2013; Beaulieu, 2002). Measures of diffusion magnitude within white matter, such as mean diffusivity (MD), tend to show age-related decreases across childhood development, and measures of diffusion directionality, such as fractional anisotropy (FA), tend to show developmental increases (Brown et al., 2012). These two age-related effects are believed to be related in part to the increasing degree of myelination that occurs around the axons of neurons, and their specific time courses vary by brain region and tract. Using DTI tractography, maps of fiber tracts in the brain can be virtually reconstructed, revealing streamlines of white matter that purportedly connect one brain region to another. Although commonly used tractography methods require manual guidance to reveal white matter tract regions of interest (Mori & Van Zijl, 2002; Mori & Zhang, 2006), recent methods provide fully automated tractography, thus avoiding the subjective biases inherent in choosing interregional streamlines by hand (Hagler et al., 2009).

One of the first studies to use DTI to examine white matter pathways in SLI was conducted by Kim et al. (2006). They found decreased anisotropy in the genu of the corpus callosum for SLI despite the appearance of “normal” brain characteristics based on MRI scans, indicating that individuals with SLI may have grossly normal brain morphology but still have that abnormalities in the brain at the microstructural level that are not evident on conventional MRI scans. For example, abnormal corpus callosum white matter microstructure might contribute to abnormal integration of information between the left and right hemispheres.

Similar to studies of brain morphology, data from DTI studies of SLI also have found diffusion properties within white matter tracts that are outside typical ranges in some, but not all, regions of the brain (Kim et al., 2006; Lee et al., 2013; Verhoeven et al., 2012). For instance, comparing FA values in individuals with autism spectrum disorder, those with SLI, and normal controls, Verhoeven and colleagues (Verhoeven et al., 2012) observed no differences in FA values in the superior longitudinal fascicle (SLF) between the normal control and autism spectrum groups, but they found that SLF FA values were significantly reduced in the SLI group as compared with normal controls. Similarly, Lee and colleagues (2013) found FA values in the hippocampus, caudate nucleus, putamen, and nucleus accumbens to be similar for those with SLI and normal controls, but FA values for thalamus, globus pallidus, and superior longitudinal fasciculus were found to be significantly *lower* in the SLI group as compared with normal controls.

Taken together, imaging studies of brain morphology in SLI suggest a notable absence of gross brain abnormalities. Instead, these studies suggest a pattern of abnormal left/right hemisphere asymmetry in some brain regions for SLI, reduced cortical and subcortical volumetric values for some brain regions but not others, and reduced measures of diffusion directionality (i.e., FA) for SLI as compared with controls, again in some regions but not in others. Data from more recent studies indicate that comparison of wide-ranging or global values and/or absolute values alone may not capture the region-specific nature of many differences and suggest that norm-referencing volume in regions of interest to individual interhemisphere/intrahemisphere/cranial volumes may be an important methodological consideration in future research.

Another important issue for future studies of SLI brain morphology and tissue properties will be to use more consistent brain segmentation techniques, including cortical surface-based reconstruction and analysis, which can accurately separate cortical volume into independent measures of surface area and thickness, which vary regionally and have very distinct normal developmental trajectories (Brown et al., 2012). Manual tracing and VBM-based methods in some regions can lead to inaccurate volume and asymmetry measurements because of partial voluming of gray matter, white matter, and CSF (or all three) at the edges of structures of interest. Further, manual tracking methods rely on subjective visual determination of specific cortical structures, and this assumes that gross structural features are clearly visible relative to the boundaries of cortical regions to be defined. Even issues such as head motion and position can introduce noise into the data. For instance, even when researchers use standardized head positioning, the slightest head rotation will result

in qualitative differences in the appearance of brain structures along the plane being imaged and this will lead to spurious “within plane” asymmetries of apparently comparable structures in the two hemispheres (Jernigan, Hesselink, et al., 1991). The methods used to measure cortical volume, area, and thickness and how these measures are related and/or distinguished from one another can also influence researcher’s interpretations of the data. New techniques now make it possible for researchers to obtain topologically accurate measurements of cortical brain morphology and relate this information to subcortical anatomy.

To gain a more accurate picture of cortical morphology in SLI, future research should use three-dimensional surface-based reconstructions to examine cortical thickness and surface area separately, instead of simply measuring cortical volume. Cortical surface area and thickness have distinct cellular mechanisms and genetic etiologies (Chen et al., 2013, 2012, 2011). For typical individuals, total cortical surface area, average cortical thickness, and total intracranial volume (TIV) (global measures and head size) are each highly heritable (Brans et al., 2010; Panizzon et al., 2009), with genetic influences accounting for 89% of the variance in cortical surface area, 81% of the variance for cortical thickness, and 78% of the variance for TIV.

A complete picture of the topological organization of brain morphology for SLI will require a developmental approach in which both age-related and gender-related aspects of regionally varying brain morphology and tissue properties are factored into any study of SLI brain structure (Brown et al., 2012; Khundrakpam et al., 2013; Squeglia, Jacobus, Sorg, Jernigan, & Tapert, 2013; Tamnes et al., 2013). Before child brain imaging became commonplace, it was assumed that the majority of changes in brain tissue occurred during the immediate postnatal brain growth spurt; however, studies comparing gray and white matter morphology and tissue properties in children and adults now show that considerable changes in brain maturation continue to take place throughout adolescence and well into adulthood, and that these changes vary considerably in girls and boys (Brown & Jernigan, 2012; Jernigan, Archibald, et al., 1991; Jernigan & Tallal, 2010).

72.4 FUNCTIONAL IMAGING OF SLI

72.4.1 Localization of Brain Activity in SLI

Degree of hemispheric specialization, so-called cerebral dominance, for language functioning in SLI has been examined using techniques such as fTCD and SPECT. fTCD compares blood flow velocity within cerebral arteries related to regional increases in associated neural activity linked to the performance of cognitive

tasks. Often in language studies, the left and right middle cerebral arteries are measured during fTCD, accounting for more than 70% of the blood supply to the respective hemispheres. As with other hemodynamic and perfusion-sensitive neuroimaging techniques, fTCD works under the premise that regional increases in neural activity are associated with greater glucose and oxygen consumption that must be replenished via enhanced blood flow to the area (Müller, Neumann, Lohmann, Mildner, & Cramon, 2005).

SPECT relies on an injection of a radioactive tracer that travels through the brain’s vasculature and provides a reading of regional blood flow concentrations detected using a ring of radioactivity sensors. The development of three-dimensional techniques used in SPECT and positron emission tomography (PET) allow for visualization of blood flow in any region of the body, including cortical, subcortical, and cerebellar brain structures. The decay of the radiotracer depends on which radionuclide is used, but typically a series of scans is completed within several minutes, providing measures of regional cerebral blood flow (rCBF) at the time of injection. Because change in the cerebral blood flow is linearly related to glucose consumption, changes in cerebral blood flow are believed to be an indication of local neuronal activity (Saper et al., 2000).

In unimpaired populations, language processing is most often characterized by relatively greater activity in the left as compared with the right cerebral hemisphere (Brown et al., 2005; Knecht et al., 1998). SLI studies using fTCD more commonly show abnormal patterns of cerebral blood flow, characterized either by relatively greater right hemisphere lateralization or by bilateral cerebral blood flow. For example, one fTCD study of 11 individuals with SLI found that two of the subjects (18.2%) had left lateralization, six subjects (54.5%) showed right lateralization, and three subjects with SLI (27.3%) showed bilateral or mixed dominance (Whitehouse & Bishop, 2008). SLI studies using SPECT also show an abnormal pattern of cerebral blood flow, characterized by reduced asymmetry and/or relative hypoperfusion of the left hemisphere—an atypical pattern as compared with unimpaired populations (Chiron et al., 1999; Denays et al., 1989; Lou, Henriksen, & Bruhn, 1990; Ors et al., 2005; Tzourio, Heim, Zilbovicius, Gerard, & Mazoyer, 1994).

A small number of SLI studies have used fMRI to investigate the cerebral functional organization of language and cognitive processing (Badcock et al., 2012; Ellis Weismer, Plante, Jones, & Tomblin, 2005; Hugdahl et al., 2004; Schmithorst, Yuan, & Plante, 2007). fMRI is a functional neuroimaging procedure using MRI technology that measures regional brain activity by detecting associated changes in the relative concentrations of oxygenated and deoxygenated hemoglobin within blood vessels. This technique, similar to other

hemodynamic methods such as PET and SPECT, relies on the fact that deoxygenated hemoglobin is paramagnetic and that increases and decreases in its concentrations are regionally coupled with changes in neural activity. The primary form of fMRI uses the blood oxygen level–dependent (BOLD) contrast. Because of the high spatial resolution of MRI, fMRI provides for a very precise localization of brain activity. However, because fMRI must rely on a sluggish hemodynamic proxy of neural activity, it provides indirect information about brain activation that is limited to much poorer temporal resolution (i.e., smeared over several seconds) than neural activity itself (i.e., in milliseconds).

Similar to the fTCD and SPECT studies, data from fMRI studies of SLI indicate abnormal patterns of brain activation during language and cognitive processing tasks (Badcock et al., 2012; de Guibert et al., 2011; Ellis Weismer et al., 2005; Hugdahl et al., 2004). These studies report reduced left lateralization in those areas viewed as core to language functions, normal lateralization, and significantly reduced activation in the left hemisphere (relative to the right) in frontal, parietal, or temporal areas (Ellis Weismer et al., 2005; Hugdahl et al., 2004). For instance, Hugdahl et al. (2004) observed reduced brain activation in left temporal and frontal lobes, primarily in the middle temporal gyrus bordering the STS in SLI as compared with normal controls during lexical processing and phonological awareness tasks. Badcock et al. (2012) also observed reduced left hemisphere as compared with right hemisphere activation in SLI as compared with normal controls, as well as reduced activation for SLI as compared with normal controls, particularly in the left IFG (pars orbitalis), right putamen, and the STS/G bilaterally. Studies of children with a documented delay in onset of spoken language (e.g., late talkers) also demonstrate significantly reduced activation in the left superior temporal gyrus as compared with normal controls (Preston et al., 2010).

What is notable about the Badcock et al. (2012) study is that the researchers also directly examined the relationship between brain structure and brain function in children with SLI, their siblings, and normal language controls. As discussed, the SLI group had significantly more gray matter as compared with normal controls in the left inferior frontal gyrus (IFG) and significantly less gray matter in the right caudate nucleus and the STS bilaterally. The SLI group also had atypical brain activation during language processing in the left IFG and posterior temporal cortex bilaterally as well. The pattern of linkage between atypical structure and function was not evident in Broca's area, however. Specifically, in regions where the children with SLI had increased gray matter as compared with controls, they showed decreased brain activation during language processing. Thus, despite the coincident atypical structure and function in SLI, gray matter

volume and brain activity may be more closely related in some brain regions than in others.

Taken together, brain activation patterns for SLI appear to be characterized by atypically reduced levels of activity within the left hemisphere as compared with the right, as well as significantly reduced overall amplitude of brain activation when compared with normal controls not only in the left hemisphere but in contralateral cortical and subcortical areas as well. One question is whether the functional brain organization is atypical for all aspects of language in SLI or only for some subcomponents or processing operations of language tasks. Studies examining the relationships between brain organization and language performance now indicate that this relationship is a dynamic one involving complex, distributed brain systems, and that simplistic concepts such as hemispheric asymmetry or cerebral dominance are not likely to capture the subtleties of these brain-behavior relationships (Dorsaint-Pierre et al., 2006; Keller et al., 2011). In particular, studies of the neurobiology of language in typical individuals suggest that while the left hemisphere is clearly dominant for many aspects of language, the functional organization of language is more complex than a simple left–right dichotomy and comprises multiple brain systems that also vary meaningfully according to the anterior and posterior dimensions of both hemispheres (Brown et al., 2014; Federmeier, Wlotko, & Meyer, 2008; Friederici, 2005; Friederici, Wang, Herrmann, Maess, & Oertel, 2000; Helenius, Parviainen, Paetau, & Salmelin, 2009; Kuhl & Rivera-Gaxiola, 2008; Poeppel, Emmorey, Hickok, & Pylkkänen, 2012; Pylkkänen & Marantz, 2003).

72.4.2 Time Course of Cortical Activation in SLI

Although the high spatial resolution of SPECT and fMRI make them well-suited to investigate the location of brain activation in SLI, the temporal resolution of SPECT and fMRI is on the order of seconds to minutes, making these techniques poorly suited to investigate the time course of brain activity. In contrast, EEG and MEG, which measure electrical and magnetic fluctuations, respectively, have a temporal resolution on the order of milliseconds, making them better suited to examine the time course of brain activity (Hansen, Kringelbach, & Salmelin, 2010; Näätänen, Ilmoniemi, & Alho, 1994). The time-locked changes in EEG and MEG activity that are triggered by an external stimulus or event can be classified in various ways according to their amplitude, timing relative to stimulus onset, polarity, and anatomical site of generation. These “event-related” potentials (ERPs) are commonly referred to by their polarity (negative/positive) and

latency in milliseconds. For instance, the large, negative-going EEG-evoked potential measured peaks in adults between 80 and 120 milliseconds after the onset of a stimulus that are referred to as the N100 or N1 (its equivalent in MEG is referred to as M100).

ERP and MEG components can also be classified in terms of the “functional” processes that are believed to be associated with each of them (Luck & Kappenman, 2012). From a functional perspective, differences in the time course of a component are often viewed as a reflection of the time course of the cognitive processes that are being engaged across different experimental conditions or experimental stimuli. Similarly, differences in the degree of amplitude modulation of a component are often viewed as a measure of cognitive processing “effort” inherent in the stimuli and/or experimental task, or expectation (Frisch, Kotz, Yves von Cramon, & Friederici, 2003; Kutas & Federmeier, 2011; Polich & Kok, 1995).

The ERP components that have been examined in SLI include, but are not limited to, mismatch negativity (MMN), T-complex, late discriminative negativity (LDN), early left anterior negativity (ELAN), N1, P2, N1-P2, P3, N400, and P600. In these studies, brain activity has been investigated within the context of different hypothesized deficits in SLI. For instance, researchers have examined the T-complex and MMN components in investigations of central auditory processing deficits in SLI (Bishop, 2007; Bishop, Hardiman, & Barry, 2012), the N400 in studies of lexical-semantic knowledge in SLI (Neville, Coffey, Holcomb, & Tallal, 1993; Weber-Fox, Leonard, Wray, & Tomblin, 2010), the P3 and N2 in studies of cognitive and working memory deficits in SLI (Evans, Selinger, & Pollak, 2011; Epstein, Shafer, Melara, & Schwartz, 2014), and the P600 and left-anterior negativity (LAN) in studies of syntactic knowledge in SLI (Epstein, Hestvik, Shafer, & Schwartz, 2013; Friederici, 2006; Fonteneau & van der Lely, 2008; Purdy, Leonard, Weber-Fox, & Kaganovich, 2014; Sabisch, Hahne, Glass, Suchodoletz von, & Friederici, 2009; Weber-Fox et al., 2010).

Much of the electrophysiological data indicate abnormal cerebral information processing for SLI, characterized by patterns of both atypical timing and peak amplitudes for the early occurring components such as MMN, N1-P2 (Kaganovich, Schumaker, Leonard, Gustafson, & Macias, 2014; Kaganovich, Schumaker, Macias, & Gustafson, 2014; Schwartz & Shafer, 2012) and N2 (Epstein et al., 2014). For the later occurring components (e.g., P3, N400, P600), the pattern is somewhat different, characterized broadly as one of more normal peak latency but of abnormal amplitude modulation and lateralization of cortical activation for SLI as compared with normal controls. There are inconsistencies in these findings, however. For instance, atypical attenuation and latency of MMN have been observed

for SLI in some, but not all, studies (Bishop, 2007). Similarly, the latency and amplitude modulation of the N1-P2 has been reported to be normal for SLI in some studies, but not others (Adams, Courchesne, Elmasian, & Lincoln, 1987; Çeponiené, Cummings, Wulfect, Ballantyne, & Townsend, 2009; McArthur, Atkinson, & Ellis, 2009; McArthur & Bishop, 2005; Neville et al., 1993; Tonquist-Uhlen, 1996).

P3 studies consistently report similar peak latencies for SLI and normal controls (Courchesne & Plante, 1996; Evans et al., 2011; Jirsa & Clontz, 1990; Lincoln Courchesne, Harms, & Allen, 1993), but some studies report normal modulation of the P300 for SLI (Lincoln et al., 1993), whereas others report abnormal modulation of the P3 (Evans et al., 2011). Similarly, for the N400, left-anterior negativity (LAN), and P600, some studies report both latency and amplitude modulation of N400, left-anterior negativity (LAN), and P600 to be abnormal for SLI as compared with normal controls, but others find that only the peak amplitudes of scalp potentials, but not the latencies, are abnormal for SLI (Epstein et al., 2013; Cummings & Çeponiené, 2010; Neville et al., 1993; Plante, Petten, & Senkfor, 2000; Polse, Sizemore, Burns, & Evans, 2011; Sabisch et al., 2009; Sizemore, Polse, Burns, & Evans, 2011; Weber-Fox et al., 2010).

Although differences in stimuli and participant selection criteria coupled with low statistical power may be contributing to the inconsistencies in ERP studies, there are methodological issues that are unique to EEG that may also be contributing to the lack of a clear pattern of evoked activity for SLI. For instance, one might find it striking, given that the wealth of behavioral data consistently show slower speed of processing in SLI (Leonard et al., 2007), that there seems to be a notable absence of a pattern of slower scalp-recorded activity in EEG studies of SLI. Although one of the advantages of EEG is that the temporal resolution is on the order of milliseconds, analysis of latency measures of the EEG components are particularly unreliable because a sharp peak often cannot be defined in the waveform (Luck, 2005; Luck & Kappenman, 2012).

This problem of identification of “peak amplitude” is compounded further in studies where individuals differ in the time course of spoken word identification. For instance, lexical-phonological processing in children with SLI is characterized not only by atypical activation of lexical-phonological competitors as compared with normal controls but also by the need for up to more than 200 ms more of the acoustic signal as compared with normal controls before spoken word are recognized (Mainela-Arnold & Evans, 2013; Mainela-Arnold, Evans, & Coady, 2008). If one assumes that semantic and/or syntactic processing of spoken words begins at the point when the child is able to pick out the word from the acoustic signal, and the point at which

children with SLI and typical children can uniquely identify a word differs on the order of 200 ms, then the time course of ERP components should be differentially affected for children with SLI as compared with normal controls, and comparison of amplitude modulation will be out of synchronization.

In addition to the timing features of ERP waveforms not necessarily reflecting the actual point in time when the brain first distinguishes the conditions, differences in the amplitude of an ERP component also may not correspond to differences in component size. For instance, it is possible that neural activity differed before a given time point but that the ERP is not sensitive to this difference. Further issues arise in comparing the time courses of ERP components across groups. A primary question of interest is differences in latency, and the measure most often used is comparing peak latencies (Jemel, Oades, Oknina, Achenbach, & Röpcke, 2003; Luck, 2005); however, there are significant issues inherent in using peak latency to infer differences in the time course of the ERP components across groups or conditions (Bishop & Hardiman, 2010; Luck, 2005).

The degree of modulation of an ERP component is measured by subtracting the average response between two conditions (i.e., standard/deviant; semantically congruent/semantically incongruent; grammatical/agrammatical) and comparing the amplitude of this difference wave in a given time window. Differences in modulation of a component for SLI as compared with normal controls may also be confounded by learning and memory in SLI, which will manifest in differences in repetition effects over the course of the trials for SLI as compared with normal controls. Finally, the topography of activity for SLI as compared with normal controls may be swamped by factors such as atypical laterality for SLI as compared with normal controls.

To address some of these methodological problems, researchers have begun to explore alternative research designs and data analysis techniques. For instance, Bishop and Hardiman (2010) recently presented a novel analysis of MMN data using an independent component analysis to reduce artifacts and remove those components having high trial-by-trial variance. Using this analysis, Bishop and Hardiman were able to show that the sensitivity and specificity of MMN could be used to identify individuals with auditory processing deficits. In an analysis of experimental data, as well as of a dummy dataset, their criterion for MMN identified 2 of 17 (12%) false-positive results and showed that some individuals evidenced atypical MMN despite showing good ability to discriminate the stimuli on behavioral tests (Bishop & Hardiman, 2010).

One limitation of ERP studies is their inherently poor spatial resolution, which significantly constrains the degree to which one can make inferences about specific locations of brain activity. MEG is a neurophysiological technique similar to EEG in that it measures neural activity with potentially sub-millisecond temporal resolution, limited only by the digitization rate. It differs from EEG in that it measures magnetic fields from electrical currents that are produced by the brain during sensory, motor, or cognitive tasks. Because magnetic fields pass through biological tissues with essentially no perturbation, the spatial relationship between active cortical sources and the sensor layout is quite correspondent, providing greater precision in the localization of brain activity as compared with EEG (Huang et al., 2007).² As a result, MEG provides a means of observing not only the temporal patterns in cortical activity underlying language processing but also, simultaneously, information regarding where in the brain this activity is occurring (Marinkovic et al., 2003).

To date, only a few studies have used MEG to investigate language processing in SLI (Brown et al., 2014; Helenius et al., 2009, 2014; Larson & Lee, 2014). For instance, Helenius et al. (2014) used MEG to investigate the spatiotemporal course of cortical activation in SLI. Peak latency and amplitude of the N400 m response in the SLI children did not differ from normal controls; however, detailed analysis revealed that functionally, the N400 m response was qualitatively different for SLI as compared with the normal controls. Specifically, although the SLI group showed activity similar to that of normal controls for the N400 m effect on words and nonwords at 600–900 ms after word onset in the left and right hemispheres, there was no repetition effect evident in the left hemisphere for the SLI group during the initial phase of the N400 m response (300–600 ms). This nearly nonexistent repetition priming in the left hemisphere in the SLI children is consistent with other studies of brain function in SLI, suggesting abnormal or reduced involvement of the left hemisphere while processing words. The findings from this study differ from the study of Helenius and colleagues involving adults with a history of SLI (Helenius et al., 2009). In this earlier study, they observed that although repetition effects were less robust for adults with a history of SLI as compared with normal controls, there was nonetheless a repetition suppression effect, albeit abnormally small but evident bilaterally, in contrast to the lack of normal lateralization and uniquely right hemisphere suppression for the children with SLI.

²Unlike PET and fMRI, MEG activity maps are still dependent on the modeling assumptions about the number and complexity of the activity sources being examined.

A technology known as aMEG (Dale & Halgren, 2001) has also recently been used to investigate individual differences in language in SLI (Brown et al., 2014). aMEG is a technique that uses anatomical MRI information about an individual subject's cortical structure to constrain the space of potential activity sources for MEG or EEG signals (Dale et al., 2000; Dale & Sereno, 1993) to generate a dynamic statistical parametric map (dSPM) similar to maps generated for fMRI. These map movies provide millisecond-wise temporal resolution with much better spatial resolution than standard EEG of real-time language and cognitive processing, revealing the dynamic unfolding of task-locked brain activity for an individual subject. Noise-normalized, anatomically constrained statistical parametric maps of MEG-derived brain activity have been shown to have strong spatial correspondence with recordings from direct intracranial EEG for a variety of stimulus types and sensory and cognitive components (Halgren et al., 1994).

In addition to its sub-millisecond temporal resolution, aMEG provides excellent signal-to-noise properties and enhanced localization of brain activity through the use of noise-normalized source estimates constrained to the cortical reconstruction of each individual subject and aligned using sulcal and gyral surface-based registration (Dale & Halgren, 2001; Dale et al., 2000). Unlike single-dipole fitting MEG methods, the aMEG technique assumes multiple, distributed, and simultaneous cortical generators, which multiple functional neuroimaging and recording studies overwhelmingly show is an appropriate assumption for complex cognitive and language tasks. Many researchers now using MEG use some model constraints that attempt to inform activity localization with information from the same subject's MRI scan.

Recently, Brown et al. (2014) used a novel technique that allowed them to investigate the dynamic functional brain organization for semantic processing for individual subjects with SLI using aMEG. In using this approach, they were able to compare the dynamic time course and cortical activity linked to semantic processing of a single participant with SLI to his sibling with normal language abilities as well as to a normal control group. Brown and colleagues found that the dynamic pattern of brain activity for the child with SLI was subjectively and statistically different from his sibling and from the average of the group of unrelated normal controls. Specifically, during the semantic processing of pictures of concrete objects, the SLI participant showed a spatiotemporal pattern of activity that was most notable for being strongly right-lateralized and delayed as compared with the normal control group and his sibling. When performing the same semantic task with word stimuli, cortical activity for the child with SLI was characterized by an even greater degree

of right hemisphere lateralization and was similarly delayed in time as compared with his siblings as well as the normal control group.

In a direct comparison with the distribution of neural activity at all cortical locations and time points within the typically developing group using z-scores, Brown and colleagues observed that the child with SLI showed marked differences from the typical dynamic functional organization that agreed with qualitative comparisons of the dSPMs. Consistent with previous studies, Brown and colleagues observed the child with SLI to evidence statistically greater right hemisphere cortical activation and statistically significant under-recruitment of left hemisphere cortical regions including perisylvian, anterior temporal, opercular, and lateral and superior frontal cortex as compared with normal controls. However, this study was novel in its characterization of the dynamic and localized patterns of cortical activity over time, using the combined spatial and temporal sensitivities of aMEG to make inferences about specific components of language that might be affected in this individual with SLI.

72.5 CONCLUSION

Structurally, a pattern that emerges across studies of brain structure in SLI is one of atypical cortical and subcortical morphology and tissue properties for some, but not all, areas of the brain. Abnormal findings in SLI have been demonstrated in measures of cortical and subcortical gray matter volumes and in the microstructural characteristics of white matter as revealed by diffusion imaging and tractography. Recent technological advances that now enable researchers to differentiate cortical and subcortical surface area and thickness, and genetic influences on these aspects of cortical and subcortical structure, suggest an important future direction in the study of SLI. Two important questions that need to be addressed are the following: (i) are the characteristics of cortical and subcortical neuronal structure in SLI reflective of "immature" or delayed cortical development, or do they reflect qualitatively different brain development and (ii) to what extent is atypical brain structure and functional organization in SLI a proximal "cause" of the language impairments, or are there some aspects of the structural and functional brain abnormalities that are more accurately thought of as merely the expression or product of the behavioral deficits of the child with SLI?

Overall, brain activity for SLI appears to be characterized by reduced activation levels for some, but not all, cortical and subcortical regions based on studies using hemodynamic measures, atypical modulation of cerebral peak latencies and amplitudes when

measured by EEG, and differences in the lateralization and timing of cortical activation patterns when assessed via MEG. Electrophysiological studies suggest that the latency of brain activity in SLI appears to be atypical during early stages, but not at later points in the time course of speech and language processing. If future research shows that this lack of difference in the time course of brain activity for SLI and typical peers at later time points (i.e., P3, N400, P600) is not an artifact of data analysis methods, then a model of SLI needs to be developed that accounts for atypical brain activation, the time course of early and late stages of cortical activity, and the substantial body of behavioral data consistently showing a pattern of generalized slower speed of processing for children with SLI.

Findings from recent studies using MEG and aMEG that suggest the language systems of individuals with SLI may be organized quantitatively and qualitatively in a different manner from those of their typically developing peers, and that, at least for some individuals, this may involve atypical right hemisphere specialization for specific subcomponents of language such as semantic representations for word meanings and object concepts. So, future research should incorporate the use of these multimodal imaging techniques that allow for a dynamic approach to examine the multiple language systems in the working brain. This may be advantageous in understanding the cortical and subcortical organization of both normal and abnormal language systems.

72.6 TOWARDS A NEUROBIOLOGY OF SLI

Historically, the focus of studies of brain structure and function in SLI has been on characterizing the underlying neurobiology in these children with the hope that a more detailed characterization of the brain structure and function might ultimately lead to the discovery of the cause of SLI. There is a debate among researchers regarding whether SLI comprises a distinct diagnostic clinical category, or if children with SLI merely represent those children whose language abilities fall at the lower end of the normal distribution (for detailed discussion see [Bishop, 2014](#); [Dollaghan, 2011](#)). This debate rests largely on the use of behavioral measures to classify SLI. From the rapidly growing body of work investigating brain structure and function in SLI, a picture is emerging that suggests that, although there are individual differences in the manifestation of the behavioral symptoms of SLI, the term SLI does not merely represent children on the low end of the normal distribution but is instead a neurodevelopmental language disorder, characterized by a disturbance in the dynamics of brain development that collectively affect

cortical and subcortical morphology in selected regions of the brain and the tissue properties of white matter connections, and that this pattern of neurobiological aberrations leads to a characteristic combination of delayed onset of language acquisition, uneven language acquisition profile, and learning and memory deficits.

Advances in noninvasive, safe, functional brain imaging technologies coupled with a richer integration between neuroscience, cognitive psychology, and linguistics have led to an explosion of new research in the neuroscience of language and in our understanding of the nature of language and cognition in the brain ([Devor et al., 2013](#); [Eicher et al., 2013](#); [Erus et al., 2014](#); [Fjell et al., 2012, 2013](#); [Lieberman, 2002](#); [Poepfel et al., 2012](#)). With the advent of better imaging technologies and a growing body of research in SLI, neurobiological models of the language impairments in SLI are being reconceptualized and are beginning to rest on richer theoretical foundations. Instead of looking for a direct link between abnormal brain morphology and brain function and language impairments in SLI, these new models are shifting away from a “single-cause” model of SLI and are beginning to take advantage of these technologies to unravel the genetic and neurobiological characteristics of SLI ([Badcock et al., 2012](#); [Bishop, 2013](#); [Bishop, 2009](#); [Li & Bartlett, 2012](#); [Paracchini, 2011](#); [Poepfel, 2011](#); [Rice, 2013](#)).

Focusing on general purpose learning systems that appear to support language acquisition in normal populations, this new work suggests that abnormal brain development and, specifically, atypical cortical structural organization may result in subsequent abnormal cerebral functional organization. In line with this new view, studies directly comparing structural and functional brain organization in SLI show both anatomical and physiological abnormalities in some regions, but in other regions abnormalities in brain structure were not correlated with brain function during language processing, raising the question regarding whether and in which direction abnormal brain morphology and atypical functional lateralization in SLI are causally linked ([Badcock et al., 2012](#); [Bishop, Holt, Whitehouse, & Groen, 2014](#)). This work also suggests that the language impairments seen for some children with SLI may be the result of a domain-general learning and memory deficit—mediated by the corticostriatal system—where abnormal functioning of this system manifests as atypical cortical organization of language ([Brown et al., 2014](#); [Lum, Conti-Ramsden, Page, & Ullman, 2012](#); [Lum, Ullman, & Conti-Ramsden, 2015](#); [van der Lely & Pinker, 2014](#)).

Importantly, similar to a host of neurodegenerative disorders, multiple genetic and environmental factors will likely be shown to contribute to disturbances in the dynamics of brain development in children with

SLI. Thus, the dynamic between these factors and atypical brain development in SLI is a complex one. However, moving away from both a “single-cause” deficit account of SLI and the classic left hemisphere dominant model of language and moving toward characterizing this dynamic neurodevelopmental phenomenon as a complex system may ultimately be the key to discovering the cause of SLI.

73.1 INTRODUCTION

The study of aphasia and its associated lesions in the 19th century by Dax (1936), Broca (1861, 1865), Wernicke (1874, 1881) and others revealed new insights about the neural organization of language. Perhaps the most reliable finding was that patients with language impairment typically had damage to the left hemisphere. Damage to the more anterior parts of the brain, particularly the left posterior inferior frontal gyrus (IFG), was often found in those whose spoken output was limited or poorly articulated (Broca, 1865); damage to the more posterior regions in the left temporal lobe (in the absence of damage to frontal regions) was found in those whose spoken output was well-articulated but meaningless (Wernicke, 1881). These early observations established that language functions are localized in the left cerebral hemisphere and provided the groundwork for Lichtheim's model of aphasia, later adapted by Geschwind (1965). Geschwind put together early observations, along with subsequent reports of behavior and associated lesions (based largely on autopsy), to characterize the collection of frequently co-occurring language characteristics that result from damage to particular areas of the brain. With the advent of computerized tomography (CT) technology in the early 1970s, it was confirmed that classic aphasic syndromes correlated with particular vascular territories (Damasio & Geschwind, 1984).

In this chapter, the vascular aphasia syndromes are described. It is emphasized that the various characteristics frequently co-occur because they all depend on areas of the brain supplied by the same artery (or branch of an artery). If only part of the territory is damaged, then only a subset of the characteristics is present.

That is, the characteristics are dissociable. Many of the vascular aphasia syndromes are associated with damage to nonlanguage functions that also depend on brain tissue supplied by the same arterial branch. For example, Broca's aphasia is associated with left arm weakness or spasticity, because left arm function (like the speech and language functions affected in Broca's aphasia) depends on territory supplied by the superior division of the left middle cerebral artery (MCA). Therefore, one can see from the outset that these syndromes are not theoretically coherent syndromes in the sense that they have a single underlying functional basis; rather, they have a shared anatomical basis. After describing the vascular syndromes, we discuss how they can be understood within more current concepts of language and aphasia, and whether they have any usefulness in aphasia research, management of stroke, or rehabilitation of aphasia.

73.2 CLASSIC APHASIA CATEGORIZATION: VASCULAR SYNDROMES

73.2.1 Broca's Aphasia

Broca's aphasia is characterized by nonfluent, telegraphic, poorly articulated verbal output in which meaning is conveyed by content or information-carrying words, such as nouns and verbs; however, nouns are named more accurately than verbs (Berndt, Mitchum, Haendiges, & Sandson, 1997; Miceli, Silveri, Villa, & Caramazza, 1984). Morphological inflections (e.g., past tense, plurals) and function words (e.g., articles, conjunctions, prepositions, auxiliary verbs,

pronouns) are often omitted or incorrectly produced, and word order may be incorrect. Thus, speech production is characterized as agrammatic. Although it is widely agreed that individuals with Broca's aphasia are nonfluent, fluency is a multidimensional construct. "Nonfluency" may be associated with diminished number of words per minute, reduced phrase length, impaired melody, disrupted articulatory agility, and/or agrammatic sentence production (Goodglass & Kaplan, 1983). The factors that affect speech fluency may vary from one individual to the next. Also, individuals with aphasia may have preserved islands of fluency, particularly for rote and overlearned speech, in otherwise nonfluent novel speech output. Because speech fluency can be defined by a complex set of features, it may be difficult to judge. Experienced speech-language pathologists analyzed the content and fluency ratings on the Western Aphasia Battery for 20 individuals with aphasia. Inter-rater reliability ratings for fluency were poor using published criteria (Trupe, 1984).

It is important to note that the severity of language impairment can vary across individuals with Broca's aphasia. In its mildest form, Broca's aphasia presents with reduced phrase length with agrammatic sentence production and relatively retained language comprehension, although there may be deficits in comprehension of multistep commands or sentences with complex syntax (e.g., The flowers that Bob gave to Susan were roses). In more severe presentations, there is reduction of all speech output, with speech being limited to one or more recurrent utterances and automatic sequences (Goodglass, Kaplan, & Barresi, 2001). Repetition is usually halting and dysfluent. Reading comprehension may parallel auditory comprehension. The mechanics of written expression are compromised because patients must write with the left, nondominant hand, because of frequently co-occurring right hemiparesis. Spelling is often impaired, and written output is agrammatic.

Broca's aphasia, as originally described by Paul Broca, was attributed to lesions of the posterior half of the left third frontal convolution (IFG; Brodmann area 44). This area became known as Broca's area and, along with surrounding areas in the posterior frontal lobe, is supplied by the superior division of the left MCA. Subsequently, neuroanatomists and aphasiologists challenged the causative association between this circumscribed lesion site and the nature of the aphasia reported by Broca. Mohr et al. (1978) reported that a more widespread region must be damaged to result in the constellation of impairments seen in the syndrome of Broca's aphasia as originally described. Damage to Broca's area alone, according to Mohr, results in only a subset of the symptoms, most notably impaired motor speech (Keller, Crow, Foundas, Amunts, & Roberts, 2009). Furthermore, advances in neuroimaging,

permitting studies of neural activity in normal adults during cognitive/language tasks, have led away from classic structure/function relationships to the role of brain networks and regions in the performance of cognitive/language tasks. Increasingly, Broca's area is tied to a variety of language functions (Davis et al., 2008; Grodzinsky & Amunts, 2006), functions that might be critical to language such as verbal working memory (Rogalsky & Hickok, 2011), and even nonlinguistic functions, such as visual searching and visual spatial cognition (Grodzinsky & Amunts, 2006). Many studies distinguish between functions of pars opercularis and pars triangularis (which are distinct cytoarchitectural fields that comprise Broca's area but have a great deal of anatomical overlap across individuals; Grodzinsky & Amunts, 2006). In individuals with stroke involving Broca's area, there is often concomitant right hemiparesis or monoparesis of the arm (and right facial weakness) due to ischemia of the nearby precentral gyrus.

73.2.2 Wernicke's Aphasia

Wernicke's aphasia is characterized by fluent, effortless, but relatively meaningless, spontaneous speech and repetition, and impaired comprehension at the word, sentence, and discourse levels. Spoken language may be limited to jargon comprising either real words or neologisms (nonwords such as "klimorata"), or a combination of the two. In milder forms, paraphasic errors are present as well as intermittent coherent "social" phrases, such as, "yes, that's right." Melodic contour of spoken language is often preserved, initially giving listeners the impression that output is intact. Comprehension may be severely compromised and impaired phonological analysis is thought to underlie the comprehension impairment in Wernicke's aphasia (Robson, Keidel, Lambon Ralph, & Sage, 2012). Repetition is generally similar to spontaneous speech—fluent jargon. These deficits have been attributed to impaired inhibition of lexical activation, so that the person cannot select the appropriate word, sound, or meaning from competing linguistic units that are also activated (Blumstein & Milberg, 2000). Although such an underlying impairment would account for many of the observed language deficits, it could not easily account for all cases. For example, there have been some reported cases of Wernicke's aphasia with relatively preserved or relatively impaired categories of words, such as animals or tools (Hillis & Caramazza, 1991a), or selectively impaired nouns relative to verbs (Zingeser & Berndt, 1990). Selective impairment or preservation of particular semantic categories of words indicates a deficit at the level of accessing lexical-semantic (Hillis & Caramazza, 1991a). Reading

comprehension and written expression are typically impaired in a very similar pattern as the impairment in auditory comprehension and verbal expression, respectively, although some individuals may be able to read aloud and spell to dictation regular words that they fail to understand (Hillis & Caramazza, 1991a). In contrast to those with Broca's aphasia, individuals with Wernicke's aphasia are typically unaware of their errors; they may have only a shallow awareness that they have some kind of difficulty communicating.

This collection of deficits is usually caused by neural dysfunction in regions supplied by the inferior division of the left MCA, including Wernicke's area (most of Brodmann area 22, in the posterior, superior temporal gyrus), and often inferior parietal cortex (angular and supramarginal gyri) and inferior and middle temporal gyri. Because the Meyer's loop of the optic radiations runs through the temporal cortex, there is often a concomitant right homonymous superior quadrantanopsia. The fact that there is individual variability in the cerebral vasculature and the areas supplied by particular arteries can account for occasional dissociations between the typical deficits in Wernicke's aphasia (i.e., only some of the usual territory is affected by stroke in some cases, such that only some of the symptoms occur) as well as occasional anomalous lesion sites in patients with Wernicke's aphasia.

73.2.3 Global Aphasia

Global aphasia refers to a profound impairment of all modalities of receptive and expressive language. Individuals with global aphasia typically present with marked impairments of comprehension of single words, sentences, and conversations, as well as severely limited spoken output. Spontaneous verbal output may be restricted to single words, nonwords, or undifferentiated phonation and some individuals' speech only consists of perseverative utterances (e.g., "no, no"). In addition, reading and writing are typically profoundly compromised. Because of the severity of language impairment, communication partners sometimes need to anticipate the communicative intentions of individuals with global aphasia or rely primarily on gestures or drawing. In most cases, both Broca's area and Wernicke's area are damaged (Mazzocchi & Vignolo, 1979) or functionally compromised (Hillis et al., 2004) because of occlusion or stenosis of the proximal MCA (affecting both the inferior and superior divisions) or the internal carotid artery (ICA).

73.2.4 Conduction Aphasia

Conduction aphasia is usually defined as a language impairment characterized by relatively fluent, although

paraphasic, spontaneous speech, intact auditory comprehension, and disproportionately impaired speech repetition. Secondary features include reading impairments, variable writing difficulties, and ideomotor apraxia (Benson et al., 1973). Individuals with conduction aphasia display well-articulated responses that are phonemically similar to target words and repetitive self-corrections resulting in increasingly closer approximations to targets. This phenomenon is termed "conduit d'approche" (Goodglass, 1992). Traditionally, conduction aphasia is thought to be caused by a lesion in the arcuate fasciculus, a white matter tract that runs between Broca's and Wernicke's areas, and thus is considered a disconnection syndrome because a lesion in the arcuate fasciculus is assumed to interrupt communication between the sensory and motor modules of the classically defined speech-language system (Geschwind, 1965). This hypothesis has been challenged. More recent evidence shows that conduction aphasia is not the result of damage only to the arcuate fasciculus. Although damage to the arcuate fasciculus is reported to be present in the setting of conduction aphasia in some contemporary accounts (Geldmacher, Quigg, & Elias, 2007; Yamada et al., 2007; Zhang et al., 2010), it is not reported in others. In fact, cortical lesions alone may produce conduction aphasia (Anderson et al., 1999; Quigg, Geldmacher, & Elias, 2006), indicating that damage to the arcuate fasciculus is not a prerequisite condition for conduction aphasia. Furthermore, lesions of the arcuate fasciculus do not always cause conduction aphasia (Epstein-Peterson, Vasconcellos-Faria, Mori, Hillis, & Tsapkini, 2012; Selnes, van Zijl, Barker, Hillis, & Mori, 2002). Substantial anatomical evidence suggests that conduction aphasia is caused by damage to the left superior temporal gyrus and/or the left supramarginal gyrus (Axer, von Keyserlingk, Berks, & von Keyserlingk, 2001; Baldo & Dronkers, 2006) due to occlusion of a branch of the inferior division of the left MCA.

73.2.5 Anomic Aphasia

Impairment of word retrieval is the primary feature of anomic aphasia with relatively well-preserved language function in other realms. Individuals with anomic aphasia may use circumlocutions for targets and display protracted pauses in verbal output and use of fillers (e.g., "What is that called?"; "You know what I mean"), resulting in empty or low-content verbal output. Anomia is present in other aphasia syndromes and may be the residual language symptom as individuals recover language abilities. Consequently, anomic aphasia is the least reliably localized aphasia in chronic stroke. However, acute, isolated anomia is most often

associated with small areas of ischemia in left inferior temporal cortex or thalamus (Hillis et al., 2006).

73.2.6 Transcortical Aphasias

Three transcortical aphasias have been characterized: transcortical motor (TCM); transcortical sensory (TCS); and mixed transcortical (MTC). The transcortical aphasias are distinguished by intact repetition ability. TCM aphasia shares many characteristics of Broca's aphasia but has the distinctive feature of fluent, grammatical repetition. This vascular syndrome is caused by lesions just anterior or superior to (surrounding) Broca's area (Freedman, Alexander, & Naeser, 1984), often caused by occlusion of the anterior cerebral artery (ACA) (Masdeu, Schoene, & Funkenstein, 1979; Rubens, 1976) or "watershed" areas between the ACA and the MCA. TCS aphasia is similar to Wernicke's aphasia, except for the presence of accurate repetition. TCS aphasia is usually attributed to lesions in areas surrounding Wernicke's area, in the watershed territories between the MCA and posterior cerebral artery (PCA), or the PCA territory (Alexander, Hiltbrunner, & Fischer, 1989). Induction of transient TCS aphasia during cortical mapping of individuals with seizure disorders is associated with multiple sites along the posterior superior and middle temporal gyri in classical Wernicke's area. Electrical interference mapping studies indicate that sparing of Wernicke's area is not a necessary condition for TCS aphasia (Boatman et al., 2000). MTC aphasia is analogous to global aphasia, with reduced or absent spontaneous speech, severely impaired language comprehension, and preserved repetition with consequent echolalia (Albert, Goodglass, Helm, Rubens, & Alexander, 1981). Lesion sites include both anterior and posterior left hemisphere cortical association areas, sparing the perisylvian language core and producing an "isolation of the speech area" (Rapcsak, Krupp, Rubens, & Reim, 1990).

73.2.7 Subcortical Aphasias

Subcortical aphasias can be classified into three groups: striato-capsular aphasia; thalamic aphasia; and aphasia associated with white matter paraventricular lesions (Kuljic-Obradovic, 2003). Preservation of repetition is common to all three subtypes, although there are features specific to each subtype. Striato-capsular aphasia and aphasia associated with paraventricular lesions are characterized by impairment of fluency, semantic paraphasias, and generally preserved comprehension. Thalamic aphasia is characterized by impaired comprehension and naming with fluent output containing predominantly semantic paraphasias

(Benson & Ardila, 1995; Demonet, 1997). The role of subcortical structures in language remains controversial and different mechanisms have been offered to explain how such subcortical lesions can lead to aphasia. Some ascribe a direct role to subcortical areas in language function (Cappa, Cavallotti, Guidotti, Papagno, & Vignolo, 1983; Damasio, Damasio, Rizzo, Varney, & Gersh, 1982). Others contend that subcortical lesions lead to aphasia through diaschisis—dysfunction of a remote area of cortex caused by impaired input from the subcortical region (Perani, Vallar, Cappa, Messa, & Fazio, 1987; von Monakow, 1914). For example, unilateral lesions of the ventromedial thalamic nucleus produce a major ipsilateral metabolic depression in the cortex and adjacent thalamic nuclei, bilateral metabolic reduction in the basal ganglia, and relatively minor effects in the contralateral cortex (Girault, Savaki, Desban, Glowinski, & Besson, 1985). Language impairments in nonthalamic subcortical infarcts have been attributed to hypoperfusion of cortical structures caused by stenosis or occlusion of a large cerebral vessel responsible at the same time as the subcortical infarct (Hillis et al., 2002).

73.2.8 Variability of Vascular Syndromes

These classic aphasia classifications have also been reviewed in detail by Damasio (1992), Goodglass (1993), and Hillis (2007). The early accounts of vascular syndromes used the lesion method in which abnormal behavior is documented in the context of brain pathology, and localization of normal function is extrapolated by assuming that the lesioned area was responsible for whatever function was impaired at the time of assessment (Benson, 1994). It is important to note that individual variability in the shape of the brain as well as the patterns of sulci and gyri renders only approximate localization of cytoarchitectural fields, so even lesions that appear to be in the identical area may not affect identical functions (Amunts et al., 1999; Rademacher, Caviness, Steinmetz, & Galaburda, 1993). Furthermore, human vasculature varies considerably, more so in disease states, so that blockage of a particular branch does not reliably affect the identical areas (Caplan & Van Gijn, 2012). Not surprisingly, studies have variably confirmed the relationship between vascular territories and the vascular syndromes (Gavrilescu & Kase, 1995; Kumral, Bayulkem, Evyapan, & Yuntun, 2002). Furthermore, recovery from aphasia varies substantially among patients (Hochstenback, den Otter, & Mulder, 2003; Lazar, Speizer, Festa, Krakauer, & Marshall, 2008). Depending on the time of evaluation, a person with damage to an entire vascular territory might present

with the entire vascular syndrome, a partial syndrome, or none of it (if the person recovered completely). One study showed that the vascular syndromes correspond to vascular territories more reliably in the acute than in the chronic stages of stroke (Ochfeld et al., 2010). In acute stroke, language impairments reflect the entire dysfunctional tissue (both infarcted and hypoperfused tissue) not always visible on structural imaging.

Beginning in the 1980s, developments in functional neuroimaging, including PET, functional MRI (fMRI), and magnetoencephalography, expanded understanding of the functional neuroanatomy of language. Safe, noninvasive imaging of the brain reveals that areas in both hemispheres of the brain are activated specifically during language tasks, although the left hemisphere shows more activation in the majority of neurologically normal adults (Binder, 1997; Crinion, Lambon Ralph, Warburton, Howard, & Wise, 2003; Fridriksson & Morrow, 2005; Petersen, Fox, Posner, Mintun, & Raichle, 1988), and that more distant areas of the cortex, such as inferior and anterior temporal cortex (Wise, 2003) and the basal ganglia and thalamus (Kraut et al., 2002), are also activated during language tasks.

73.3 VASCULAR SYNDROMES AND CONTEMPORARY PARADIGMS

How do the vascular syndromes fit with more contemporary frameworks of the functional neuroanatomy of language that postulate a dual stream of language processing (Hickok & Poeppel, 2000, 2004, 2007)? The brain is assumed to compute a transformation between thought and an acoustic signal (Schwartz, Faseyitan, Kim, & Coslett, 2012), and it executes parallel processing to synthesize input via interconnected neural networks (Ueno, Saito, Rogers, & Lambon Ralph, 2011). In the neuroanatomical model of speech processing, proposed by Hickok and Poeppel (2007), speech perception involves auditory-responsive areas in the superior temporal gyrus bilaterally, left more so than right. The processing system then diverges into two streams. The ventral stream is a sound-meaning interface responsible for processing speech signals for comprehension. In the dorsal stream, acoustic speech signals are translated into articulatory representations essential for speech development and production involving auditory-motor integration. These streams are also thought to be bidirectional; the ventral stream mediates the relationship between sound and meaning for perception and production, and the dorsal system can also map motor speech representations onto auditory speech representations (Hickok & Poeppel, 2004, 2007).

When a map of the vascular territories is superimposed onto this neuroanatomical model of speech

processing (Figure 73.1), one can see that the dorsal stream is supplied by the superior division of the left MCA, and the ventral stream is supplied largely by the inferior division of the left MCA. Therefore, it is not surprising that individuals with the vascular syndrome of Broca's aphasia typically have deficits that can be attributed to disruption of the dorsal stream: the articulatory network or sensorimotor interface. Likewise, it is not surprising that individuals with the vascular syndrome of Wernicke's aphasia have deficits that can be attributed to the lexical interface and/or combinatorial network to map sound onto meaning. The repetition deficit in conduction aphasia is attributed to damage in the Sylvian parietal-temporal (Spt) area, which is located within the Sylvian fissure at the parietal-temporal boundary, reflecting disruption of the dorsal stream route (Hickok & Poeppel, 2004). This hypothesis is supported by fMRI data that show that the region of maximal overlap in lesion distribution in 14 conduction aphasics includes area Spt (Buchsbaum et al., 2011). This is consistent with recent evidence that suggests that conduction aphasia is caused by damage to the left superior temporal gyrus and/or the left supramarginal gyrus (Axer et al., 2001; Baldo & Dronkers, 2006), both of which are anatomical regions associated with the dorsal stream (Schwartz et al., 2012). Further support is found in studies using computational models to synthesize aphasia. Conduction aphasia is produced after damage to the dorsal pathway in a neuroanatomically constrained computational dual dorsal-ventral pathway computational model (Ueno et al., 2011). Other relevant work includes voxelwise lesion behavior mapping to investigate the association of language impairments and dorsal-ventral streams. Although these studies do not typically associate lesions in particular voxels with specific aphasia syndromes, findings are that deficits in naming and repetition are associated with the dorsal stream (Hanley, Kay, & Edwards, 2002; Ueno et al., 2011) and deficits in comprehension are associated with the ventral pathway (Hillis & Caramazza, 1991b). Finally, it should not be surprising that unilateral vascular syndromes do not typically disrupt the conceptual system, which is bilaterally and widely represented in this model. Rather, conceptual meaning is disrupted in neurodegenerative disease, such as semantic variant primary progressive aphasia.

73.4 COGNITIVE PROCESSES UNDERLYING APHASIA

What is lost by characterizing an individual as an exemplar of a particular vascular syndrome? As noted, each vascular syndrome is a collection of frequently

FIGURE 73.1 A schematic representation of the cortical organization of speech processing proposed by Hickok and Poeppel (2007), on which we have superimposed a map of the vascular territories on the left hemisphere only. The left ACA is shown in transparent yellow; the left superior division MCA is shown in transparent blue; the left inferior division MCA is shown in transparent pink; and the left PCA is shown in green.

co-occurring impairments to functions that depend on an area of brain supplied by a particular blood vessel. In the past, these deficits were characterized as impairments to particular tasks (e.g., sentence repetition). However, it is now understood that each language task comprises a number of cognitive representations and processes that might depend on different areas of the brain. For example, some of the controversy regarding the anatomical correlates of conduction aphasia may have arisen by characterizing patients as having impaired sentence repetition, rather than identifying what cognitive processes underlying sentence repetition were impaired in individual patients. Cognitive models of language processing include both a semantic and nonlexical phonological mechanism for word and sentence repetition (Hanley et al., 2002). Evidence for this model is found in case reports of performance on language tasks in individuals with neurologic impairments (Hanley, Dell, Kay, & Baron, 2004; Hillis & Caramazza, 1991b). More recently, in a study of sentence recall in healthy adults and an individual with aphasia, phonological information was judged to contribute to sentence recall performance as a complement to semantic and conceptual information (Schweppe, Rummer, Bormann, & Martin, 2011). Some patients may have a disrupted phonological short-term

storage system, whereas others may have a disrupted semantic working memory system or disrupted “central executive” component of working memory as the cause of impaired sentence repetition. Each of these impairments might be associated with different lesion sites. Error rates on syllable and pseudoword repetition tasks were increased with inhibitory transcranial magnetic stimulation (TMS) to the posterior part of the superior temporal sulcus and temporoparietal junction in normal volunteers, implicating the role of the dorsal pathway. Differences in error rates were not seen during sentence repetition tasks, suggesting that the ventral pathway may have been recruited for sentence repetition (Murakami, Kell, Restle, Ugawa, & Siemann, 2013).

73.5 POTENTIAL USEFULNESS OF VASCULAR SYNDROMES

73.5.1 Aphasia Research

Grouping patients for research assumes that individuals in the group are homogeneous with respect to something of theoretical interest. The vascular syndromes are frequently co-occurring symptoms.

Individuals with Broca's aphasia often have both apraxia of speech and more difficulty naming verbs than nouns (Miceli et al., 1984); they also often have weakness of the right arm. These symptoms may all stem from damage to the posterior frontal lobe, supplied by the left superior division MCA. But they do not have a common underlying cause, and they dissociate in individuals. It has been argued that because only a subset of deficits in a vascular syndrome is likely to be present in an individual (depending on the portion of the vascular territory affected by stroke, the degree of recovery, individual variation in anatomy), the syndrome approach has limited usefulness for aphasia research. For example, patients in the group "Broca's aphasia" might each have different disruptions to cognitive processes underlying articulation and/or sentence production (Caramazza & Badecker, 1989), all due to lesions in areas supplied by the superior division of the left MCA. Alternatives include single subject designs (Caramazza & Coltheart, 2006) and case series analysis (Schwartz & Dell, 2010), or grouping by cognitive impairment (DeLeon et al., 2007). However, classification by vascular syndrome remains the standard basis for describing groups of participants in aphasia research.

73.5.2 Treatment of Stroke

Furthermore, grouping patients by affected vascular territory may be quite useful for a stroke neurologist. For example, grouping by vascular aphasia syndromes allowed the discovery that inferior division MCA strokes (associated with Wernicke's aphasia) were more likely due to cardioembolism (Bogousslavsky, Van Melle, & Regli, 1989), and superior division MCA strokes (associated with Broca's aphasia) were more likely due to carotid dissection and carotid occlusion (Trupe et al., 2013). Because it is often essential to initiate treatment before the lesion is seen on imaging, a good idea of the volume and location of the affected territory is useful in planning intervention. Furthermore, acute presentations of vascular aphasia syndromes provide the stroke neurologist with information about the likely areas of brain that are dysfunctional (either infarcted or hypoperfused). When there is mismatch between the vascular aphasia syndrome and the structural lesion seen on diffusion-weighted imaging (DWI; which is very sensitive to ischemic tissue even early in stroke), the stroke neurologist knows there is brain tissue that is hypoperfused and at risk for further ischemia. This "diffusion-clinical mismatch" is frequently a prompt for intervention (Reineck, Agarwal, & Hillis, 2005). To illustrate, the patient whose scans are shown in Figure 73.2 had Wernicke's

aphasia at onset but only a tiny lesion on DWI in the insula that could not account for his deficits. His "diffusion-clinical mismatch" prompted further imaging with perfusion-weighted imaging (PWI) the same day and intervention to reperfuse Wernicke's area. His Wernicke's aphasia resolved by day 3 with restored blood flow to Wernicke's area.

73.5.3 Aphasia Treatment

Is it useful to group patients by vascular aphasia syndrome for treatment of their aphasia? Certainly, there have been treatments described for Broca's aphasia, Wernicke's aphasia, and so on (Carlomagno, Zulian, Razzano, DeMercurio, & Marini, 2013; Conklyn, Novak, Boissy, Bethoux, & Chemali, 2012; Helm-Estabrooks, Fitzpatrick, & Barresi, 1982; Helm-Estabrooks & Ramsberger, 1986). Treatment on the basis of syndrome classification alone would obviously neglect important individual differences known to exist in each of the aphasia syndromes as well as

FIGURE 73.2 MRI scans of an individual with Wernicke's aphasia at day 1 (top panel). DWI (left) shows a tiny area of ischemia in the left insula. PWI the same day shows severe hypoperfusion of Wernicke's area and the surrounding left superior temporal cortex. Repeat imaging at day 3 (lower panel) shows restored blood flow to the entire area in association with resolution of Wernicke's aphasia.

personal preferences of individual patients, vital aspects of therapy consistent with evidence-based practice. In fact, most of these treatments are therapies for particular deficits within each syndrome. For example, in a case series study including individuals with Broca's, Wernicke's, and anomia, a cueing hierarchy was developed to treat anomia due to impaired access to word meaning or word form in all participants (Best et al., 2013). It would be at least as rational in most cases to describe the intervention as a therapy for "constructing a sentence planning frame" (rather than Broca's aphasia) or "mapping lexical representations to meaning" (rather than Wernicke's aphasia). Therapy for specific aphasia syndromes may be optimized by considering the respective roles of the ventral and dorsal streams. For example, the ventral pathway could be leveraged by encouraging patients to process the meaning of a target word during a repetition task in the treatment of conduction aphasia (Ueno & Lambon Ralph, 2013).

However, characterizing patients as exemplars of a vascular aphasia syndrome might be useful for neuro-modulatory treatments that are, by hypothesis, directed to particular sites of the brain. Aphasia treatment is just beginning to take advantage of targeted brain-based interventions, such as transcranial direct current stimulation (tDCS) and TMS designed to facilitate synaptic plasticity (Mottaghy, Sparing, & Topper, 2006; Schlaug, Renga, & Nair, 2008). Most studies have selected patients for treatment on the basis of vascular syndrome (Vines, Norton, & Schlaug, 2011) and have carefully targeted particular areas of the brain based on fMRI (Dmochowski et al., 2013; Fridriksson, Richardson, Baker, & Rorden, 2011) or predetermined regions. However, it is yet to be shown whether the localization of these treatments or the site of lesion/vascular syndrome of patients receiving these treatments (in conjunction with behavioral therapies) is critical to their effectiveness.

73.6 CONCLUSION

The value of classifying aphasias as vascular syndromes continues to be deliberated as the field of aphasiology evolves. The usefulness of classification depends on the goal. Characterizing someone as having a particular vascular syndrome communicates: (i) a set of likely symptoms; (ii) the area of the brain most likely to be affected (at least if the individual has not shown substantial change in either the lesion or the language symptoms since onset); and (iii) the arterial branch most likely to be involved if the cause of aphasia is ischemic stroke. Advances in neuroimaging have allowed refinements in characterizing lesions, so we

can now identify areas of the brain associated with impairments in specific cognitive functions underlying language. We are no longer limited to describing the symptoms associated with a vascular territory. New theories of language processing and production complement long-established classification systems, and these novel and emerging perspectives will certainly translate to changes in the conducting of research and treatment of stroke.

Psycholinguistic Approaches to the Study of Syndromes and Symptoms of Aphasia

Sheila E. Blumstein

Department of Cognitive Linguistic and Psychological Sciences, Brown University,
Brown Institute for Brain Sciences, Providence, RI, USA

74.1 INTRODUCTION

One of the fascinating aspects of aphasia is that language breakdown is not unitary. Not all aspects of language are affected in the same way and, crucially, depending on the site and extent of the lesion, brain injury to the left hemisphere results in a clinically diverse set of impairments and abilities. Persons with aphasia may show a constellation of impaired and spared abilities in auditory comprehension, speech output, repetition, naming, reading, and writing that together comprise a particular syndrome.

There is a long history of the characterization of the aphasia syndromes (Geschwind, 1965; Benson, 1979 for review), and although there are differences in nomenclature, there is general consensus on the clinical features that comprise a particular syndrome. However, syndromes provide a description of clinical behaviors. They do not provide an explanation of the language deficits that give rise to these behaviors. For example, a failure to understand language could be due to any number of factors—among them, impairment in processing the sound structure of language, impairment in mapping sounds to word meaning, and/or failure to process the syntactic structure or the semantic structure of words. To understand the nature of language deficits in aphasia requires taking a different approach, one that takes into consideration the potential language processes and mechanisms underlying these deficits. Roman Jakobson (1956) was probably the first linguist to take such a psycholinguistic approach to aphasia. Since then, there has been a history and tradition of using the theoretical framework and experimental tools provided by psycholinguistics to examine the nature of deficits among the different types of

aphasia (Goodglass, 1993). As discussed, such a study has provided the framework for much of the recent work using functional neuroimaging and electrophysiological approaches to the neurobiology of language.

This chapter reviews the contributions that this approach has made to our understanding of the neurobiology of language. We begin by describing those classical aphasia syndromes and their associated lesion profiles that have served as the focus of much of the research on language impairments in aphasia. The psycholinguistic studies that were conducted were designed to understand the basis of the underlying deficits giving rise to particular clinical features of these syndromes and the functional role of the brain areas involved. The findings have also been used to provide insight into the functional architecture of language, that is, how the system fractionates provides a window into its structural properties and the mechanisms and processes involved in normal language use.

74.2 THE APHASIA SYNDROMES

The aphasia syndromes typically result from damage to perisylvian areas of the left hemisphere. Although there have been many syndromes described in the literature (see Geschwind, 1965 for a review), the three that have probably been studied in the most detail and have served as the foundation for psycholinguistic studies of aphasia are Broca's, conduction, and Wernicke's aphasia. These syndromes provide a rich tapestry of impaired and spared language abilities. Of importance, they are defined in terms of the *relative* performance of patients among a set of language functions, including speaking, auditory comprehension, repetition, naming,

and comprehension and production in reading and writing. Thus, an absolute score on a particular language function cannot be used to classify a patient. Rather, it is performance on a particular language function in relation to the other clinical characteristics that defines a patient's syndrome.

Focusing solely on a particular language function will result in grouping patients together who have different syndromes and potentially different underlying deficits. For example, there are a number of aphasia syndromes that are characterized by poor auditory comprehension, including Wernicke's aphasia, transcortical sensory aphasia, and global aphasia (Goodglass & Kaplan, 1972). Similarly, there are a number of syndromes that are characterized by fluent speech output, including Wernicke's aphasia, conduction aphasia, transcortical sensory aphasia, and anomic aphasia. It is the relationship between these various language functions that differentiate between and among the aphasia types.

Broca's aphasia is characterized by impairment in language expression in the face of relatively good auditory comprehension. Speech output of these patients is typically nonfluent: production is slow, labored, with many speech errors, and is often dysarthric, (i.e., characterized by motor weakness that affects speech articulation). Additionally, these patients often display agrammatism in their speech output, with a tendency to omit freestanding function words such as *the* and *is* and to either delete or substitute grammatical endings. Repetition is usually similar to or a little better than spontaneous speech output. Lesions associated with Broca's aphasia typically involve the frontal operculum (Broca's area, i.e., BA44 and 45) and premotor and motor regions posterior and superior to the frontal operculum, and extend to the white matter structures including the basal ganglia and insula (Damasio, 1998).

Wernicke's aphasics show a very different clinical picture. They have fluent well-articulated speech in the context of impairment in auditory language comprehension. These patients often produce paraphasias, which are errors in their output that are either phonologically based (phonemic paraphasias, e.g., *top* → *dop*) or semantically based (verbal paraphasia, e.g., *wife* → *sister*). Some Wernicke's aphasics produce jargon or neologisms, which are productions that are phonologically possible but are not words in the language (e.g., *tufbei*). Although speech output is fluent, containing grammatical words and endings, sentences are often described as paragrammatic, characterized by the inappropriate juxtaposition of words often rendering the sentence ungrammatical. Additionally, the content of the discourse is typically empty semantically, partly because of the overuse of semantically empty high-frequency words such as *thing*, *is*, *this*. Wernicke's

patients also have repetition impairment as well as a naming deficit. The lesions associated with Wernicke's aphasia include the posterior superior temporal gyrus (BA22), often extending to the middle temporal, supra-marginal, and angular gyri (Damasio, 1998; Dronkers, Redfern, & Ludy, 1995; Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004).

In conduction aphasia, repetition is the presenting deficit in the context of fluent, well-articulated speech and relatively good auditory language comprehension. Speech output contains phonemic paraphasias and relatively few semantic paraphasias. The patient appears to be aware of these errors because they often attempt to correct them, producing *conduite d'approche* or successive approximations to the target word. The lesions associated with conduction aphasia include the supra-marginal gyrus and the white matter structures deep to it (the arcuate fasciculus). Importantly, the posterior portion of the superior temporal gyrus (Wernicke's area) is typically spared (Damasio, 1998; but see Hickok et al., 2000).

These clinical characteristics and associated lesion loci have raised a series of questions about the functional and neural architecture of language. With respect to the functional architecture of language, it is generally assumed that both expressive and receptive language functions comprise different linguistic domains involving multiple stages of processing. These domains include phonological/phonetic, lexical, syntactic, and conceptual/semantic. It is also generally assumed that information flows from one stage of processing to the other and that this information flow is interactive, with activation at one stage of processing influencing activation at other stages of processing both upstream and downstream from it (Dell, 1986; Marslen-Wilson & Warren, 1994). For example, phonetic/phonological information affects lexical processing (bottom-up processing), and lexical processing, in turn, can affect phonetic/phonological processing (top-down processing).

The clinical characteristics of Broca's, conduction, and Wernicke's aphasia suggest potential deficits in the representations and processes involved in the reception and/or expression of speech, words, and syntax. And it is these domains that we review here. At the same time, they also provide potential insight into the neural systems underlying these domains, allowing for an examination of whether the neural areas are functionally autonomous.

74.3 SOME CAVEATS AND CHALLENGES

The use of the aphasia syndromes as the framework to investigate the neurobiology of language has been met with challenges in the literature that are

worthwhile to briefly review and consider. In particular, there have been challenges to the assumption that clinical syndromes can be used to reliably classify and study participants with aphasia (Caramazza, 1984), and there have been challenges to the assumption that there is one-to-one mapping between clinical syndrome and underlying neuropathology (Willmes & Poeck, 1993). This has led to two other approaches over the past 30 years in the investigation of language deficits in aphasia. The first has focused on detailed case studies of patients as a means of informing current theories of language processing (Caramazza, 1986; see Rapp & Goldrick, 2006 for a review). The single case methodology has been used throughout the history of neuropsychology and has provided many insights into not only how language may fractionate but also what neural areas give rise to the deficit (Geschwind, 1965 discussion of Dejerine). However, the more recent case study approach has largely been agnostic with respect to the underlying neuropathology of the patient (Rapp & Goldrick, 2006). Thus, a downside of this approach is that it cannot provide insight into the neural architecture underlying the patient's deficit, nor can it provide *predictions* of patterns of deficits to new patients. In the second approach, a psycholinguistic question is raised and then studied in a group of patients unselected for either syndrome or lesion (see Schuell & Jenkins, 1959). The assumption here is that the underlying deficit is the same irrespective of lesion localization. Under these assumptions, it is impossible to determine whether there are distinct deficits that arise as a function of a particular area of damage and whether the basis of the deficit differs as a function of lesion site.

In the end, it is lesions that produce language impairments in aphasia. And the rationale for focusing on syndromes is that they not only present with a constellation of impairments but also are the result of lesions to particular neural areas. With advances in neuroimaging techniques over the past 20 years, we know that lesions of patients are rarely focal and typically include both cortical and subcortical structures. No individual with aphasia has exactly the same lesion profile, and there are differences not only in the extent of the lesion but also in the degree of damage to a particular area. With regard to behavioral effects of lesions, we know that within a syndrome there are differences in severity and that not all patients can be classified into a particular syndrome, in both cases presumably because of the extent and location of the lesion. We also have learned that damage in one area can result in hypometabolism in areas distant from it, even in the absence of overt structural damage (Metter, Hanson, Jackson, & Kempler, 1990). Such findings suggest that deficits may reflect neural systems, rather than solely being due to local pathology.

Taken together, such observations identify the complexities of this research endeavor. That the picture is more complex than what the classical aphasiologists from the 1920s to the 1960s had proposed in terms of clinical diagnosis and lesion locus is not surprising. However, these facts do not obviate the existence of the aphasia syndromes or that lesions are localizable and ultimately produce different patterns of language impairment broadly in line with the classical aphasia syndromes (Kreiser et al., 2000; Richardson, Fillmore, Rorden, LaPointe, & Fridriksson, 2012). The results of this approach converge with recent neuroimaging findings focusing on the neural substrates of language.

74.4 LANGUAGE DEFICITS UNDERLYING APHASIA SYNDROMES

It is beyond the scope of this article to review the extensive literature on psycholinguistic investigations of aphasia. Rather, we examine two main classes of findings that have been shown in each of the domains of phonetics/phonology, the lexicon, and syntax. The first class of findings has shown similarities in patterns of deficits across patients presenting with different aphasia syndromes. Such results provide insight into the functional architecture of language, typically showing integrity of the structural properties of language. They also suggest that such processing recruits a broadly distributed neural system. The second class of findings has shown deficits in patients presenting with different aphasia syndromes; however, of interest and importance, the patterns of deficits differ as a function of clinical syndrome. Such findings suggest that the nature of the deficit giving rise to the pathological performance is due to a different functional impairment presumably reflecting the neural locus of the lesion.

74.4.1 Phonetic/Phonological Impairments

74.4.1.1 Speech Production

Although all aphasic patients make speech production errors across a number of language tasks, based on the clinical picture of the patients, it was generally assumed that the source of those errors differed. In particular, given that the lesions of Broca's aphasics involved frontal structures typically including motor areas, they were considered to have phonetic impairments reflecting articulatory planning and articulatory implementation deficits. In contrast, given that Wernicke's and conduction aphasics' lesions involved posterior areas, these patients were considered to have phonological impairments reflecting selection deficits. Experimental results showed that these

characterizations were both correct and wrong. In particular, acoustic analysis of the patterns of production of a number of parameters of speech showed clear-cut phonetic impairments for Broca's aphasics that were not present in either Wernicke's or conduction aphasics. Broca's aphasics showed deficits in the timing relations required for voicing in stop consonants (voice-onset time) (Blumstein, Cooper, Goodglass, Statlender, & Gottlieb, 1980; Gandour & Dardarananda, 1984; Kent & Rosenbek, 1983), timing of voicing onset and amplitude properties required for voicing in fricative consonants (Kurowski, Hazen, & Blumstein, 2003), and duration and amplitude measures required for the production manner of articulation for nasal consonants (Kurowski, Blumstein, Palumbo, Waldstein, & Burton, 2007). Although the two posterior aphasic groups showed normal articulatory implementation, they did show more variability in their productions than normal individuals. Taken together, these findings support the view that Broca's aphasics have articulatory planning and implementation deficits, and that frontal brain structures including Broca's area, premotor and motor regions posterior and superior to the frontal operculum, and white matter structures deep to them are functionally involved in these stages of production. That the posterior patients only showed variability in their productions in the context of normal articulatory implementation suggests that speech production not only recruits frontal structures but also invokes posterior structures, presumably as part of a feedback mechanism for error detection, monitoring, and sensorimotor integration from auditory (temporal cortex) and somatosensory (inferior parietal cortex) areas (Guenther, Ghosh, & Tourville, 2006; Hickok, 2012; Hickok, Houde, & Rong, 2011; Houde & Nagarajan, 2011; see Blumstein & Baum for discussion of neuroimaging studies supporting this view, Chapter 55, this volume).

In contrast to phonetic deficits, studies of phonological analysis of the speech of Broca's, conduction, and Wernicke's aphasia failed to show different patterns of errors. Analyses of speech output errors showed that patients from all three groups made similar phonological errors, including phoneme substitutions (phonemic paraphasias), addition or deletions of sounds, transposition of sounds either within a word or between words, and contextual errors based on the phonological context of the word (Blumstein, 1973). For all patients, errors reflected structural principles of the language. In particular, sound substitutions were more likely to occur between sounds that were distinguished by a single phonetic feature, and both addition and deletion errors were more likely to result in the canonical syllable structure CV (e.g., segments were typically added if a word began with a vowel,

e.g., "elevator" → /kɛləvɛtr/, sound segments were added to produce a word with a CV onset, e.g., "cloudy" → /kəlawdi/, and consonant clusters were simplified, "French" → /fɛnʃ/). The similar pattern of errors irrespective of clinical syndrome suggests that whether the error occurred at selection, articulatory planning, or implementation stages of production, the basic structure of words and the phonological principles underlying them are preserved. It is not surprising that when errors occur, they are more likely to be manifest among phonologically similar sounds and to result in "simpler" phonological structures.

74.4.1.2 Speech Perception

As described, one of the distinguishing clinical features for Wernicke's aphasics is poor auditory comprehension. The question is, what is the basis or bases of this impairment? Because the primary auditory areas surface in the temporal lobe and the superior temporal gyrus has been implicated in speech perception (Binder, 2000; Hickok & Poeppel, 2007), one likely candidate deficit that has been studied in detail is an impairment in the processing of the sounds of speech. Luria (1966) proposed that Wernicke's aphasics have a deficit in phonemic hearing. In this view, an inability to correctly perceive the phonological properties of speech sounds leads to poor auditory comprehension and results in what appears to be semantic impairments. For example, it is not uncommon for such patients to select the incorrect picture of a word such as "pea" if it is presented in an array of phonologically similar items such as "bee," "T," or "key."

A series of studies was conducted investigating discrimination and identification of both naturally produced and synthetically constructed stimuli (Csepe, Osman-Sagi, Molnar, & Gosy, 2001; Leeper, Shewan, & Booth, 1986). Results showed that Wernicke's aphasics displayed severe speech perception deficits (Basso, Casati, & Vignolo, 1977; Blumstein, Baker, & Goodglass, 1977; Caplan, Gow, & Makris, 1995; Gow & Caplan, 1996; Robson, Keidel, Lambon Ralph, & Sage, 2012; see Hickok, 2009 for an alternative view). In addition, however, Broca's and conduction aphasics also showed deficits, although they were milder (see Hickok, Costanzo, Capasso, & Miceli, 2011 for an alternative view). Of interest, the predictive relationship between performance on these tasks and comprehension ability was inconsistent across studies; some failed to show a relationship (Basso et al., 1977; Blumstein et al., 1977), whereas others did show a relationship (Miceli, Gainotti, Caltagirone, & Masullo, 1980; Robson et al., 2012). These findings suggest that Wernicke's aphasics do have a speech perception deficit, but that other aspects of language, particularly semantic processing, may also be impaired (Baker, Blumstein, &

Goodglass, 1981; Basso et al., 1977; Robson, Sage, & Lambon Ralph, 2012; but see Walker et al., 2011). The possibility that Wernicke's aphasics have not only speech perception impairment but also a deficit in semantic processing is also supported by the neuroimaging literature. As described, it is not uncommon for the lesion profile of Wernicke's aphasics to extend into the middle temporal gyrus, an area that is involved in semantic processing and appears to be recruited in accessing stored semantic representations (see Binder, Desai, Graves, & Conant, 2009 for a review).

The findings that speech perception impairments emerge not only in Wernicke's aphasics but also in milder forms in Broca's and conduction aphasics are consistent with neuroimaging results showing that multiple neural areas are recruited in the processing of speech. Studies examining phonological contrasts (Burton, Small, & Blumstein, 2000) and acoustic phonetic properties of speech (Blumstein, Myers, & Rissman, 2005; Joanisse, Zevin, & McCandliss, 2007; Lieberthal et al., 2010) have shown activation in a neural network, including temporal (superior temporal gyrus), parietal (supramarginal gyrus), and frontal (inferior frontal gyrus) areas. It has been argued that the functional role of these areas differs with superior temporal areas (potentially bilaterally) recruited in earlier stages of speech processing, temporoparietal areas (posterior superior temporal and supramarginal gyri) involved in phonological processing (Buchsbbaum, Hickok, & Humphries, 2001; Hickok et al., 2008; Hickok, 2009), and frontal areas engaged in executive processes related to phonetic category decisions (Burton et al., 2000; Myers, Blumstein, Walsh, & Eliassen, 2009; see also Venezia, Saberi, Chubb, & Hickok, 2012).

Nonetheless, of interest, despite differences in overall performance of the patients in speech perception tasks, their patterns of impairment were similar. Namely, all patients were more likely to make discrimination errors on stimulus pairs that were distinguished by a single phonetic feature than several features, and they were more likely to make errors discriminating stimulus pairs contrasting in the features corresponding to place of articulation than for the feature voicing (Blumstein et al., 1977). Finally, all patients displayed more deficits in perceiving the sound structure of nonsense syllables compared with real words. That Wernicke's aphasics showed a systematic pattern of impairment similar to other aphasic patients indicates that their behavior is not random and does not reflect a loss of sensitivity to the phonetic/phonological properties of speech.

The patterns of performance displayed by the patients reflect the integrity of the structural properties of the sound structure of language. Sounds

distinguished by a single phonetic feature not only share more phonological features but also are more similar acoustically than are sounds distinguished by multiple features. Thus, it is not surprising that they are more difficult to discriminate. Nonetheless, despite the difficulty that all patients have in either discriminating or categorizing acoustic cues associated with either voicing or place of articulation, the locus and shape of the phonetic boundary are similar to those of normal individuals. The superiority of performance for real words compared with nonsense syllables is consistent with current models of the functional architecture of language (Dell, 1986; McClelland & Elman, 1986). Here, information flow is interactive; namely, information flows from phonetic/phonological analysis stages to activate potential lexical candidates. These candidates, in turn, boost the activation of phonological units downstream from them. Because nonwords do not match any words in the lexicon, they may only weakly activate phonologically similar words (Milberg, Blumstein, & Dworetzky, 1988). In such a case, they do not have the same degree of support of the lexical-semantic network; hence, they are more vulnerable in tasks that focus on phonological/phonetic properties.

74.5 LEXICAL IMPAIRMENTS

Models of the cognitive architecture of language have proposed that the words of a language (the mental lexicon) are organized in terms of a network-like architecture of shared or partially overlapping sound structure or semantic properties (Gaskell & Marslen-Wilson, 1999; Plaut, 1995). In this view, a word not only activates its phonological and semantic representations but also partially activates words that share sound structure and semantic properties with it. As a consequence, accessing a word for either spoken production or auditory word recognition requires selecting the target word from this set of activated competitors. Thus, both the production and recognition of words require a multistage process including access to the mental lexicon, activation of a network of potential word candidates, and, ultimately, the selection of the target word from the set of semantically related and phonologically related competitors.

One of the most common and least localizing clinical features in aphasia is a word retrieval deficit. This may be shown either in spoken word production or in auditory word recognition. In spoken word production, patients may fail to come up with a word either in spontaneous speech output or when presented with a picture or verbal description of a word (naming) (Goodglass & Kaplan, 1972). Typically, naming errors include phonemic paraphasias, where the patient

makes a sound error on the target word, or verbal (semantic) paraphasias, where the patient produces an incorrect word, often semantically or associatively related to the target word. Clinically, Wernicke's aphasics tend to make more semantic paraphasias, and conduction aphasics make more phonemic paraphasias. In auditory word recognition, Broca's, conduction, and Wernicke's aphasics may fail to select a picture of a word from an array of pictures whose names are either phonemically or semantically related to the target (Baker et al., 1981).

Evidence suggests that although Broca's, conduction, and Wernicke's aphasics display word processing deficits, it is not because they have lost either the "concept" of a word or its phonological representation. Rather, they appear to have difficulty accessing or retrieving the word. Improved naming occurs for these patients with contextual support provided by either a phonological cue (e.g., producing [bə] for the word "bear") or a semantic cue ("Smoky, the _").

The relative preservation of semantic/conceptual representations has been shown in studies examining semantic priming. Both Broca's and Wernicke's aphasics show semantic priming in a lexical decision task (Blumstein, Milberg, & Shrier, 1982; de Salles, Holderbaum, Parente, Mansur, & Ansaldo, 2012; Hagoort, 1997; Milberg & Blumstein, 1981). That is, they display shorter reaction time latencies to target words preceded by semantically related ("dog-cat") compared with semantically unrelated ("ring-cat") words. These findings support the integrity of the lexical-semantic network in these patients. In contrast to the classical aphasias, however, recent research suggests that degradation of semantic structure does occur, but in patients with semantic dementia or aphasic patients with lesions extending to the anterior temporal lobe (an area not included in the lesion profile of Wernicke's aphasics) (Jefferies & Lambon Ralph, 2006; Walker et al., 2011).

The relative preservation of phonological representations has been shown in studies examining the tip-of-the-tongue state in aphasic patients. The tip-of-the-tongue state is a phenomenon in which subjects are unable to come up with a word but "feel" that they know what the word is and, in fact, that the word is on the "tip of their tongue." Brown and McNeil (1966) showed that normal individuals retain the sound structure properties of words that they failed to retrieve; they can identify its first letter, the number of syllables it has, and words that are semantically related to it. Although aphasics show a similar sensitivity to the sound structure of words they cannot name (Barton, 1971), Goodglass, Kaplan, Weintraub, and Ackerman (1976) showed that conduction aphasics were better able to recall the sound properties of

words compared with both Broca's and Wernicke's aphasics. Thus, they suggested that the differences in the pattern of performance reflected different stages in word retrieval.

Despite the relative preservation of the lexical-semantic and phonological structure of words in Broca's, conduction, and Wernicke's aphasics, these patients do show deficits in the various stages involved in lexical access. In particular, a series of studies have shown that Wernicke's aphasics are able to activate lexical candidates; however, the lexical competitors remain active longer (or fail to get inhibited). In contrast, Broca's aphasics also activate lexical candidates; however, they are unable to resolve competition in selecting the target word from among competing lexical candidates. These findings have been shown using a variety of paradigms, including lexical decision (Janse, 2006; Milberg, Blumstein, & Dworetzky, 1987) and eyetracking (Yee, Blumstein, & Sedivy, 2008). Additional support for selection deficits comes from both verb generation (Thompson-Schill et al., 1998) and lexical decision studies (Bedny, Hulbert, & Thompson-Schill, 2007) that focused on lesion location, in this case a portion of the inferior frontal gyrus (BA45), and not clinical diagnosis of aphasia.

The lexical processing deficits of Broca's and Wernicke's aphasics emerge whether the source of the competition is semantic or phonological. For example, in the semantic case, the patient must select a word from competing meanings of ambiguous words presented in congruent and incongruent contexts (e.g., the subject is required to make a lexical decision on the third word of a triplet such as "coin-bank-money" versus "river-bank-money") (Bedny et al., 2007; Milberg et al., 1987). Another study required the patient to select words that have high versus low selection demands (e.g., the subject is asked to generate a verb for the word "scissors" versus "ball") (Thompson-Schill et al., 1998).

Several paradigms have been used to investigate the effects of resolving phonological competitors. One set of experiments used eyetracking and examined the potential effects of onset competitors in selecting a target word (Yee et al., 2008). Here, the subject was asked to point to a picture given the auditory presentation of a word from an array that included the picture of the target word, a word with an onset competitor, and two semantically and phonologically unrelated foils (e.g., the target word is "hammock" and the pictures include "hammock," "hammer," "monkey," and "chocolate"). Another series of experiments examined the effects of acoustically degraded prime stimuli on the magnitude of semantic priming (Misiurski, Blumstein, Rissman, & Berman, 2005; Utman, Blumstein, & Sullivan, 2001). Stimulus pairs included semantically related stimuli

with and without voicing competitors, “time-clock” (with a voiced competitor “dime”) and “cat–dog” (with no voiced competitor, “gat” is not a word). Similar to normal individuals, Broca’s aphasics showed semantic priming for phonologically clear, semantically related pairs, and reduced semantic priming for degraded prime stimuli without a voiced competitor. In contrast to normal individuals, Broca’s aphasics lost priming only when the degraded prime had a voiced competitor.

Taken together, these findings indicate that aphasic patients have lexical processing impairments. In particular, aphasics retain the underlying semantic and phonological representations of words, but they show impairments in *accessing* them. Moreover, different patterns of performance emerge between Broca’s and Wernicke’s aphasics, suggesting that the basis of their deficit differs (see Blumstein, 2009, for review; Janse, 2006). For Wernicke’s aphasics, word candidates stay active longer either due to an inability to inhibit word competitors or due to their overactivation. In contrast, Broca’s aphasics show a deficit in selection processes and an inability to select among competing semantic and phonological competitors.

Neuroimaging findings support the view that both spoken word production and word recognition processes engage a temporoparietal and frontal network. Semantic processing recruits both temporal and frontal structures (see Binder et al., 2009 for a review); selection among competing semantic alternatives recruits the inferior frontal gyrus (Thompson-Schill, D’Esposito, Aguirre, & Farah, 1997); and selection among competing phonological alternatives also recruits the inferior frontal gyrus as well as the posterior superior temporal and supramarginal gyri (Righi, Blumstein, Mertus, & Worden, 2010).

74.6 SYNTACTIC IMPAIRMENTS

As described, one of the clinical characteristics of some Broca’s aphasics is agrammatism in speech output in the context of generally good auditory comprehension. There is a long and controversial history of the potential basis of the grammatical deficit in these patients. Early hypotheses (Kolk & Heeschen, 1990; Kolk & Van Grunsven, 1985) suggested that the deficit reflected a compensatory mechanism of the patient to provide the most semantic content with the least amount of speech. In this view, the output disorder reflects an “economy of effort” and thus is secondary to nonfluent output and difficulty in producing and articulating speech. Evidence in support of this view came from analyses of the error patterns in production. Results showed that there was not only a tendency to

omit function words but also a tendency to simplify morphological structures, particularly in contexts where the morphological ending was redundant (e.g., “two books” → “two book”) (Dick, Bates, Wulfeck, Utman, & Gernsbacher, 2001). As shown by analyses of inflected languages, morphological errors produced by agrammatic aphasics were in fact substitutions of one morphological ending for another, not a “loss” of endings (Grodzinsky, 1990; Menn & Obler, 1990). Analyses showed that there was a tendency to produce a linguistically less marked structure such as a verb in the present tense or in infinitival form rather than a verb with a past tense or future tense inflection.

A series of seminal studies by Zurif and colleagues (Caramazza & Zurif, 1976; Goodenough, Zurif, & Weintraub, 1977; Zurif, Caramazza, & Myerson, 1972), however, suggested that the agrammatic deficit of Broca’s aphasics was not limited to speech production, but rather was a “central” impairment affecting not only speech production but also comprehension. This was originally shown using a hierarchical clustering paradigm in which subjects were presented the written form of a sentence such as “the dog chased a cat” (Zurif et al., 1972). With the sentence always in display, subjects were given a random selection of three cards, each containing one of the words in the sentence. They were asked to put “the two words that went best together.” Results showed that Broca’s aphasics did not know where/how to cluster the function words. They were as likely to cluster “the” and “a” with each other than within their associated noun phrases. Thus, Broca’s aphasics showed impairment in their linguistic “intuitions” about the syntactic structure of sentences.

From there, a plethora of studies examined sentence comprehension in aphasia focusing on syntactic structures. Results have shown that Broca’s aphasics displayed impairments in comprehending sentences when the only cue to comprehension was syntax (e.g., “the lion chased the tiger” versus “the boy ate the hamburger”) (Caramazza & Zurif, 1976). They had difficulty in understanding noncanonical syntactic structures such as passive sentences compared with active sentences (“the girl is liked by the boy” versus “the boy likes the girl”), syntactically complex compared with simple sentences (“the boy who sees the man likes the girl” versus “the boy likes the girl”) object-embedded compared with subject-embedded sentences (“the boy the girl likes reads a book” versus “the girl likes the boy who reads the book”) and sentences that did and did not contain traces (Caplan, Baker, & Dehaut, 1985).

These findings gave rise to a large number of hypotheses to characterize the underlying impairment, the details of which are beyond the scope of this article. The proposals are far-reaching,

invoking either representational (Grodzinsky, 1986, 2000; Mauener, Fromkin, & Cornell, 1993) or processing deficits (Grodzinsky & Friederici, 2006; Love, Swinney, Walenski, & Zurif, 2008) involving potential impairments in syntactic structures governing movement and/or binding (Choy & Thompson, 2010; Swinney & Zurif, 1995), thematic role assignment (Saffran, Schwartz, & Linebarger, 1998), working memory or resource limitations (Caplan & Waters, 1995; Carpenter, Miyake, & Just, 1995), and time-course delay of processing (Ferrill, Love, Walenski, & Shapiro, 2012; Love, Swinney, & Zurif, 2001). See Chapter 47 (Rogalsky) of this volume for further discussion.

Beyond the debate concerning the underlying deficit in Broca's aphasics, there is a more critical issue—namely, is it truly the case that only Broca's aphasics display syntactic comprehension impairments? Unfortunately, much of the literature examining the basis of syntactic impairments has tested only Broca's aphasics. Thus, it is not clear whether other types of patients also show impairments. Those studies that have looked at other patient groups or patients with different lesion sites show similar patterns of impairment as those of Broca's aphasics (Caplan et al., 1995; Caplan, Hildebrandt, & Makris, 1996; Dick et al., 2001; Zurif & Caramazza, 1976). It is not surprising to find that structurally complex sentences are more difficult to understand not only for aphasic patients but also for neurologically intact subjects tested under adverse listening conditions (Dick et al., 2001; cf. also Obleser, Meyer, & Friederici, 2011).

What is not clear from these studies is whether the *basis* of the impairment is different across aphasia syndromes. Although some hypotheses have been proposed (Friederici, 2011), no studies have yet been conducted that distinguish behavioral performance of patients based on some operational measure of the purported functional deficit. One challenge inherent in this research is assessing syntactic comprehension independent of meaning.

The neuroimaging literature has shown similar conflicting findings. Some studies have shown selective activation of the inferior frontal gyrus in auditory processing of syntactic structure (Moro et al., 2001; Stromswold, Caplan, Alpert, & Rauch, 1996), and others have shown a broad fronto-temporo-parietal network (Fedorenko, Nieto-Castañon, & Kanwisher, 2012; Friederici, Meyer, & von Cramon, 2000; Just, Carpenter, Keller, Eddy, & Thulborn, 1996; see Kaan & Swaab, 2002 for a review).

Although it remains unclear whether there are functional distinctions in the auditory processing of syntactic structure as a function of clinical syndrome and/or lesion site, the original observation that only Broca's aphasics display agrammatism in production remains.

This leaves open the possibility that these patients do have a selective syntactic impairment, but it is restricted to spoken language production. It is for future research to determine whether this is the case and what the underlying basis of this impairment may be.

74.7 CONCLUSION

Psycholinguistic studies of the clinical syndromes of aphasia have provided a unique window into the neurobiology of language. Such studies offer insights that behavioral and neuroimaging studies alone cannot. Behavioral studies do not provide evidence of the neural systems underlying a particular deficit. Neuroimaging studies are unable to determine whether activation of a neural area indicates that it is *necessary* for a particular linguistic function. Coupled with these approaches, technological advances now available for detailed mapping of lesion profiles coupled with careful clinical examination and classification of patients hold the promise of not only gaining a deeper understanding of the functional and neural architecture of language but also providing critical insights into the bases of language deficits that can be used in developing rehabilitation programs for patients with aphasia.

Introduction to Primary Progressive Aphasia

Maria Luisa Gorno-Tempini¹ and Peter Pressman²

¹UCSF Memory and Aging Center, Sandler Neurosciences Center, University of California, San Francisco, CA, USA;

²Memory and Aging Center, Department of Neurology, University of California, San Francisco

75.1 INTRODUCTION AND HISTORY OF PRIMARY PROGRESSIVE APHASIA

The sudden appearance of aphasia due to stroke or brain trauma is prominent in neurological history. Such acute injuries permitted seminal insights into the neural underpinnings of language. The left inferior frontal gyrus injury described by Paul Broca (Broca, 1861; Dronkers, Plaisant, Iba-Zizen, & Cabanis, 2007) and the left temporoparietal lesions described by Karl Wernicke (Wernicke, 1874) both led to distinctive and now-eponymous aphasias, and introduced the anatomy of the first left perisylvian language circuit.

Injury to the language brain system, however, does not always occur abruptly. Neurodegenerative diseases, such as Alzheimer disease (AD) and frontotemporal degeneration (FTD) spectrum disorders, more widely recognized to cause insidious changes in memory or personality, have been associated with selective decline of language functions since the earliest descriptions. In 1892, the Czech psychiatrist Arnold Pick described the first case of progressive aphasia, which he called “semantic aphasia” (Pick, 1892).

Despite Pick’s early discovery, for several decades the prevailing view in medicine was that neurodegenerative dementia was virtually synonymous with AD, which primarily impacted memory. While aphasia was a recognized complication of dementia, a more serious amnesia was believed to precede and accompany any language deficit. This paradigm was contested in 1982 when Dr. M. Marcel Mesulam and colleagues published a case series describing slowly progressive aphasia associated with degeneration of the perisylvian region of the left hemisphere (Mesulam, 1982). Rather than being accompanied by signs of a more generalized dementia, aphasia remained the predominant symptom for many years after disease onset.

Such patients were otherwise functional in everyday life and had relatively preserved nonverbal neuropsychological scores.

Reports of similar cases were found from around the world (Heath, Kennedy, & Kapur, 1983; Mesulam, 1987, 2007). The term “primary progressive aphasia” (PPA) was subsequently created, and more refined diagnostic criteria for the syndrome were established (Mesulam, 1987, 2007). The PPA diagnosis can be made in a patient with a disorder of language (aphasia) due to a neurodegenerative disorder (progressive) and in whom the aphasia is the most prominent symptom for about 2 years (primary) (Mesulam, 2001, 2003) (Table 75.1). Mesulam’s original description required that the most frequent initial symptom be anomia.

Initially, PPA was a unified diagnosis, but as more cases became documented the concept of “fluent and nonfluent” cases was introduced. However, much confusion arose over the years as it became clear that the stroke aphasia classification scheme was not applicable to PPA. PPA was initially distributed into two main variants: fluent and nonfluent. Such a schema preliminarily attempted to correlate PPA symptoms with those caused by vascular lesions. Almost from the outset, the existence of a third variant was suspected, and in 2004 Gorno-Tempini and colleagues published a study that compared cognitive and neuroimaging features of a large group of PPA patients, thereby describing the features of what was dubbed the logopenic variant of PPA (Gorno-Tempini, Dronkers, et al., 2004). What had previously been known as the nonfluent variant was refined into the nonfluent/agrammatic variant, sometimes also called the PPA-grammatical subtype or progressive nonfluent aphasia (nfvPPA, PPA-G, PNFA). The more fluent variant was reclassified as semantic variant, sometimes called PPA-semantic subtype or semantic

TABLE 75.1 Inclusion and Exclusion Criteria for the Diagnosis of PPA

Inclusion: criteria 1–3 must be answered positively

1. Most prominent clinical feature is difficulty with language
2. These deficits are the principal cause of impaired daily living activities
3. Aphasia should be the most prominent deficit at symptom onset and for the initial phases of the disease

Exclusion: criteria 1–4 must be answered negatively for a PPA diagnosis

1. Pattern of deficits is better accounted for by other nondegenerative nervous system or medical disorders
2. Cognitive disturbance is better accounted for by a psychiatric diagnosis
3. Prominent initial episodic memory, visual memory, and visuoperceptual impairments
4. Prominent, initial behavioral disturbance

Updated diagnostic criteria for PPA from Gorno-Tempini et al. (2011).

Source: Modified from Mesulam (2003).

TABLE 75.2 Characteristics of PPA Variants

PPA subtype	Supporting clinical features	Relevant neuropsychological tests	Anatomical correlate	Common histopathology
lvPPA	Poor repetition of prolonged phrases, intermediate fluency, phonemic paraphasias, spared motor speech and semantic knowledge	Boston Naming, repetition tasks, digit span	Dominant temporo-parietal junction	AD
svPPA	Poor object knowledge and confrontation naming, limited single-word comprehension, surface dyslexia, spared motor speech and grammar	Pyramids and Palm Trees, Boston Naming, Famous Faces testing	Dominant anterior temporal lobe	TDP-43 type C
nvPPA	Agrammatism, effortful speech, impaired comprehension of syntactically complex sentences, spared single word comprehension and object knowledge	Grammatically complex sentences, Northwestern Anagram Test, Boston Naming	Dominant posterior fronto-insular region	Tau (CBD, PSP, Picks), TDP-43-A

A table depicting some major characteristics of the variants of PPA. CBD, corticobasal degeneration; lvPPA, logopenic variant primary progressive aphasia; nvPPA, nonfluent variant primary progressive aphasia; PSP, progressive supranuclear palsy; svPPA, semantic variant PPA; TDP-43, trans-activator regulatory deoxyribonucleic acid (TAR-DNA) binding protein 43.

dementia (svPPA, PPA-S, SD). The third variant is the logopenic variant (lvPPA, PPA-L), many members of which had originally been incorporated into the other two subtypes (Table 75.2).

The combination of speech and language symptoms in PPA depends on patterns of neuroanatomical degeneration. Although regions of neurodegeneration in PPA share some anatomical boundaries with acute aphasias due to ischemic stroke, the symptoms produced in PPA are not identical to a vascular counterpart. In addition to neural susceptibility to neurodegeneration differing from vascular anatomy, this symptomatic dissociation is due to the brain's ability to adapt with time to a slowly evolving injury. Neuronal loss in PPA is gradual and partial, allowing the synaptic connections of the brain to reorganize as the disease progresses. As such compensation is incomplete, however, discrete language deficits emerge.

Language consists of many subdomains. Comprehension entails a cascade of processes including correctly identifying relevant sounds and words,

retrieving conceptual information conveyed by these symbols, and furthermore identifying the meaning behind different syntactical and grammatical word arrangements. Language production depends on an intricate process that relays and arranges semantic, lexical, and phonological information, and furthermore coordinates the muscles of the pharynx, larynx, and face required for speech, all the while relying on sensory feedback to guarantee the movements are correctly performed. Each of these tasks relies on different, highly interacting neural subnetworks within the greater left hemispheric language network. Early loci of degeneration in gray and white matter within this network lead to distinctive patterns of language symptoms, which can reveal the underlying neuroanatomy to the trained diagnostician. The regions of degeneration in PPA are predominantly left hemispheric, reflecting high hemispheric specialization of language networks in the general population, although interaction with right hemisphere structures assures proper use of language and speech in social context. As the disease progresses, atrophy

becomes more generalized, extending through the language network and ultimately involving the opposite hemisphere as well. Among the approximately 40% of left-handed individuals in whom language dominance localizes to the right hemisphere, PPA is characterized by atrophy of that part of the brain (Mesulam, Weintraub, Parrish, & Gitelman, 2005).

In addition to each of these clinical syndromic subtypes resulting from atrophy of a distinct neuroanatomical location, each subtype is associated with different probabilities of associated pathological findings on autopsy (Gorno-Tempini et al., 2011; Mesulam, Wieneke, Thompson, Rogalski, & Weintraub, 2012).

Overall, PPA patients are found to most often have frontotemporal lobar degeneration (FTLD)-type pathology, with abnormal precipitates of either tau or of transactive response DNA binding protein (FTLD-TDP-43). However, 30% to 40% of PPA patients have been found to have either Alzheimer pathology or biomarkers indicative of brain amyloid deposition (Mesulam, 2013). As discussed later, many of the PPA cases with AD pathology have the clinical-anatomical presentation of the logopenic variant.

Although PPA has taught us much about the language network, many debates are still being held regarding needed adjustments to diagnostic schematics and neuroanatomy (Chare et al., 2014). The hope is that accurate diagnoses will guide counseling regarding disease progression and may have implications for treatments now and as targeted therapies become available in the future.

75.2 THE NONFLUENT/AGRAMMATIC VARIANT

Damage to the left inferior frontal lobe underlies some of the earliest noted vascular and neurodegenerative aphasias. Also called Broca's area, this region was also atrophied in at least two patients described in Dr. Mesulam's seminal 1982 description of what is now called PPA (Mesulam, 1982).

75.2.1 Demographics

The incidence and prevalence of nonfluent/agrammatic variant (nfvPPA) can be estimated from those of FTLT, which are approximately 2.2 to 3.5 per 100,000 and 2.7 to 15 per 100,000, respectively. Approximately 45% of FTLT cases have PPA, with a little less than half of these having nfvPPA (Grossman, 2012). These statistics permit an estimated nfvPPA prevalence of 0.65 to 3.9 per 100,000, with an incidence of 0.5 to 0.9 per 100,000, although admittedly the estimate is rough.

Patients with nfvPPA may be more likely to be female (Johnson et al., 2005), although this is contested—other studies have found no gender bias (Grossman, 2012). Some have also suggested that the age of onset may be later than other forms of FTLT (Johnson et al., 2005; Rosso et al., 2003). One study described that nfvPPA had a mean age of onset of 63 years compared with 57.5 in bvFTD and 59.3 in svPPA (Johnson et al., 2005). The range is quite broad, however, ranging from the 30s to the early 80s. Survival is quite variable but is thought to average around 7 years (Grossman, 2012).

75.2.2 Clinical Characteristics

One of the first descriptions of the nonfluent variant was in 1996 by Murray Grossman and colleagues, who noted agrammatism and nonfluent speech, but also mentioned paraphasias and repetition deficits as prominent features (Grossman et al., 1996). Neary and colleagues included descriptions of the diagnostic criteria for "progressive aphasia," which was described as nonfluent but that likely included what we now call nonfluent/agrammatic and logopenic variants (Neary et al., 1998). The consensus classification introduced by Gorno-Tempini and a group of international colleagues in 2011 de-emphasize any problems with paraphasias and repetition in nfvPPA, proposing that effort speech (as in apraxia of speech [AOS]) and/or agrammatism should be the core features of this variant and further specify that single word comprehension and object knowledge are typically unimpaired (Gorno-Tempini et al., 2011) (Table 75.3).

In most cases, the most immediately notable symptom among those with nfvPPA is the effortful and halting quality of their speech. The average rate of speech produced by patients with nfvPPA is about 45 words per minute compared with 140 words per minute in healthy controls (Grossman et al., 2013). Patients mainly experience difficulty articulating words that they "have in their head." A combination of motor speech hesitations and grammatical processing problems are the main contributors to diminished fluency, although in mild cases patients could still be considered fluent by classic aphasiology batteries because symptoms are very mild (Gunawardena et al., 2010).

Coordinating the movements needed for speech is frequently difficult among those with nfvPPA. AOS refers to this incoordination of subtle movements required for production of distinct speech, even in the absence of any primary muscular dysfunction to cause dysarthria (Duffy, Peach, & Strand, 2007). Patients with AOS may describe a sensation of knowing what they want to say, but being unable to form the desired

TABLE 75.3 Diagnostic Features for the Nonfluent Variant of PPA

I. Clinical diagnosis of nonfluent/agrammatic variant PPA
At least one of the following core features must be present:
1. Agrammatism in language production
2. Effortful, halting speech with inconsistent speech sound errors (AOS)
At least two of three of the following other features must be present:
1. Impaired comprehension of syntactically complex sentences
2. Spared single-word comprehension
3. Spared object knowledge
II. Imaging-supported nonfluent/agrammatic variant diagnosis
Both of the following criteria must be present:
1. Clinical diagnosis of nonfluent/agrammatic variant PPA
2. Imaging must show one or more of the following results:
a. Predominant left posterior fronto-insular atrophy on MRI or
b. Predominant left posterior fronto-insular hypoperfusion or hypometabolism on SPECT or PET
III. Nonfluent/agrammatic variant PPA with definite pathology
Clinical diagnosis (criterion 1 below) and either criterion 2 or 3 must be present:
1. Clinical diagnosis of nonfluent/agrammatic variant PPA
2. Histopathologic evidence of a specific neurodegenerative pathology (e.g., FTLT-tau, FTLT-TDP, AD, other)
3. Presence of a known pathogenic mutation

AD, Alzheimer's disease; FTLT, frontotemporal lobar degeneration; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single proton emission computed tomography.

Source: From *Gorno-Tempini et al. (2011)*.

words with their lips and tongue. AOS may occur in spontaneous speech, but may be most pronounced with particularly difficult articulatory phrases, such as “first British field artillery,” or by repeating multisyllabic words multiple times (*Ogar, Slama, Dronkers, Amici, & Gorno-Tempini, 2005*). Some authors propose a separate classification when patients have mainly progressive motor speech deficits without agrammatism (*Josephs, Duffy, et al., 2013*).

Agrammatism is usually present, although it may be mild, and has been called a core feature nfvPPA, to the point that Mesulam and colleagues refers to this variant as the agrammatic subtype (PPA-G) (*Mesulam, 2013*). Abnormal syntax, inappropriate use of pronouns, misused pronouns, decreased verb use, and a dearth of article and prepositions correlate with nonfluency in nfvPPA. Limited verb production also correlates with decreased speech rate, perhaps due to the crucial role of verbs in sentence structure. Difficulty

constructing complex sentences and words may only be apparent in writing in early stages, but they will ultimately involve both written and spoken language (*Grossman, 2012*). Patients may attempt to avoid these deficits by using shortened sentences, resulting in an abbreviated mean utterance length as patients attempt to simplify their speech.

Comprehension of single words and simple sentences is generally spared in nfvPPA. Comprehension deficits only become apparent with complex syntactic constructions such as passive or relative sentences (e.g., “The lion was not eaten by the tiger”) (*Weintraub et al., 2009*). Such errors are among the most distinctive equalities of nfvPPA used to distinguish the subtype from other PPA variants (*Mesulam et al., 2009; Wilson, Henry, et al., 2010*). In addition to spontaneous speech, such comprehensive agrammatism may be present in reading and writing as well. Overall, however, there is little difficulty reading written words aloud. Spelling is also largely preserved in nfvPPA, although nonword spelling may be more problematic (*Shim, Hurley, Rogalski, & Mesulam, 2012*).

As time passes, speech becomes increasingly effortful (*Sapolsky et al., 2010*). Working memory and executive control also become involved. Specifically, working memory, planning, and dual tasking become impaired. Letter-guided naming fluency seems to decline over time as well. Episodic memory seems to be relatively preserved, as is visuospatial functioning—although some exceptions occur in the context of the corticobasal syndrome (CBS) (*Murray et al., 2007*). Early symptoms of PPA may erroneously be attributed to depression, anxiety, or stress. Such symptoms are not uncommon in nfvPPA, although these may represent a natural response to the deep awareness that these patients often demonstrate for their language deficit. As the disease progresses, damage to frontal circuits may lead to more evident depression and frustration (*Neary et al., 1998*). Apathy, diminished empathy, and lack of insight can also emerge (*Rohrer & Warren, 2010*).

On the neurological examination, mild motor symptoms affecting the right side of the body are not uncommon. Mild rigidity, motor slowing, and reduced dexterity may be present. Limb apraxia may also be present, as it often is when the left parietofrontal network is disrupted (*Zadikoff & Lang, 2005*). Although AOS is not to be confused with dysarthria, dysarthria may co-occur with nfvPPA. Features of CBS or progressive supranuclear palsy syndrome (PSPS) often occur during disease progression, causing extrapyramidal findings such as rigidity and bradykinesia. Frontotemporal dementias such as nfvPPA have been associated with symptoms of motor neuron diseases such as amyotrophic lateral sclerosis (ALS), and symptoms of this disease may also appear.

75.2.3 Neuroanatomy and Imaging

The peak atrophy site in nfvPPA is the posterior inferior frontal gyrus, also known as Broca's area. Such regions of atrophy are usually studied using volumetric magnetic resonance imaging (MRI) studies. Clinically, neuroimaging also helps exclude other non-degenerative potential causes of aphasia such as tumor or vascular disease.

The area of degeneration in nfvPPA typically extends from the inferior frontal gyrus to the adjacent frontal operculum, premotor cortex, and anterior insula, and sometimes extends into prefrontal regions and into the superior aspect to the left anterior temporal lobe (Rogalski, Cobia, Harrison, Wieneke, Weintraub, et al., 2011) (Figure 75.1). These regions of atrophy are closely related to reduced speech fluency (Ash et al., 2009; Rogalski, Cobia, Harrison, Wieneke, Thompson, et al., 2011; Wilson, Henry, et al., 2010). Premotor area and supplementary motor area (SMA) and basal ganglia are frequently also impacted when

motor speech difficulties are especially pronounced (Josephs et al., 2006). While the left hemisphere is usually more damaged than the right in nfvPPA, bilateral damage is common, impacting up to 31% of cases (Westbury & Bub, 1997).

Although grey matter losses have been emphasized in the MRI studies described, the white matter is not spared in nfvPPA. Diffusion tensor imaging (DTI) demonstrates fractional anisotropy and mean diffusivity changes in many projections related to the inferior frontal lobe (Galantucci et al., 2011). Intrafrontal connections between inferior frontal, SMA, and basal ganglia are related to speech difficulties in nfvPPA (Mandelli et al., 2014). A dorsal stream in the perisylvian language network seems instead related to major grammatical category and syntactic features of language, respectively (Agosta et al., 2012; Borroni et al., 2007; Galantucci et al., 2011; Grossman, 2012; Mahoney et al., 2013; Schwindt et al., 2013; Whitwell et al., 2010) (Figure 75.2).

FIGURE 75.1 Atrophy patterns in patients with PPA variants versus controls. The statistical parametrical mapping depicts patterns of grey matter atrophy in patients with logopenic variant, nonfluent variant, and semantic variant PPA compared with healthy controls matched for age, gender, scan, and sample size, thresholded at a family-wise error (FWE) rate of $P < 0.001$. From Müller, Mandelli, et al. (2013) with permission from the publisher.

FIGURE 75.2 Changes in DTI measurements in three variants of PPA compared with controls. From left to right, there is a significant increase in mean diffusivity in patients with logopenic variant ($P < 0.05$) and a significant decrease in fractional anisotropy in both ($P < 0.001$) semantic variant and nonfluent variant of PPA, with distinctive anatomical distributions for each variant. Image courtesy of Nico Papinutto.

In addition to the structural imaging modalities described, nuclear medicine techniques have been used to investigate how brain activity is altered by nfvPPA. Positron emission tomography, for example, may demonstrate decreased metabolism in the left frontal operculum and anterior insula even before atrophy becomes apparent on structural neuroimaging. PiB binding can also examine whether amyloid is present, suggestive of an underlying Alzheimer etiology, although dual pathology is also possible (Rabinovici et al., 2008). SPECT can also demonstrate blood flow changes in the left inferior frontal lobe in nfvPPA (Nestor et al., 2003).

Although fMRI studies have not yet found a place in the clinical diagnosis of nfvPPA, studies have shown networks in the ventral aspect of the frontal lobe to be inactive during a task of syntactically complex sentence comprehension among patients with nfvPPA compared with controls (Cooke et al., 2003). Resting state functional connectivity MRI has also been used to outline in healthy controls the left frontal network impacted in nfvPPA (Seeley, Crawford, Zhou, Miller, & Greicius, 2009).

75.2.4 Histopathology and Genetics

The nonfluent/agrammatic variant is considered a subtype of frontotemporal dementia. There are three forms of frontotemporal dementia: the behavioral variant (bvFTD), semantic variant of PPA (svPPA), and nfvPPA. Whereas both svPPA and AD are fairly histopathologically homogenous, both bvFTD and nfvPPA can be caused by a number of different pathological changes. The nonfluent variant most often heralds neurodegenerative disease such as FTLD-4R tauopathies, such as PSP or corticobasal degeneration (CBD). Pathological changes of FTLD-TDP-A are also found in different frequencies depending on the research group. Less frequently, AD may be involved (Caso et al., 2013).

Pathologically, the nonfluent variant of PPA is most commonly associated with deposits of tau or transactive-response DNA-binding protein of approximately 43 kD (TDP-43) types A or B. Causative tauopathies include PSP, CBD, and less commonly Pick's disease (Figure 75.3). Among those cases of nfvPPA associated with TDP-43, type A is most

FIGURE 75.3 (A) CBD. Immunostaining for phospho-tau. The * demonstrates white matter, where tau density is higher than in the gray matter of the outer layer. Scale bar: 1,000 μm . (B) PSP. Immunostaining for phospho-tau. The red arrow indicates a higher number of inclusion bodies in gray matter than in white matter. Scale bar: 1,000 μm . (C) Pick disease. Immunostaining for phospho-tau. The red arrow indicates an astrocytic inclusion, and the green arrow indicates a Pick body. Scale bar: 50 μm . (D) Transactive response DNA-binding protein of approximately 43 kD type A (TDP-A). Immunostaining for TDP-43. The red arrow indicates a typical “cat-eye” intranuclear inclusion, and the green arrow indicates short neurites. (E) Transactive response DNA-binding protein of approximately 43 kD type C (TDP-C). Immunostaining for TDP-43. The red arrow denotes granular neuronal cytoplasmic inclusions. (F) A typical Alzheimer disease plaque is depicted left of center, revealed by Bielschowsky silver staining. Several neurofibrillary tangles are also present. Slides (A)–(E) courtesy of Dr. Lea T. Grinberg, UCSF Memory and Aging Center. From Pressman and Miller (2014) with permission from the publisher. (F) From Pressman and Rabinovici (2014).

common (Josephs, Stroh, Dugger, & Dickson, 2009) (Figure 75.3). Although both of these histological patterns are more commonly associated with syndromes of the same name, it is possible that no symptoms of those syndromes may appear in nfvPPA. Beyond typical FTLD patterns of tau and TDP-43, reports show that many cases diagnosed with nfvPPA are ultimately found to have AD pathology, although some of these reports were retrospective and may not have investigated specifically for the logopenic pattern of impairment (Chare et al., 2014). In addition, while rare, other pathologies such as dementia with Lewy bodies have been associated with nfvPPA (Grossman, 2010).

Distinguishing *in vivo* among these pathological causes of nfvPPA is difficult. One small study comparing nfvPPA due to tau or TDP pathology indicated that the presence of extrapyramidal signs and agrammatism plus imaging signs of white matter damage might help in early differential diagnosis of nfvPPA caused by a 4R-tauopathy (Caso et al., 2013). The near-availability of tau radioligands will soon permit better distinction between TDP and tau pathologies *in vivo*.

Despite family history being strongly positive in up to 40% of FTD syndromes (Goldman et al., 2011; Rohrer et al., 2009), there is little to suggest that nfvPPA is usually inherited in an autosomal dominant manner. *MAPT* mutations have occasionally been associated with nfvPPA. The H1/H1 haplotypes on chromosome 17 may be associated with PPA (Sobrido et al., 2003). *MAPT* mutations do not seem to result in disproportionately high rates of nfvPPA, however, and phenotypes may be highly variable.

75.3 THE SEMANTIC VARIANT

The semantic variant of PPA (svPPA) has gone under various identities over the past century, perhaps including Pick's original descriptions, which included pronounced temporal lobe atrophy associated with semantic aphasia. Several similar reports followed (Compston, 2008; Rosenfeld, 1909; Stertz, 1926). In 1943, the Japanese researcher Tsuneo Imura further described an aphasia in which knowledge of the kanji characters depicting relatively complete concepts was lost while the more phonemic hiragana were preserved in Japanese patients. Originally named "Gogi" aphasia, this is now thought to represent the semantic variant of PPA in the Japanese population (Ralph & Howard, 2000; Sasanuma & Monoi, 1975). In 1975, Elizabeth Warrington proposed that such patients' word loss, associated agnosia, and impaired comprehension resulted from a fundamental loss of semantic knowledge (Warrington, 1975). Such knowledge refers to our

ability to place an object in a network of associations with words, meanings, and concepts.

Until the 1980s, the language network had been widely perceived as consisting of Wernicke's and Broca's areas, connected by the arcuate fasciculus. The role of the anterior temporal lobe was not appreciated. This region rarely suffers isolated damage due to strokes, and when included in vascular injuries larger swaths of cortex are typically also damaged, confounding previous clinicopathological correlations.

In recent decades, however, the anterior temporal lobe has been recognized as being involved with several aspects of semantic and conceptual processing. Soon after Mesulam's 1982 description of what he would ultimately term PPA, it became recognized that those with fluent aphasia frequently had predominant degeneration of the left anterior temporal lobe, although mixed cases were also described (Adlam et al., 2006; Hodges, Patterson, Oxbury, & Funnell, 1992).

The term "semantic dementia" was proposed in 1989 by Julie Snowden to describe those with fluent aphasia and a loss of comprehension (Snowden, Goulding, & Neary, 1989). The diagnosis of semantic dementia was later included in the 1998 Neary criteria as one of the subtypes of frontotemporal dementia, in addition to being considered a subtype of PPA (Neary et al., 1998). The criteria were updated again in 2011 to further describe the distinctive language deficits in these patients, solidifying the term "svPPA" (Gorno-Tempini et al., 2011). Although aphasic symptoms, such as anomia, are a key component of this syndrome when it initiates in the left temporal lobe, both temporal lobes ultimately become involved in the disease, and the disease may also start in the right lobe instead of the left (Seeley et al., 2005). The right temporal variant of this disorder may demonstrate how semantic loss can extend beyond verbal abilities, including diminished social pragmatics, empathy, and complex behavioral symptoms (Seeley et al., 2005).

75.3.1 Demographics

The age of onset for svPPA has been thought to be generally earlier than that for nfvPPA or lvPPA, but later than bvFTD (Johnson et al., 2005). Studies suggest that the mean onset may be about 60 years of age (Hodges et al., 2010; Rohrer et al., 2011). The rate of progression is thought to be relatively slow in svPPA, with an average time from symptom onset to death of about 10 to 14 years, with much individual variation (Davies et al., 2005; Hodges et al., 2010; Nunnemann et al., 2011). There may be a male predominance, with approximately 60% of svPPA patients being men.

As with nfvPPA, the incidence and prevalence of svPPA can be estimated from those of FTLD because

approximately 8.6% to 20% of all FTLD comprise the semantic variant (Forman et al., 2006; Johnson et al., 2005; Rohrer et al., 2011; Shi et al., 2005; Snowden et al., 2011). This allows for an estimated population incidence of 0.19 to 0.7 per 100,000 and an estimated prevalence of 0.23 to 3.0 per 100,000.

75.3.2 Clinical Characteristics

Although some people presenting with svPPA may initially report “loss of memory,” it soon becomes apparent that their problem is actually “loss of words” (Hodges et al., 2010). Severe anomia is the clearest deficit in neuropsychological testing. On further examination, orientation and visuospatial skills are well-preserved in svPPA, as is episodic memory. Knowledge of facts that are detached from a spatio-temporal and emotional context, that is, concepts or semantics, is diminished. In addition to words, patients have difficulty identifying objects and famous people. By doing specific tests that avoid linguistic content, a broader semantic deficit can be demonstrated. For example, the Pyramid and Palm Trees test shows a picture of an object and then requires the participant to choose which of two additional objects best goes with the initial stimulus (Howard & Patterson, 1992). Loss of conceptual knowledge for objects and words is highly influenced by familiarity of the object or concept. Early on, only unfamiliar, atypical concepts are lost, whereas knowledge of high-frequency or prototypical words and objects can be spared. Because classic stroke aphasia test batteries mainly contain high-frequency items, they might miss the comprehension and semantic deficits in early cases.

Linguistically, svPPA features impaired object naming and single-word comprehension, with preservation of fluency, phonology, and grammar (Gorno-Tempini et al., 2011) (Table 75.4). The discrepancy between conversational speech and object naming can be quite striking, especially early in the disease. The subject may be able to fluently discuss his or her life events, but then react to a commonplace word such as “watermelon” as if it were part of a foreign language. Spontaneous speech is often filled by nonspecific or “passe-partout” words, such as “this,” “that,” “the place where I used to go,” or “thing.”

In a study of language and semantic loss in left temporal atrophy, object-naming deficits were the most severe and consistent deficit (Mesulam et al., 2013). Evidence has suggested that this results predominantly from a loss of semantic knowledge rather than pure word-retrieval deficits. Patients with svPPA are less likely to think of the word later than those with other forms of PPA, and they are consistent in the names

TABLE 75.4 Diagnostic Features of the Semantic Variant of PPA

I. Clinical diagnosis of semantic variant PPA
Both of the following core features must be present:
1. Impaired confrontation naming
2. Impaired single-word comprehension
At least three of the following other diagnostic features must be present:
1. Impaired object knowledge, particularly for low-frequency or low-familiarity items
2. Surface dyslexia or dysgraphia
3. Spared repetition
4. Spared speech production (grammar and motor speech)
II. Imaging-supported semantic variant PPA diagnosis
Both of the following criteria must be present:
1. Clinical diagnosis of semantic variant PPA
2. Imaging must show one or more of the following results:
a. Predominant anterior temporal lobe atrophy
b. Predominant anterior temporal hypoperfusion or hypometabolism on SPECT or PET
III. Semantic variant PPA with definite pathology
Clinical diagnosis (criteria 1 below) and either criterion 2 or 3 must be present:
1. Clinical diagnosis of semantic variant PPA
2. Histopathologic evidence of a specific neurodegenerative pathology (e.g., FTLD-tau, FTLD-TDP, AD, other)
3. Presence of a known pathogenic mutation

AD, Alzheimer’s disease; FTLD, frontotemporal lobar degeneration; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single proton emission computed tomography.
Source: From Gorno-Tempini et al. (2011).

they cannot recall (Ralph & Howard, 2000). Cuing with the initial sounds of a word is less beneficial, and providing multiple choice options provides little help compared with other types of aphasia (Graham, Patterson, & Hodges, 1995).

However, in at least one study addressing object naming deficits in very early left temporal atrophy, many errors were pure retrieval failures as judged by the denoting word still being understood, the object recognized, and object–word matching remaining intact. The authors suggest that this may be due to a more bilateral or right-hemispheric localization of object knowledge (Mesulam et al., 2013). An alternative explanation could be that the information embedding for more general semantic loss differs from that between word and concept. A concept is connected to

several other concepts, of which a word is only one. If a connection between the concept of an apple and the word “apple” is lost, the concept is still connected to a number of other neuronal representations for red, fruit, sweet, and so on. Compared to these sensory associations, the association with the word “apple” may be relatively arbitrary and weak, and relatively susceptible to loss in the face of a disease. When conceptual knowledge erodes, the more arbitrary and isolated connection vanishes first (Hodges, Davies, & Patterson, 2009). The appearance of a predominant naming deficit in svPPA, then, may result less from neuroanatomic localization than relative robustness of connections within the neural network.

In addition to loss of single-word comprehension, loss of object knowledge, and object naming deficits, the 2011 criteria specifically mention surface dyslexia, which is a tendency to read irregularly spelled words phonetically. Patients with surface dyslexia regularize words with an atypical spelling pattern. The word “yacht,” for example, may be pronounced to rhyme with “latch (lætʃ).” This phenomenon stems from an inability to remember atypical word spellings as a type of semantic information, and so needing to read the word phonologically. Normally, words not spelled phonologically must be identified as an object in and of themselves, which svPPA patients are unable to endow with meaning. In addition to reading errors, when writing such patients may struggle with spelling exception words and make phonetically plausible spelling errors (e.g., “fruit” and “froot”) (Shim et al., 2012). In languages that use a more pictographic system of writing, those symbols that encapsulate a more semantic meaning, such as Japanese kanji, lose meaning before those symbols that are phonological, such as Japanese hiragana and katakana (Sasanuma & Monoi, 1975). Similarly, the inability to recall irregular past tense forms of verbs, such as “knew,” has also been considered as a symptom of semantic loss. In this instance patients tend to apply general morphological rules, thereby producing verbs such as “knewed.”

Phonemic paraphasias are relatively rare in svPPA compared to other PPA subtypes (Mesulam et al., 2013). Semantic paraphasias, however, in which one word is switched for another rather than one part of a word for another, are more common in svPPA. Specific and low-frequency words are replaced by the prototypical exemplar of that category of its prototypical exemplar or supraordinate, so all “cow” might become “dog” or “animal.” As svPPA progresses, semantic paraphasias tend to become more vague. Accordingly, conversation becomes less specific, more superficial, and difficult to understand, although speech might still be fluent.

In addition to conceptual knowledge for objects and words, the anterior temporal lobe is involved with identification of known people from names, voices, and

faces (Evans, Heggs, Antoun, & Hodges, 1995; Imaizumi et al., 1997), high-level visual and auditory processing (Horel, Keating, & Misantone, 1975; Lambon Ralph, 2014), socioaffective concepts such as empathy and theory of mind (Duval et al., 2012; Gorno-Tempini, Rankin, et al., 2004; Irish, Hodges, & Piguet, 2014), and the regulation of eating and sexual behavior. Dysfunction in these arenas become more readily apparent in the right temporal variant of svPPA but also occur in left svPPA as disease progresses and starts involving the right anterior temporal lobe and ventromedial frontal regions. As might be predicted, language is initially not as impaired in the right temporal variant, and it can be initially diagnosed as bvFTD. However, considering that identification of people and social concepts can be considered as part of semantic knowledge (one does not know when they learned to identify facial expressions), the right temporal form of svPPA should still be considered a semantic variant as opposed to bvFTD. In general, patients with svPPA tend to underestimate the extent of their behavioral and semantic changes, often only reporting word-finding deficits (Eslinger et al., 2005; Zamboni, Grafman, Krueger, Knutson, & Huey, 2010). Although they may also overestimate their empathic ability, data here are mixed (Duval et al., 2012).

Despite their deficits, it is important to recognize that many aspects of cognition remain intact in patients with svPPA. For example, they may remember life events well, find their way around without difficulty, and engage in complex hobbies with retention of many practical, visuo-spatial and creative skills. As stated in the 2011 criteria, repetition and grammar are relatively spared.

75.3.3 Anatomy and Imaging

MRI most often shows left greater than right anterior temporal lobe atrophy. Volume loss is greatest in the polar, parahippocampal middle, and inferior temporal regions, including the anterior fusiform gyrus (Pereira et al., 2009). This is typically more on the left than the right (Figure 75.1). Some have postulated that this apparent predilection toward the left lobe reflects a referral bias for a plausibly more obvious clinical presentation, that is, aphasia, rather than the comparatively subtle behavioral changes inherent in a right-temporal variant. Others, however, have pointed out that there is no significant difference between right and left predominant cases in the mean length of time from symptom onset to diagnosis (Hodges et al., 2010). Nevertheless, as awareness of these diseases increases, more cases of right greater than left anterior temporal atrophy are starting to be referred to neurology clinics. Even at this greater rate of recognition, however, the

proportion of right to left temporal variants in our UCSF cohort is about 1:4.

Although the appearance of the temporal lobes is asymmetric, atrophy is often bilateral in most cases, even early in the disease course (Chan et al., 2001). As time passes, those who begin with language impairment increasingly develop a social and emotional behavioral syndrome increasingly develop language problems. This corresponds with a spread of atrophy from the predominant lobe toward the opposite lobe, with subsequent spread to posterior temporal regions and orbitofrontal cortex as well (Brambati et al., 2009).

Initial reports described relative sparing of the hippocampus in svPPA, although volumetric analyses, in fact, demonstrate some atrophy of the hippocampus, which may be as severe if not more so in svPPA than AD when patients are matched for disease duration (Davies, Graham, Xuereb, Williams, & Hodges, 2004). Such hippocampal loss averages about 20%, compared with 50% loss suffered by the temporopolar and perirhinal cortices, giving the illusion of relative preservation. The amygdala is also universally involved with svPPA. This may contribute to some of the behavioral symptoms and lack of social cues such as reading of facial emotions (Rosen et al., 2002).

The anterior temporal lobe is described as a hub that binds together modality-specific information to create a unitary concept (Patterson, Nestor, & Rogers, 2007). The existence of an anterior temporal semantic hub does not exclude the possibility of some differential hemispheric specialization, depending on the connectivity of role of neighboring regions (Gainotti, 2006). In this framework, nonverbal and socio/emotional semantic information might be more right dominant or bilateral (Gainotti, 2006; Mesulam et al., 2013). A resting-state functional connectivity MRI study performed by Guo and colleagues suggests that the anterior temporal hub is a conglomerate or “transmodal” hub but with multimodal upstream contributing regions. For example, the superior temporal lobe was demonstrated to be more involved with auditory processing, and the inferior was demonstrated to be more involved with visual processing (Guo et al., 2013). DTI studies have shown that the inferior longitudinal fasciculus, the uncinate fasciculus, and the temporal portion of the arcuate bundle are particularly impacted in svPPA. The fronto-parietal portions of the superior longitudinal fasciculus (SLF) and the intrafrontal speech network are instead relatively spared (Galantucci et al., 2011) (Figure 75.2).

75.3.4 Histopathology and Genetics

svPPA has one of the tightest associations between clinical syndrome and pathology. TDP-43 type C is

the most common cause of svPPA and is found in about 90% of affected patients (Rohrer, Geser, et al., 2010) (Figure 75.3). Although this pathology most commonly localizes to the temporal lobes, cases have been described in which TDP-43 type C pathology is associated with corticospinal tract degeneration (Josephs, Whitwell, et al., 2013). Pick’s disease can also present as semantic variant, although atrophy is usually more fronto-temporal. AD can also rarely affect the anterior temporal lobe and cause selective semantic loss.

While up to 40% of FTD cases are said to have a family history of a neurodegenerative disorder, of which 10% to 20% show a clear positive family history of FTD, there is a much lower familial rate in svPPA compared with other subtypes (Goldman et al., 2005). This suggests a strong role of neurodevelopmental, environmental exposure, and the possibility of an autoimmune process. Interestingly, at 18%, the rate of certain autoimmune diseases in svPPA is higher than that found in healthy controls or AD (Miller, Rankin, et al., 2013). As autoimmune diseases frequently cluster together, there is a possible role for immunotherapy in svPPA in the future. Furthermore, there is a disproportionate number of left-handed individuals in those with svPPA, at nearly twice the incidence of the general population (Miller, Mandelli, et al., 2013).

75.4 THE LOGOPENIC VARIANT (lvPPA)

When PPA was initially divided into the nonfluent and fluent subtypes, non-Alzheimer pathology was considered the likeliest cause, although Alzheimer presenting with aphasia was also discussed (Kertesz, Davidson, McCabe, Takagi, & Munoz, 2003; Weintraub, Rubin, & Mesulam, 1990). Following the clearer descriptions of the semantic and nonfluent subtypes, Gorno-Tempini and colleagues published a comparison of cognitive and neuroimaging features of a large group of PPA patients in 2004, therein describing a third variant called logopenic PPA (lvPPA or PPA-L) (Gorno-Tempini et al., 2004). Patients with lvPPA have specific cognitive and neuroimaging characteristics that distinguish them from the other variants. In retrospect, many cases of lvPPA had previously been included among nonfluent or fluent aphasia cases.

In the decade that followed, the cognitive mechanism and resulting symptoms of lvPPA have been further elucidated. The role of phonological processes and phonological short-term memory was elucidated (Fuxe, Irish, Hodges, & Piguet, 2013; Gorno-Tempini et al., 2008; Leyton, Piguet, Savage, Burrell, & Hodges, 2012), and in contrast to the FTLN underlying svPPA and nfvPPA, the most common pathological process in

lvPPA has been found to be AD (Kirshner, 2012; Mesulam et al., 2008) (Figure 75.3). Possible links between PPA, especially lvPPA, and neurodevelopmental disorders have been suggested to predispose to this focal presentation of AD (Miller, Mandelli, et al., 2013; Rogalski, Johnson, Weintraub, & Mesulam, 2008; Rogalski, Weintraub, & Mesulam, 2013). Despite this progress, many questions remain regarding the neuroanatomical, linguistic, and histopathological characteristics of lvPPA.

75.4.1 Demographics

At our center, the mean age of patients with lvPPA is 68 years, with a standard deviation of 8.6 years; 77.3% of our lvPPA patients have been right-handed, and about 47% have been male. The incidence and prevalence of lvPPA are uncertain.

75.4.2 Clinical Features

The term logopenia is derived from Greek, meaning “lack of words.” The neologism was coined to describe those PPA patients who were fluent when engaging in small talk and when permitted to use circumlocutions, but who had word-finding hesitations when precise word selection was required (Mesulam, 1982, 2007). The result is a decrease in verbal output, with decreased rate of speech production, although fluency is usually intermediate between svPPA and nfvPPA, that appears similar to the vascular conduction aphasia syndrome (Gorno-Tempini et al., 2004).

As a symptom of phonological impairment, deficits in sentence and nonword repetition are key features of lvPPA, although this deficit may appear mild unless rigorously tested, which has led some to question this criterion’s inclusion in the current classification scheme (Mesulam et al., 2009; Mesulam, 2013; Mesulam et al., 2012). Phrase repetition is especially detectable, however, if phrases are long or have improbable word combinations. For example, patients with lvPPA will struggle more to repeat the phrase “the pastry cook was elated” compared to “the telephone is ringing” (Gorno-Tempini et al., 2008). They may also engage in circumlocution, returning a phrase that uses more common words, such as “something about a happy baker.” Although other forms of PPA, such as nfvPPA, may involve difficulty with repetition, the nature of the errors differs. Those with nfvPPA tend to err even in short sentences if they are sufficiently grammatically complex, typically dropping articles or pronouns (Wilson, Dronkers, et al., 2010).

The observation of the pronounced repetition deficits in those with lvPPA guided the hypothesis

that auditory phonological short-term phonological memory deficits are the key mechanism behind the disorder. Short-term phonological memory (or the phonological loop) refers to our ability to briefly retain a certain amount of verbal auditory information, usually between five and nine components in length, until we can manipulate that information or store it for a longer period. lvPPA involves a disruption in the short-term memory circuit dedicated to manipulation of phonemes, which are small contrastive units in the sound of a word, such as “fo” and “neem.” This process is particularly necessary to arrange sounds into long words, to accurately reproduce sequences of words and digits (as in digit span tasks), and to compose sentences (Baddeley, 1988; Vallar, Di Betta, & Silveri, 1997). Patients with lvPPA cannot retain this information long enough to repeat the exact phonemic sequence of a long pseudoword or the sequence of words into a phrase, although they can usually comprehend the general meaning if the sentence is not too long. Such patients may be unable to retain verbal information long enough to integrate the end of a long sentence with the sentence’s beginning, and so shorter and simpler sentences are preferentially used conversationally by lvPPA patients. Comprehension of sentences in lvPPA is improved by providing the stimuli in written form, thus decreasing the load on the phonological loop. The neural basis of the phonological loop is likely sustained to the left temporo-parietal junction to inferior frontal circuit.

In lvPPA, lexical retrieval deficits and phonological errors in speech production likely result from greater impairment in phonological processing, likely related to posterior temporal atrophy. Word retrieval can be assisted by phonological cues (e.g., “pa” to cue “palette”). Similarly, single word comprehension deficits in lvPPA are initially subtle, but they become more pronounced as the disease progresses involving more anterior and ventral temporal regions. Unlike svPPA, nonverbal semantic association and single-word comprehension are initially spared, although exceptions may exist in cases with progranulin mutations who show logopenic symptoms often accompanied by other impairments (Rohrer, Crutch, Warrington, & Warren, 2010). Although lvPPA patients may seem to have difficulty comprehending syntax, the cognitive mechanism differs from the agrammatism of nfvPPA. Sentence comprehension deficits in lvPPA more likely result from difficulty integrating long strings of words in short-term memory, rather than a true grammatical problem (Gorno-Tempini et al., 2008; Wilson, Dronkers, et al., 2010).

Phonological processing deficits also distinguish the paraphasias sprinkled through the speech of those with lvPPA. Unlike the production errors in svPPA, in

which an entire word is initially replaced with something taxonomically similar, those with lvPPA stumble over part of the word. The intended word is thereby replaced with a similar sounding substitute, such as “cantaloupe” for “antelope” (Wilson, Henry, et al., 2010). That said, phonological paraphasias are typical of, but not specific to, the lvPPA phenotype, as mentioned, likely in relation to the spreading of anatomical damage to posterior temporal cortex (Croot, Ballard, Leyton, & Hodges, 2012; Mesulam et al., 2012). lvPPA patients with such severe phonological issues may have had a relatively weak phonological system in the form of lifelong neurodevelopmental disorders such as dyslexia, which are further weakened by neurodegeneration.

In lvPPA, phonological processing deficits likely underlie reading and spelling errors that take the form of phonological dyslexia, characterized by greater difficulty in pseudo-words (meaningless words that still follow general rules of English) that require the use of grapheme to phoneme mechanisms and cannot rely on whole word semantic processes (Brambati, Ogar, Neuhaus, Miller, & Gorno-Tempini, 2009; Sepelyak et al., 2011; Shim et al., 2012).

Additional nonverbal symptoms may accompany language problems in lvPPA due to anatomical proximity to the left temporoparietal region most atrophied in the disease. Functionality of nearby cortical regions may result in dyscalculia and limb apraxia, for example (Rohrer et al., 2008). Degrees of impairment in cognitive domains such as visuospatial ability, divided attention, and cognitive flexibility have also been reported (Galantucci et al., 2011; Gorno-Tempini et al., 2004; Machulda et al., 2013; Rohrer & Warren, 2010; Wicklund, Johnson, Rademaker, Weitner, & Weintraub, 2007; Wilson, Henry, et al., 2010). Possibly reflecting the underlying Alzheimer pathology, those with lvPPA also tend to have greater general memory impairment than other PPA variants (Mesulam et al., 2008). Mood changes are not uncommon, especially anxiety, agitation, and irritability (Rohrer & Warren, 2010).

The international classification scheme requires the presence of both word-finding difficulties and repetition deficits for a diagnosis of lvPPA (Table 75.5). The utility of including both these criteria has been recently challenged (Wicklund et al., 2014), as sentence repetition deficits appear to be not as common as initially thought (Mesulam & Weintraub, 2014). More evidence from prospectively collected cohorts is needed to determine the frequency of sentence repetition deficits in lvPPA because particular sentence types are necessary to uncover the problem. It is likely that, as is often the case for operationalized diagnostic criteria of complex cognitive syndromes, sensitivity might come to the detriment of specificity.

TABLE 75.5 Features of the Logopenic Variant of PPA

I. Clinical diagnosis of logopenic variant PPA
Both of the following core features must be present:
1. Impaired single-word retrieval in spontaneous speech and naming
2. Impaired repetition of sentences and phrases
At least three of the following other features must be present:
1. Speech (phonologic) errors in spontaneous speech and naming
2. Spared single-word comprehension and object knowledge
3. Spared motor speech
4. Absence of frank agrammatism
II. Imaging-supported logopenic variant diagnosis
Both criteria must be present:
1. Clinical diagnosis of logopenic variant PPA
2. Imaging must show at least one of the following results:
a. Predominant left posterior perisylvian or parietal atrophy on MRI
b. Predominant left posterior perisylvian or parietal hypoperfusion or hypometabolism on SPECT or PET
III. Logopenic variant PPA with definite pathology
Clinical diagnosis (criterion 1 below) and either criterion 2 or 3 must be present:
1. Clinical diagnosis of logopenic variant PPA
2. Histopathologic evidence of a specific neurodegenerative pathology (e.g., AD, FTLT-tau, FTLT-TDP, other)
3. Presence of a known pathogenic mutation

AD, Alzheimer’s disease; FTLT, frontotemporal lobar degeneration; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single proton emission computed tomography.

Source: From Gorno-Tempini et al. (2011).

75.4.3 Anatomy and Imaging

MRI studies in lvPPA demonstrate volume loss in the left hemisphere, specifically in the posterior temporal and inferior parietal regions (Figure 75.1). Detailed voxel-based morphometry (VBM) methods demonstrate grey matter loss in the angular gyrus, supramarginal gyrus posterior third of the middle temporal gyrus, and superior temporal gyrus, as well as some involvement of the left anterior hippocampus and precuneus. More generally, the atrophy can be said to predominantly involve the left temporoparietal junction (Gorno-Tempini et al., 2008; Rohrer et al., 2013). As suggested by the term “frontotemporal degeneration,” the pattern of atrophy of lvPPA is decidedly unlike the other two forms of PPA, which are also considered subtypes of FTD.

The rate of whole brain atrophy has been shown to be greater in those with lvPPA compared with controls

(2.0% per year compared with 0.3% in controls). The rate of volume loss is significantly greater in the left hemisphere compared with the right (2.3% compared with 1.6%). Time leads to involvement of more anterior regions, including caudate, hippocampus, and medial parietal lobes (Rohrer et al., 2013). DTI suggests white matter damage in the left temporo-parietal component of the arcuate fasciculus (Galantucci et al., 2011) (Figure 75.2). These white matter deficits may be less severe than in other forms of PPA, however, again in relation to the fact that lvPPA is most often caused by AD. However, other studies have found more widespread white matter changes, including the whole arcuate and the inferior longitudinal fasciculus (Agosta et al., 2012).

FDG-PET studies have confirmed hypometabolism in the left temporoparietal lobe. Similar patterns have been described in early-onset AD. Consistent with those findings, binding with the nuclear ligand tracer ¹¹C-labeled Pittsburgh Compound-B is more likely to show evidence of cortical amyloid in lvPPA compared with controls (REFS). There is little correlation between location of amyloid, however, and the patient's symptoms. Although lvPPA symptoms do not correlate with location of amyloid plaques, as evidenced on PiB-PET imaging and pathology, the temporoparietal atrophy in lvPPA correlates with increased neurofibrillary tangles in that region.

75.4.4 Histopathology and Genetics

Even in some of the earliest detailed descriptions of the logopenic subgroup, the potential for causative Alzheimer pathology was apparent. As mentioned, Gorno-Tempini and colleagues discovered a posterior pattern of volume loss (Gorno-Tempini et al., 2004). Moreover, they found a 67% frequency of the APOE4 haplotype, commonly associated with Alzheimer pathology, in the logopenic group, compared with 0% in the semantic group and only 20% of svPPA (Gorno-Tempini et al., 2004). Although this connection between ApoE4 and lvPPA is not always found in different research groups, the association between Alzheimer pathology and lvPPA was subsequently demonstrated by several groups by pathological examination (Gefen et al., 2012; Josephs, Dickson, et al., 2013; Mesulam et al., 2008). In addition, cases of lvPPA have been associated with argyrophilic thorny astrocyte clusters on microscopic examination, a finding that may be associated with asymmetric and focal presentations of degenerative disease (Munoz, Woulfe, & Kertesz, 2007).

Retrospective studies of patients with PPA who were later found to have AD found significant

logopenic symptoms (Rohrer, Rossor, & Warren, 2012). Other supporting evidence includes cortical amyloid binding in nuclear imaging studies and cerebrospinal fluid studies consistent with a diagnosis of Alzheimer disease in logopenic patients (Gil-Navarro et al., 2013; Gorno-Tempini et al., 2004; Rohrer, Rossor, & Warren, 2010). Thus, lvPPA is more correctly classified as an atypical presentation of early-age-of-onset AD than a variant of the FTD-spectrum diseases (Migliaccio et al., 2012; Rabinovici et al., 2008).

The relationship between lvPPA and Alzheimer pathology is not absolute, however. Other pathological processes may also lead to syndromes that at least resemble lvPPA, including Creutzfeldt-Jakob disease and Lewy body dementia (Martory et al., 2012; Teichmann, Migliaccio, Kas, & Dubois, 2013). VBM studies suggest that there is more posterior-superior temporal atrophy in lvPPA, whereas non-AD etiologies of lvPPA have more severe perisylvian atrophy (Hu et al., 2010).

Furthermore, in some cases of lvPPA, atrophy may extend into areas commonly associated with other PPA variants, leading to a blurring of clinical syndromes that can start to resemble a global aphasia (Rogalski, Cobia, Harrison, Wieneke, Thompson, et al., 2011; Rogalski, Cobia, Harrison, Wieneke, Weintraub, et al., 2011). Rohrer and colleagues discovered that 2 out of 9 patients with lvPPA had a mutation in the progranulin gene (*PGN*). Progranulin has been associated with frontotemporal dementia and is thought to predispose toward asymmetric cortical atrophy such as that in PPA. Although those who had *PGN* mutations had symptoms that best fit lvPPA, they also had severe single word comprehension deficits, severe anomia, and irregular word reading that was more suggestive of svPPA. VBM analysis revealed more anterior temporal atrophy in these patients than other forms of lvPPA, explaining the semantic deficits and highlighting that the syndrome is really logopenic "plus" (Rohrer, Crutch, et al., 2010).

75.5 FUTURE DIRECTIONS IN PPA

The classification scheme for PPA devised in 2011 has given clarity to diagnosing these disorders, but intentionally leaves room for clinical judgment. Objective classification based on test cutoffs, for example, is difficult and perhaps inappropriate in such complex cognitive syndromes in which deficient performance can be caused by different underlying mechanisms. The criteria are best applied to patients at early disease stages and for sporadic (nongenetic) cases of PPA.

The current classification scheme is not intended to limit the variety of presentations of PPA. One report

by Wicklund and colleagues suggests that while almost 70% of patients are assigned to an existing category, 31% did not meet the criteria of any of the categories (Wicklund et al., 2014). Some patients appear to be unclassifiable, and others fulfill criteria for more than one subtype (Harris et al., 2013; Mesulam & Weintraub, 2014; Sajjadi, Patterson, Arnold, Watson, & Nestor, 2012). In fact, each patient will present slightly differently, and it may be possible to further subtype these clinical presentations that relate to the patterns of underlying atrophy. For example, some have suggested that there is a motor speech disorder that impacts speech more than underlying language processes, and a primary progressive AOS diagnosis is more appropriate (Josephs et al., 2010; Josephs, Duffy, et al., 2013). Some have suggested that PGN mutations or TDP-C with corticospinal tract involvement might involve distinct diagnoses.

Although the current criteria allow some prediction of different probabilities of underlying pathology, different histopathologies sometimes still appear clinically indistinguishable within the same subgroup of PPA. Biomarkers assist *in vivo* molecular diagnosis and will increase our accuracy in predicting pathology. Dedicated PET scans will soon be available that permit tau imaging in a manner currently performed with amyloid, which will allow further distinction between TDP-43 and tau pathology (Maruyama et al., 2013).

Accurate diagnoses are of more than academic interest—the hope is that they will permit for better treatments. Unfortunately, treatments are still elusive. Patient care in PPA is currently symptomatic, meaning that no treatment currently addresses the underlying neurodegeneration. A knowledgeable speech therapist can guide the patient toward useful communication techniques and devices, and small studies indicate that early language rehabilitation has proven useful when different strategies are applied for each variant (Beeson et al., 2011; Henry et al., 2013). For those with word-retrieval deficits, focusing on personally relevant words may provide sufficient relief to merit the time and effort involved with such therapy (Henry et al., 2013). In cases of Alzheimer disease, a cholinesterase inhibitor such as galantamine or donepezil may be of some benefit (Kertesz et al., 2008). Preliminary benefits of techniques such as transcranial magnetic stimulation have been described, at least for nfvPPA (Cotelli et al., 2014).

PPA is still relatively rare, and it can be difficult to connect patients with appropriate resources. Web sites such as the international PPA connection (ppaconnection.org) may offer opportunities for patients and families to access information about the disorder and any clinical trials that may become available.

The Declarative/Procedural Model: A Neurobiological Model of Language Learning, Knowledge, and Use

Michael T. Ullman

Brain and Language Laboratory, Department of Neuroscience, Georgetown University, Washington, DC, USA

Not surprisingly, most research on the neurobiology of language has focused on language itself. Yet even after decades of investigation, we know much less about the neurobiological correlates of language than we do about the neurobiology of many other domains, such as vision, motor function, and memory. This relative lack of progress is likely due not only to the complexity of language and to a lack of animal models, but also to an overly narrow “isolationist” approach to language research. A complementary approach of examining links between language and other domains and their neurobiological substrates could significantly advance our understanding of the neurobiology of language, particularly if the neurobiology of these other domains is well-understood. Such an approach would likely be very powerful in that it could generate novel well-motivated predictions about language based on our independent knowledge of these other domains.

There is, in fact, no clear evidence that the neurobiological bases of language underlie language alone, that is, that they are domain-specific (Ullman, Lum, & Conti-Ramsden, 2014). On the contrary, we should expect language to depend heavily on neurobiological substrates that also subserve(d) other domains. In evolution, mechanisms and structures are constantly being reused for new purposes. For example, fins evolved into limbs, limbs into hands and wings, and scales into feathers (Woltering, Noordermeer, Leleu, & Duboule, 2014). Such co-optation of a given substrate for new functions takes place not only phylogenetically (evolutionarily) but also ontogenetically (developmentally). For example, reading likely depends on brain circuitry that is co-opted for this function during learning and development. A given

structure can even be co-opted for new functions without any further changes in the underlying mechanism (this has been referred to as exaptation) (Gould & Vrba, 1982). For example, certain species of heron spread their wings to provide shade so they can better see their prey.

Therefore, language should depend importantly on previously existing neurobiological systems, whether or not these systems have subsequently become further specialized for language, either phylogenetically or ontogenetically. I will call this the *co-optation hypothesis of language*. Various neurobiological systems may be good candidates for such co-optation, including working memory (Caplan & Waters, 1999; Just & Carpenter, 1992), and dorsal and ventral stream processing (Bornkessel-Schlesewsky & Schlesewsky, 2013; Hickok & Poeppel, 2007; Petrides & Pandya, 2009).

Two learning and memory systems in the brain—declarative memory and procedural memory—are also excellent candidates. Most of language must be learned, whether or not there are innately specified aspects of this domain. Moreover, declarative and procedural memory seem to be the two most important learning and memory systems in the mammalian brain, including in humans, in terms of the range of domains, tasks, and functions that they underlie (Eichenbaum, 2012; Mishkin, Malamut, & Bachevalier, 1984; Squire & Wixted, 2011). The declarative/procedural (DP) model simply posits that these systems should therefore play wide-ranging roles in language learning, knowledge, and use. That is, the DP model posits that these two memory systems have been co-opted for language—whether or not they have become further specialized phylogenetically or ontogenetically for this domain.

Importantly, these memory systems have been well-studied both in humans and in nonhuman animals, and are thus quite well-understood at many levels—including their behavioral, computational, neuroanatomical, electrophysiological, cellular, biochemical, and genetic correlates. Many of these levels are far better understood for the two systems than for language. Because the posited co-optation of the memory systems for language leads to the expectation that the systems play similar roles in language as in other domains (although not necessarily identical roles, in part because the systems may have become further specialized for language), our understanding of the memory systems should generate a wide range of specific predictions for language. Crucially, these predictions are generated independently from the study of language itself, and are well-motivated from this independent knowledge. Moreover, many of them are likely to be novel because there would often be no reason to make such predictions based on the more limited study of language alone. Finally, linking language to the memory systems should not only generate new predictions, but may also help to account for already-observed language phenomena for which no good explanation independent of language currently exists.

Here, I first present an overview of the two memory systems, whose neurobiological and other correlates constitute the foundation of our predictions. Next, I present key predictions regarding the roles of these systems in language, with a focus on functional neuroanatomy. Then, I summarize a range of evidence testing these predictions. Converging evidence from multiple methodological approaches provides support for many of the predictions, thus supporting the DP model as well as the co-optation hypothesis more generally, and advancing our understanding of language and its underlying neurobiology. Note that the purpose of this chapter is to present the theory and its predictions; therefore, I focus on the motivating background (the memory systems) and the predictions, and more briefly summarize the evidence.

76.1 THE MEMORY SYSTEMS

Here, I provide an overview of the declarative and procedural memory systems, and discuss interactions between the two systems as well as with other neurocognitive systems. Note that the declarative and procedural memory systems refer here to the entire neurocognitive systems involved in the learning, representation, and use of the relevant knowledge, not just to those portions underlying learning and consolidating new knowledge, which is how some researchers

refer to the systems. For additional information on the memory systems, see Stark and Stark chapter in this book (Chapter 67).

76.1.1 The Declarative Memory System

The declarative memory brain system is quite well-understood (Cabeza & Moscovitch, 2013; Eichenbaum, 2012; Eichenbaum, Sauvage, Fortin, Komorowski, & Lipton, 2012; Henke, 2010; Mishkin et al., 1984; Squire & Wixted, 2011; Stark and Stark chapter in this book; Ullman, 2004). Briefly, the hippocampus and other medial temporal lobe (MTL) structures are critical for learning and consolidating new knowledge that depends on this system, although ultimately the storage of this knowledge depends largely on neocortical regions, particularly in the temporal lobes.

Within the MTL, evidence from human and animal studies suggests that the hippocampus underlies the rapid linking (binding, associating) of different bits of knowledge or experience across multiple domains and modalities, including what may be characterized as knowledge of “what” (e.g., facts, meanings), “where” (e.g., landmarks), and “when” (when an event occurred) (Henke, 2010; Squire & Wixted, 2011). Other MTL structures closely connected with the hippocampus are also important, including the entorhinal, perirhinal, and parahippocampal cortices (Stark and Stark chapter in this book). Perirhinal cortex may underlie the familiarity of newly learned information, whereas the hippocampus subserves its explicit recollection (Brown, Warburton, & Aggleton, 2010; but see Wixted & Squire, 2011). Perirhinal cortex may support memories of single items (at least in the visual modality), whereas the hippocampus underlies more complex relational associations. MTL structures also appear to play a role in detecting and learning novel stimuli, perhaps perirhinal cortex for novel individual items and the hippocampus for novel relational information (Yonelinas, Aly, Wang, & Koen, 2010). Different nonhippocampal MTL regions may preferentially underlie memories in different domains: for example, perirhinal cortex for object recognition and parahippocampal cortex for spatial recognition as well as temporal information (Eichenbaum & Lipton, 2008; Eichenbaum et al., 2012; Squire & Wixted, 2011). Auditory information may particularly rely on parahippocampal cortex (Munoz-Lopez, Mohedano-Moriano, & Insausti, 2010), perhaps due to the temporal nature of this information. In contrast, as mentioned, the hippocampus binds information from a wide variety of domains and modalities, including time (which may explain its importance in episodic memory). More complex high-level concepts (e.g., about Jennifer Aniston) may also be represented in the hippocampus (Quiroga, Reddy, Kreiman, Koch, & Fried, 2005). More generally,

the hippocampus and other MTL structures may be not only involved but also required for learning arbitrary bits of information and binding them, as evidenced by the virtual lack of such information acquired by densely amnesic individuals with extensive MTL lesions such as patient H.M. (Henke, 2010; Squire & Zola-Morgan, 2011; although some such information may still be learnable; see Stark and Stark chapter in this book). Finally, other structures connected to the MTL also play a role in declarative memory, including the fornix and various diencephalic structures and tracts (especially the mammillary bodies, the mammillothalamic tract, and the medial dorsal and anterior thalamic nuclei) (Squire & Zola-Morgan, 2011).

The MTL, including the hippocampus, is not just involved in learning and memory. As we have seen, the MTL plays a role in novelty detection, perirhinal cortex may subserve object recognition, and parahippocampal cortex may underlie spatial recognition and temporal information. It has been suggested that perirhinal cortex plays both memory and perceptual roles that link the declarative memory system with the ventral stream (“what pathway”) in the visual modality (Bussey & Saksida, 2007). In contrast, parahippocampal cortex is closely linked to the dorsal stream (“where”) pathway, particularly in the representation of landmarks (Kravitz, Saleem, Baker, & Mishkin, 2011). Additionally, the hippocampus may underlie other functions not strictly related to long-term memory, including short-term memory and aspects of imagination and prediction (Eichenbaum & Fortin, 2009; Kumaran & Maguire, 2009). Thus, MTL structures may play a number of (very possibly interrelated) roles in learning, memory, and other functions.

As mentioned above regarding the long-term memory functions of this brain system, knowledge that critically depends on the MTL during learning and consolidation eventually relies largely on neocortex. The MTL may rapidly bind neocortical representations together, which, over time and/or experience, eventually develop cortical-cortical links, thereby no longer requiring the MTL (McClelland, McNaughton, & O’Reilly, 1995). However, the MTL continues to play a role in this knowledge. As we have seen, it seems to be involved in object recognition (perirhinal cortex), spatial recognition (parahippocampal cortex), and recognition of higher-level concepts (hippocampus). Moreover, it has been suggested that the MTL continues to underlie long-term memories, particularly for autobiographical (episodic) knowledge (Winocur & Moscovitch, 2011), although this claim has been disputed (Squire & Zola-Morgan, 2011).

Within neocortex, different regions appear to underlie different types of knowledge (Martin, 2007; Squire & Zola-Morgan, 2011). For example, knowledge for

living and nonliving things seems to involve different neocortical regions. An important organizational principle appears to be that neocortex proximate to particular sensory cortices underlies knowledge closely linked to those sensory modalities. Thus, knowledge with strong auditory associations depends on superior temporal regions (near primary auditory cortex), whereas knowledge with visual associations involves temporal and other regions downstream from visual cortex. Higher-level knowledge may also be organized neuroanatomically. For example, knowledge of faces involves the “fusiform face area” and knowledge of written words involves the “visual word form area.” More generally, higher-level concepts may rely on more anterior temporal lobe areas (Barense et al., 2012). Information may flow from posterior to anterior regions of the temporal lobe, such that, at least in vision (and possibly in audition, Rauschecker & Scott, 2009), features are represented hierarchically in increasingly complex conjunctions, with low-level features represented more posteriorly and higher-level features represented more anteriorly—perhaps with the most complex conjunctions (e.g., higher-level concepts) in MTL regions, such as in the hippocampus.

Neocortical regions outside of temporal cortex also play roles in declarative memory—not only in the representation of long-term knowledge but also in particular processes associated with declarative memory. A region in inferior frontal neocortex corresponding largely to Brodmann’s areas (BAs) 45 and 47 (within and near classical Broca’s area) seems to underlie the encoding as well as the selection or recall of declarative memories (Ullman, 2004). Portions of the basal ganglia, perhaps with connections to these areas, may play analogous roles (Ullman, 2006). And a posterior parietal region seems to underlie aspects of encoding or retrieval (Uncapher & Wagner, 2009; Wagner, Shannon, Kahn, & Buckner, 2005).

The behavioral correlates of this network of brain structures rooted in the MTL are reasonably well-characterized (Eichenbaum, 2012; Henke, 2010; Squire & Zola-Morgan, 2011; Ullman, 2004). The system may be specialized for learning arbitrary bits of information and associating them; it may even be necessary for learning this information. It underlies the learning, representation, and use of knowledge about both facts (semantic memory) and events (episodic memory), such as the fact that Catalan is derived from Latin, or the event of you having a bowl of delicious pho yesterday for lunch. More broadly, the system can learn a wide range of information across sensory modalities and cognitive domains, and may also support various non-long-term memory functions. Unlike other types of long-term memory such as procedural memory or fear conditioning, multiple types of knowledge can be

learned very rapidly in this system with as little as a single exposure to the stimulus, although additional exposures strengthen memories. The acquired knowledge is at least partly, although not completely (Chun, 2000; Henke, 2010; Schendan, Searl, Melrose, & Stern, 2003), explicit—that is, available to conscious awareness. Indeed, this appears to be the only long-term memory system that underlies explicit knowledge; thus, any knowledge that is explicit should have been learned in declarative memory. Once learned, information in declarative memory can be generalized and used flexibly across different contexts.

The molecular bases of declarative memory have also been reasonably well-studied in humans and animals (Green & Dunbar, 2012; Pezawas et al., 2004; Ullman, 2004). Various genes, including those for brain-derived neurotrophic factor (BDNF) and apolipoprotein E (APOE), play roles in declarative memory and hippocampal function, as do the neurotransmitter acetylcholine and the hormone estrogen (higher levels are associated with better declarative memory in humans and rats). BDNF may play a role in consolidation (as may estrogen). Estrogen may modulate declarative memory functionality via BDNF and/or acetylcholine.

Finally, various subject-level factors appear to modulate learning and retention in declarative memory, including not only genetic variability but also age (declarative memory improves during childhood, plateaus in adolescence/early adulthood, and then declines), sex (females seem to have an advantage at declarative memory over males), handedness (left-handedness may be associated with a declarative memory advantage), sleep (memory consolidation seems to improve during sleep), and exercise (which can enhance declarative memory) (Erickson et al., 2011; Marshall & Born, 2007; Ullman, 2005; Ullman et al., under revision; Ullman, Miranda, & Travers, 2008).

76.1.2 The Procedural Memory System

Although procedural memory is still not as well-characterized as declarative memory, its neurobiological and behavioral correlates are becoming clearer (Ashby, Turner, & Horvitz, 2010; Doyon et al., 2009; Ullman, 2004). Procedural memory involves a network of interconnected brain structures rooted in frontal/basal-ganglia circuits, including frontal premotor and related regions, particularly BA 6 and BA 44. (Note that we use the term procedural memory to refer to a particular brain system and its characteristics, rather than implicit memory more generally, which is how some researchers use the term.) The basal ganglia play a critical role in the learning and consolidation of

motor and cognitive skills, whereas neocortical regions may be more important for processing skills after they have been automatized. Within the basal ganglia, the caudate nucleus (and the anterior putamen) may be especially important for skill acquisition.

This circuitry underlies the implicit (nonconscious) learning and processing of a wide range of perceptual-motor and cognitive skills, tasks, and functions (Eichenbaum & Cohen, 2001; Henke, 2010; Ullman, 2004), including navigation, sequences, rules, and categories. It may be specialized for learning to predict (perhaps especially probabilistic outcomes), for example, the next item in a sequence or the output of a rule. Learning in the system requires practice, and thus is slower than learning in declarative memory—though what is eventually learned seems to be processed more rapidly and automatically than knowledge in declarative memory. Although the system is rooted in the basal ganglia, the cerebellum may also play a role; however, exactly how and in what ways it interacts with the basal ganglia remain unclear.

Some aspects of the molecular bases of procedural memory are also beginning to emerge. The neurotransmitter dopamine plays an important role, particularly in learning and consolidation (Ashby et al., 2010). Certain genes involved in procedural memory have been identified, including *FOXP2*, *PPP1R1B* (for the protein DARPP-32), and *DRD2* (Meyer-Lindenberg et al., 2007; Ullman & Pierpont, 2005; Wong, Ettliger, & Zheng, 2013). A recent study found that humanized *Foxp2* in mice (i.e., with human-specific amino acid substitutions) sped up learning, in particular by promoting the transition from declarative to procedural memory (Schreiweis et al., 2014). Finally, other factors may also affect procedural memory, including age. Unlike declarative memory, procedural memory functionality seems to be well-established early in life, after which learning or consolidation in this system may attenuate (Adi-Japha, Badir, Dorfberger, & Karni, 2014; Ullman, 2005). In contrast, sleep and exercise, among other factors, appear to show similar effects in the two memory systems, improving learning in both.

76.1.3 Interactions Between the Memory Systems

The declarative and procedural memory systems interact in a number of ways. First, evidence suggests that the two systems can, to some extent, acquire the same or analogous knowledge or skills (Poldrack & Packard, 2003; Ullman, 2004). According to the *redundancy hypothesis*, they therefore play at least partly redundant roles. Such redundancy can be found for multiple tasks and functions, including navigation,

sequences, rules, and categories. Perhaps not surprisingly, the type and form of knowledge learned in the two systems are often quite different, even while this knowledge underlies the same or similar outcomes. For example, evidence from rodents suggests that navigation can be learned in procedural memory, such that animals learn to turn at a particular point (response strategy), or in declarative memory, by using landmarks (place strategies). Similarly, humans can learn sequences, rules, and categories implicitly in procedural memory or explicitly (and perhaps also implicitly) in declarative memory.

Various factors appear to modulate which of the two systems is used for a given task or function that can be learned or processed by either system. The declarative memory system often acquires knowledge initially, thanks to its fast acquisition abilities, whereas the procedural system gradually learns analogous knowledge that is eventually processed rapidly and automatically. The knowledge in declarative memory seems to remain intact even when procedural memory takes over; for example, lesions of the basal ganglia can lead to a reversion of dependence on knowledge that was initially learned in declarative memory (Packard, 2008). The learning context can also affect which system is relied on more. Explicit instruction (e.g., of sequences), or even just paying attention to the stimuli and underlying rules or patterns, can increase learning in declarative memory. Conversely, a lack of explicit instruction, as well as manipulations that reduce attention to the stimuli (e.g., in dual task paradigms), or a high level of complexity of rules or patterns (thus decreasing the subject's ability to explicitly detect patterns) may all shift learning toward procedural memory.

Many other factors likely also play roles affecting which system is relied on more. Any factor that enhances learning, retention, or retrieval preferentially in one of the memory systems should lead to an increased dependence on that system. Thus, the relative functionality of the two systems can affect which one is relied on more. For example, likely due in part to a female advantage at declarative memory (perhaps thanks to higher estrogen levels), females may rely more on this system, while males correspondingly rely more on procedural memory, for tasks that can be performed by either system (Ullman et al., 2008). And disorders that affect one system can lead to a compensatory role for the other. For example, individuals with Specific Language Impairment (SLI), dyslexia, autism, or obsessive-compulsive disorder, all of which have been associated with abnormalities of procedural memory but relatively intact declarative memory, appear to rely more on this intact system (Ullman & Pullman, 2015). Thus, multiple within- and

between-subject factors may modulate the relative dependence on the two systems.

Second, animal and human studies suggest that declarative and procedural memory also interact *competitively*, resulting in a “seesaw effect” (Ullman, 2004). The dysfunction of one system may lead not only to an increased dependence on the other system for those tasks and functions that can depend on either one, but *also* to the enhanced functioning of that system. Evidence for such a seesaw effect comes from both animal and human studies (Packard, 2008; Poldrack & Packard, 2003; Ullman, 2004). Additionally, estrogen may not only enhance declarative memory but also inhibit procedural memory. Note that the seesaw effect, and compensation due to redundancy, are distinct notions: if only one system is dysfunctional, then the other can compensate whether or not its functionality is enhanced—although, of course, any enhancement from the seesaw effect would bolster any such compensation.

Third, the learning and/or retrieval of knowledge in declarative memory may block (inhibit) the learning and/or retrieval of analogous knowledge in procedural memory (Ullman, 2004). The converse may hold as well. For example, even when a task is learned initially in declarative memory, it can be overridden by procedural memory when it is subsequently learned in that system (Packard, 2008).

The two memory systems are also linked to and interact with *other* neurocognitive brain systems. First, working memory seems to be closely related to (at least) declarative memory. For example, frontal brain structures involved in working memory also underlie declarative memory in both encoding and recall (Ullman, 2004). And deficits of working memory are associated with deficits of declarative memory (Lum, Ullman, & Conti-Ramsden, 2015; Ullman & Pullman, 2015). More generally, we suggest that working memory may constitute input and output mechanisms for at least explicit knowledge in declarative memory. Second, priming depends importantly on knowledge initially learned in the memory systems. For example, the priming of concepts and word forms seems to rely on representations learned in declarative memory, as suggested by the inability of dense amnesics to learn new information of this sort. Finally, as indicated above, there are links between the memory systems and the ventral and dorsal streams (Ullman, 2004). The ventral stream seems to be linked strongly to the declarative memory system. The dorsal stream may also interact with this system, with projections to parahippocampal cortex, which plays a role in representing landmarks. However, the dorsal stream may be particularly tied to procedural memory. While “what” knowledge seems to depend on a combination of the ventral stream

(for processing) and declarative memory (for learning), “how” knowledge may depend on a combination of the dorsal stream (for processing) and procedural memory (for learning). Indeed, learning supported by the basal ganglia may link inputs from parietal structures to motor regions (Ashby et al., 2010; Doyon et al., 2009). This posited interdependence between learning in the declarative and procedural memory systems and respective processing of this knowledge in the ventral and dorsal streams may be referred to as the *memory-processing interdependence hypothesis*.

76.2 PREDICTIONS FOR LANGUAGE

Here, I summarize some key predictions of the DP model—that is, predictions for language that are derived from our understanding of the two memory systems. For each memory system I first present predictions regarding *what* types of language-related knowledge and functions the system should underlie, and then *how* exactly these should be subserved by the system, with a focus on functional neuroanatomy.

Note that the DP model does *not* predict that the memory systems underlie language and other domains in identical ways—both because language is not identical to other domains and because portions of the systems may have become specialized for language (either evolutionarily or developmentally). Rather, because the co-optation hypothesis leads to the expectation that the systems play at least similar if not identical roles across domains, our substantial independent knowledge of the systems’ roles in other domains is an excellent starting point for making predictions about language. Empirical studies will reveal exactly where and how the systems’ roles in language might diverge from those in other domains.

76.2.1 Declarative Memory: Predictions for Language

76.2.1.1 What Should Declarative Memory Underlie in Language?

First, because declarative memory seems to be critical for learning, storing, and accessing arbitrary bits of information, as well as arbitrary associations among them, aspects of language that involve such bits or associations should critically depend on this memory system. Thus, declarative memory should be crucial for all learned idiosyncratic linguistic knowledge at the word or multi-word level (though presumably not for any such knowledge that may be purely innately specified, if such knowledge exists). Simple (i.e., not rule-governed and fully derivable) content words (e.g., *cat*,

devour), including their phonological forms, meanings, (sub)categorization knowledge (e.g., *devour* requires a complement), and mappings between them (e.g., sound-meaning mappings), should be learned in this system. Knowledge about irregular morphological forms, both inflectional and derivational (e.g., *dig-dug*, *solemn-solemnity*), should be stored in declarative memory, as should knowledge about idioms, proverbs, and so on. In principle, such stored knowledge could be represented in a variety of ways, even in parallel for the same forms in the same individuals, such as structured or unstructured, as wholes or as collocations with probabilistic associations between their parts, or even as stored links to rules as suggested by Distributed Morphology (Halle & Marantz, 1993). Storing representations in declarative memory does not preclude the additional involvement of rule-governed aspects of procedural memory, for example, for inflecting forms within larger stored sequences (e.g., *jumps the gun*). Finally, in addition to these types of idiosyncratic language knowledge, which correspond broadly to traditional notions of semantic memory (world knowledge not bound to a particular personal experience), declarative memory should also underlie aspects of episodic knowledge in language—for example, memories regarding whether and in which context one has recently encountered or learned a particular word.

Second, due to its ability to learn a wide range of information, declarative memory should be able to acquire much more than idiosyncratic knowledge. Indeed, there may be few constraints on the types of linguistic knowledge that this system can learn. At the least, all the types of information that it can learn about idiosyncratic aspects of language should also be learnable for nonidiosyncratic, rule-governed aspects. Thus, just like simple and irregular words, one should be able to store fully rule-governed complex forms (e.g., “*walked*,” “*the cat*,” and even longer sequences). More abstract representations could also be stored, such as portions of linguistic hierarchies (e.g., Noun Phrase), as has been posited by linguistic theories such as Tree-Adjoining Grammar (Joshi & Rambow, 2003). More productive aspects of grammar may also be achieved by relying on declarative memory, for example, by generalizing across already-stored representations to new representations (e.g., analogic generalization across similar forms) (Hartshorne & Ullman, 2006) or by “shallow” parsing of sentences (Clahsen & Felser, 2006), which relies on lexical-semantic knowledge (which is learned in declarative memory). Grammatical rules and constraints themselves should also be learnable by declarative memory, either explicitly or implicitly, even though these are generally acquired by procedural memory. Other types of

linguistic knowledge or functions normally learned in procedural memory should also be learnable in declarative memory, such as word segmentation. However, just because such grammatical and other knowledge *can* be learned by declarative memory does not mean it is, or if it is learned, that it is consistently used; rather, this will depend on factors that modulate the relative dependence on declarative and procedural memory and the interactions between them (e.g., blocking).

As we have seen, the brain structures underlying declarative memory, including the MTL, underlie not only learning and long-term memory but also other cognitive processes, including object recognition, spatial recognition, novelty detection, short-term memory, and prediction. Analogous roles for such functions may thus be found in language. Additionally, given the rapidity with which new associations can be learned in this memory system, we might expect it to play an active role in online processes involving integration and binding in language.

76.2.1.2 How Should Declarative Memory Underlie Language?

Based on our independent knowledge of declarative memory, we can make numerous specific neurobiological and other predictions about those aspects of language that should depend on declarative memory. Here, I summarize some of them. First, the functional neuroanatomy of those aspects of language that are learned, stored, and processed by declarative memory should reflect the functional neuroanatomy of this system. Thus, linguistic knowledge learned in this system should depend on the hippocampus and/or other MTL structures, at least during learning and consolidation. The hippocampus itself may be heavily engaged in language-related learning, given the multiple types of information and modalities involved in this domain and the importance of linking and integrating this information. Individual items such as words, however, might rely particularly on perirhinal cortex. Novel linguistic items or relations should involve the MTL, perhaps especially the hippocampus (novel associations) and perirhinal cortex (novel items). These structures should be active mainly during learning, but perhaps also for storage and use. MTL structures may also play roles in language-related short-term memory and prediction. Other structures linked to MTL, such as the fornix and mammillary bodies, may also play learning roles in language.

With time and/or experience, the MTL should play a decreasingly important role for linguistic knowledge learned in declarative memory, with an increasing role for neocortical structures. Linguistic knowledge

should show similar neuroanatomical patterns as non-linguistic knowledge of the same concepts. For example, words, phrases, or sentences referring to living or nonliving things, or with strong visual attributes of particular sorts (e.g., color, form), should involve neocortical regions independently linked to these features. More complex, higher-level linguistic representations may depend on more anterior temporal lobe regions, and perhaps also on MTL structures, particularly the hippocampus. For example, abstract linguistic categories such as Noun or Verb might depend on anterior temporal or even more upstream areas. Inferior frontal cortex, especially BA 45/47, should underlie the encoding of new linguistic information being learned in declarative memory, as well as the recall of that knowledge once it is learned. Posterior parietal cortex may also play a role in the encoding and retrieval of this information.

Linguistic knowledge should be rapidly learnable in declarative memory, even from a single presentation of the information, although repeated exposures should improve learning and retention. Thus, we expect that words can be quickly acquired. Linguistic knowledge in declarative memory could be either explicit (e.g., verbalizable word or rules) or implicit. Conversely, however, if linguistic knowledge is explicit, then it must be stored in declarative memory, because this is the only long-term memory system to underlie explicit knowledge. Once learned in this system, linguistic knowledge can be used flexibly across different contexts.

Finally, molecular and other factors that modulate declarative memory should play analogous roles in language. For example, polymorphisms of BDNF and APOE should modulate declarative memory-dependent aspects of language in a similar manner as for nonlinguistic knowledge, and likewise for estrogen and acetylcholine. For example, higher levels of estrogen may improve language learning in this system. Based on the available evidence, it seems likely that language learning in declarative memory should ameliorate during childhood, plateau in adolescence/early adulthood, and then decline. Thus, word learning should follow this pattern. Females may show advantages at language learning in this system as compared to males. Sleep, exercise, and other factors should improve language learning and retention in declarative memory.

76.2.2 Procedural Memory: Predictions for Language

It is important to emphasize that we know less about this system than about declarative memory; therefore, our predictions are more tentative and less specific.

76.2.2.1 What Should Procedural Memory Underlie in Language?

Procedural memory should underlie the learning and processing of sequences and rules in language, perhaps especially those that are probabilistic rather than deterministic. The system may be particularly important in “learning to predict” in language, such as predicting the next item in a sequence or the output of a linguistic rule. Only rules or sequences that are implicit should be learned by procedural memory (I emphasize that implicit procedural knowledge of a rule or sequence does not preclude either explicit or implicit analogous knowledge in declarative memory). Given that grammar involves largely implicit rules, both probabilistic and deterministic, particularly ones that involve (hierarchical) sequencing, procedural memory should play a major role in this aspect of language. This should hold across linguistic subdomains, including syntax, morphology, and phonology. Exactly what computational roles procedural memory should play in linguistic sequencing and rules cannot be clearly predicted at this point because of our lack of understanding of these issues regarding procedural memory itself. However, also based on our understanding of grammar, it seems likely that procedural memory somehow underlies the learning of rules and the implicit rule-governed composition of both hierarchical and nonhierarchical sequences.

Other aspects of language may also be learned in procedural memory, including categories and other knowledge, especially if the knowledge is implicit and involves probabilistic patterns, sequences, and learning to predict. For example, the implicit learning of word boundaries in a speech stream (Saffran, Aslin, & Newport, 1996) should depend on procedural memory.

76.2.2.2 How Should Procedural Memory Underlie Language?

As with declarative memory, predictions for language follow from what we know about procedural memory from animal and human studies. First, linguistic skills and knowledge that are learned, stored, and processed by procedural memory should reflect this system’s underlying functional neuroanatomy. Thus, these should involve frontal and basal ganglia structures, and perhaps the cerebellum. Learning and consolidation should engage the basal ganglia, especially the caudate nucleus and the anterior putamen. (Note that this learning role of the basal ganglia does not preclude other language roles for this set of subcortical structures, including grammar, because the structures subserve other functions as well, including working memory and attention.) Once automatized,

knowledge and skills should rely especially on neocortical regions, particularly BA 6 and BA 44. Only implicit, not explicit, linguistic knowledge should rely on procedural memory (although of course not all implicit knowledge should depend on this system). Because procedural memory learns only with repeated exposure, this knowledge should be learned and automatized gradually.

Given its role in procedural memory, dopamine should play a role in grammar and other aspects of language, especially in learning and consolidation. Certain genes, such as *FOXP2*, *PPP1R1B*, and *DRD2*, should also be involved. Because procedural memory learns gradually and declarative memory learns rapidly, grammar rules should generally be acquired more slowly than words. Given the developmental trajectory of procedural memory, linguistic learning and consolidation in this system should be better in childhood than adolescence or adulthood, and thus proceduralization of grammar should be slower and more incomplete in later (e.g., second language) learners. Sleep, exercise, and other factors should improve language learning and retention in procedural memory.

76.2.3 Interactions Between the Memory Systems: Predictions for Language

Our understanding of interactions between the two memory systems, and between these and other systems, also leads to various predictions for language.

First, to some extent, we expect the two memory systems to acquire the same or analogous knowledge or skills, that is, to play at least partly redundant roles. According to the redundancy hypothesis, in language as in nonlinguistic domains, such redundancy may be found for any tasks or functions that could be subserved by either system. Given the learning power of declarative memory, and the fact that it can underlie implicit as well as explicit knowledge, it may be able to at least partly support most if not all aspects of language subserved by procedural memory, including grammar and word segmentation.

Various factors should modulate which memory system is relied on more for linguistic knowledge that can be learned by both systems. Such knowledge should often be learned first by declarative memory, but eventually by procedural memory, at which point it should be more automatized. Thus, both first and second language learners should generally depend initially on declarative memory for grammatical functions (e.g., by chunking or explicit rules, with the exact nature of this dependence perhaps differing between first and second language learners), but both should gradually learn grammar in procedural memory.

(For more on the DP model and second language, see Ullman, 2005; Ullman, 2015). After such proceduralization, the declarative knowledge may still remain intact and could become accessible again in certain circumstances, such as subsequent procedural memory dysfunction. Explicit instruction or attention to the input may increase learning in declarative memory, whereas a lack of such instruction or attention, or greater complexity of rules or patterns (e.g., more complex grammatical rules or constraints), may lead to a greater dependence on procedural memory. Estrogen may promote linguistic learning in declarative memory at the expense of procedural memory. Females may rely more on declarative memory than males for aspects of language (e.g., grammar) that can rely on either system, and they may show superior learning of idiosyncratic linguistic knowledge (which must be learned in declarative memory). The developmental trajectories of the two systems suggest that young children should more easily proceduralize their grammar (in first or second language) than adults. And a relative dysfunction of one system should lead to a greater (compensatory) dependence of language on the other.

Second, we might expect a seesaw effect in language. Estrogen might not only promote language learning or use in declarative memory but may also inhibit it in procedural memory. Similarly, a dysfunction of one system might lead not only to language compensation by the other but also to its enhanced functioning.

Third, learning or processing in one system may block or inhibit the other. For example, grammar learning in declarative memory may inhibit grammar learning in procedural memory. And successful retrieval of irregular forms (e.g., *dug*), or chunked rule-governed forms (*walked*), should block the rule-based computation of corresponding forms in procedural memory (*dig* + *-ed*, *walk* + *-ed*). Conversely, a highly automatized rule in procedural memory should tend to override the use of analogous declarative knowledge, especially if this declarative knowledge is not well-learned. Thus, over the course of language learning, grammar should depend increasingly on procedural memory and correspondingly less on declarative memory.

Finally, the two memory systems should interact with other neurocognitive brain systems in the learning and processing of language. First, working memory in language processing should be closely related to declarative memory. For example, some of the same frontal structures should play roles in verbal working memory and in the encoding and recall of language knowledge learned in declarative memory. Second, linguistic knowledge that can be primed (e.g., lexical or grammatical knowledge) should, in most cases, have been learned by one or the other memory system.

Finally, there should be close links between language learning in the two memory systems and language processing in the dorsal and ventral streams. For example, language knowledge processed in the ventral stream should be learned mainly in declarative memory, which in turn should facilitate further processing of this knowledge in the ventral stream, while a similar relation may hold for procedural memory and the dorsal stream.

76.3 EVIDENCE

Parallel to the predictions presented above, for each memory system I summarize first, evidence regarding *what* types of language knowledge and functions depend on it, and second, *how* the system subserves these, with a focus on functional neuroanatomy.

76.3.1 Declarative Memory in Language: Evidence

76.3.1.1 What Does Declarative Memory Underlie in Language?

Evidence from various methodological approaches, including behavioral, neurological, neuroimaging, and electrophysiological studies, has implicated declarative memory in the learning, storage, and retrieval of idiosyncratic aspects of language. First, behavioral evidence indicates that words can be learned very quickly (fast mapping) and are generally acquired earlier than grammatical rules (in both first and second language) (Bloom, 2000; Marcus et al., 1992; Ullman, 2015). More direct behavioral evidence comes from studies of children that reveal correlations, across participants, between vocabulary abilities and learning abilities in declarative memory (but not procedural memory), whereas grammar shows the opposite pattern (Kidd, 2012a; Lum, Conti-Ramsden, Page, & Ullman, 2012). Behavioral studies using other techniques, such as the examination of frequency and imageability effects, have also revealed links between lexical and declarative memory (Babcock, Stowe, Maloof, Brovotto, & Ullman, 2012; Prado & Ullman, 2009). Second, neurological evidence shows that dense amnesia from substantial MTL lesions seems to preclude word learning, as demonstrated in H.M. and other patients (Davis & Gaskell, 2009; Postle & Corkin, 1998). In contrast, H.M. retained idiosyncratic word forms that were common in English prior to his surgery, as expected if the MTL does not remain crucial for knowledge well after it has been learned (Kensinger, Ullman, Locascio, & Corkin, 1999). Third, functional neuroimaging evidence strongly implicates the MTL in word learning

(Breitenstein et al., 2005; Davis & Gaskell, 2009; Raboyeau, Marcotte, Adrover-Roig, & Ansaldo, 2010). Fourth, the presentation of words, including novel words (pseudowords), reliably leads to N400 event-related potentials (ERPs) (Kutas & Federmeier, 2011), which have independently been tied to nonlinguistic idiosyncratic knowledge (e.g., faces and objects) and the MTL (Kutas & Federmeier, 2011; McCarthy, Nobre, Bentin, & Spencer, 1995; Meyer et al., 2005).

Declarative memory has also been tied to nonidiosyncratic aspects of language. First, behavioral evidence suggests that regular morphological forms can be stored (e.g., as chunks), generalized across similar forms, or computed from explicit rules, all indicating a reliance on declarative memory. For example, like irregulars, regular inflected forms can show frequency, imageability, and phonological neighborhood effects (Alegre & Gordon, 1999; Babcock et al., 2012; Dye, Walenski, Prado, Mostofsky, & Ullman, 2013; Hartshorne & Ullman, 2006; Prado & Ullman, 2009; Ullman et al., under revision). However, whereas these effects are found reliably for irregulars, consistent with their obligatory storage in declarative memory, regulars show them inconsistently, and mainly for those conditions where a dependence on declarative memory is expected (e.g., higher frequency forms, females, left-handers, second language learners). Evidence suggests that even more complex rule-governed forms, that is, surface syntactic structures, can also be learned in declarative memory (Hamrick, 2014). And a recent study found that learning an “analogic grammar” (posited to involve generalization over stored forms) correlated with abilities at declarative but not procedural memory, whereas learning a rule-governed concatenative grammar showed the opposite pattern (Wong et al., 2013). However, as would be expected given faster learning by declarative than procedural memory, syntactic processing at early stages of learning a rule-governed artificial language correlated with declarative (and not procedural) memory, whereas the reverse pattern was found at later stages (Morgan-Short, Faretta-Stutenberg, Brill-Schuetz, Carpenter, & Wong, 2014). Second, neurological evidence from SLI, dyslexia, autism, and agrammatic aphasia suggests that individuals with these disorders compensate for grammatical impairments by relying on declarative memory, via chunking, explicit rules, or other means (Ullman & Pullman, 2015). Third, neuroimaging studies of artificial grammar learning have found MTL activation (Lieberman, Chang, Chiao, Bookheimer, & Knowlton, 2004; Yang & Li, 2012). And neuroimaging evidence has implicated the MTL in online sentence integration and processing, including of syntax (Duff & Brown-Schmidt, 2012; Meyer et al., 2005). Fourth,

electrophysiological evidence from ERPs has found that (morpho)syntactic processing can elicit N400s, primarily in those conditions where a dependence on declarative memory is expected (e.g., females, second language learners, and individuals with SLI, dyslexia, or agrammatic aphasia) (Ullman, 2015; Ullman et al., 2008; Ullman & Pullman, 2015).

76.3.1.2 How Does Declarative Memory Underlie Language?

Thus, significant language knowledge is learned and even processed in the MTL. But which portions of the MTL are involved and in which circumstances? First, the hippocampus is heavily implicated. Multiple neuroimaging studies of word learning report hippocampal activation (Breitenstein et al., 2005; Davis & Gaskell, 2009), as has a study of chunking in artificial grammar learning (Lieberman et al., 2004). Similarly, the hippocampus has been implicated in the integration of linguistic knowledge (Duff & Brown-Schmidt, 2012; Meyer et al., 2005).

However, other MTL structures also play roles in language. Although lesions restricted to the hippocampus can impair word learning, at least some such patients can still learn words (Davis & Gaskell, 2009; Vargha-Khadem, Gadian, & Mishkin, 2001). It may be that MTL lesions that extend beyond the hippocampus, such as H.M.’s, are required to eliminate word learning altogether. Some evidence suggests that rhinal cortex, in particular perirhinal cortex, may be important for words, perhaps especially for word learning. One study found that remembering the context in which a word was recently presented engaged the hippocampus, whereas the word itself activated perirhinal cortex (Davachi, Mitchell, & Wagner, 2003). In the MTL, N400s have been tied mainly to perirhinal cortex, particularly for novel words (Fernandez, Klaver, Fell, Grunwald, & Elger, 2002). In one study, lexical/semantic violations that typically elicit N400s were tied to rhinal cortex, whereas syntactic violations were linked to the hippocampus, likely due to P600 effects that involve controlled (conscious) syntactic integration (Meyer et al., 2005).

Other structures in the declarative memory system also play roles in language. One study found deficits in word learning after lesions to the mammillary bodies (Martins, Guillery-Girard, Jambaque, Dulac, & Eustache, 2006). Linguistic as well as nonlinguistic stimuli associated with particular concepts engage neocortical regions linked to those concepts (e.g., living things) (Martin, 2007). BA 45/47 is involved in word encoding and recall. For example, word encoding and recall tasks activate this region, and lesions to this area are associated with word recall deficits (Buckner,

Wheeler, & Sheridan, 2001; Wagner et al., 1998). Posterior parietal cortex has been found to correlate with vocabulary size in monolinguals (Lee et al., 2007) and to be larger in bilinguals than in monolinguals (possibly due to the larger total vocabulary of the former) (Mechelli et al., 2004), and it has been implicated in lexical/semantics in both first and second language (Abutalebi et al., 2012; Chee, Hon, Lee, & Soon, 2001) as well as in grammar in second (but not first) language (Wartenburger et al., 2003). For a functional neuroanatomical meta-analysis of first and second language revealing such a pattern, see Tagarelli, Turkeltaub, Grey, and Ullman (in preparation).

There has also been some work on the genetic and molecular bases of linguistic aspects of declarative memory. Quite a few studies have implicated BDNF and APOE, as well as estrogen and acetylcholine, in episodic memory tasks involving words (Ullman, 2007; Ullman et al., 2008). For example, performance at such tasks improves with cholinesterase inhibitors (Freo, Pizzolato, Dam, Ori, & Battistin, 2002). And estrogen has been found to improve retrieval of irregular (but not regular) inflected forms (Estabrooke, Mordecai, Maki, & Ullman, 2002). More research is needed to examine links between language and the genetic and molecular bases of declarative memory.

Finally, evidence suggests that females may be better than males at learning words (Kaushanskaya, Marian, & Yoo, 2011; Ullman et al., 2008), and likewise left-handers as compared with right-handers (Ullman et al., under revision). And, consistent with the developmental trajectory of declarative memory, word learning improves during childhood into adolescence (Bloom, 2000).

76.3.2 Procedural Memory in Language: Evidence

Consistent with our more impoverished understanding of procedural than declarative memory, there is less empirical evidence thus far regarding the role of this system in language.

76.3.2.1 What Does Procedural Memory Underlie in Language?

Evidence from various methodologies suggests links between grammar and procedural memory. First, behavioral evidence has revealed correlations between grammar measures (e.g., syntactic priming and processing) and learning in procedural memory, but not with declarative memory in the same individuals (Kidd, 2012b; Lum et al., 2012). Procedural (but not declarative) memory has also been found to correlate with

learning a rule-governed concatenative grammar (Wong et al., 2013). In another artificial language study, syntactic processing correlated with procedural (and not declarative) memory, but only at later stages of learning (Morgan-Short et al., 2014). In an interference study, syntactic (but not word) processing interfered with procedural memory (Nemeth et al., 2011). And, as mentioned above, regular morphological forms generally do not show signs of reliance on declarative memory; rather they show evidence for composition, consistent with a primary dependence on procedural memory (Walenski, Prado, Ozawa, Steinhauer, & Ullman, under revision).

Second, neurological evidence has tied grammar to procedural memory. (Here, I focus on SLI; for other disorders, including agrammatic aphasia and Parkinson's and Huntington's diseases, see Ullman, 2004, 2013). Children with SLI, who typically have grammatical deficits (of syntax, morphology, and phonology) but less consistent lexical impairments, show reliable procedural memory impairments (Lum, Conti-Ramsden, Morgan, & Ullman, 2014; Ullman & Pierpont, 2005) and consistent brain abnormalities only in frontal cortex and the basal ganglia, as revealed by a recent neuroanatomical meta-analysis (Ullman et al., under review). Moreover, the grammar difficulties in SLI have been directly linked to procedural memory deficits (Hedenius et al., 2011).

Third, neuroimaging evidence has tied artificial grammar learning to the basal ganglia (Lieberman et al., 2004; Petersson, Folia, & Hagoort, 2012; Yang & Li, 2012). Basal ganglia activation is also reliably elicited by grammatical (but not lexical) processing in second language learners, but not in native speakers, as revealed by our recent neuroanatomical meta-analysis of first and second language (Tagarelli et al., in preparation). This is consistent with the prediction that the basal ganglia play a particularly important role in grammar acquisition.

Finally, some research has begun to examine links between procedural memory and nongrammatical implicit aspects of language. For example, a recent fMRI study implicated the basal ganglia in the implicit learning of word boundaries in a speech stream (Karuza et al., 2013).

76.3.2.2 How Does Procedural Memory Underlie Language?

Although evidence is still limited, some specific neurobiological patterns appear to be emerging regarding the role of procedural memory in language. First, within the basal ganglia, the caudate nucleus, and perhaps the caudate head in particular, may play a particularly important role in grammar learning. These structures have been implicated in neuroimaging

studies of artificial grammar learning and of grammar in second (but not first) language (Tagarelli et al., in preparation). And our neuroanatomical meta-analysis of brain abnormalities in SLI revealed that the consistent structural abnormalities in the basal ganglia occur only in the caudate nucleus, with particular involvement of the caudate head (Ullman et al., under review).

Once learned, grammar depends heavily on BA 44, as well as BA 6 (especially the frontal operculum), particularly on the left side. Activation in these regions is strongly associated with syntactic processing in both first and second language (Friederici, 2006; Tagarelli et al., in preparation). And a recent functional neuroimaging meta-analysis of regular and irregular morphology strongly implicates BA 44 in the former but not the latter (Ullman, Campbell, McQuaid, Tagarelli, & Turkeltaub, in preparation).

There has been far less work to date examining links between nongrammatical aspects of language and procedural memory. Nevertheless, as mentioned above, one recent study of the implicit learning of word segmentation reported basal ganglia activation (Karuza et al., 2013)—indeed, mainly in the caudate head and anterior putamen.

Genetic evidence has also tied language to procedural memory. The *FOXP2* gene has been linked to grammar, including syntax, morphology, and phonology, as well as to procedural memory (Ullman & Gopnik, 1999; Ullman & Pierpont, 2005). Moreover, the recent finding that humanized *Foxp2* speeds up learning by promoting the transition from declarative to procedural memory (Schreiweis et al., 2014) suggests that evolutionary changes to procedural memory may be critical for the evolution of language, particularly of grammar. This underscores the utility of the co-optation hypothesis by showing that investigating preexisting systems, and these memory systems in particular, can reveal not only how they work similarly in language as in nonlanguage functions, but also how they might become further specialized for language itself. In other words, the systems constitute *targets* for studying the potential evolutionary changes that may facilitate language (whether or not those changes were due to adaptation for language alone). Finally, *DRD2* (for the dopamine receptor D₂) has also been linked to grammar learning, as well as to basal ganglia activation during the learning of a rule-governed concatenative grammar (Wong et al., 2013).

Some research has also examined the effect on language of subject-level factors that modulate procedural memory. For example, as would be expected if learning and/or consolidating in procedural memory becomes more difficult between early childhood and adulthood, adult second language learners have particular difficulty with grammar (Ullman, 2005).

76.3.3 Interactions Between the Memory Systems in Language: Evidence

First, evidence from multiple methodologies suggests that declarative and procedural memory play redundant roles for grammar, but not for lexical/semantics, which seems to require declarative memory. Much of the evidence for such redundancy has been discussed above. In brief, rule-governed compositional forms can be not only learned and computed by procedural memory but also stored and processed by declarative memory, via chunking, analogical generalization in associative memory, composition by explicit rules, and other processes. This dependence on declarative memory seems to be modulated by various factors. It occurs more for higher than lower frequency or imageability items; more for second than for first language learners; more for early versus later stages of learning (at least in second language; it remains unclear whether this predicted pattern is also found in first language); more for females than for males; more for left-handers than for right-handers; and more in disorders associated with a procedural memory system dysfunction but relatively intact declarative memory (e.g., SLI, dyslexia, autism, agrammatic aphasia).

Second, some evidence, though still limited, supports the predicted seesaw effect in language. Thus far, the only evidence we are aware of, which is somewhat indirect, is findings from neurodevelopmental disorders. Children with dyslexia or autism, both of which are linked to grammatical and procedural memory abnormalities (Lum, Ullman, & Conti-Ramsden, 2013; Walenski, Tager-Flusberg, & Ullman, 2006), may also show enhanced lexical or declarative memory abilities (Hedenius, Ullman, Alm, Jennische, & Persson, 2013; Ullman & Pullman, 2015; Walenski, Mostofsky, Gidley-Larson, & Ullman, 2008). Similarly, children with SLI may show not only grammatical and procedural memory deficits but also enhanced declarative memory, in particular at consolidation (Lukacs, Kemeny, Lum, & Ullman, in preparation; Lum, Hedenius, Tomblin, & Ullman, in preparation).

Third, some evidence suggests linguistic inhibition by one or the other system. Perhaps the best studied phenomenon is blocking. For example, the retrieval of a stored irregular form blocks the computation of its corresponding overregularization (e.g., retrieving *dug* blocks *digged*), whereas retrieval difficulties due to lexical/declarative memory deficits yield overregularizations (Ullman, 2004, 2013). Similarly, retrieval of a chunked regular may at least partially block the rule-based computation of the same form (Prado & Ullman, 2009). Inhibition between the systems has also been observed in learning. In a recent study of second language learning, explicit training (which should encourage learning in declarative

memory) delayed the development of automatic syntactic processing that has been associated with procedural memory (Morgan-Short, Finger, Grey, & Ullman, 2012; Morgan-Short, Steinhauer, Sanz, & Ullman, 2012). Conversely, even when an N400 is found for grammar at early stages of second language learning, the later emergence of automatic syntactic processing overrides this lexical/semantic process (Morgan-Short, Finger, et al., 2012; Morgan-Short, Steinhauer, et al., 2012).

Finally, some evidence exists regarding language-related interactions between the two memory systems and other neurocognitive systems. For example, BA 45/47 seems to be involved not only in word encoding and word recall but also in verbal working memory. And words that entered the language after H.M.'s resection do not show priming, whereas amnesic patients do show priming both for previously learned words and for syntax (Ferreira, Bock, Wilson, & Cohen, 2008; Postle & Corkin, 1998).

76.4 SUMMARY AND CONCLUSION

The DP model is premised on three principles of biology and language. First, new biological functions commonly recruit pre-existing biological mechanisms, whether or not those mechanisms then become further specialized—either evolutionarily or developmentally—for the functions. That is, biological mechanisms are often co-opted for new purposes. Second, most of language must be learned, whether or not aspects of this capacity are innately specified. Third, declarative memory and procedural memory are perhaps the two most important learning and memory systems in the brain, in terms of the range of domains and functions that they subserve. Based on these principles, the DP model simply posits that these two memory systems are highly likely to play important roles in language learning, knowledge, and use.

If language depends heavily on the two memory systems, then what we know independently about these memory systems should tend to apply to language as well. That is, the memory systems should play similar roles in language as in nonlanguage functions, and thus our independent knowledge of how these memory systems work should generate predictions for language. Because the memory systems are quite well-understood at many levels, from work with both humans and animal models, the theory can generate a wide range of well-motivated specific predictions, many of which there would be no reason to make based on the more limited study of language. For example, we can make predictions about MTL, or perirhinal cortex, or certain genes, or estrogen, or sex

differences, or age effects in first versus second language, that there might be no *independent* reason to make based on the study of language alone. Thus, this is a very powerful theoretical approach.

As we have seen, converging evidence from multiple methodologies provides support for many of the general as well as specific predictions of the theory. The findings suggest that language does indeed depend on the two memory systems. More generally, the results yield insights that advance our understanding of language and its underlying neurobiology. Importantly, unlike language-specific accounts, the theory can predict and explain aspects of linguistic and neurolinguistic phenomena in the broader context of our understanding of the brain and mind. Thus, the theory has substantial explanatory power.

Finally, many of the predictions I have summarized in this chapter have not yet been tested. In fact, additional predictions have not even been discussed. For example, the theory predicts that behavioral or pharmacological interventions that have been shown to enhance learning or processing in the memory systems are likely to also enhance the learning or processing of language. This prediction may have important educational and translational/clinical outcomes, in particular for second language learning and language disorders. Thus, the theoretical approach presented here promises to continue to be fruitful and to lead to advances in multiple aspects of language and its underlying neurobiology.

Acknowledgments

Perinatal Focal Brain Injury: Scope and Limits of Plasticity for Language Functions

Susan C. Levine¹, Anjali Raja Beharelle^{2,5}, Özlem Ece Demir^{3,6} and Steven L. Small⁴

77.1 PERINATAL FOCAL BRAIN INJURY: LANGUAGE DEVELOPMENT AND NEURAL PLASTICITY

The study of children with perinatal focal brain injury provides a unique window into the plasticity of language development. A large body of research reveals normal or near-normal language development in these children even when lesions are large and encompass classic left hemisphere perisylvian language networks. Strikingly, children with unilateral perinatal lesions (PLs) do not exhibit the marked aphasias that are common when anatomically comparable lesions are incurred during adulthood (Basser, 1962; Bates et al., 2001; Bishop, 1993; Lenneberg, 1967; Reed & Reitan, 1969; Rowe, Levine, Fisher, & Goldin-Meadow, 2009). Plasticity for language functions after early brain injury presents a challenge to theories that posit an immutable brain basis for human language by demonstrating that alternative neural networks can support language, at least when unilateral injuries occur at certain developmental stages. Thus, although the neural networks that are typically involved in language may be optimal, they do not appear to be necessary for the development of normal or near-normal levels of language function.

The normal or near-normal language skills of children with PL are consistent with the view of a dynamically developing, plastic brain—a developing brain capable of responding to internal biological signals, including those associated with the lesion, and to information provided by the environment (Demir, Fisher, Levine, &

Goldin-Meadow, 2013; Demir, Rowe, Heller, Levine, & Goldin-Meadow, 2015; Elman et al., 1996; Huttenlocher, 2002; Rowe et al., 2009; Stiles, Reilly, Levine, Trauner, & Nass, 2012; Stiles, Reilly, Paul, & Moses, 2005). This adaptive view of brain development has dramatically expanded the focus of research on children with PL from one that considers plasticity as a lesion-induced phenomenon (Teuber, 1974; Witelson, 1985) to one that considers plasticity after early lesions in the context of biological and environmental factors that affect brain and behavior over the course of development in typically developing (TD) children (Greenough, Black, & Wallace, 1987; Rowe et al., 2009; Stiles et al., 2012, 2005; Thomas & Karmiloff-Smith, 2002; Witte, 1998). Thomas and Karmiloff-Smith (2002) argue that the processes of development cannot be ignored in constructing models of developmental disorders. Within this broader view, our understanding of brain and behavioral development in children with early brain injury can inform and be informed by our understanding of normative brain development.

Language functioning in TD children is known to depend on the development of widespread neural networks, and development of these networks is influenced by variations in the language experiences of individual children (Hart & Risley, 1992; Hoff, 2006; Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 1991). When a lesion is superimposed on the developing brain, the lesion itself becomes a factor in this dynamic development. Outcomes are likely to depend on all of the factors that affect language development in TD children

as well as many factors introduced by the lesion, including the timing of the lesion within the developmental period and the location and extent of the lesion.

It is important to point out that the study of children with PL remains an important scientific enterprise even in the context of powerful brain imaging tools that can be used to study brain–behavior relationships in TD children. In particular, whereas brain imaging studies of children developing language with an intact brain can tell us about the brain networks that are typically involved in language functioning at particular ages, they cannot tell us about the alternative networks that are able to support language functioning after an early brain injury, or which regions are necessary or sufficient for development of language. In addition, although animal studies have played a major role in increasing our knowledge about the plasticity of the developing nervous system with respect to biological perturbations and with respect to variations in experience (Greenough et al., 1987; Kolb & Gibb, 2010), these studies do not provide an ideal model for specific questions about the plasticity of language networks because humans are the only species with language.

77.2 FOUR CENTRAL QUESTIONS

Studies of language development in children with PL have largely focused on examining the scope and limits of plasticity for language functions in this population (Bates et al., 1997; Bates, Vicari, & Trauner, 1999; Reilly, Levine, Nass, & Stiles, 2008; Stiles et al., 2012; Trauner, Eshagh, Ballantyne, & Bates, 2013). To the extent that language is disrupted in similar ways after early and later lesions, we gain evidence for the importance of particular brain regions for language, beginning early in life, and for the limits of early functional plasticity. In contrast, to the extent that the process of language development proceeds normally in children with PL, regardless of lesion location, we gain evidence for the robustness of language development and for the ability of the young brain to adapt to injury.

We organize this chapter around four key questions that have been addressed by researchers studying language development in children with perinatal stroke, reviewing the literature relevant to each.

These questions are:

1. How do focal PLs affect language development?
2. How do biological characteristics of early focal lesions relate to language development?
3. What is the role of language input on the language development of children with PLs?
4. What are potential mechanisms of language plasticity after early lesions?

77.3 HOW DO FOCAL PERINATAL LESIONS AFFECT LANGUAGE DEVELOPMENT?

During the 19th century, Broca (1865) and others noted that aphasias observed in adults with brain injury were not present when lesions were acquired early in life. Jules Cotard, a colleague of Broca's, wrote: "Intelligence may be normal when a hemisphere is destroyed during infancy. . . in these cases one never encounters aphasia" (Ritti, 1894, see Stiles et al., 2012). These observations have largely stood the test of time. That is, the language deficits of children with early focal lesions are subtle and do not resemble the aphasias observed when lesions are acquired during adulthood.

Bates et al. (1997) and Bates, Thal, Finlay, and Clancy (2003) pointed out a fundamental but often ignored difference between the situations faced by the individual with an early versus later brain injury. When an injury occurs during adulthood, it is superimposed on a developed brain that has already acquired a language. In contrast, when a lesion occurs early in life, it is superimposed on a developing brain that has yet to acquire language. Thus, the adult with an acquired lesion is faced with the task of relearning language with a brain that is already mature and has become specialized over time. The neuroanatomical changes that occur over the course of childhood and adolescence have been well-documented and many changes in both gray and white matter structures support the observed specialization (Giedd et al., 1999; Huttenlocher, 2002; Huttenlocher & Dabholkar, 1997; Sowell, Trauner, Gamst, & Jernigan, 2002). In contrast, the child with PL is faced with the task of learning language for the first time with an injured brain, which, although compromised by the injury, is still a highly flexible, adaptable neural substrate. The fundamental differences between the learning task as well as the developmental state of the brain at the time of injury undoubtedly affect the different outcomes that are observed in the postlesion language functioning of these groups.

77.3.1 Severity of Language Deficits in Children with perinatal lesions

Children with PL have delays when beginning language and show delays in babbling, gesturing, and productive and expressive vocabulary and syntax (Bates et al., 1997; Feldman, 1994; Feldman, Holland, Kemp, & Janowsky, 1992; Marchman, Miller, & Bates, 1991; Trauner et al., 2013). These initial delays are followed by a period of "catch-up" by the start of elementary school, when children's vocabulary and syntactic skills generally fall in the low-average to average range (Bates & Roe, 2001; Bates et al., 1997,

1999; Demir, Levine, & Goldin-Meadow, 2010; Levine, Huttenlocher, Banich, & Duda, 1987).

The catch-up that has been found for some linguistic tasks does not extend to all language tasks. At the group level, children with PL experience difficulty on a variety of complex linguistic tasks during the elementary school period and adolescence, although there is wide individual variability. For example, on a demanding morpho-syntactic task, by generating tag endings to questions (e.g., “John wants to go the 6 o’clock movie, *doesn’t he?*”), children with PL perform significantly worse than TD children at ages 12–16 years, but not between 4 and 7 years of age or between 8 and 11 years of age, suggesting that linguistic deficits may emerge or become more apparent over the course of development (Weckerly, Wulfeck, & Reilly, 2004).

Children with PL also have difficulty on narrative tasks. In one study, the narrative production skills of young elementary school children with PL were compared with those of TD control children (Demir et al., 2010). Children were asked to generate a story in response to a story stem such as, “Once there was a big gray fox who lived in a cave near a forest...” (Stein & Albro, 1997). The children with PL produced significantly shorter narratives than the TD children and included fewer unique words and clauses. Additionally, they were less likely to tell goal-based stories than their TD peers, even though the groups did not differ in receptive vocabulary or in their syntactic skills. Similar results have been reported on other tasks tapping narrative skill such as retelling a story from a wordless picture book, from a wordless cartoon, or from a story told by a storyteller (Chapman, Max, McGlothlin, Gamino, & Cliff, 2003; Demir, et al., 2013; Reilly, Bates, & Marchman, 1998; Reilly, Losh, Bellugi, & Wulfeck, 2004).

Producing a well-structured narrative may be a challenging task because it puts heavy demands on planning and organizing events in a hierarchical manner. It also involves producing an extended monologue that is removed from the here and now. Consistent with the view that narratives are computationally demanding, narrative tasks engage a wide neural network (Nichelli et al., 1995), and early brain injury may compromise such networks (Feldman, 2005; Feldman, MacWhinney, & Sacco, 2002; Levine, Kraus, Alexander, Suriyakham, & Huttenlocher, 2005).

Children with PL also have difficulty on other complex linguistic tasks during elementary school and beyond. For example, a study by MacWhinney, Feldman, Sacco, and Valdes-Perez (2000) revealed that 5- to 11-year-old children with PL scored significantly lower than TD children in “language planning” skills, including difficulty composing sentences that include specific words and using the linguistic information in

a sentence to perform a set of actions. These language planning skills go beyond the basic lexical and syntactic skills that are tapped by vocabulary and syntax tasks on which children with PL perform relatively well. Interestingly, producing a coherent narrative also puts demands on language planning skills.

A few studies have examined online language processing skills of children with perinatal brain injury and TD children, allowing them to examine not only errors in processing but also speed of processing of various kinds of linguistic structures. Generally, children with PL are less accurate and slower at processing complex sentences (Dick, Wulfeck, Krupa-Kwiatkowski, & Bates, 2004; Feldman et al., 2002; MacWhinney et al., 2000). For example, Dick et al. (2004) presented children with PL (7–18 years of age; mean, 10.8 years) and TD children (5–17 years of age; mean, 10–8 years) with a task involving pointing out the agent of sentences. The sentences had subjects and objects that were either in a canonical order (active: *The dog is biting the cat* or subject cleft: *It is the dog that is biting the cat*) or in noncanonical order (passive: *The cat is bitten by the dog* or object cleft: *It is the cat that the dog is biting*). Findings showed no difference in performance between the groups on the canonical sentences, but showed significantly more errors and slower reaction times among children with PL on the noncanonical sentences. The performance of the group with PLs was found to be similar to that of the younger TD children, suggesting that their language processing skills follow a normal course, but at a slower rate.

Although very few studies have examined written language skills of children with PL, there is some indication that they experience difficulty with reading comprehension and spelling (Aram & Ekelman, 1988; Demir, Carlson, Levine, & Goldin-Meadow, 2013; Woods & Carey, 1979). This is clearly an area in need of further research.

It is possible that the language processing problems of children with PL, which are apparent on complex language tasks, are related to subtle deficits in executive functioning, notably verbal working memory after PL (Nichols et al., 2004; Westmacott, Askalan, MacGregor, Anderson, & Devebar, 2010). However, there has been very little work probing this relationship, and more is needed before concluding that this is the case.

77.3.2 Relation of Gesture and Language

Examining the role of gesture in language learning provides another way to compare the process of language learning in children with PL with that of TD children. Several studies show that the production of gestures not only precedes but also predicts the

production of words in TD children (Acredolo & Goodwyn, 1989; Bates, Benigni, Bretherton, Camaioni, & Volterra, 1979). Further, in TD children, gesture–speech combinations in which the gesture supplements the information conveyed in speech precede and predict early sentences expressed in speech alone (Goldin-Meadow & Butcher, 2003; Iverson & Goldin-Meadow, 2005; Özcaliskan & Goldin-Meadow, 2005). If these relations hold for children with PLs, this would suggest that similar processes govern language acquisition in the two groups of children.

With respect to vocabulary development, Sauer, Levine, and Goldin-Meadow (2010) examined the relation of early gesture and later vocabulary development in children with perinatal brain injury. Those whose gesture production was above the 25th percentile of TD children at 14 months of age had productive vocabularies in the normal range when tested again at 22 and 26 months of age and receptive vocabularies in the normal range when tested at 30 months. In contrast, those whose gesture production was below the 25th percentile of TD children at 14 months had productive and receptive vocabularies below the normal range at these same ages. Importantly, these later productive and receptive vocabulary difficulties were not predicted by children's productive vocabulary at 14 months. Thus, as for TD children, early gesture predicts later vocabulary development at an age when early language does not.

With respect to syntactic development, Özcaliskan, Levine, and Goldin-Meadow (2013) found that children with PL, like TD children, produce simple sentences across gesture and speech (point at box + “open”) several months before producing them entirely in speech (“open box”). However, unlike TD children, children with PL produced complex sentences (sentences with two predicates) in speech alone before producing them in gesture and speech, albeit approximately 8 months later than their TD peers.

Özcaliskan et al. propose that children with PL may have difficulty producing the complex gestures that occur in predicate–predicate utterances because of their hemiparesis. Studies that examined children with congenital hemiplegia (which is primarily due to periventricular, cortical, and subcortical lesions that can be unilateral or have asymmetric bilaterality) have shown that, to varying degrees, these children experience hand weakness and decreased dexterity in the hand contralateral to the lesion, difficulties that affect both unimanual and bimanual coordination (Gordon & Steenbergen, 2008; Sakzewski, Ziviani, & Boyd, 2010; Stiles et al., 2012). Some studies also report impaired strength and coordination in the hand ipsilateral to the lesion (the “unimpaired” hand) (Brown et al., 1989; Duque et al., 2003; Kuhtz-Buschbeck, Sundholm, Eliasson, & Forssberg, 2000).

These hand-motor difficulties may account for the paucity of predicate–predicate utterances in gesture–speech produced by children with PL, which in turn may account for their delay in producing complex predicate–predicate utterance in speech alone. This scenario is consistent with the theory that gesture milestones not only predict language milestones but also promote these milestones. An interesting possibility raised by these findings is that an intervention that involves encouraging young children with PL to gesture may support their language development (Goldin-Meadow et al., 2014).

77.3.3 Summary

Considered together, the findings that have emerged from the study of children with PL clearly show that their language difficulties are much more subtle than those seen in adults with similar lesions. However, early brain injuries do appear to have some cost to language development—that is, plasticity is not complete. The degree to which one observes plasticity for language appears to depend on the demands of the tasks administered and the age of the child when they are administered (Banich, Levine, Kim, & Huttenlocher, 1990; Feldman, 2005; Levine et al., 2005). For example, when one assesses a complex linguistic skill prior to the age at which TD children have much success with it, deficits may not be apparent. However, when one assesses this skill later, children with PL may exhibit delays or deficits. At this later time point, the neural networks that underlie efficient processing may be sufficiently mature to support strong performance in TD children but remain compromised in the children with PL (Goldman, 1974; Levine et al., 2005). As we have seen, some of the difficulties that children with PL experience appear to be transient (e.g., the delay in beginning language). Other difficulties emerge later, such as difficulty with tag questions, narrative production, and language planning, but longitudinal data are needed to determine whether these difficulties represent an iterative pattern of delay and catch-up or more persistent delay (Stiles et al., 2005).

77.4 HOW DO BIOLOGICAL CHARACTERISTICS OF EARLY FOCAL LESIONS RELATE TO LANGUAGE FUNCTIONING?

77.4.1 Lesion Location

There are two prevalent views concerning the association of lesion laterality and language difficulties in children versus adults with focal injury (Bates et al., 1997;

Bates, Vicari, & Trauner, 1999; Rowe et al., 2009). According to one view, early left hemisphere lesions result in more marked language deficits than early right hemisphere lesions (Annett, 1973; Aram & Ekelman, 1986; Aram, Ekelman, Rose, & Whitaker, 1985; Dennis & Whitaker, 1976; Levine et al., 1987; Rankin, Aram, & Horwitz, 1981; Riva & Cazzaniga, 1986; Vargha-Khadem, O’Gorman, & Watter, 1985; Woods & Teuber, 1978). For example, Chilosi, Cipriani, Bertuccelli, Pfanner, and Cioni (2001) found that 2-year-old and 4-year-old children with left hemisphere injury generally scored lower than those with right hemisphere injury on tasks assessing lexical and syntactic skills. The other view is that language delays and deficits are not associated with the laterality of early lesions (Ballantyne, Spilkin & Trauner, 2007; Bates et al., 2001; Dall’Oglio, Bates, Volterra, De Capua & Pezzini 1994; Dick et al., 2004; Feldman et al., 1992; Marchman et al., 1991; Reilly et al., 1998; Vargha-Khadem, Isaacs, & Muter, 1994). Although there is inconsistency across studies with respect to these views, the strong relation between language deficits and left hemisphere lesions that emerges from studies of adult stroke patients is clearly much weaker after PL.

Two prospective studies have examined whether language profiles of children with PL correspond to the site-specific profiles that have been described in adults with focal brain injury. Thal et al. (2001) examined the receptive and productive vocabularies of children with PL based on parents’ reports. They found stronger and more consistent delays in productive than receptive vocabulary when children were 12–35 months old. They also found that children with right hemisphere damage were particularly delayed in receptive vocabulary, a surprising finding in view of the adult literature indicating that left posterior lesions are associated with comprehension deficits. Another surprising finding was that expressive vocabulary was more delayed in 17- to 35-month-olds with left posterior lesions (retrorolandic, with or without prerolandic involvement) than in those with left anterior lesions. This is the opposite of what one expects from the adult aphasia literature. However, some caveats are that these results were based on a relatively small sample and the group of children without left posterior damage was extremely heterogeneous, including children with lesions restricted to anterior left hemisphere and children with unilateral right hemisphere lesions.

Bates et al. (1997) reexamined these site-specific relations with a larger sample that included some children from the Thal et al. (1991) study. They again found that between 10 and 17 months of age, children with right hemisphere lesions, regardless of location, had lower receptive vocabularies than those with left hemisphere lesions, according to parental report. In

addition, children with right hemisphere lesions were particularly delayed in the production of communicative gestures. With respect to expressive vocabulary in this early period, children with PL were delayed regardless of lesion location. These delays were also found later, between 19 and 31 months age, which encompasses the typical vocabulary burst. However, during this later period, having a lesion that involved the left temporal cortex increased the magnitude and the likelihood of delay. Further, children with lesions of the frontal cortex of either hemisphere showed marked delays in expressive vocabulary. Parallel results were found for a measure of syntax production based on parental report, indicating that lexical and syntactic skills are associated in children with PL, as is the case in TD children (Fenson et al., 1994).

Bates et al. (1997) also examined the mean length of utterance (MLU) of children with PL from free speech samples between 20 and 44 months. Results were consistent with prior findings showing productive delays in children with PL as a group, but with an added risk when lesions involved the left temporal lobe. As noted by the investigators, it is possible that the lesions that involved the left temporal lobe were larger than those that did not, simply by requiring that this particular area be damaged in one group but not in the comparison group. A subsequent study showed that children with left temporal lesions continued to have a disadvantage in grammar up to 6 years of age, but that after age 6 years there were no site-specific deficits (Reilly et al., 1998).

77.4.2 Lesion Size

Not surprisingly, most studies report that the size of perinatal focal lesions is associated with the severity of deficits in gesture, language, reading, and other cognitive functions (Booth et al., 2000; Cioni et al., 1999; Levine et al., 2005; Rowe et al., 2009; Sauer et al., 2010), although there are exceptions (Ballantyne, Spilkin, Hesselink, & Trauner, 2008). One small study reports a curvilinear rather than a linear relationship between lesion size and language function, such that medium lesions are associated with more marked language deficits than either small or large lesions (Thal et al., 1991). There is some support for the curvilinear hypothesis from studies of monkeys with brain lesions (Irle, 1990). However, a later study that expanded the size of the sample in the Thal et al. (1991) study did not replicate the finding of better language function in children with small and large PL than in children with medium lesions (Bates et al., 1999). Lesion size and lesion type are correlated, which may explain some of the inconsistencies in findings.

77.4.3 Lesion Type

Early vascular lesions (stroke) result from hemorrhage (bleeding in the brain) or ischemic infarction (death of brain tissue from lack of blood delivery). The hemorrhages typically occur in highly cellular regions of the developing brain adjacent to fluid-filled spaces (ventricles) and primarily affect white matter tracts, and have been called *periventricular*. The ischemic infarctions typically involve disruptions of blood flow (or *ischemia*) to parts of the brain supplied by the middle cerebral artery and primarily affect gray matter structures including the frontal, temporal, and parietal lobes as well as the basal ganglia, and have been called *vascular* lesions (Goldin-Meadow et al., 2014). In addition to these differences in location, these lesions also tend to differ in size, with vascular (ischemic) lesions tending to be larger (Rowe et al., 2009). These two different lesion types also differ with respect to the time of lesion onset: periventricular lesions tend to occur mainly during the early third trimester of pregnancy, whereas ischemic infarctions tend to occur mainly during the late third trimester of pregnancy or perinatally (Krägeloh-Mann, 2004; Staudt et al., 2004). Rowe et al. (2009) examined the growth of productive vocabulary and MLU in children with PL and in TD children between 14 and 46 months of age. They found that children with vascular lesions produced significantly fewer word types (unique words) and shorter utterances than TD children and children with periventricular lesions who did not differ from the control children. Additionally, Sauer et al. (2010) found that children with vascular lesions were more likely to be in the low gesture group at 14 months of age than children with periventricular lesions. Because of the correlations noted, it is difficult to disentangle whether the better language functioning of the children with periventricular lesions is due to lesion location, lesion size, or lesion timing (Staudt et al., 2004). Further, although Sauer et al. did not include children born before 36 weeks of gestation, periventricular lesions are often associated with prematurity, which introduces an additional factor that needs consideration when comparing the effects of these different lesion types.

77.4.4 Seizure History

There is some inconsistency in reports concerning the association of seizures with language difficulties in children with PL. Bates et al. (1999) stress that the effects of early unilateral brain injury are found in children who have never experienced a seizure and are therefore not solely the result of seizures. Some studies found no significant effects of seizures on language function or IQ in this population (Bates et al., 1997;

Levine et al., 2005). Other studies, in contrast, found that seizures negatively affect functioning in children with early brain injury (Ballantyne et al., 2008; Ballantyne et al., 2007; Chilosi et al., 2001; Cioni et al., 1999; Cohen & Duffner, 1981; Dall'Oglio et al., 1994; Vargha-Khadem, Isaacs, Van Der Werf, Robb, & Wilson, 1992). Notably, Vargha-Khadem et al. (1992) found that among children with early unilateral lesions, those with seizures had lower verbal and performance IQ than that of children with lesions who never experienced seizures and lower than that of TD children. Although the seizure-free group had lower performance IQ than TD children, this was not the case for their verbal IQ.

These findings are difficult to interpret because of the heterogeneity of the seizure groups, which consisted of children with a wide range of severity of seizure disorders. A large study of the relation of seizures with IQ suggests that it may specifically be the children with recurrent seizures who experience intellectual deficits (Huttenlocher & Hapke, 1990). It is possible that epilepsy may interfere with plasticity by transforming a focal lesion into a more global pathology (Stiles et al., 2012). Consistent with this possibility, Ballantyne et al. (2008) found that the full-scale IQ of children with PL and seizures declined over time, whereas this was not the case for children who did not have seizures. The potential role of seizure medications also needs to be considered (Levine et al., 2005).

77.4.5 Motor and Language Functions

A number of studies report a negative relation between degree of motor impairment and verbal and performance IQ (Levine et al., 1987; Riva & Cazzaniga, 1986), but other studies do not report such a relationship (Carlsson et al., 1994) in children with PL. Levine et al. (1987) found that degree of hemiparesis, lesion size, and Electroencephalogram (EEG) abnormality were all negatively correlated with IQ scores. However, hemiparesis was the strongest predictor of IQ, and neither lesion size nor EEG abnormality accounted for added variance above this variable. It is possible that degree of hemiparesis is an index of underlying neural impairment. It is also possible that motor difficulties impede the development of language and cognitive skills, a theory that would align with theories of embodiment, which posit a close relation between sensorimotor representations and more abstract concepts (Barsalou, 1999; Glenberg, 1997; Zwaan, 2008). What is clear from studies of children with PL and TD children is that motor and language functions can dissociate. In TD children, there is not a significant correlation between motor and language milestones between 9 and

13 months of age (Bates et al., 1979). Further, in children with PL, hemiparesis commonly persists even though language functions develop quite normally.

77.4.6 Lesion Timing

Although most studies report greater plasticity for language functions after PL than after lesions later in life, few studies have compared the effects of variations in lesion timing during the perinatal period, when we know that there are rapid changes in brain development (Bates et al., 2003; Stiles et al., 2012). The answer to the question of whether there is greater plasticity after lesions early in life than later in life may depend on several factors. One of these factors is the developmental status of brain structures that are compromised by the lesion and the dependence of undamaged regions on connectivity to these damaged regions.

Studies involving animal models and studies of humans show that the “Kennard Principle”—the general rule that early lesions result in less severe deficits than later lesions—is an oversimplification (Kennard, 1936). For example, Goldman and colleagues showed that neonatal lesions of the dorsolateral prefrontal cortex of monkeys have minimal effects on spatial working memory tasks compared with later lesions (when the monkeys were tested between 12 and 18 months of age). However, when testing was performed later, the monkeys with early lesions showed clear deficits, although they were still less severe than those exhibited by the monkeys with later lesions. The emerging deficits of the monkeys with early lesions may reflect the increasing maturation of the dorsolateral frontal lobes in the control monkeys, allowing them to outperform the monkeys with early lesions to this region. Goldman found a very different pattern when a subcortical structure, the caudate nucleus, was lesioned in the early compared with the later period. That is, caudate lesions resulted in deficits that were just as devastating after early and later lesions (Goldman, 1974), perhaps due to the greater maturity of the caudate than the prefrontal cortex at the time of injury.

Other findings highlight the interaction of lesion timing with the extent of the lesion (Kolb, Holmes, & Wishaw, 1987; Kolb & Tomie, 1988). In these studies, rats received lesions involving hemidecortication or bilateral lesions of the frontal or parietal cortex at different postnatal ages. Early hemidecortication resulted in less severe spatial memory deficits on the Morris water maze (Morris, 1984) than later hemidecortication, consistent with greater plasticity early in life. In contrast, for bilateral lesions of frontal or parietal cortex, early lesions resulted in greater deficit than later lesions. Thus, the reorganizational capacity of the

young brain after early lesions may depend on lesions being unilateral. It may also depend on maturity of the structures that are damaged at the time of the injury as well as at the time of testing.

A few studies have probed the effects of timing of lesions during the perinatal period in humans. In a landmark study, Staudt et al. (2004) studied hand-motor function in children whose lesions date from different periods during prenatal development—congenital malformations, which date from the first and second trimesters of pregnancy, periventricular lesions, which date mainly from the early third trimester, and middle cerebral artery infarctions, which date mainly from the late third trimester or perinatally. They found better function of the hand contralateral to the lesion after periventricular lesions, largely based on the fact that with these earlier lesions, ipsilateral corticospinal pathways are able to contribute to the functioning of the contra-lesional hand. By late in the third trimester, ipsilateral corticospinal connections may be sufficiently reduced, based on normal neuronal competition, that they are no longer sufficient to enable good hand-motor control.

Another recent study examined the IQ scores of children who sustained a lesion at different ages. The investigators compared the IQs of children who had lesions dating from before versus after age 3 years (Anderson et al., 2014). Results showed that the late lesion group had higher full-scale, verbal, and performance IQs (controlling for lesion location, volume, and seizure history) than the early lesion group. The researchers interpret these findings as supporting an early vulnerability hypothesis rather than an early plasticity hypothesis. The etiologies of lesions at various ages differed markedly, from brain trauma in the older lesion groups to dysplasia in the early lesion groups. Additionally, the extent of the lesions was larger in the early lesion groups. It is unclear whether similar results would be obtained if different lesion age categories were chosen, for example, categories that are more likely to include children with particular lesion etiologies, as was performed by Staudt et al. (2004), who examining the effects of age at lesion on hand-motor functioning. At the very least, it seems important to use finer age categories in view of the rapid changes in brain development that are occurring during the time spanning the prenatal period to age 3 years (Bates et al., 2003).

Considered together, these studies suggest that the answer to the question of whether there is greater plasticity for language functions after early than after later focal lesions is a resounding yes when one compares children with PL with patients with adult-onset lesions. However, the answer to the question of when during the early developmental period lesions are least

disruptive to the development of language functions is not as firmly established, and it appears to depend on the developmental status of the areas of the brain that are injured, their connectivity with other regions, and the etiology, location, and extent of the injury

77.5 WHAT IS THE ROLE OF LANGUAGE INPUT ON THE LANGUAGE DEVELOPMENT OF CHILDREN WITH PERINATAL LESIONS?

Animal models of brain injury provide strong evidence that input can mitigate the effects of brain injury, and that the effects of experience vary depending on the age of the animal at the time of injury (Kleim & Jones, 2008; Kolb & Gibb, 2010; Kolb, Gibb, & Gorny, 2003). One would think that such findings would lead to research on how the effects of early variations in language input can result in different outcomes after early PL. However, even though variation in language input is known to be an important predictor of the language growth trajectories of TD children (Hart & Risley, 1992; Hoff, 2006; Huttenlocher et al., 1991), studies of children with PL have focused almost exclusively on biological characteristics of children's lesions in attempting to explain variations in language development among these children. Recently, this has started to change as researchers have begun to consider how variations in the language input that children experience may affect the development of language functions in children with early unilateral lesions, and how input variations and the biological characteristics of lesions may interact to predict language development trajectories.

By comparing the effects of language experiences on language development in children with perinatal brain injury and TD children, one can examine whether the effects of environmental factors differ depending on the biological characteristics of the learner. One possibility is that environmental input plays the same role in children with and without early brain injury. Such a finding would suggest that the environment plays a role in language learning in children with early lesions that is similar to that of TD children, supporting the robustness of language development in the face of early injury. A second possibility is that environmental input plays a less important role than it does in TD children, possibly because the lesion limits the child's ability to profit from the input provided. Finally, a third possibility is that environmental input may play a more important role in supporting language development after early brain injury, suggesting that input can help

compensate for the deleterious effects of brain injury. Existing studies present a complex picture such that language input appears to play a similar role in the development of some aspects of language in TD children and children with early brain injury. For other aspects of language function, input appears to play a more important role for children with early brain injury, particularly for the subset of children who show initial delays.

The small number of studies that have examined the effect of environmental factors on cognitive outcomes in children with early brain injury have largely focused on global indices of input (e.g., socioeconomic status, stability of the home environment, parental attitudes, patterns of management) and global indices of child outcomes (e.g., IQ, behavioral and psychiatric problems) (Seidel, Chadwick, & Rutter, 1975; Thomas & Chess, 1975). Recent studies have explored specific relations between parental input and children's later language outcomes. For example, Rowe et al. (2009) examined the impact of lesion characteristics and parent-child-directed talk on the growth of productive vocabulary and syntax between 14 and 46 months of age. Both lesion characteristics and input variations predicted vocabulary growth and syntactic growth in children with PL. Controlling for parental socioeconomic status and characteristics of children's lesions, the diversity of parent vocabulary did not differentially predict growth in the vocabulary of children who were in the brain lesion and control groups. In contrast, the syntactic complexity of parent input played a larger role in predicting later syntax in children with PL than in TD children. Importantly, the speech of children with PL was lower in syntactic complexity than that of TD children, but it did not differ in terms of vocabulary diversity.

Building on this research, another recent study explored the effect of a complex type of parental talk—decontextualized talk during naturalistic parent-child interactions—on subsequent child vocabulary, syntax, and narratives, again comparing input effects for children with PLs and TD children. Decontextualized language refers to talk that parents produce regarding abstract and invisible entities, is typically seen in parents' conversations about the past and future, pretend play, and explanations, and is a strong predictor of later language outcomes in TD control children (Rowe, 2012; Snow, 1991). In this study, Demir et al. (2015) showed that for both groups of children, decontextualized talk by a parent to a 30-month-old child was a significant predictor of child language performance in kindergarten, controlling for parental contextualized talk, demographic factors, and the preschool language skill of the child. Decontextualized talk played a greater role in predicting kindergarten narrative

outcomes for children with PL than for control children. This difference stemmed primarily from the fact that the children with PL had lower narrative (but not vocabulary or syntax) scores than the control children. When the two groups were matched in terms of narrative skill at kindergarten, the impact that decontextualized talk had on their narrative skills did not differ for children with PL and for TD children.

These two studies suggest that differences in the effects of input on the language skills of children with PL and control children may be due to the relatively low level of language skills on certain tasks in some children with PL. This hypothesis was supported in another study that experimentally manipulated the input children receive. [Demir, Fisher, et al. \(2013\)](#) found that co-speech gesture of an experimenter provided in a narrative retelling task was particularly helpful in supporting the narratives of children with larger lesions (associated with vascular [ischemic] infarcts) who had the most difficulty telling a well-structured narrative.

Only a small number of studies have examined later language-related academic achievement in children with PL. In general, these studies report lower academic achievement scores in the PL group, with some reporting specific deficits associated with left hemisphere lesions ([Frith & Vargha-Khadem, 2001](#); [Woods & Carey, 1979](#)) and others reporting no laterality effects ([Ballantyne et al., 2008](#)). A recent study examined the effect of school input on development of reading skills by charting growth of decoding (grapheme–phoneme conversion; “phonics”) and reading comprehension skills in TD children and children with PL between kindergarten and second grade ([Demir, Carlson, et al., 2013](#)). Children with PL performed lower than control children on reading comprehension, but not on decoding. Moreover, the difference between school and summer growth rates in reading comprehension was greater for the children with PL. This finding suggests that the structured learning environment of school may play a more crucial role in the development of reading comprehension for children with PL than for TD children.

Overall, a small but increasing number of studies on the role of language input in the language development of children with early brain injury show that variations in language development in children with PL are influenced not only by the biological characteristics of their lesions but also by the environmental input they receive. These studies also show that the effect of the environmental input might vary depending on what language skill is examined; input might play a greater role for children with PL than for TD children in language tasks that are challenging for them.

77.6 WHAT IS THE MECHANISM OF LANGUAGE PLASTICITY AFTER EARLY LESIONS?

The lack of association of left hemisphere lesions with persistent language difficulties is one of the most striking findings that has emerged from the study of children with early brain injury. Various theories have been proposed to explain the lack of association of left hemisphere lesions with language difficulties after lesions early in life. Until recently, these theories focused mainly on the degree to which language functions were lateralized to the left hemisphere during early development as a potential mechanism for age-related differences in functional plasticity (see [Bates et al., 1999](#); [Bishop, 1993](#) and [Stiles et al., 2012](#) for reviews).

77.6.1 Equipotentiality

One theory, equipotentiality, primarily associated with [Lenneberg \(1967\)](#), posited that left hemisphere specialization for language functions emerged over the course of development as a consequence of language learning and was achieved by puberty. At this point, the period of plasticity is diminished, making it difficult to withstand an injury to the left hemisphere without showing marked language deficits. This critical period theory provides an explanation for why language deficits would not be more common after left than after right hemisphere lesions in children, as well as for why the language deficits observed after early lesions would be more subtle when lesions occur early in life.

77.6.2 Left Hemisphere Specialization from the Start

Lenneberg’s theory has been challenged by a variety of evidence supporting a more nativist position—that the left hemisphere may be specialized for language from the start (see [Feldman, 2005](#) for review). [Witelson and Pallie \(1973\)](#), for example, reported that the left planum temporale, a region of the left hemisphere associated with language functioning, is larger than the corresponding region in the right hemisphere in infants, just as it is in adults ([Geschwind & Levitsky, 1968](#)). Further, differential left hemisphere sensitivity to speech sounds has been supported by behavioral and EEG measures ([Entus, 1977](#); [Molfese & Molfese, 1980](#)). More recently, neuroimaging studies reveal that infants’ speech processing is supported by the same left frontotemporal brain networks as that in adults ([Dehaene-Lambertz, Dehaene, & Hertz-Pannier, 2002](#); [Dehaene-Lambertz et al., 2006](#)). Thus, the strong form of Lenneberg’s hypothesis—that the two hemispheres

initially provide equally attractive neural real estate for language—does not appear to be correct. Further, as pointed out by Bates et al. (1999), the equipotentiality hypothesis fails to provide an explanation for the emergence of left hemisphere specialization for language. Such a predominant pattern is much more consistent with the presence of a bias from the beginning.

77.6.3 Emergent Specialization of Language Networks

Recent studies provide some support for a middle ground. That is, they show that the left hemisphere is specialized for some language functions early, but that there is also developmental change characterized by emergent left hemisphere specialization (Szaflarski, Holland, Schmithorst, & Byars, 2006). Consistent with this view, diffusion tensor imaging (DTI) shows that some of the fiber tracts that connect language-relevant brain areas in adults are in place in infants whereas others are not (Perani et al., 2011). Further, an Event-related potential (ERP) study showed a shift from more bilateral to more left hemisphere patterns of activation for processing words between 13 and 20 months of age, with the timing of the shift dependent on the level of the child's vocabulary development (Mills, Coffey-Corina, & Neville, 1997). Similarly, several studies report a shift from more bilateral to more left hemisphere activation between ages 5 years and adolescence on a verb generation task (Brown et al., 2005; Holland et al., 2001). Thus, certain aspects of language are lateralized early in life, whereas for others lateralization emerges much more slowly. Moreover, the timing of this emergent specialization may vary with the individual's level of language function, which, in turn, is influenced by his or her language learning experiences (Hart & Risley, 1992; Huttenlocher et al., 1991).

77.6.4 Neural Underpinnings of Language in Children with perinatal lesions

Functional magnetic resonance imaging (fMRI) studies provide a way to examine the functional neural organization supporting language after early brain injury to perisylvian regions of the left hemisphere. Many of these studies report bilateral activity or increased activity in homotopic right hemisphere areas (Booth et al., 1999; Duncan et al., 1997; Fair, Brown, Petersen, & Schlaggar, 2006; Jacola et al., 2006; Müller et al., 1999; Papanicolaou et al., 2001; Staudt et al., 2001, 2002), suggesting that right hemisphere language-related activity is associated with better language outcomes after early focal injury to the left hemisphere.

Lidzba and Staudt (2008) suggest that early left hemisphere injury may disrupt emergent left hemisphere specialization, and the maintained bilateral involvement in language processing may serve as a potential mechanism underlying functional plasticity. However, a few studies have shown that injury to the left hemisphere does not necessitate recruitment of right hemisphere homologues (Hertz-Pannier et al., 2002; Liégeois et al., 2004; Rasmussen & Milner, 1977). For example, Liégeois et al. found that damage to Broca's area in the left hemisphere does not always lead to right lateralization of activity during a verb generation task. In fact, patients with lesions within this classical language area showed greater perilesional activation in the left hemisphere, whereas patients with lesions remote from the classical language areas demonstrated interhemispheric language reorganization. Overall, the outcome patterns of neural organization for language after early focal brain injury are highly variable (Fair et al., 2010; Raja Beharelle et al., 2010), and analyses investigating brain organization postinjury and relationships with behavior need to focus on interindividual differences rather than group averages.

Although there is heterogeneity of language-related organization after early focal insult, few studies have tested whether certain patterns of organization are more optimal for language functioning than others. Staudt and colleagues (2002) found that greater whole brain activation predicted poorer verbal and full-scale IQ; however, there were no relationships between lateralized activity and outcome measures, and the sample size was likely too small ($n = 5$) to examine these associations. In a larger study of individuals with PL, recruitment of left inferior frontal regions and bilateral inferior parietal and posterior temporal areas during a category fluency task predicted better language outcomes across a range of measures (Raja Beharelle et al., 2010). These relationships held regardless of lesion size or extent of damage to classical language areas, suggesting that maintaining a more typical neural organization by recruiting classical left hemisphere language areas may better support language function than recruiting right hemisphere areas. However, a recent study with a relatively small number of participants combined patients with perinatal and childhood stroke and found that increased left lateralization was related to lower expressive language scores (Ilves et al., 2014). Thus, it is not clear whether certain patterns of neural organization are optimal for language after early focal brain injury, or how a variety of factors (e.g., age at lesion, age at testing, lesion aetiology, lesion location, lesion size, and seizure history) might influence the answer to this question.

Current neuroimaging studies have largely focused on left versus right hemisphere differences in brain activity after early focal brain injury. However, research shows that early injury causes both local and distributed effects in the brain, leading to global changes of the neural architecture. Structurally, early injury can result in changes in anatomic connections to areas remote from the site of injury (Pascual-Leone & Amedi, 2005), and repair processes involve regeneration around the lesion site as well as extensively throughout the brain (Anderson, Spencer-Smith, & Wood, 2011). Thus, to more comprehensively understand the changes in language organization occurring after early injury, it will be necessary to move beyond the narrow lens of laterality of activation and more broadly investigate postinjury patterns of organization and their relation to functioning.

77.7 SUMMARY AND FUTURE DIRECTIONS

Our review indicates that considerable progress has been made in understanding how focal lesions of perinatal onset impact language functioning. Some general patterns emerge from the existing literature. In particular, on a background of remarkable plasticity, children with PL do experience some language difficulties, and these tend to be more marked during the period when language is beginning and for later developing, more complex language skills. This perhaps represents a cycle of difficulties that are apparent when one examines the aspects of language that are particularly challenging at different developmental time points. That is, once a particular aspect of language is acquired, a later, more challenging aspect of development may show a subsequent delay (Stiles et al., 2005).

In terms of lesion characteristics that are associated with greater delays and deficits, lesion size appears to be a more important predictor of language functioning in this population than lesion laterality. Further, early language experiences predict language outcomes and, for some aspects of language, high-quality input appears to be even more important for children with PL than for TD children, perhaps related to the lower levels of functioning of some children with PL (Wilcox, Hadley, & Ashland, 1996). An important next step will be to examine how variations in language experiences map onto variations in the neural networks that are recruited for language processing after a PL.

The tools provided by sensitive behavioral measures used in combination with brain imaging are allowing for new ways to advance our understanding of the mechanisms of plasticity for language functions after PL. It is clear that these advances will depend on increasing

our understanding of normal neurodevelopmental processes and how these processes combine with processes set in motion by an early brain injury to impact plasticity and language learning trajectories. It will also require increasing our understanding of how experiences at particular times during development can exacerbate or ameliorate the effects of lesions.

Exciting new findings are emerging from animal research concerning the mechanisms of plasticity (Hensch, 2005), including studies showing how periods of plasticity can be delayed and extended. Notably, these studies have shown that gamma-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the brain, plays a key role in the opening and closing of periods of plasticity. Although we are not yet at the point of applying these findings to humans, these findings hold promise for boosting plasticity in populations such as children with PL.

In the meantime, we do have evidence that rich language input has the potential to boost plasticity, and we can test whether this is the case using rigorous experimental designs. Further, by examining the neural signatures of language improvements after interventions, we can gain insights into the mechanisms of change. Because language difficulties in children with PL may only become apparent when the child confronts demanding linguistic tasks, it may be best to intervene proactively, before children experience difficulties. In this way, we may be able to close developmental gaps before they emerge and help children attain optimal outcomes.

Motor Speech Impairments

Wolfram Ziegler and Anja Staiger

Clinical Neuropsychology Research Group, Clinic for Neuropsychology, City Hospital, Munich, Germany

78.1 INTRODUCTION

According to conventional clinical taxonomies for neurological speech and language disorders, the term *motor speech impairment* comprises the different *dysarthria* syndromes as well as the syndrome of *apraxia of speech* (AOS). Although the dysarthria syndromes are considered to result from pathologies afflicting the control and execution of speech movements, apraxia of speech is usually ascribed to a dysfunction of speech motor planning or programming functions (Duffy, 2013).

Historically, many neurolinguistic theories have explicitly or implicitly embraced a fundamental divide between the biological foundations of *language* and those of *motor speech* (and *auditory processing*). Aphasiologists have willingly adopted the *langue–parole* distinction made by de Saussure and its continuance in structuralist and early generative phonology, in which the motor aspects of speaking (and the auditory aspects of understanding) are almost completely excluded from the arena of language biology. From this standard perspective, the dysarthrias and AOS have been neglected because they are viewed as disorders of a physical organ whose relationship to language is incidental or external rather than structurally or functionally linked.

In this chapter, we regard motor speech disorders from three vantage points. First, we describe them as syndromes resulting from the recognized neuropathologies of body movement disorders, more or less following the standard view of speech as a motor function that is sealed from its overarching linguistic framework. Second, we discuss how the speech motor system is specialized to serve its linguistic-communicative goal. Third, we expand on the sensorimotor aspects of speech motor impairments with the aim of illuminating the different neural stages during which auditory, somatosensory, and motor information is integrated.

78.2 MOTOR IMPAIRMENTS WITHIN A NEUROLOGICAL FRAMEWORK

Since Darley's seminal work, the taxonomy of neurogenic motor speech impairments largely mirrors the taxonomy of (body) movement disorders, with the dysarthric syndromes corresponding to the paretic (flaccid, spastic), ataxic, akinetic, and dyskinetic motor syndromes. AOS, in this terminology, is considered to correspond with the syndrome of limb apraxia (Darley, Aronson, & Brown, 1975).

In this section we describe the major CNS neuropathologies leading to speech impairment, focusing on the question of how a pathomechanism described for disorders of body movements may translate into speech motor mechanisms (for a fully comprehensive survey and detailed descriptions of clinical symptoms, see Duffy, 2013).

78.2.1 Spastic Paresis

Lesions on areas representing the speech muscles in the ventral part of the Rolandic motor cortex and on the corticobulbar motor pathways cause a syndrome characterized by a paresis of the musculature involved in speaking. This dysarthria type, termed *spastic dysarthria*, may arise from lesions either at the motor cortex level or along the descending motor neuron fiber tracts to the pontine and medullary motor nuclei. Such lesions can be caused, for example, by infarctions or by disseminated MS plaques, by traumatic brain injuries, by congenital or very early brain damage, as in cerebral palsy (CP), or by progressive disorders affecting the upper motor neuron pathways, such as progressive supranuclear palsy (PSP) or motor neuron disease (MND). Because all bulbar motor nuclei, except the facial nucleus, receive considerable bilateral motor cortical input, lesions restricted to one hemisphere often

lead to only mild and transient speech impairment (Muellbacher, Artner, & Mamoli, 1999), whereas lesions affecting the upper motor neuron system of both hemispheres, such as in the Foix–Chavany–Marie syndrome (with infarctions in the left and right motor cortices) or after bilateral brainstem stroke or traumatic brain injury, may lead to a persisting syndrome including, among others, severe dysarthria and dysphagia (Duffy, 2013).

Although the presence of spasticity, as defined in the limb muscles, cannot easily be verified in the lingual, pharyngeal, or laryngeal musculature, the general understanding is that lesions to the corticobulbar motor system cause a spastic speech syndrome characterized by muscle weakness and loss of fine motor skill (as a consequence of lesions to the monosynaptic fibers of the upper motor neuron system) in combination with excessive muscle tone (as a consequence of lesions to indirect fibers targeting the motor nuclei via multiple “extrapyramidal” synapses; Duffy, 2013). The combination of upper motor neuron weakness and spasticity is considered to cause reduction of respiratory support, slowing of articulator movements, imprecise consonant articulation, or, when the velopharynx is affected, hypernasality. Increased muscle tone can be visible in the lower face muscles or, via endoscopic inspection, in the larynx. Hypertonicity may lead to a strained or strangled voice because of glottal hyperadduction or increased tension in the hypopharynx.

78.2.2 Ataxia

Dysarthria may also arise when cerebellar contributions to speech motor control are compromised due to lesions of either the cerebellum itself or its efferent or afferent projections. Such lesions may result, for example, from cerebellar infarctions, multiple sclerosis, or hereditary ataxic disorders (e.g., Friedreich’s ataxia, spino-cerebellar ataxias). Conflicting theories exist regarding the lateralization and particular parts of the cerebellum implicated in ataxic dysarthria (Mariën’s contribution in Manto et al., 2012). Recently, two functional subsystems have been hypothesized on the basis of functional imaging data. They include a *superior cerebellar circuit* (encompassing connections of superior parts of the cerebellar hemispheres with the inferior frontal gyrus, anterior insular cortex, and the supplementary area), mainly involved in preparatory and motor planning aspects of speech production, and an *inferior cerebellar circuit* (encompassing inferior-cerebellar thalamo-cortical connections), mainly involved in the motor execution aspects of speaking (Ackermann, 2008). On the basis of clinical considerations, a similar distinction between two functional

levels of cerebellar contributions to motor speech has been proposed that distinguishes between a motor planning/programming circuit (mainly involving connections of the right cerebellar hemisphere with left inferior-frontal speech planning centers in the cerebral cortex) and a motor execution circuit involving superior parts of both cerebellar hemispheres (Spencer & Slocumb, 2007).

The clinical pattern of ataxic dysarthria may vary considerably across patients. Among the ataxic pathomechanisms, impaired motor timing, sequencing, and movement coordination have been considered preeminent explanations for speech characteristics such as irregular articulatory inaccuracy, slow articulatory rates, prolonged phonemes, inappropriate pitch and loudness variation, voice tremor, or temporally disorganized or paradoxical respiratory movement patterns during speech breathing (Brendel et al., 2013; Duffy, 2013). Other symptoms may result from compensatory mechanisms serving to suppress tremor or dysmetria, such as a strained or strangled voice quality or a regularly paced, scanning speech rhythm. Overall, the pattern of cerebellar speech impairment cannot be easily divided into a group of features reflecting a planning deficit and others reflecting impaired motor execution, as would be predicted by the two-level model of cerebellar speech motor functions mentioned. Cerebellar speech signs fit into the symptom pattern traditionally described as *ataxia*, with dysmetria, incoordination, and deficient timing as its preeminent pathomechanisms; they differ substantially from the *apraxic* signs observed after lesions to the anterior perisylvian and subsylvian cortex of the left cerebral hemisphere (Ziegler’s contribution in Mariën et al., 2013; Section 78.2.5).

78.2.3 Akinesia

The pathomechanism of akinesia in movement disorders has been ascribed to dysfunction at the level of the striato-thalamo-cortical motor circuit, with idiopathic Parkinson’s disease as the prototypic clinical model of the akinetic condition (Jankovic, 2008). Akinesia is considered to encompass a *hypokinetic* component, mainly characterized by a reduction in the range of rhythmical movements (e.g., gait, breathing) as a result of excessive inhibition of central pattern generators in the brainstem, and a *bradykinetic* component, characterized by slowness of movements as a result of reduced striato thalamic “energisation” of appropriately selected motor commands at the motor cortical level, through a defect of the striatal motor circuit that facilitates recruitment of cortical motoneurons for an intended movement. Both mechanisms, hypokinesia and bradykinesia, are

presumably the result of a progressive loss of dopaminergic striatal innervation (Rodriguez-Oroz et al., 2009). It is not clear whether parkinsonian speech impairment originates from exactly the same mechanisms, especially because dysarthria in Parkinson's disease is much less (if at all) responsive to dopaminergic drugs and deep brain stimulation treatment than akinetic motor impairment of the limbs and trunk (Rodriguez-Oroz et al., 2005). Moreover, symptoms such as a slowing of the serial control of sequential movements involving different body parts, which are considered characteristic of Parkinson's disease (Rodriguez-Oroz et al., 2009), are not typically present in hypokinetic dysarthria. On the contrary, Parkinson's patients often demonstrate a normal or even accelerated speaking rate and chains of tightly conjoined and rapidly produced syllables ("short rushes of speech"; Ackermann & Ziegler, 1992). Nonetheless, the overall pattern of speech motor signs in Parkinson's disease, with its visible undershooting of labial and mandibular movements, its loss of sufficiently distinct consonant and vowel articulations, its hypophonic voice, and its monotonous intonation, is largely compatible with the predicted consequences of an akinetic condition. In addition, Rodriguez-Oroz et al. (2009) suggest that increased responsiveness of the subthalamic nucleus (STN) and internal segment of the globus pallidus (GPi) in Parkinsonism may contribute to a progressive attenuation of sequential movements as in handwriting (micrographia), which might also serve as an explanation of progressive hypophonia and articulatory undershoot and progressive acceleration phenomena occurring across stretches of speech.

Reduced spontaneous speech and hypophonia may also be observed in patients with lesions on the medial premotor areas (supplementary motor area [SMA]) and the anterior cingulate gyrus (ACG), for instance, during recovery from akinetic mutism (Krainik et al., 2003). These data fit within a model of a limbic striatal circuit encompassing the ACG and SMA, which may serve as a starting mechanism for speech production and as a gateway for motivational and affective modulation of vocal and articulatory processes (Ackermann, Hage, & Ziegler, 2014; see Section 78.3.1).

78.2.4 Dyskinesia

Although akinesia is attributed to excessive striatal inhibition of thalamo-cortical and brainstem mechanisms, opposite mechanisms may lead to a loss of inhibition or an imbalance of thalamo-cortical motor activations as a consequence of reduced STN-GPi activity (Hallett, 2011). These pathophysiological conditions result in hyperkinetic or dystonic motor impairments characterized by abnormal postures,

uncontrollable movements or muscle spasms, and a loss of selectivity of muscular activation. They are classified into rhythmic (*tremor*) and arrhythmic variants, with the latter including the *dystonias* as a form of sustained motor abnormalities and *chorea*, *myoclonus*, and *tics* as rapid forms (Albanese & Jankovic, 2012). Dyskinetic conditions may result from a variety of neuropathologies, including genetic, drug-induced, toxic or metabolic, traumatic, or vascular etiologies. In many cases, especially in the dystonias, the etiology is unknown.

Speech can be afflicted by all types of dyskinetic syndromes. Leaving aside the different variants of vocal tremor (e.g., in Parkinson's disease, cerebellar ataxia, essential tremor), the dyskinetic dysarthria syndromes that have received particular consideration are the choreatic and athetotic forms occurring in Huntington's disease (Duffy, 2013) and in a subtype of CP, and the focal dystonias of the laryngeal and the oromandibular muscles (*spasmodic dysphonia*, *oromandibular lingual dystonia*; Duffy, 2013). Choreatic hyperkinesias of the speech muscles may lead to intermittent disruptions of respiratory activity, uncontrolled vocalizations, intermittent noise productions with the tongue or lips, excessive pitch and loudness variations, overshooting and undershooting of articulatory movements, intermittent hyponasality and hypernasality, and irregular pauses or sound prolongations (Duffy, 2013). Spasmodic dysphonia may affect the adductor and/or abductor muscles of the larynx and lead to a strained–strangled or breathy or aphonic voice quality, respectively (Simonyan, Berman, Herscovitch, & Hallett, 2013). Oromandibular lingual dystonia may interfere with speaking secondary to, for example, excessive jaw opening or closing and involuntary tongue protrusion (Ushe & Perlmutter, 2012).

78.2.5 Apraxia of Speech

The concept of AOS dates back to Liepmann (1900), who considered the articulation impairment of a patient with Broca's aphasia (then termed "motor aphasia") an "apraxia of the language muscles" ("*Apraxie der Sprachmuskeln*"; Liepmann, 1900, p. 129). Much later, in their neurologically based classification of motor speech impairments, Darley et al. (1975) resurrected the term to describe a speech impairment occurring after infarction of the anterior branch of the left middle cerebral artery whose characteristics were not compatible with any of the neuromotor pathomechanisms of the dysarthrias. Similar to limb apraxia, the original definition of AOS consisted of largely negative designations; the speech symptoms cannot be explained by "slowness, weakness, incoordination, or

change of tone" of the involved musculature (Darley et al., 1975, p. 251). The problem was interpreted as a consequence of impaired motor programming (Darley et al., 1975, p. 255).

A specific feature of limb apraxia is that lesions of the left hemisphere may lead to motor impairment of not only the contralesional (right) but also the ipsilesional (left) limb. In speech this corresponds, in a way, with the observation that AOS is a left hemisphere syndrome and that, unlike (hemi-) paretic dysarthria, it cannot be compensated for by innervations from intact right hemisphere homologues. However, modern theories of apraxia, with their strong focus on failures of motor functions of the upper extremities, such as pantomime or tool use (Goldenberg, 2013), confuse the issue of drawing analogies between speech and limb apraxia. Without any specific reference to the latter, AOS may best be characterized as a loss of the acquired implicit knowledge of how the muscular aerodynamic apparatus of the speech organs is manipulated for the generation of syllables, words, and phrases (Ziegler, Aichert, & Staiger, 2012).

Regarding the sites of the lesions responsible for AOS, there remains controversy about the roles of left inferior frontal gyrus (area 44) and left anterior insular cortex (Richardson, Fillmore, Rorden, Lapointe, & Fridriksson, 2012). Greater agreement exists about the implication of left ventral premotor and motor regions in the origin of AOS (Graff-Radford et al., 2014). In the majority of cases, AOS results from left middle cerebral artery stroke, but other etiologies have also been reported. Furthermore, speech abnormalities consistent with AOS have been observed as a primary progressive condition (Josephs et al., 2006). However, the patient groups with alleged primary progressive AOS described so far are probably rather heterogeneous. In particular, patients showing substance loss in the region of the SMA, as described, for instance, by Josephs et al. (2006), may suffer from dysfluencies due to mesiofrontal speech initiation problems (Ziegler, Kilian, & Deger, 1997) rather than from a frontolateral speech motor planning impairment.

In modern psycholinguistic terminology, AOS is allocated to the phonetic planning stage of speech production (Ziegler, 2008). Speech errors in AOS differ from dysarthria in that they can be inconsistent and often are only evident at a segmental level rather than spreading over larger parts of an utterance. For instance, excess nasality may occur selectively and locally on single phonemes in AOS, whereas in dysarthric speakers hypernasality, if present, occurs more as a global feature that extends, as a consequence of velar weakness or slowness, almost uniformly across the segments of a word or phrase. This makes apraxic speech errors less predictable than dysarthric

distortions (Staiger, Finger-Berg, Aichert, & Ziegler, 2012). Nonetheless, unlike the phoneme errors observed in many aphasic patients without AOS, the distortions observed in AOS appear motoric because they often lack the quality of well-articulated phonemes through, for example, excess plosive aspirations, audible phoneme transitions, or nasal releases in stop consonants. AOS patients usually are fully aware of their speech problems and, unlike individuals with dysarthria, tend to grope for the correct articulation before they start speaking. They often self-correct their false starts and speech errors, which renders their speech dysfluent and halting.

78.3 MOTOR IMPAIRMENTS FOR SPOKEN LANGUAGE PRODUCTION

Speaking differs from other motor functions in several ways. It is more skillful than many other activities within the human motor repertoire. Among the more advanced motor skills, such as playing a musical instrument, it is the only one that every healthy child acquires without specific instruction. Speaking is acquired over more than the first decade of life, is usually exercised daily, and is continuously adapted to the gradual and sometimes abrupt anatomical changes that occur from childhood to old age. Speech movements are tuned to the generation of (speech) sounds through aerodynamic mechanisms and, hence, are conducted within an acoustic rather than a spatial reference frame (Perkell, 2012). Finally, the evolution of the speech motor system is intrinsically tied to the requirements of spoken communication and is entrenched with the linguistic framework of human language and of a speaker's native language. For these reasons, speaking should be considered a highly specific motor activity that, through mechanisms of practice-related plasticity, shapes a neural basis dedicated to its linguistic and communicative goals (Ziegler & Ackermann, 2013). In the following subsections we discuss evidence from speech disorders that illuminate the particularities of speaking across the different motor activities of the respiratory, laryngeal, and vocal tract muscles.

78.3.1 Speech and Emotional Expression

The laryngeal and facial muscles are used not only in speech but also in emotional expressions such as laughter and crying. According to a dual pathway model of acoustic communication developed by Jürgens and Ploog (Jürgens, 2002), the motor activities of these muscles during emotional expression versus propositional speech are tied to different brain

networks. The motor pathways engaged in emotional and intrinsic vocalizations, as understood from primate vocalization studies, have their origin in mesio-frontal cortex (ACG) and travel through the midbrain periaqueductal gray and adjacent tegmentum to the reticular formation and brainstem motor nuclei (Ackermann et al., 2014). The motor pathway involved in voluntary motor activities of the vocal tract, especially in speaking, takes a separate route encompassing corticobulbar, striatal, and cerebellar systems (Section 78.2). Several clinical observations corroborate the distinct courses of these two motor systems. A striking example in this regard relates to the Foix–Chavany–Marie syndrome, which results from bilateral lesions to the upper motor neuron system (Section 78.2.1). Patients with this syndrome are severely dysarthric or anarthric because of bilateral upper motor neuron paralysis of the bulbar speech muscles. At the same time, these patients are able to completely adduct their vocal folds and activate their facial musculature during emotionally driven laughter or crying (Mao, Coull, Golper, & Rau, 1989). This so-called automatic–voluntary movement dissociation is taken as evidence for the separate courses of emotional and volitional motor pathways for the speech muscles. A less dramatic but equally convincing dissociation may occur after unilateral cerebral lesions that may cause contralateral lower facial paresis during speaking and volitional mouth spreading (“show your teeth”) but symmetric spreading during spontaneous smiles (“volitional facial paresis”) or, conversely, asymmetric smiling but symmetric lip spreading in speech and the “show your teeth” task (“emotional facial paresis”; Hopf, Müller-Forell, & Hopf, 1992).

Although these dissociations relate to distinct actions with either a volitional/linguistic or an emotional content, natural speaking is usually linked to motivational and emotional states. The impact of a speaker’s attitudes, motivations, and emotions on his/her speech movements is reflected in the prosodic modulation of spoken utterances. This interaction implies the existence of a neural interface through which the emotional/intrinsic (“limbic”) vocalization system modulates speech motor pathway activity. In a recent extension of Jürgens’ (2002) dual pathway model, Ackermann et al. (2014) proposed that the basal ganglia provide a platform for the integration of limbic mechanisms of acoustic communication with articulate speech. According to this theory, a cascade of striato-nigro-striatal circuits extending from ventromedial (limbic) to dorsolateral (motor) components of the striatum is the substrate for the limbic-motor integration process. These circuits interconnect two parallel cortico–basal ganglia–thalamo–cortical loops, one conveying motivation-related information via ventromedial–dorsolateral pathways and the other

conveying speech motor information via the cortico-striatal motor loop (Ackermann et al., 2014). The hypokinetic dysarthria associated with Parkinson’s disease may illustrate how this integration can fail. That is, the depletion of striatal dopamine leads to a diminished impact of attitudinal, motivational, and emotional states on speech motor control and thereby results in the flattened, monotonous prosody and the hypophonic voice that is characteristic of many people with Parkinson’s disease. This illustrates how evidence from speech motor impairments may contribute to a deeper understanding of the neural organization and the interaction of laryngeal and oral motor activity for speech and for emotional expression.

78.3.2 Speech Versus Volitional Nonspeech Vocal Tract Movements

In the automatic–voluntary motor dissociations described in the preceding section, speech was subsumed among a broader class of willed motor actions involving the vocal tract, including movements such as volitional lip spreading, tongue protrusion, and the like. If we assume, as outlined, that the speech motor system co-evolves within the structural framework of linguistic communication and that the domain-specific properties of speech motor control are represented at the neural level, then we would expect that brain lesions may selectively affect or preserve speech relative to nonspeech volitional motor activities.

There is substantial evidence that speech and nonspeech motor impairments can be dissociated. Patients with brain lesions may show impairments of the oral (voluntary) phase of swallowing or may have problems imitating tongue protrusion or other labial or lingual displays, but at the same time have normal or almost normal speech. Conversely, some patients may present with marked dysarthric or speech apraxic symptoms but have a relatively preserved ability to perform nonspeech vocal tract movements. Dissociations have been found for a number of nonspeech motor tasks, including chewing and swallowing, movement imitation, strength and endurance tasks, rapid syllable production, or visuomotor tracking (Ziegler, 2003). One of the reasons for these findings is that nonspeech oromotor activities used in research and assessment differ from speech along a number of dimensions, such as timing, strength, and airflow requirements, the degree of interaction between subsystems, the rhythmical entrainment of movements, and the role of acoustic output as a reference frame. The specific requirements of producing intelligible and naturally sounding speech by manipulating the respiratory, laryngeal, and supralaryngeal muscles in a particular way, and the fact that the highly

adaptive interplay of these muscles in speaking is acquired over time during childhood, call for the engagement of a specialized neural network in adult motor speech. This conclusion receives strong theoretical support from investigations into experience-dependent neuroplasticity (Ostry, Darainy, Mattar, Wong, & Gribble, 2010; Zatorre, Fields, & Johansen-Berg, 2012). For example, neuroimaging studies comparing speech with oral nonspeech movements converge on the observation that motor speech is more lateralized to the left hemisphere and is associated with less neural activation than nonspeech oral motor tasks (Moser et al., 2009; for a more extensive review of these arguments see Ziegler and Ackermann, 2013).

In summary, the selective and domain-specific nature of motor speech impairments is consistent with highly specialized neural organization of the motor aspects of speaking. This contributes to evidence that the speech motor system constitutes an integral part of the biology of human language.

78.3.3 Language-Specific Phonological Structure Interacts with Speech Motor Impairment

From early childhood, speech acquisition is shaped by the phonological structures the child encounters in his/her native language. The maturation of vocal tract, laryngeal, and respiratory functions for speaking separates rather early from nonspeech metabolic motor patterns (Moore, Caulfield, & Green, 2001) and takes a course toward mastering the specific motor requirements of the language's phoneme repertoire and the phonotactic and prosodic patterns of the child's ambient language (Astruc, Payne, Post, Vanrell, & Prieto, 2013). As a consequence, the speech motor system in the adult brain is shaped by the properties of the speaker's native language. When the system breaks down after a brain lesion, observed motor speech failures reflect universal and language-particular aspects of phonological structure (Ziegler & Ackermann, 2013).

This is quite obviously the case in AOS. The sound level errors and phonetic distortions of speakers with AOS are sensitive to syllable structure, respect syllable boundaries, and are influenced by language-particular frequency-related properties of syllables and words (Aichert & Ziegler, 2004; Romani & Galluzzi, 2005; Schoor, Aichert, & Ziegler, 2012; Staiger & Ziegler, 2008). A further potential source of influence on apraxic errors is the metrical pattern of the speaker's language. For example, in German speakers with AOS, more errors are observed on disyllabic nouns with stress on the second (iambic) as compared with the

first syllable (trochaic), which conforms to expectations because trochees are by far more frequent than iambs in German (Aichert, Büchner, & Ziegler, 2011).

We examined the influences of phonological structure on speech errors in German speakers with AOS using a nonlinear probabilistic model based on the hierarchical architecture of words, extending from the level of articulatory gestures to the level of metrical feet (Ziegler, 2009). The model was built to estimate the likelihood that a word with a particular syllabic and metrical structure would be produced accurately by an apraxic speaker. It was fitted to a large sample of words for which accuracy data from 120 apraxic productions were available. The findings revealed a motor planning hierarchy that was consistent with phonological models of syllable constituency and metrical structure of German with, for instance, relatively strong bonds between nucleus and coda gestures compared with onset–rime gesture combinations or between syllable pairs forming a trochaic foot relative to nontrochaic combinations.

Analyses of apraxic speech errors demonstrate that the architecture of speech motor programs conforms to the phonological architecture of words, implying that speech motor control and linguistic structure are mutually interconnected. These findings are at odds with theories postulating a strict dualism of linguistic versus motor functions.

78.4 SENSORY-MOTOR ASPECTS OF SPEECH SOUND PRODUCTION IMPAIRMENT

The interaction between sensory and motor processing mechanisms has been a core issue in the understanding of the biology of language ever since the development of the Wernicke–Lichtheim model (Lichtheim, 1885). In that model, language production relies on the activation of information from sensory centers in which the *sound images* (German *Klangbilder*) of words are stored (Lichtheim, 1885, p. 211). This theory was derived from Wernicke's observation that lesions to auditory association centers in the left posterior superior temporal lobe not only caused auditory comprehension problems but also was associated with paraphasic language production. Later, Liepmann (1900) developed his influential theory that motor action (of the upper extremities) relies on a posterior-to-anterior stream of information located in the left hemisphere that conveys an *ideatory blueprint* (German: *ideatorischer Entwurf*) based primarily on sensory information (Liepmann, 1913, pp. 488–490). In modern accounts of speech production, these ideas are vested in computational models based on *auditory goals*—not

of words but rather of phonemes or syllables—that provide an acoustic reference frame for speaking (Guenther, Hampson, & Johnson, 1998). More recently, new techniques enabling online perturbations of somatosensory information during articulation have led to an extension of sensory-motor theories of speech production by including a proprioceptive feedback processing route (Tremblay, Shiller, & Ostry, 2003). Speech production models based on experimental data relating to auditory and somatosensory feedback processing have invoked the concept of *internal models* that guide motor action (Hickok, 2014; Tourville & Guenther, 2011). Parallel to these developments, a new research focus based on fiber-tracking methods has refined the connective anatomy related to Liepmann’s model of anterior-posterior information processing streams in language production (Dick & Tremblay, 2012; Rauschecker, 2012). Clinical data from patients with speech sound impairments have not yet had much influence on this research.

78.4.1 Auditory and Somatosensory Feedback and Speech Impairment

The role of *auditory* feedback in the genesis of speech impairment has been addressed in research focused on stuttering (Cai et al., 2012) and the effects on speech in those with hearing loss and cochlear implants (Perkell, 2012). Although this research is clearly relevant to the field, it is not considered further here.

Regarding the role of *somatosensory* afferent information in speech, only scarce clinical data exist because lesions causing a complete extinction of trigeminal somatosensory input are rare and the degree to which such information is still available cannot be assessed reliably enough by clinical methods. Duffy (2013) conjectures the existence of a “sensory dysarthria” syndrome resulting from impaired oral somatosensory processing that may lead to imprecise articulation that could reflect compensations for reduced sensory input through increased range of articulatory movement (e.g., exaggerated jaw movements). Hoole (1987) described a patient who, after a closed head trauma and whiplash injury, had experienced substantial sensory deficits in the oral-facial region as assessed by standard clinical methods. After initial severe dysarthria the patient’s speech recovered quickly, although his sensory deficits remained unresolved. Experimental investigations of isolated vowel articulation after motor speech recovery revealed reduced ability of this patient to compensate for proprioceptive perturbations with a biteblock, especially when auditory feedback was blocked by noise-masking. This result corroborates assumptions that somatosensory

processing supports adaptive mechanisms in speaking and that auditory and somatosensory processing can partially complement each other in this role (Perkell, 2012). Yet, clinical cases of this kind will always leave the possibility that residual sensory information that evades clinical physiological detection may still provide sufficient afferent information to support normal speech, at least when the lesion is acquired in adulthood.

78.4.2 Cerebellar Sensorimotor Integration Mechanisms in Speech Impairment

The cerebellum is classically considered as a site in the brain where sensorimotor integration takes place (Bhanpuri, Okamura, & Bastian, 2013). Ataxic dysarthria after cerebellar lesions might therefore be considered as a clinical model of impaired integration of proprioceptive and motor information in speech. However, most current theories conceptualize cerebellar dysarthria to result from impaired *feedforward* processing mechanisms (Spencer & Slocumb, 2007; Mariën, in Manto et al., 2012). Yet, for instance, the fact that Friedreich’s ataxia is primarily viewed as an afferent ataxic syndrome suggests that the dysarthric impairment observed in these patients may at least partly reflect an impairment of proprioceptive feedback processing in speech (Pandolfo, 2009).

The disturbance of sensory feedback mechanisms in ataxic patients becomes more apparent in paraspeech or nonspeech oral motor tasks that involve strong feedback integration capacities, such as sustained vowel production, visuomotor tracking, or rapid syllable repetition. Maintenance of a stable pitch and loudness level in sustained vowels is often disproportionately impaired in ataxic patients who often demonstrate fluctuating pitch or voice tremor during sustained phonation over several seconds, but not necessarily during speaking (Ackermann & Ziegler, 1991; Brendel et al., 2013). This may reflect a failure of correction mechanisms based on reafferent laryngeal proprioceptive or auditory information. Severely impaired adaptive sensorimotor mechanisms of patients with hereditary ataxias were also observed in a visuomotor tracking task requiring control of airflow velocity during expiration to track a ramp signal (Deger, Ziegler, & Wessel, 1999), but there was no correlation between the tracking and the speech impairment. Finally, in several studies patients with cerebellar pathology have had difficulty adapting to the specific demands of a task requiring repetition of a syllable (e.g., puh, tuh, kuh) at maximum speed (Brendel et al., 2013; Ziegler & Wessel, 1996), a task considered to rely strongly on sensory mechanisms for the selection of a

jaw angle that supports maximally rapid labial or lingual opening and closing movements. The patients had dramatically reduced acceleration ratios of syllable repetition relative to speaking rates (Ziegler, in Mariën et al., 2013). Taken together, these results point to vulnerability of patients with cerebellar lesions to motor demands requiring a strong reliance on sensorimotor adaptation mechanisms.

78.4.3 Striatal Mechanisms of Sensorimotor Integration in Speech Impairment

The motor functions of the basal ganglia are considered to rely, at least partly, on striatal and pallidal sensory processing mechanisms involved in kinaesthesia or somatosensory discrimination (Maschke, Gomez, Tuite, & Konczak, 2003). Altered sensory processing is thought to contribute to the motor deficits of patients with Parkinson's and Huntington's disease (Boecker et al., 1999), and a somatosensory disinhibition mechanism has been proposed to underlie dystonic motor impairment (Frasson et al., 2001). According to a hypothesis advanced by Yin (2014), the basal ganglia control movement velocity through kinaesthetic reafferent input.

It is not known if similar sensory mechanisms can also serve as an explanation for the speech motor patterns of patients with basal ganglia dysfunction. Patients with Parkinson's disease demonstrate consistent proprioceptive deficits in the oral region, but the relationship of these abnormalities to speech impairment is unclear (Schneider, Diamond, & Markham, 1986). In a recent report of two patients with oromandibular dystonia (Møller et al., 2013), evidence was found supporting abnormal sensorimotor integration or somatosensory dysfunction for afferent input from the oral region as an explanation for the motor impairment.

Other sensory processing functions of the basal ganglia relevant for speech relate to the self-perception of speech loudness. Ho, Bradshaw, and Iansek (2000) examined the hypothesis that reduced loudness (hypophonia) in Parkinson's disease is due to impaired motor scaling mechanisms based on patients' misperception of their own speech loudness. In an "immediate self-perception rating," Parkinson's patients overestimated their loudness relative to normal subjects, which the authors interpreted as an exaggeration of self-perceived effort during speaking. Likewise, the patients also overestimated their speech volume in a playback condition, even though they had spoken more quietly than controls. Ho et al. (2000) suggested that their findings provide support for the presence of sensory anomalies in Parkinson's disease, which may cause inappropriate scaling of loudness.

78.4.4 Sensorimotor Connectivity at the Cortical Level

As already discussed, recent functional neuroanatomic accounts of the dorsal stream system connecting posterior superior-temporal cortex with inferior-parietal and posterior-inferior frontal areas constitute a modern version of Liepmann's idea of a posterior-to-anterior stream of information governing motor actions through sensory-based goals (Saur et al., 2008). The cortical target areas of this system are interconnected by a massive fiber bundle, the superior longitudinal fascicle, which constitutes a circuit that includes auditory, somatosensory, and motor association areas. The dorsal pathway of the left (dominant) hemisphere is considered to be involved in higher sensorimotor integration by mapping acoustic speech sounds, and eventually also somatosensory representations, onto their corresponding articulatory actions. The prototype task targeting this system in functional imaging studies is the word repetition task (Saur et al., 2008), but more complex tasks involving phonological transformations of words have also been used (Kellmeyer et al., 2013).

Although a simplification, the anterior target area of the left dorsal stream approximately coincides with the lesion site reported for AOS. This could support an inference that the pathomechanism of AOS predominantly reflects damage to feedforward processing components of speech motor control while leaving sensory feedback mechanisms intact. This is compatible with clinical experience and some experimental evidence that patients with AOS have intact monitoring of their speech errors and preserved auditory speech processing. Jacks (2008) performed a bite-block experiment with apraxic speakers to test this feedforward hypothesis and found that AOS participants compensated for the biteblock perturbation in a manner similar to normal speakers. This normal adaptation to proprioceptive perturbation was taken as evidence of intact somatosensory feedback.

Historically, and in modern research, the dorsal pathway of the left hemisphere has been associated with aphasic phonological impairment. A long-standing hypothesis is that the phonemic paraphasias of patients with conduction aphasia result from a disconnection of the auditory from the motor representation areas of words (Geschwind, 1965). In conventional aphasiology, a strict boundary is drawn between aphasic phonological impairment as purely *abstract-symbolic*, and AOS as purely *motor* by nature. However, one may question whether such a clear-cut dichotomy is tenable, taking the aforementioned dorsal pathway hypothesis into consideration. As said, the dorsal pathway *inter-faces* motor with sensory information (Hickok, 2014; Rauschecker, 2012). This interface can be assumed to

act on a representational level, which is sufficiently abstract to make any additional assumptions about symbolic representations dispensable.

78.5 CONCLUSION

In this chapter we have characterized the nature of the speech motor system and its integration with sensory processes as a part of human linguistic behavior. Future theories and clinical models of motor speech disorders should consider, to a greater extent, the evidence consistent with such an account.

Acknowledgment

We are grateful to Joe Duffy for his valuable comments and suggestions regarding a former version of this manuscript.

The Neurobiology of Developmental Stuttering

Kate E. Watkins, Jennifer Chesters and Emily L. Connally

Department of Experimental Psychology, University of Oxford, Oxford, UK

79.1 INTRODUCTION

Dysfluency occurs when the normal flow and smooth delivery of speech are disrupted. Often, normal speech dysfluencies, such as silent pauses and nonlexical vocalizations (e.g., “uh” or “um”), can usefully add emphasis or draw attention to the content of upcoming utterances. In some people, however, speech dysfluencies are pathological and interfere with speech communication to such an extent that a fluency disorder is diagnosed. The most commonly diagnosed fluency disorder is *developmental stuttering*, which is distinguished from *acquired or neurogenic* stuttering that is associated with brain disease or injury. In this chapter, we describe the current state of our understanding of the neural basis of developmental stuttering. It is rare to be able to study a developmental disruption to a brain function such as speech that does not have consequences for other aspects of cognition. However, such specificity is the case for developmental stuttering. A better understanding of the neurobiological bases of stuttering will assist the development of novel and effective therapies. Furthermore, it will increase our understanding of the neural basis of normal speech production. Here, we first describe the key features of developmental stuttering. We then outline the evidence for the neurobiological differences between people who stutter and fluent speakers, and consider these differences in the context of a number of theories that attempt to explain stuttering.

79.2 DEVELOPMENTAL STUTTERING

Stuttering is a long-documented speech disorder that appears to exist in all languages and cultures.

Records of this type of halted or repetitious speech date back to the Old Testament; the speech of Moses and the Roman Emperor Claudius have been described as showing features of stuttering. A current definition describes stuttering as:

Speech that is characterized by frequent repetition or prolongation of sounds or syllables or words, or by frequent hesitations or pauses that disrupt the rhythmic flow of speech. It should be classified as a disorder only if its severity is such as to markedly disturb the fluency of speech. The International Classification of Diseases, Version 10 (World Health Organisation, 2010; <http://www.who.int/classifications/icd/en/>).

People who stutter produce utterances that are characterized by periods of normal fluency interspersed with occasions when speech is interrupted temporarily. On such occasions, the person knows what he/she wants to say but has difficulty moving forward in the speech sequence.

The moments of dysfluency experienced by a person who stutters are not randomly distributed in the speech stream. Dysfluencies tend to occur at the beginnings of words or sentences. An example of a sentence containing three types of dysfluency is shown in Figure 79.1. As can be seen from the spectrogram, the first word in the sentence is preceded by a tense pause indicating that speech is blocked. There is a low-amplitude band of acoustic energy visible in the spectrogram that would be heard as a “creaking” voice, but often these pauses are inaudible. The “l” sound before the successful production of the word “like” is prolonged, resulting in a longer band of higher-amplitude energy. Finally, the first sounds of the words “didn’t” and “like” are repeated and shown as brief bursts of energy.

It should be noted that the occasional dysfluencies of fluent speakers also typically occur in sentence or

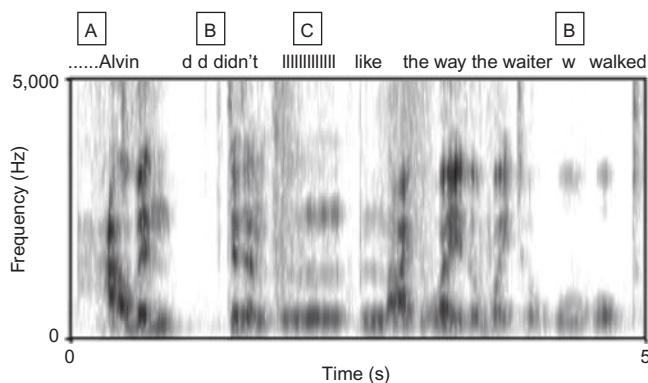

FIGURE 79.1 Sound spectrogram of a sentence spoken by a male who stutters. The sentence is transcribed above the spectrogram. Dysfluencies are indicated above the spectrogram by the letters (A–C). (A) Tense pause or “block”. (B) Repetition. (C) Prolongation. This visual representation of the sentence shows the variation in frequencies (*y*-axis) in the acoustic signal across time (*x*-axis), with the amplitude (loudness) of the signal indicated by the intensity of the grayscale.

word initial positions. The pattern of dysfluency in developmental stuttering suggests difficulty in the initiation of speech segments or in transition between segments. The characteristic repetition of speech sounds in stuttered speech may reflect repeated attempts to successfully transition to the next sound in the speech sequence. There are also linguistic and affective influences on stuttered speech. Children’s stuttering is increased if the planned speech utterance is syntactically complex or long (Zackheim & Conture, 2003). Speech fluency is also negatively affected by stress and fatigue in people who stutter, as it is for fluent speakers.

In addition to these core characteristics of disrupted speech in developmental stuttering, secondary behaviors are often evident. These may include increased or abnormal muscular tension in the face and neck and extraneous movements of the head or body when speaking. It is also common for people who stutter to avoid words or sounds that they find difficult to produce, or situations in which they are more likely to stutter (Bloodstein & Ratner, 2008). Anxiety is more commonly reported in people who stutter than in the general population, to the extent that some early theories suggested that “nervousness” or anxiety caused stuttering. However, arguments that a shy or nervous disposition may be a precursor to development of stuttering have now been debunked by prospective studies (Yairi & Ambrose, 2013). Furthermore, the strongest evidence to date is that social anxiety specifically, not anxiety in general, is related to stuttering (Iverach, Menzies, O’Brian, Packman, & Onslow, 2011). Because speech is fundamental to normal everyday functioning, it is not surprising that living with a speech

disorder can cause anxiety. As such, anxiety in social contexts would be a likely consequence of continual negative experience of speaking situations, as is often the case for someone who stutters.

Developmental stuttering typically starts early in childhood and affects approximately 1 in 20 children. It develops between the ages of 2 and 4 years, although onset later in childhood has often been described. The early age at which stuttering starts might reflect vulnerability in the speech motor system at approximately the time when language skills rapidly expand. The majority of children recover from stuttering during early childhood, with another half of the remainder recovering before puberty (Yairi & Ambrose, 2013). The disorder persists to adulthood in approximately 1%. A major challenge for researchers and clinicians is to determine factors that predict persistence or recovery in stuttering. One clear predictor of persistence in developmental stuttering is male gender. Approximately twice as many boys as girls stutter during early childhood. In adulthood, the ratio increases to approximately four or five males to one female who stutters. Genetic differences between males and females might confer greater or lesser mechanisms of plasticity or reorganizational capacity, which in turn would affect recovery and persistence.

79.3 ENHANCING FLUENCY IN PEOPLE WHO STUTTER

There is no “cure” for stuttering, but many therapeutic interventions have been designed to increase fluency. Early historic approaches included holding pebbles in the mouth, as practiced by Demosthenes, an orator of Ancient Greece. The more extreme practice of excision of parts of the tongue was popular in 18th century and 19th century France. Contemporary fluency therapies that directly target speech focus primarily on changing speech motor patterns. These may include slowing speech, producing gentle onsets to syllables, or producing continual voicing during speech.

It is well-known that the characteristic symptoms of stuttering are absent during singing. Fluency can be enhanced in people who stutter through a variety of other modes that involve changing the way speech is produced, including adopting a different accent or using an external stimulus such as a metronome or another speaker. Using a metronome to pace speaking (known as “syllable-timed speech”) was a popular method in stuttering therapy in the late 20th century. Choral speech (speaking in time with another person) is also very effective, perhaps because it also provides external timing cues, although hearing another speaker’s voice may also serve to mask that of the person

who stutters. It is likely that these different methods work to enhance fluency because they involve changing speech rhythm or prosody or both. People who stutter report that they are fluent when speaking to babies or to animals. This might be because these are contexts in which prosody is usually exaggerated. Altering the rhythm and stress patterns of speech involves moving from a habitual overlearned motor speech pattern to a novel one. This may engage distinct neural systems for the timing and sequencing of speech sounds.

Another way to increase fluency in people who stutter is to alter the sensory feedback of their own speech production. Simple masking to prevent auditory feedback of a stuttering speaker's voice is effective. Recording speech production and feeding it back with either a short (50 ms) delay or a shift in frequency can achieve complete or nearly complete fluency and also results in natural-sounding speech (Lincoln, Packman, & Onslow, 2006). The mechanism by which altered auditory feedback is effective in inducing fluency is not understood. Delayed auditory feedback can reduce speech rate and even induce dysfluency in otherwise fluent speakers (Lee, 1951). Frequency-shifted feedback, however, does not alter the rate of speech production but could "trick" the brain into thinking another person is speaking, producing an effect similar to choral speech. Devices to alter speech feedback in these ways have become commercially available and smartphone applications used to aid fluency are increasing in popularity. However, it can be cognitively demanding to use these devices, and there is evidence that the fluency enhancing effects may "wear off" over time. The effectiveness of altered auditory feedback in enhancing fluency suggests that the core deficit in developmental stuttering may be one of integrating sensory and motor information. Consistent with this hypothesis are findings that providing or changing visual feedback through a mirror and somatosensory feedback through vibro-tactile devices can also reduce stuttering (Snyder, Blanchet, Waddell, & Ivy, 2009; Snyder, Hough, Blanchet, Ivy, & Waddell, 2009).

Pharmacological interventions have been investigated to treat developmental stuttering. Medications that modulate dopamine can be effective, although there is considerable population heterogeneity with regard to the direction of dopamine regulation. A recent study trialed a partial GABA-A agonist (pagoclone) as a potential therapeutic agent in stuttering, but the results were not compelling (Maguire et al., 2010). Pharmacological approaches might benefit from genetic studies that could yield insights into the molecular basis of developmental stuttering. Drugs could also be effective if paired with therapy. New methods

to noninvasively stimulate the brain, such as transcranial direct current stimulation, have been identified as promising adjuncts for treating neurological conditions. Noninvasive brain stimulation has been applied to other communication disorders (predominantly aphasia due to stroke) along with speech therapy. It is an interesting possibility that this combination could also be used to enhance fluency in people who stutter.

79.4 GENETIC STUDIES OF DEVELOPMENTAL STUTTERING

There is strong evidence that developmental stuttering can be inherited. The risk of stuttering is considerably higher if a first-degree relative stutters (Kidd, Heimbuch, & Records, 1981). Twin studies show high heritability, with concordance rates in identical (monozygotic) twins being six-times greater than in fraternal (dizygotic) twins (Andrews, Morris-Yates, Howie, & Martin, 1991). Genetic models of the twin data estimate that 70% of the variance in liability to stuttering can be attributed to genetic effects, and 30% can be attributed to the nonshared environment (Andrews et al., 1991; Felsenfeld, 2002). Despite this evidence, the search for genes that may cause stuttering has been hampered by complex patterns of inheritance, early recovery, and the imbalance in the numbers of males and females affected.

Linkage analysis of large pedigrees with a high density of stuttering individuals has been used to identify several chromosomal regions where genes for stuttering might be located. Unfortunately, the outcomes of these studies rarely produced similar or overlapping loci. One study examined a very large pedigree from Cameroon containing 71 individuals, 33 of whom stuttered (Raza et al., 2013). Genome-wide linkage failed to identify a single locus; rather, analysis of smaller subfamilies indicated susceptibility for stuttering on previously identified loci on chromosomes 3q and 15q, as well as novel loci. This pattern of linkage to several loci and the high density of stuttering in this pedigree can be explained by nonrandom mate selection, which may have introduced variants of stuttering to the family.

Another approach for linkage analysis involves the study of inbred extended families and has yielded identification of the first causative genes for stuttering (Kang et al., 2010). Initially, significant linkage to chromosome 12q was identified in 44 families in Pakistan. Further analysis of this chromosomal region identified a missense mutation in the *GNPTAB* gene in 28 family members who stuttered. The same mutation was found in three members of other inbred families in Pakistan, and another nine unrelated individuals of

Pakistani or Indian origin. Subsequently, other mutations of the *GNPTAB* gene and related genes *GNPTG* or *NAGPA* were identified in approximately 10% of unrelated Pakistani and North American individuals who stutter. Mutations in these genes cause lysosomal storage disorders resulting in serious and severe disease. None of the affected individuals who stuttered had any disease normally related to mutations in this gene, and how their speech-specific impairment is explained by these findings is still unknown (Kang & Drayna, 2012).

Another potentially fruitful approach to identifying genes for stuttering is to look for *de novo* mutations in individuals with no family history of stuttering. The theory is that such people will have new, highly penetrant mutations that are causative. To our knowledge, this approach has not yet been implemented, but it is attractive because it does not require large sample sizes and thus may be more suitable in combination with further behavioral and imaging investigations.

79.5 THE NEURAL BASIS OF DEVELOPMENTAL STUTTERING

The advent of neuroimaging offered unprecedented research opportunities and insights into the neurobiology of developmental stuttering. There are no reports of *post mortem* examinations of the brains of people with persistent developmental stuttering that predate the imaging reports. Regardless of the lack of physical evidence for a neurological explanation of stuttering, hypotheses were widespread during the 19th and early 20th century. The link between left-handedness and stuttering and abnormal cerebral dominance was first proposed at this time. The relationship between diseases affecting the striatum, such as the *encephalitis lethargica* (which was epidemic in the 1920s), and speech disturbances, including stuttering, may have been the origin of theories implicating basal ganglia abnormalities as causes of developmental stuttering.

The earliest functional imaging studies of developmental stuttering used positron emission tomography (PET) to measure regional cerebral blood flow. More recent studies have used functional MRI to scan people who stutter. MRI has the advantage of being widely available, but it should be noted that whereas PET scans are silent, MRI is very noisy and therefore could affect feedback mechanisms and even enhance fluency. The functional imaging literature on developmental stuttering was summarized in 2005 by a meta-analysis of eight studies, six of which used PET and two used functional MRI (Brown, Ingham, Ingham, Laird, & Fox, 2005). The review identified three

“neural signatures” of stuttering: (i) overactivation of the right frontal operculum or anterior insula or both; (ii) overactivation of the cerebellar vermis; and (iii) an “absence” of activity in auditory cortex (Figure 79.2). The first of these neural signatures of stuttering—overactivation of the right hemisphere homologue of Broca’s area—is consistent with the proposal that stuttering is due to incomplete cerebral dominance for speech processing (Travis, 1978). The second and third neural signatures—abnormal cerebellar and auditory cortex activation—might reflect abnormalities in the brain’s ability to integrate the sensory consequences of the motor acts that produce speech. This deficit could be due to poor internal models, noisy feedback, or both (Max, Guenther, Gracco, Ghosh, & Wallace, 2004). The cerebellum is thought to play a critical role in integrating sensory afference and motor efference copy to build forward models that predict the consequences of motor acts (Wolpert, Miall, & Kawato, 1998). Under normal circumstances, the prediction signal (corollary discharge) produced by the internal model should match the sensory consequences (sensory reafference) of speech and should be utilized for purposes such as attenuating the activity in sensory cortex to self-generated signals. A fourth candidate neural signature of developmental stuttering, which was absent from the imaging meta-analysis, is abnormal basal ganglia activity (Figure 79.2). Basal ganglia dysfunction has been suspected to be related to stuttering for several decades due, in large part, to studies using dopamine blockers, such as haloperidol, to treat stuttering. The early imaging studies of dopamine, oxygen, and glucose metabolism in developmental stuttering supported this hypothesis (Wu et al., 1997). We discuss each of these theories of developmental stuttering in more detail and evaluate the degree to which they are supported by findings from brain imaging studies.

FIGURE 79.2 Brain abnormalities in people who stutter. (A) Overactive right inferior frontal cortex. (B) Underactive auditory cortex. (C) Overactive cerebellum. (D) Dysfunctional basal ganglia. X indicates reduced integrity of white matter tracts underlying left sensorimotor cortex.

79.5.1 Incomplete Cerebral Lateralization in Developmental Stuttering

The hypothesis that stuttering is caused by incomplete cerebral lateralization dates back to Samuel Orton, who made a similar proposal to explain reading disability. The proposal appears to be based on observations of stuttering emerging after enforced use of the right hand for writing in children who earlier showed a tendency for left-handedness. The idea was that the enforced use of the nondominant hand weakened the (presumably reversed) pattern of cerebral lateralization, producing conflict between the two hemispheres. Stuttering results, therefore, from incomplete lateralization of function between the two cerebral hemispheres. This theory fell out of favor with stuttering researchers until it received something of a revival when it found support from the results of early imaging studies (Pool, Devous, Freeman, Watson, & Finitzo, 1991; Wood, Stump, McKeehan, Sheldon, & Proctor, 1980). For example, one study of two young adults indicated right-lateralized blood flow in the homologue of Broca's area during stuttered speech, which reversed to become left-lateralized when fluency was induced using haloperidol medication (Wood et al., 1980). Subsequent imaging work used PET to measure regional cerebral blood flow during stuttered speech and while fluency was induced by chorus reading (Fox et al., 1996). Right-greater-than-left asymmetry of motor and auditory areas was observed during stuttered speech but was normalized when fluency was induced. In recent functional MRI studies, overactive right frontal opercular cortex extending to the anterior insula and the orbito-frontal surface is commonly described in adults who stutter (Kell et al., 2009; Watkins, Smith, Davis, & Howell, 2008). This rightward overactivity can be reduced if fluency is improved by therapy, however, resulting in more typical patterns of left-lateralized activity (De Nil, Kroll, Lafaille, & Houle, 2003; Kell et al., 2009; Preibisch et al., 2003).

Perhaps the best recent evidence supporting altered cerebral lateralization in stuttering comes from a study using near-infrared spectroscopy (Sato et al., 2011). Asymmetry in auditory processing was determined for speech that contained either a phonetic or a prosodic contrast. Adults and children who do not stutter show left-hemisphere lateralization for the phonemic contrast and right-hemisphere lateralization for the prosodic one. None of the adults and children who stutter showed the expected pattern of leftward lateralization, however.

It is unclear, however, whether the consistently observed right hemisphere overactivity and the reduced pattern of lateralization of function is a cause

of stuttering, a consequence, or merely a correlate. Activation of the right hemisphere homologue of Broca's area in some patients with nonfluent aphasia is known to be maladaptive. In stuttering, the right hemisphere activity could also be compensatory, reflecting reorganization of function in response to a left-hemisphere structural abnormality (Preibisch et al., 2003).

A reliable finding of a brain structural abnormality associated with developmental stuttering is a reduction in the integrity of the white matter underlying the sensorimotor cortex close to the Sylvian fissure in the left hemisphere (Figure 79.2). Fractional anisotropy, a measure of white matter microstructure, was first described as reduced in this area by Sommer and colleagues. They proposed it reflected a disconnection of the white matter tracts connecting the frontal and temporal cortical areas in the left hemisphere that are typically involved in speech (Buchel & Sommer, 2004; Sommer, Koch, Paulus, Weiller, & Buchel, 2002). Subsequent diffusion imaging studies in children who stutter, including a group who had recovered, and in adolescents and adults who stutter found a disruption to white matter integrity in the same region (Chang, Erickson, Ambrose, Hasegawa-Johnson, & Ludlow, 2008; Connally, Ward, Howell, & Watkins, 2013; Cykowski, Fox, Ingham, Ingham, & Robin, 2010; Watkins et al., 2008).

Another robust finding in structural imaging studies of white matter tracts in developmental stuttering is an abnormality of the corpus callosum (Choo, Chang, Zengin-Bolat kale, Ambrose, & Loucks, 2012; Choo et al., 2011; Connally et al., 2013; Cykowski et al., 2010). The integrity of interhemispheric connections is thought to be critical for integrating information across the two hemispheres and for functional lateralization and changes in cortical asymmetry.

Structural imaging studies in people who stutter have also reported reduced leftward asymmetry in the planum temporale, which is more rightward in those with severe stuttering (Foundas et al., 2004). However, it is possible that the inclusion of left-handed individuals and females influenced the findings of altered planum temporale asymmetry in stuttering. Two studies using only right-handed males found the typical leftward asymmetry of the planum temporale in adults and children who stutter compared with fluent controls (Chang et al., 2008; Cykowski et al., 2008).

Further structural analyses of cortical areas involved in speech and language have not noted any additional alteration in underlying asymmetries, for example, in Broca's area. However, they have described unusual sulcal patterns in the brains of people who stutter (Foundas, Bollich, Corey, Hurley, & Heilman, 2001).

An extra diagonal sulcus (a shallow indentation on the surface of the pars opercularis) and extra gyri along the upper bank of the Sylvian fissure have been described in both hemispheres of adults who stutter (Cykowski et al., 2008; Foundas et al., 2001).

In summary, although initially the reports of overactivity in the right hemisphere in developmental stuttering revealed by brain imaging seemed consistent with Orton's proposal of incomplete cerebral dominance, further studies are needed to elaborate on the precise nature of this activity. Brain stimulation techniques could be used to address questions relating to compensatory or maladaptive reorganization to the right hemisphere in response to left hemisphere damage. Furthermore, longitudinal analyses starting early in development are needed to chart the course of changes in lateralized brain function and brain structure in people who stutter.

79.5.2 Abnormal Sensorimotor Integration in Developmental Stuttering

Another of the neural signatures revealed by the meta-analysis of functional imaging studies in developmental stuttering was reduced or absent activation of the auditory cortex (Brown et al., 2005). The authors of the meta-analysis attributed this attenuation to increased inhibitory efference copy input from overactive motor areas. Such a mechanism is used to explain how we distinguish between sensory inputs that result from our own actions and external ones. During speech production, the sensitivity of a speaker's auditory cortex is altered in expectation of the sensory consequences of speech, which are predicted from motor commands sent to the articulators. Magnetoencephalography (MEG) can be used to measure changes in the sensitivity of auditory cortex to speech-evoked signals. These signals are suppressed when the participant speaks relative to when they listen to recordings of the same speech sounds (Houde, Nagarajan, Sekihara, & Merzenich, 2002). This speech-induced suppression has been measured in children and adults who stutter to test the hypothesis that stuttering is related to impairment in the efference copy mechanism. The size of the effect was not different in people who stutter compared with fluent-speaking controls, although there were abnormalities in the timing of the effect in the stuttering groups (Beal et al., 2010, 2011).

In addition to reduced activity in the auditory cortex, overactivity of the cerebellar vermis was noted as a neural signature of stuttering according to the meta-analysis described. The cerebellum is thought to be involved in using the efference copy of motor commands and sensory information about the current state of the periphery to predict the sensory consequences

of movement (Wolpert et al., 1998). Differences between the predicted outcomes and the intended ones are then used to adjust ongoing movements without the need for long latency feedback. Mismatches between the actual sensory consequences and the expected ones generated by the internal model are used to train and update the model. Such models have been developed to explain sensorimotor control in general and have focused primarily on visuo-motor control of the limbs. Models based on the same principles have been developed for speech motor control (Guenther & Vladusich, 2012; Hickok, Houde, & Rong, 2011). The overactivation of the cerebellum in stuttering is consistent with impairment in the internal model (Max et al., 2004). This could lead to excessive error detection when comparing the model's predictions with the actual sensory consequences. When therapy is successful in treating stuttering, the overactivity in the cerebellum, evident even at rest, normalizes to the levels seen in fluent speakers (Lu et al., 2012).

The cerebellum receives copies of motor commands conveyed directly from the primary motor cortex via the pons and the middle cerebellar peduncles and sensory inputs from the periphery via the inferior cerebellar peduncles. Signals from the cerebellum return to the cerebral cortex from the cerebellar nuclei via the superior cerebellar peduncles and the thalamus. In people who stutter, diffusion tensor imaging revealed abnormal white matter microstructure in each of the three pairs of cerebellar peduncles (Connally et al., 2013). Reduced integrity of these important tracts could affect the quality or timing of the cerebellar inputs and outputs in developmental stuttering.

It is worth considering, in the context of deficient internal models being a potential cause of stuttering, how the techniques known to temporarily enhance fluency might be effective. As noted in the introduction, these techniques change either the sensory feedback of speech or the way speech is produced, typically encouraging slower speech rate. Producing slower movements could be helpful if sensory inputs are noisy or delayed by allowing the relevant information to accumulate during speech production and online adjustments to be made. Slowing speech could also compensate for a weak or unstable model by allowing time for the actual sensory feedback to be used to inform the system of the consequences of speech rather than relying on the model's predictions. Altering auditory feedback or masking it with noise tends to activate the auditory cortex, which, as noted, is typically underactivated in people who stutter. Sensory input that is very obviously different from that expected could result in elimination of the feedback stage of internal modeling and minimize the error signals. This is presumably what happens when noise is used to

mask feedback and, as a result, fluency is enhanced in people who stutter. It is necessary to use feedback to build the internal model and maintain it, however. Delayed auditory feedback was shown to increase the degree to which the time courses of activity in the auditory and motor cortex (at the level of the representation of the face) were synchronized in people who stutter. MRI signals from these areas in people who stutter were less correlated during speech production with normal auditory feedback than they were during silent rest. When speaking with delayed auditory feedback, the correlation between the time courses of activity in these areas increased to the same levels as seen in control speakers (Watkins, 2011).

The idea that stuttering is caused by an impairment in internal modeling of speech movements and its sensory consequences has obvious appeal. So far, however, tests of this theory have not found measureable differences in the response of the auditory cortex to self-generated speech. Structural abnormalities in the auditory cortex and in the pathways that link auditory cortex and the motor speech areas in the frontal cortex (i.e., the arcuate fasciculus) have been described in people who stutter. White matter tracts conveying sensory and motor signals to and from the cerebellum, a key structure in integrating this information, also show reduced integrity in developmental stuttering (Connally et al., 2013). Whether these white matter abnormalities play a causal role in the disorder or are an effect of it remains unknown, however.

79.5.3 Abnormal Basal Ganglia Function in Developmental Stuttering

The evidence that developmental stuttering is caused by impairment in basal ganglia function or dopamine activity, or both, has been reviewed by Alm (2004). He proposed that the core impairment in stuttering related to a deficit in the basal ganglia output to the supplementary motor cortex, which disrupted the production of timing cues used to initiate the next speech sound in a sequence. Consistent with the idea that this circuit is functionally abnormal, imaging studies report overactivation of the supplementary motor area and several nuclei in the basal ganglia circuitry in people who stutter (Fox et al., 1996; Giraud et al., 2008; Watkins et al., 2008). Activity in these areas normalizes when fluency is induced temporarily in people who stutter or is improved by successful therapy (Fox et al., 1996; Giraud et al., 2008; Kell et al., 2009). Furthermore, a small group of males who stutter showed a three-fold increase in dopaminergic activity in the medial frontal cortex and caudate nucleus relative to controls (Wu et al., 1997).

Reports that drugs that block dopamine improve fluency in people who stutter are consistent with the notion that there is excessive dopaminergic activity in the disorder. Specifically, drugs that block D2 receptors can alleviate the symptoms of stuttering (Maguire, Yu, Franklin, & Riley, 2004). These receptors are found primarily on striatal neurons in the indirect pathway, which is involved in the inhibition of competing motor programs. Unfortunately, D2 antagonists also produce problematic side effects, meaning they are not well-tolerated as a treatment for stuttering. In some people who stutter, drugs that stimulate dopamine, either directly or indirectly, can also improve fluency, suggesting the possibility of different subtypes of the disorder (Alm, 2004). Similarly, reports of patients with Parkinson's disease who develop stuttering with disease onset (i.e., during dopamine depletion) or who worsen on dopamine replacement therapy indicate that the relationship between speech fluency and dopaminergic activity is not straightforward. As with other cognitive functions, dopamine levels appear to show an inverted U-shape relationship with speech fluency.

Interestingly, patients with Parkinson's disease also benefit from external cues to initiate and perform sequences of movements fluently. For example, gait can markedly improve with either auditory rhythmic (e.g., music with a strong beat) or visual structured (e.g., stripes on the floor) cues (Glickstein & Stein, 1991). This effect bears striking similarity to the known fluency enhancing effects of external cues such as a metronome in developmental stuttering. Alm (2004) proposes that external cues for speech initiation are effective in enhancing fluency in people who stutter because they engage a circuit comprising the cerebellum and lateral premotor cortex. The premotor-basal ganglia circuit is important for producing speech patterns that are overlearned motor sequences. Dysfunction in the basal ganglia loops could be compensated for by engaging the lateral premotor-cerebellar circuit to produce speech motor sequences in a novel way, such as with an accent or melody, or in time with an external cue.

Stuttering can be aggravated by deep brain stimulation of the subthalamic nucleus in patients with Parkinson's disease (Toft & Dietrichs, 2011) or by stimulating the globus pallidus or thalamus to relieve dystonia (Allert, Kelm, Blahak, Capelle, & Krauss, 2010; Nebel, Reese, Deuschl, Mehdorn, & Volkmann, 2009). The symptoms are reversible, however, and are relieved by turning off the stimulator. As with the pharmacological treatment studies, the opposite effects have also been obtained; stuttering can also be relieved by deep brain stimulation of the subthalamic nucleus in Parkinson's disease (Walker et al., 2009) and stimulation of the ventral intermediate nucleus of the

thalamus (the main cerebellar thalamic relay) in the case of essential tremor (Maguire et al., 2012).

Neurogenic stuttering can be acquired due to brain damage or disease and results in symptoms that are sometimes indistinguishable from the symptoms of developmental stuttering. Cases of neurogenic stuttering have been reported to be primarily due to left hemisphere cortical and subcortical areas. In a recent lesion-symptom mapping study, patients who acquired stuttering-like dysfluencies due to stroke were found to have damage to nine left-hemisphere areas. These areas overlapped a cortico-striatal-thalamo-cortical loop involving frontal and temporal lobe cortex, the basal ganglia, and the white matter tracts connecting them (Theys, De Nil, Thijs, van Wieringen, & Sunaert, 2013).

There is evidence from brain imaging, pharmacological, and lesion studies implicating abnormal function of the basal ganglia circuitry in stuttering. Previously described structural abnormalities such as the white matter abnormalities underlying sensorimotor cortex could affect cortico-striatal projections in developmental stuttering, and damage to these tracts can cause neurogenic stuttering. A recent neuro-computational model of stuttering proposed that either impaired cortico-striatal projections or dopaminergic hyperactivity could result in dysfluent syllable sequencing (Civier, Bullock, Max, & Guenther, 2013). Both of these abnormalities would affect function in cortico-striatal-thalamo-cortical loops and cause stuttering either independently or in concert. The evidence appears to suggest that stuttering can occur due to impairment in many different locations that each contribute to the function of basal ganglia circuitry. This might explain why imaging studies that rely on averaging data across subjects do not reliably produce evidence of functional abnormality in these nuclei. The possible relationship between different basal ganglia circuit abnormalities and stuttering subtypes remains an important challenge for future studies.

79.6 CONCLUSION

Neuroscientific investigation of developmental stuttering is providing useful information regarding possible causes. The first genes have been identified. Imaging studies reveal consistent patterns of structural and functional correlates of the communication disorder. These findings lend support to several different models of the neurobiological causes of developmental stuttering. Future studies will explore whether these different models can be reconciled or, in fact, reflect heterogeneity in the disorder due to different subtypes. Because stuttering is a developmental disorder, there is also a considerable

opportunity for compensatory and maladaptive reorganization that could further add to individual differences in the underlying brain abnormalities. Longitudinal investigations during development and therapy are needed to address outstanding questions relating to cause and effect.

Neuroplasticity Associated with Treated Aphasia Recovery

Julius Fridriksson and Kimberly Smith

The Aphasia Lab, Department of Communication Sciences and Disorders,
University of South Carolina, Columbia, SC, USA

Aphasia therapy typically refers to clinician administered behavioral approaches that use language-based drills or the learning of compensatory strategies to ameliorate the effects of impairment. Aphasia treatment is most often administered through didactic interactions between a patient and a clinician—a speech-language pathologist—who provides targeted language stimulation or task instructions focusing on a specific process or communication skill. Other increasingly common forms of treatment administration include group treatment or computerized language therapy. Although its effectiveness has been debated, recent meta-analyses suggest that aphasia treatment is generally beneficial, although much work is needed to better understand which treatment approach might work best for a specific patient (Brady, Kelly, Godwin, & Enderby, 2012; Kelly, Brady, & Enderby, 2010; Robey, 1998). That is, aphasia therapy promotes improved language function even though only a few therapy techniques have been established to tackle the different aspects of aphasic language impairment.

Regardless of treatment mode or maximum efficacy, it is an implicit assumption that treatment-assisted recovery from aphasia is supported by plastic brain changes, either functional or structural. Whether these changes are transient or permanent may determine the long-term effectiveness of aphasia treatment. The brain mechanisms that support aphasia recovery are not clear, and research in this area has yielded seemingly conflicting results (Saur & Hartwigsen, 2012; Saur et al., 2006; Szaflarski, Allendorfer, Banks, Vannest, & Holland, 2013). In this chapter, we address treated aphasia recovery in the context of contemporary understanding of neuroplasticity.

80.1 NEUROPLASTICITY

A paramount characteristic of the human brain, among other species, is its ability to continuously adapt its structure and function based on internal and external environmental changes. Typically, this ability is known as neuroplasticity. A generally accepted assumption of neuroplasticity states that to change behavior, the brain must also change. Considerable evidence suggests that structural changes to existing neural circuits or the generation of new circuits at the neuronal level underlie the behavioral changes associated with neuroplasticity (Cramer, 2008; Kolb & Whishaw, 1998). Dendritic morphology (i.e., dendritic form and structure) has been stressed as a critical contributor to these neuronal changes, whereas additional neuronal changes are likely contributory, such as number of synapses, synapse size, and metabolic activity. Neuroplasticity is made possible by coordinating changes of neuronal morphology, glia, and vascular and metabolic processes. These modifications are stimulated by several factors, including sensory-motor experiences, task learning, gonadal and stress hormones, psychoactive drugs, neurotrophic factors, cortical stimulation, aging, and diet (Cramer, 2008; Johansson, 2000; Kolb & Whishaw, 1998; Kleim & Jones, 2008; Rijntjes & Weiller, 2002). In broad terms, synaptic and dendritic changes allow the brain to be structurally and functionally plastic as a response to experiences during development, learning, recovery from injury, and aging (Hebb, 1949).

Typically, neuroplasticity has been considered in the context of behavioral stimulation and response to the external environment. Although it is straightforward to see why this is the case—much of what we know about

neural plasticity is derived from highly controlled animal studies with optimized experimental manipulations and carefully controlled environments—it is important to consider aphasia recovery in the context of potentially adaptive and maladaptive sequelae of recovery. Most cases of aphasia are caused by ischemic stroke in which the vascular supply to the cortex has been interrupted. Aphasia is often viewed as the consequence of frank brain damage to the cortical language network. However, John Hughlings Jackson, the eminent English physician who studied many forms of neurological disorders in the late 19th century, suggested that aphasic language impairment should be considered not only the direct behavioral result of the brain damage but also a reflection of the function of remaining brain tissue in the absence of cortical areas damaged by the stroke (Jackson, 1874).

The cortical reorganization and plastic changes after stroke probably occur to optimize function; however, the location and extent of injury dictate what kinds of recovery processes can be engaged and may influence whether cortical maladaptation occurs. In the case of maladaptation, it could be that plastic changes in response to cortical damage actually hinder recovery or promote suboptimal reorganization in the early phases after stroke. Moreover, it is possible that early training (e.g., aphasia therapy) may actually negatively affect long-term recovery. Adverse consequences of acute rehabilitation have been demonstrated in a mouse model after motor stroke (Allred & Jones, 2008) in which early training of the spared forelimb had a negative effect on long-term improvement of the affected limb. Whether the same principle could be attributed to early aphasia treatment is questionable, yet this study demonstrates that we know very little about the effects—positive or negative—of plastic brain changes on recovery, and we also do not know the optimal timing for initiation of aphasia treatment. Several studies have suggested that neuroplasticity is greatest soon after brain damage, with lesser changes seen over time (Hartman, 1981; Kim, Ko, Parrish, & Kim, 2002; Robey, 1998). This could mean that targeted treatment seeking to capitalize on these changes should be dispensed as early as possible after aphasia onset. Clearly, there is an urgent need for a better understanding of the capacity for adaptive neuroplasticity as a consequence of initial brain damage and subsequent aphasia treatment, as well as the risk of maladaptive neuroplasticity that could stifle spontaneous and treated recovery.

80.2 ACUTE AND CHRONIC CONSIDERATIONS

In some cases of acute stroke, the recovery from aphasia can be very substantial in the first few hours

and days after onset. As demonstrated by Hillis et al. (2001), Hillis and Heidler (2002), and Hillis et al. (2004), some of this recovery is supported by vascular changes leading to reperfusion of the ischemic penumbra and critical language areas. For patients who make it to the hospital within 4.5 hours of ischemic stroke onset and who are candidates for thrombolysis with tissue plasminogen activator (tPA), the effects of stroke may be partially ameliorated by dissolving the blood clot that caused the stroke. For some of these patients, the return of language function can be quite dramatic and, in some cases, complete (Felberg et al., 2002; Maas et al., 2012; Saur et al., 2006). However, thrombolysis is administered in approximately 10% of cases (Bray et al., 2013; Minnerup et al., 2011; Monks, Pitt, Stein, & James, 2012), which means that many stroke patients do not benefit from early intervention and may ultimately face a life-altering injury to which they must adapt.

Immediate efforts to dissolve or remove the blood clot in acute ischemic stroke are crucial for the preservation of as much neural tissue as possible and to prevent subsequent negative effects on behavior. However, neuroplasticity that occurs after cell death is completed probably takes place over weeks, months, and even years (Cramer, 2008; Johansson, 2000; Kleim & Jones, 2008). Although some of these plastic changes may occur in response to inherent homeostatic factors, it is likely that neuroplasticity supporting aphasia recovery primarily occurs in subacute (e.g., during the first 90 days after onset) and chronic phases of stroke recovery. That is, very early recovery from aphasia may be driven in part by neurovascular changes, whereas later recovery appears to rely more on actual neuroplasticity and, possibly, angiogenesis (the formation of new blood vessels from preexisting ones) (Carmichael, 2008; Cramer, 2008; Wei, Erinjeri, Rovainen, & Woolsey, 2001) as well as neurogenesis (the formation of new neurons) (Carmichael, 2008; Johansson, 2000). At this time, far more work is needed to determine whether and to what extent angiogenesis and neurogenesis play roles in aphasia recovery.

In chronic aphasia, recovery is mediated by relearning lost information, retraining specific processes that were impaired as a result of brain damage, learning compensatory strategies that aid in communication, and psychosocial adaptations such as those afforded by environmental enrichments and increased access to appropriate social environments (Turkstra, Holland, & Bays, 2003). Regardless of the kinds of behavior modifications that take place, neuroplasticity is at the crux of mediating and supporting such changes. Specific patterns of neuroplasticity that support aphasia recovery are being explored and considerable research has been devoted to this issue (Crosson et al., 2005, 2009;

Fridriksson, 2010; Fridriksson et al., 2012; Fridriksson, Morrow-Odom, Moser, Fridriksson, & Baylis, 2006; Heiss, Kessler, Thiel, Ghaemi, & Karbe, 1999; Heiss & Thiel, 2006; Heiss, Thiel, Kessler, & Herholz, 2003; Hillis et al., 2001, 2004; Hillis & Heidler, 2002; Kim et al., 2002; Marcotte et al., 2012; Meinzer & Breitenstein, 2008; Meinzer et al., 2004; Meinzer, Streiftau, & Rockstroh, 2007; Menke et al., 2009; Musso et al., 1999; Postman-Caucheteux et al., 2010; Saur & Hartwigsen, 2012; Saur et al., 2006; Schlaug, Marchina, & Norton, 2009; Szaflarski et al., 2013; Thompson, 2000a, 2000b; Thompson, den Ouden, Bonakdarpour, Garibaldi, & Parrish, 2010).

80.3 STRUCTURAL BRAIN CHANGES AND APHASIA RECOVERY

A few studies have examined structural brain changes associated with aphasia recovery. Probably the first, and perhaps best, known study of this kind was conducted by Schlaug and colleagues (2009), who treated six aphasic patients using Melodic Intonation Therapy (MIT) (Albert, Sparks, & Helm, 1973; Helm-Estabrooks, Nicholas, & Morgan, 1989), a treatment approach that targets nonfluent speech production and emphasizes the patient imitating intoned speech modeled by a clinician. The main idea behind MIT is that it targets activation of the right hemisphere, where melody is thought to be processed (Albert et al., 1973; Conklyn, Novak, Boissy, Bethoux, & Chemali, 2012; Helm-Estabrooks et al., 1989; Norton, Zipse, Marchina, & Schlaug, 2009; van der Meulen, van de Sandt-Koenderman, & Ribbers, 2012; Schlaug et al., 2009). Diffusion tensor imaging (DTI) was used to assess changes in white matter density in the right hemisphere before and after a therapy program consisting of 75 MIT sessions. In summary, this study revealed an increase in volume and number of fibers in the right arcuate fasciculus, suggesting that structural connectivity was increased as a result of aphasia treatment. A case study of a 12-year-old patient with a large left hemisphere lesion and severely nonfluent speech yielded similar results (Zipse, Norton, Marchina, & Schlaug, 2012). That patient underwent 120 hours of treatment using MIT, and DTI was used to assess white matter changes in the right hemisphere. Increased volume was found at the mid-point of the treatment phase and at 1 year after treatment in the right arcuate fasciculus and the uncinate fasciculus, a white matter tract that, in the left hemisphere, is commonly associated with semantic processing (Catani et al., 2013; Harvey, Wei, Ellmore, Cris Hamilton, & Schnur, 2013). Intriguingly, these studies suggest that the type and location of neuroplastic changes associated

with treated aphasia recovery might be dependent on the type of treatment. That is, treatments that involve processes that are supported by the right hemisphere (e.g., intonation) are more likely to yield plastic changes in the right hemisphere, whereas approaches that focus more on language processes (which primarily tax the left hemisphere in neurologically intact subjects) may be more likely to recruit preserved areas of the injured left hemisphere.

In another study that specifically examined structural brain changes with DTI, Allendorfer et al. (2012) used intermittent theta burst transcranial magnetic stimulation (iTBS) to target preserved anterior left hemisphere regions in eight patients with different types of chronic aphasia. Although the specific mechanism is unknown, iTBS has been shown to enhance motor-evoked potentials, suggesting that it has excitatory effects on neural tissue. All patients underwent 10 iTBS sessions (without behavioral language treatment), after which increased fractional anisotropy (FA) was found in the targeted regions, including left inferior and superior frontal gyri, as well as in the right midbrain and several bilateral regions such as the temporal and parietal cortices. With regard to language changes, improvements were found on a semantic fluency test but not on the Boston Naming Test (Kaplan, Goodglass, & Weintraub, 2001) or the Peabody Picture Vocabulary Test (Dunn & Dunn, 2007). Importantly, no relationship was revealed between the extent of FA changes and language improvement. Nevertheless, studies of this kind suggest that treatment of aphasic patients, using either behavioral language treatment or transcranial cortical stimulation, can change the structure of the brain. However, it is far too early to postulate what might be the specific patterns of structural brain changes that support aphasia recovery. More research including a larger number of patients, detailed descriptions of language ability, and consistent methods across studies is needed to better understand structural neuroplasticity in aphasia recovery.

80.4 FUNCTIONAL BRAIN CHANGES AND APHASIA RECOVERY

Compared with studies of structural neuroplasticity, far more research has focused on functional brain changes associated with spontaneous and treated recovery from aphasia. One of the challenges of understanding how functional brain changes support aphasia recovery is that many different approaches, methods, and behavioral tasks have been used to relate cortical modulation to behavioral changes. This can be expected because of the many types and varying

severity levels of aphasia. Future investigations cannot ignore these differences because each may contribute uniquely to plasticity.

It is also a concern that most studies of functional brain changes associated with aphasia treatment have relied on single case studies or very small sample sizes. This is because of the extensive variability that characterizes both the language behaviors and the associated patterns of brain tissue either spared or destroyed by stroke and other causes of aphasia. A case study by Epstein-Peterson, Vasconcellos Faria, Mori, Hillis, and Tsapkini (2012) demonstrates this point well. Their patient had a large left hemisphere stroke affecting most of the structures supplied by the middle cerebral artery, including areas that typically are thought to be crucial for normal language processing (Broca's area and most of the middle and superior temporal lobe). Despite this severe injury to the left hemisphere, the patient had a relatively mild language impairment characterized mostly by somewhat restricted speech fluency, relatively spared auditory comprehension of canonical sentences, and only very limited anomia. Although the patient was diagnosed with global aphasia (or severe impairment in all language modalities) immediately after stroke, testing at the time of study inclusion (3 years after stroke) indicated fairly mild aphasia. This case is unusual in that most patients with similar damage continue to present with more severe aphasia during the chronic phase, most typically consistent with Broca's or even global aphasia (Fridriksson, Fillmore, Guo, & Rorden, 2014; Fridriksson et al., 2012). However, such rarities clearly do exist and remain unexplained. Such mild language impairment after extensive left hemisphere damage likely demonstrates premorbid differences in language organization and unique behavioral characteristics. The presence of such patients also demonstrates extensive variability in the process(es) by which recovery from severe brain damage can be achieved. Finally, and not insignificantly, it must be remembered that environmental manipulations, in many guises ranging from the quality, extent, and intensity of treatment to the amount and type of external personal support, also play a role. At the very least, this case and others like it (Berthier, 2001; Heilman, Rothi, McFarling, & Rottmann, 1981; Pulvermüller & Schönle, 1993) demonstrate the current difficulty and uncertainty of ascribing language recovery to a single process or to specific changes in functional or structural neuroplasticity.

As stated, many different methods have been used to investigate changes in functional activation associated with aphasia treatment. These include functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), positron emission tomography (PET),

and transcranial cortical stimulation. Two patterns of functional brain activation have been described to support language recovery in aphasia: (i) functional reactivation, which suggests greater reliance on preserved language areas, including cortex immediately adjacent to the lesion (Cappa, 2000; Heiss et al., 2003); and (ii) functional reorganization, which refers to activation of nontraditional language areas, either residual left hemisphere structures or right hemisphere homologues (Marcotte et al., 2012). Several studies have provided evidence that supports a more favorable outcome when left hemisphere perilesional areas are recruited (Fridriksson, 2010; Fridriksson et al., 2009; Fridriksson, Richardson, Fillmore, & Cai, 2012; Postman-Caucheteux et al., 2010; Warburton, Price, Swinburn, & Wise, 1999) and, in fact, show detrimental outcomes when right hemisphere regions are recruited (Naeser et al., 2005), whereas others report better outcomes associated with right hemisphere modulation (Crosson et al., 2005; Leff et al., 2002; Musso et al., 1999; Peck et al., 2004). There is also evidence that suggests aphasia recovery is supported by bilateral hemispheric recruitment (Belin et al., 1996; Fridriksson et al., 2006, 2007; Thulborn, Gindin, Davis, & Erb, 1999; Weiller et al., 1995). Saur and colleagues (2006) discussed a plausible explanation for these seemingly incompatible findings in detail, suggesting three phases of language recovery where neural recruitment transitions: weak activation of intact left hemisphere regions in the early acute phase; strong activation of the entire language network—but especially right hemisphere regions—in the subacute phase; and, finally, normalization of activation as peak cortical recruitment returns to the left hemisphere during the chronic phase of recovery. In this study, language recovery systematically improved at each phase of recovery. Thus, there seem to be implications of different patterns of recovery that are potentially adaptive at different times.

Based on the evidence discussed, there is support for functional brain changes associated with both spontaneous and treatment-induced recovery of language in patients with aphasia. Many studies over the past several years have documented recovery in both scenarios, although fewer have looked exclusively at spontaneous recovery during the first few weeks after stroke. Despite the limited research, the studies seem to support a hierarchical model of language recovery during the acute and subacute stages, because dramatic improvements in language function are demonstrated within the first 2 weeks up to a few months after onset (Fernandez et al., 2004; Heiss et al., 1999; Karbe, Herholz, Halber, & Heiss, 1998; Pedersen, Stig Jørgensen, Nakayama, Raaschou, & Olsen, 1995; Saur et al., 2006). These improvements may be accounted

for by diaschisis resolution and strong bilateral activation (Saur & Hartwigsen, 2012). Most patients recruited for these studies received speech-language therapy as part of standard poststroke care, although the details of the implemented therapies were not reported; therefore, it is nearly impossible to identify the functional outcomes that occur purely as a result of spontaneous recovery as opposed to being driven by aphasia treatment.

In contrast, an increasing number of studies have assessed treatment-induced neural plasticity. Treatment approaches associated with neural plastic changes have focused on anomia training (Crosson et al., 2007, 2005, 2009; Fridriksson, 2010; Leger et al., 2002; Menke et al., 2009), semantic feature analysis (Marcotte et al., 2012), auditory comprehension (Musso et al., 1999), and sentence processing (Thompson et al., 2010), and changing activation patterns are most commonly assessed using fMRI. Meinzer and Breitenstein (2008) completed a review of 13 fMRI studies that implemented intervention paradigms to investigate language recovery in patients with chronic aphasia and reported that most studies found treatment-induced neural changes in both hemispheres. Because these findings were predominantly based on word retrieval interventions and not other aspects of impaired language, and because there were only three studies with more than 10 patients in the sample, we must interpret these findings with caution.

MEG, EEG, and PET studies have also documented treatment-based functional brain changes. MEG was used to assess treatment-induced plasticity after constraint-induced language treatment (CILT) (Breier et al., 2009; Meinzer et al., 2004). Results suggest that although the right hemisphere may support language recovery immediately after treatment, recruitment of perilesional regions is fundamental for prolonged, stable effects. This assumption holds true for the majority of studies described, and it supports the premise that treatment-induced changes occurring during the chronic stage of recovery may be attributed to the application of model-based therapies compared with generalized stimulation techniques applied during the acute stage of recovery (Saur & Hartwigsen, 2012).

Further, to optimize neural plasticity post-injury, new approaches to enhance treatment-induced recovery have been explored. Brain stimulation, a class of techniques that modifies cortical excitability, has been coupled with traditional speech-language therapy with the goal of facilitating increased learning and treatment outcomes, either by suppressing or by exciting targeted cortical regions. For example, Baker, Rorden, and Fridriksson (2010) found improved naming outcomes when anomia training was paired with anodal transcranial direct cortical stimulation (atDCS). Similarly, Meinzer and

colleagues (2007) paired repetitive transcranial magnetic stimulation (rTMS) with CILT in two patients with aphasia and reported that both patients demonstrated improved outcomes when CILT was paired with rTMS compared with receiving rTMS in isolation.

In summary, the current evidence is encouraging yet nascent. Given the heterogeneity and small sample size, and given the variability in treatment approaches, more controlled group studies are required to confirm the present findings for both spontaneous and treatment-induced recovery. Despite variability in the current literature, as a whole, the implication is that the neural reorganization that occurs during spontaneous recovery is the same as therapy-induced reorganization, which takes place in the bilateral temporo-frontal network (Saur & Hartwigsen, 2012). Future work is necessary to further inform our knowledge of functional language recovery and to contribute to improved treatment efficacy for individuals with aphasia.

81.1 THE IMPACT OF NONFLUENT APHASIA

Of the estimated 750,000–800,000 new strokes occurring in the United States each year, approximately 25–50% present with some form of aphasia, as estimated based on studies performed in other countries (Engelter, Gostynski, Papa, Frei, & Born, 2006; Pedersen, Jorgensen, Nakayama, Raaschou, & Olsen, 1995; Pedersen, Vinter, & Olsen, 2004). Approximately 40% of these acute patients were available for follow-up at 1 year (attrition was due to death or other inability to participate in trial). Approximately two-thirds of these 40% of patients from the original cohort showed abnormal scores on aphasia testing, with approximately one-quarter of them being in the severe, nonfluent category (Kertesz & McCabe, 1977; Pedersen et al., 1995, 2004; Wade, Hewer, David, & Enderby, 1986). In right-handed individuals, nonfluent aphasia generally results from lesions in the left frontal lobe, including the portion of the left frontal lobe known as Broca's region. Named after Paul Broca (1961), who first linked this area of the brain with nonfluent aphasia, this region is thought to consist of the posterior inferior frontal gyrus (IFG) encompassing Brodmann's areas 44 and 45. However, subsequent reports have shown that different lesion locations and larger lesion volumes involving not only the inferior and middle frontal gyrus but also the inferior peri-rolandic regions and subcortical brain structures can have a clinical presentation similar to that of Broca's aphasia (Kertesz, Lesk, & McCabe, 1977). Recent research has shown that the location of the lesions in relation to the arcuate fasciculus (AF), a white matter tract connecting frontal and temporal brain regions, is a strong predictor of fluency impairment (Fridriksson, Guo, Fillmore, Holland, & Rorden, 2013; Marchina et al., 2011; Wang,

Marchina, Norton, Wan, & Schlaug, 2013). The AF lesion load (AF-LL) might serve as a biomarker for fluency impairment in chronic aphasic patients (Figure 81.1). The AF-LL can also be used to predict fluency outcomes in patients with acute aphasia and to stratify patients (by AF-LL) for experimental studies.

Patients with large left hemispheric lesions or a high AF-LL resulting in severe nonfluent aphasia typically do not show good natural recovery from such an insult, nor do they appear to be as responsive to nonintonation-based speech therapy as patients with smaller lesions or other types of aphasia. Although there is no generally agreed on definition of nonfluent aphasia, for the purpose of this chapter nonfluency is defined as having less than 10 correct information units (CIUs) per minute in propositional speech assessments.

There are also no universally accepted methods or "gold standards" for the treatment or treatment outcomes of severe nonfluent aphasia against which new or existing interventions could be compared, nor have any criteria been established for measuring meaningful treatment efficacy. Nevertheless, most therapists, clinicians, and researchers in the field of aphasiology would probably agree that treatment could be considered effective if patients show improvements in speech output that generalizes to untrained language structures and/or contexts (Thompson & Shapiro, 2007) and not just an improvement in items that were practiced with the patient. Although a meta-analysis by Robey (1998) determined that an array of treatment methods for all kinds of aphasic syndromes is, on average, beneficial, treatment effect sizes have varied widely (Moss & Nicholas, 2006; Robey, 1998). Furthermore, a meta-analysis by Bhogal, Teasell, and Speechley (2003) concluded that aphasia treatments are more likely to achieve positive results if the total

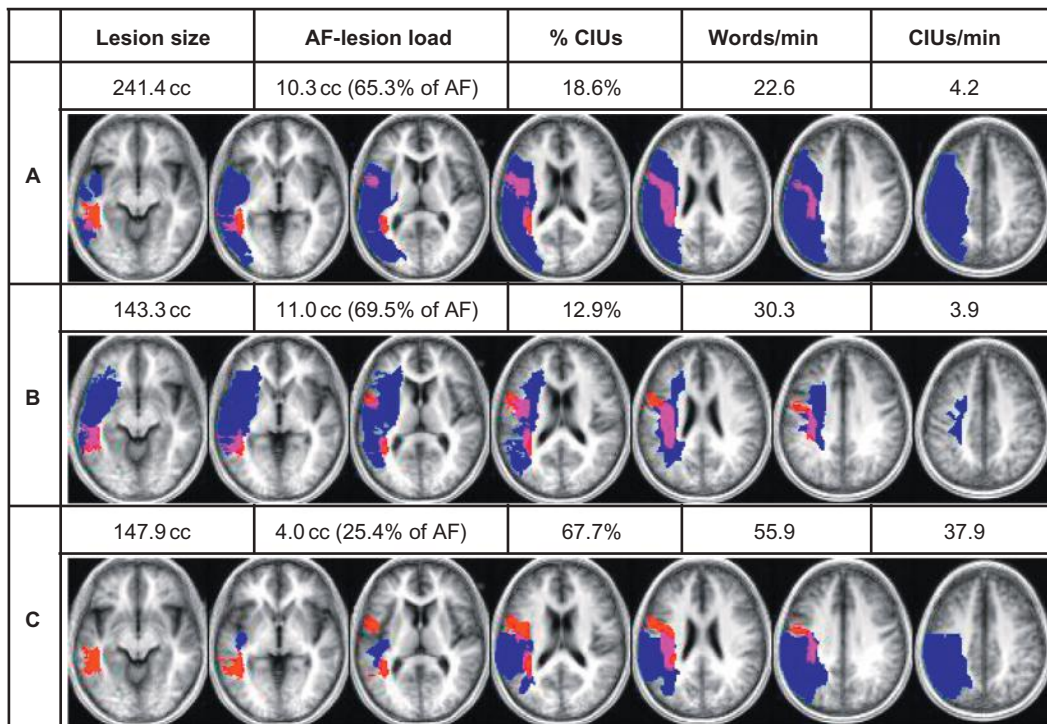

FIGURE 81.1 AF-LL and fluency. Examples (A–C) of behavioral scores, lesion sizes, and AF-LLs of three patients, as well as their individual lesion maps (depicted in blue) overlaid onto the probabilistic AF map (depicted in red). Overlap between lesion and AF is displayed in purple. The axial slices depicted correspond to $z = -10, -2, 8, 18, 26, 34,$ and 42 in Talairach space. Comparison of patients A and B shows how two patients can display comparable AF-LLs and behavioral scores despite drastically different overall lesion volumes. Similarly, comparison of patients B and C shows how a similar lesion size can produce two markedly different AF-LLs and, accordingly, result in very different levels of impairment.

amount of therapy exceeds 55 h, emphasizing the importance of intensity and duration of the treatment applied.

81.2 THE BASIS AND COMPONENTS OF INTONATION-BASED SPEECH THERAPY FOR PATIENTS WITH NONFLUENT APHASIA

Melodic Intonation Therapy (MIT) is an intonation-based treatment method for nonfluent or dysfluent patients with aphasia that was developed in response to the observation that severely aphasic patients can often produce well-articulated, linguistically accurate words while singing but not during speech (Gerstman, 1964; Geschwind, 1971; Hebert, Racette, Gagnon, & Peretz, 2003; Keith & Aronson, 1975; Kinsella, Prior, & Murray, 1988; Yamadori, Osumi, Masuhara, & Okubo, 1977). MIT is a hierarchically structured treatment that uses intoned (sung) patterns that exaggerate the normal melodic content of speech across three levels of increasing difficulty. These different levels (Elementary Level, Intermediate Level, Advanced Level) are characterized

by an increase in the length of the phrase, an increase in the speed of production, and a decrease in the level of support provided by the therapist. The intonation works by translating prosodic speech patterns (spoken phrases) into melodically intoned patterns using just two pitches. The higher pitch represents the syllables that would naturally be stressed (accented) during speech. At the simplest level, patients learn to intone (sing) a series of two-syllable words/phrases (e.g., “Water,” “Ice cream,” “Bathroom”) or simple two- or three-syllable social phrases (e.g., “Thank you,” “I love you”). As each level is mastered, patients move to the next, and phrases gradually increase in length (e.g., “I am thirsty,” “A cup of coffee, please”). Beyond the increased phrase length, the primary differences between the three levels of MIT lie in the way the treatment is administered and the level of support that is provided by the therapist. More details regarding the intervention and the differences between the three levels can be found elsewhere (Norton, Zipse, Marchina, and Schlaug, 2009).

Compared with nonintonation-based speech therapies, MIT contains two unique components: (i) the melodic intonation (singing) with its inherent continuous

voicing and (ii) the rhythmic tapping of each syllable (using the patient's left hand) while phrases are intoned and repeated. The relative contribution of either intonation (pitch) or rhythm in a therapeutic context has not been examined in any study, mostly because it would be difficult to power such a longitudinal study considering the similarities between the melodic intonation, which is typically done at one syllable per second using stressed and unstressed syllables, and the rhythmic tapping with the unaffected hand, which is also done at one tap per second. Furthermore, melodic intonation and rhythmic tapping might have an additive effect and, ultimately, rhythm-based or melody-/pitch-based intervention would have to be compared with a combined intervention. Although the melodic intonation and the rhythmic tapping have been recognized as the unique features of MIT, there are other aspects of the MIT method that might be of equal importance. MIT has been introduced as an intensive treatment program that requires a commitment of up to 1.5 h/day, 5 days/week over a period of several months (as recommended by the developers of MIT) (Helm-Estabrooks, Nicholas, & Morgan, 1989), resulting in at least 75 treatment sessions until the patient has mastered all three levels of MIT. In addition to the intensity of the therapy, the slow rate of vocalization (one syllable per second) and an administration protocol that includes one-on-one sessions with a therapist who introduces and practices words/phrases using picture cues while giving continuous feedback to the patient make MIT stand out among particular intervention programs that have been described with such elaborate details within the speech therapy literature. All of these features mentioned (some of them are shared between MIT and other speech therapies) must be carefully considered when the efficacy of MIT is tested against a control intervention (Schlaug, Marchina, & Norton, 2008).

81.3 EXPERIENCES WITH THE APPLICATION OF MIT

Because the initial account of its successful use with three chronic, nonfluent (Broca's) aphasic patients (Albert, Sparks, & Helm, 1973), reports have outlined a comprehensive program of MIT (Helm-Estabrooks & Albert, 1991; Helm-Estabrooks et al., 1989; Norton et al., 2009; Sparks & Holland, 1976) including strict patient selection criteria (Helm-Estabrooks et al., 1989) and data that showed significant improvement on the Boston Diagnostic Aphasia Examination (BDAE) (Goodglass & Kaplan, 1983) after treatment (Bonakdarpour, Eftekhazadeh, & Ashayeri, 2000; Sparks, Helm, & Albert, 1974). In a case study

comparing MIT to nonintonation-based control therapy (Wilson, Parsons, & Reutens, 2006), the authors found that MIT had a general facilitating effect on articulation and a longer-term effect on phrase production that they attributed specifically to its melodic component. However, the outcomes of that study were measured by the patient's ability to produce practiced phrases prompted by the therapist rather than by the transfer of language skills to untrained structures and/or contexts. In one of our own studies (Schlaug et al., 2008), we compared two patients with similar speech output impairments and similar lesion size and location that completed MIT or a control intervention also geared toward enhancing verbal output termed Speech-Repetition-Therapy (SRT). After treatment, both interventions yielded significant improvements in propositional speech that generalized to nonpracticed words and phrases; importantly, the MIT-treated patient's gains surpassed those of the control-treated patient. Another case series of six patients treated with MIT (Schlaug, Marchina, & Norton, 2009) showed a more than 200% improvement in propositional speech, measured as CIUs. In a comparison between after therapy and before therapy, the behavioral improvement was highly significant compared with baseline variations in repeated test assessments. The change in CIUs showed a strong trend for a correlation ($P = 0.08$) with the change in the size of the right AF, a fiber bundle connecting temporal and frontal brain regions (Schlaug, Marchina, et al., 2009).

van der Meulen, van de Sandt-Koenderman, Heijenbrok-Kal, Visch-Brink, and Ribbers (2014) recently conducted the first randomized controlled trial (RCT) examining the efficacy of MIT with regard to language production in subacute patients with nonfluent aphasia contrasting MIT against a wait-list control in which patients were focused on writing, language comprehension, and nonverbal communication strategies, but not on spoken output. Considering that this RCT might have been underpowered, the observed findings are still very encouraging in that the MIT-treated group did significantly better in repetition tests of trained items than the control group. Strong nonsignificant trends in the group comparisons were found in a test measuring verbal communication in daily life.

The main differences in these single cases and case series (Bonakdarpour et al., 2000; Schlaug et al., 2008; Sparks et al., 1974; Wan, Zheng, Marchina, Norton, & Schlaug, 2014; Wilson et al., 2006) and randomized trials (van der Meulen et al., 2014) are whether the studies adhere to the original description of MIT. Variations in the MIT technique can include differences in the intonation pattern and rhythmic tapping with the unimpaired hand, the intensity and total

amount of treatment sessions as well as the type of control intervention with which MIT is compared, and the outcome variables that assess whether there is not only an improvement in treated words/phrases but also transfer to untreated items or improvements in propositional speech.

MIT has also been examined in combination with other recovery-enhancing interventions. In a cross-over design, [Vines, Norton, and Schlaug \(2011\)](#) combined MIT with simultaneous noninvasive anodal transcranial direct current stimulation (tDCS) in six patients with severe nonfluent aphasia to increase excitability in the right posterior frontal region. Significant effects in fluency were seen after only three sessions compared with MIT simultaneously applied with sham stimulation. [Al-Janabi et al. \(2014\)](#) used three treatment sessions of intermittent theta-burst stimulation with transcranial magnetic stimulation (TMS), which increases excitability in the underlying right posterior frontal gyrus, followed by 40 min of MIT. These three sessions were compared with sham TMS also followed by 40 min of MIT. The two patients treated in this study showed somewhat different effects. Improvements in verbal fluency and repetition were only seen in one of the two patients. Functional imaging changes were seen in both patients using overt speech tasks, although only the patient with the behavioral improvement showed right hemispheric functional changes. Overall, the combination of MIT with noninvasive brain stimulation might be a fruitful development; however, target regions that drive the therapeutic effect of MIT should be clearly identified and more patients should be examined to control for variability in lesion location, lesion size, and baseline impairment level.

81.4 EXAMINING ASPECTS OF RHYTHM AND MELODY IN CROSS-SECTIONAL STUDIES

There are several cross-sectional studies that have examined particular aspects of intonation (melody) or rhythm to better understand mechanisms that underlie the therapeutic effects of an intonation-based therapy such as MIT. Previous studies suggested that patients with severe nonfluent aphasia were able to produce words in familiar songs, but they had reduced speech output without the use of songs. However, when this was tested in several cross-sectional studies, no clear advantage of the singing condition over normal speech condition for word production was found ([Hebert et al., 2003](#); [Stahl, Kotz, Henseler, Turner, & Geyer, 2011](#)). These authors report that the automatic status of lyrics in over-learned songs could account for the

earlier clinical descriptions of better verbal production in familiar songs compared with spontaneous speech. This was taken one step further by [Racette, Bard, and Peretz \(2006\)](#) in a study examining the effects on speech output of “singing along” with other singers versus “singing alone.” Singing along with other singers produced more speech output than singing alone. Racette and colleagues concluded that sung lyrics are more regular in rhythm than spoken words and greater temporal regularity would allow for better synchronization. Others have used this to suggest that rhythmic aspects of MIT might be a more important factor than melodic aspects and that intoned speech facilitation could depend on the rhythmic properties of the underlying spoken language ([Stahl et al., 2011](#)). One should not forget that one important aspect of MIT is that it slows the verbal output to less than one syllable per second, which is quite slow compared with natural speech. This slowing of articulation, together with an underlying melodic contour, leads to more bihemispheric involvement in vocal-motor tasks ([Ozdemir, Norton, & Schlaug, 2006](#)) and could even lead to a right hemisphere dominance by making use of the increased sensitivity of the right hemisphere to slow temporal features in acoustic signals ([Abrams, Nicol, Zecker, & Kraus, 2008](#); [Poeppel, 2003](#); [Zatorre & Gandour, 2008](#)).

81.5 NEURAL CORRELATES OF MIT: NEUROIMAGING FINDINGS

It was originally thought that the success of MIT lies in its ability to engage areas for articulation and speech output in the right hemisphere, and that these regions on the right hemisphere could be engaged, because they are involved in music processing ([Albert et al., 1973](#); [Sparks et al., 1974](#)). An alternative interpretation is that MIT might exert its effect either by unmasking existing music/language connections in both hemispheres or by engaging preserved language-capable regions in either or both hemispheres due to particular aspects of music. Because MIT incorporates both the melodic and rhythmic aspects of music ([Albert et al., 1973](#); [Boucher, Garcia, Fleurant, & Paradis, 2001](#); [Cohen & Masse, 1993](#); [Helm-Estabrooks et al., 1989](#); [Norton et al., 2009](#); [Sparks et al., 1974](#); [Sparks & Holland, 1976](#)), it may be unique in its potential for engaging not just the right but both hemispheres. [Belin, Van Eeckhout, Zilbovicius, Remy, and Francois \(1996\)](#) suggested that MIT-facilitated recovery is associated with the reactivation of left hemisphere language-related regions, most notably the left prefrontal cortex, just anterior to Broca’s region. Although [Belin et al. \(1996\)](#) were the first to examine patients

FIGURE 81.2 Activation maps of overt speaking tasks. fMRI activation maps (superimposed onto the surface projections of a spatially standardized normal brain) of the contrast between overt speaking versus silence (control condition) in the top row and overt speaking versus vowel production in the bottom row ($P < 0.05$; Family-Wise Error (FWE) corrected) before therapy (A) and after therapy (B), as well as a voxel-by-voxel comparison of the two time points (C). The color codes represent different magnitudes of activation: yellow indicates stronger activation than red. All comparisons are thresholded at $P < 0.05$ (FWE-corrected). See [Ozdemir et al. \(2006\)](#) for more details regarding the functional MRI tasks and fMRI data analysis. TP1 = before therapy, TP3 = after therapy. TP3 > TP1 = voxel-by-voxel comparison of the two fMRI acquisitions.

FIGURE 81.3 AF before and after therapy. AF was reconstructed from diffusion tensor imaging scans of a patient before and after an intense course of MIT. There is a visible increase in the size (number of fibers, volume of tract, and length of fibers) of the right AF when the acquisition before therapy (A) is compared with those acquired after treatment (B).

treated with an MIT-like intervention using functional neuroimaging, their findings were surprising and somewhat contrary to the hypotheses that had been put forth by the original developers of MIT and those that have been observed using MIT in a clinical research setting ([Albert et al., 1973](#); [Bonakdarpour et al., 2000](#); [Schlaug, Marchina, et al., 2009](#); [Sparks et al., 1974](#)). It is interesting to note that although the primary finding Belin and colleagues was an activation of left prefrontal regions when participants were asked to repeat intoned words, there is an important aspect of their study that is not often reported. In their analysis comparing the repetition of spoken words with the hearing of those words, Belin and colleagues found blood flow changes that occurred predominantly in the right hemisphere (including the right temporal lobe and the right central operculum), which is consistent with some of our findings ([Schlaug et al., 2008](#); [Schlaug, Marchina, et al., 2009](#)). [Figure 81.2](#) shows fMRI activation maps (superimposed onto the surface

projections of a spatially standardized normal brain) of one of our other patients treated with MIT. Results of two imaging contrasts are shown: overt speaking versus silence (control condition) and overt speaking versus vowel production ($P < 0.05$ FWE) before ([Figure 81.2A](#)) and after ([Figure 81.2B](#)) therapy. Furthermore, a direct voxel-by-voxel comparison of the two acquisitions is shown in [Figure 81.2C](#). The color codes represent different magnitudes of activation: yellow indicates stronger activation than red. The pronounced differences in activation seen in the comparison between after therapy and before therapy show that there is more activation in the right temporal, premotor, and posterior inferior frontal regions after therapy. Details of our functional imaging tasks using overt speech repetition tasks as well as the analysis of sparse temporally acquired fMRI data are outlined in [Ozdemir et al. \(2006\)](#).

[Figure 81.3](#) shows a diffusion tensor imaging study of one of our patients before and after 75 sessions of

MIT. The AF is typically not as strongly developed in the right hemisphere as it is in the left hemisphere in right-handed individuals (Glasser & Rilling, 2008). The treatment-induced increase is evident when the pretherapy (Figure 81.3A) and posttherapy (Figure 81.3B) images are compared. An even stronger effect of structural plasticity was seen in a teenager with a very large left hemisphere lesion who completed our intense MIT protocol. The therapeutic effects were quite remarkable and the structural changes seen in the AF could be clearly attributed to the treatment and observed improvements in verbal output, because normal developmental changes over the treatment period could be controlled by imaging the unimpaired monozygotic twin of this patient (Zipse, Norton, Marchina, & Schlaug, 2012).

The AF is a structure that plays an important role in auditory-motor mapping and, therefore, in language development and in the feedforward and feedback control of any vocal output. Furthermore, it may well be the remodeling of this fiber tract as a result of the intense therapy that supports long-term behavioral effects in severely nonfluent patients (Schlaug, Forgeard, Zhu, Norton, & Winner, 2009; Schlaug, Marchina, et al., 2009). The most likely explanation for these imaging results are changes in myelination (Alexander, Lee, Lazar, & Field, 2007; Jito et al., 2008; Vorisek & Sykova, 1997); however, changes in axon diameter due to changes in myelin or axon density due to axonal sprouting are also possible (Carmichael, 2006; Dancause, Barbay, Frost, Plautz, & Chen, 2005; Fields, 2008). In patients with large left hemispheric lesions, the right AF may play a crucial role in facilitating the mapping of sounds to motor actions and its feedback control.

81.6 POSSIBLE MECHANISMS EXPLAINING THE EFFECTS OF AN INTONATION-BASED SPEECH THERAPY

The traditional explanation for the dissociation between speaking and singing in aphasic patients is the presence of two routes for word articulation: one for spoken words through the brain's left hemisphere and a separate route for sung words that uses either the right or both hemispheres. The small amount of empirical data available support a bihemispheric role in the execution and sensorimotor control of vocal production for both speaking and singing (Bohland & Guenther, 2006; Brown, Martinez, Hodges, Fox, & Parsons, 2004; Guenther, Hampson, & Johnson, 1998; Jeffries, Fritz, & Braun, 2003; Ozdemir et al., 2006), with a tendency for greater left-lateralization for speaking under normal physiological conditions (i.e.,

faster rates of production during speaking than singing). The representation of the sensory elements of music and language may be either separate or in different locations with smaller degrees of overlap (for more details on this see also Koelsch, Fritz, Schulze, Alsop, & Schlaug, 2005; Koelsch et al., 2002; Patel, 2003; Peretz & Coltheart, 2003). Nevertheless, if there is a bihemispheric representation for speech production, then the question of why an intervention that uses singing, or a form of singing such as MIT, has the potential to facilitate syllable and word production still remains. In theory, there are four possible mechanisms by which the therapeutic effect of MIT could be achieved. The first is *reduction of speed*. In singing, words are articulated at a slower rate than in speaking, thereby reducing dependence on the left hemisphere. The rate of one syllable per second is the rate suggested by the developers of MIT (Helm-Estabrooks et al., 1989). Although we have made some adjustments to the original MIT protocol (Norton et al., 2009), we did find the slow rate of vocalization particularly useful as a starting rate for our patients. In fact, many of our patients are so severely impaired at baseline that one syllable per second might even be too fast for them initially. Although rate is not used as an outcome measure in the daily sessions, we do train our therapists to adhere to the one syllable per second rate. When patients reach the "advanced level" of MIT, the rate is gradually increased to approximately two syllables per second as they are transitioned from singing back to speaking. The second is *syllable lengthening*. This provides the opportunity to distinguish the individual phonemes that together form words and phrases while the continuous vocalization inherent in singing "strings" the sound together and thereby encourages fluency. This connected segmentation (i.e., overemphasizing the individual phonemes but still connecting them into meaningful words and phrases), coupled with the reduction of speed in singing, may help nonfluent aphasic patients practice auditory-motor mapping under feedback control and increase fluency and may receive greater support from right hemisphere structures. The third is *syllable "chunking"*. Prosodic features such as intonation, change in pitch, and syllabic stress may help patients group syllables into words and words into phrases, and this "chunking" may also enlist more right hemisphere support. The fourth is *left hand tapping (one tap per syllable, one syllable per second)*. It is likely that the tapping component engages a right-hemispheric sensorimotor network that may, in turn, provide an impulse for verbal production in much the same way that a metronome has been shown to serve as a "pacemaker" in other motor activities (rhythmic anticipation, rhythmic entrainment) (Thaut & Abiru, 2010; Thaut, Kenyon,

Schauer, & McIntosh, 1999). In addition, there may be a set of shared neural correlates that control both hand movements and articulatory movements (Gentilucci, Benuzzi, Bertolani, Daprati, & Gangitano, 2000; Meister et al., 2003; Tokimura, Tokimura, Oliviero, Asakura, & Rothwell, 1996; Uozumi, Tamagawa, Hashimoto, & Tsuji, 2004). Further, the sound produced by the tapping may encourage auditory-motor coupling (Lahav, Saltzman, & Schlaug, 2007). In theory, reduction of speed, syllable lengthening, and syllable chunking can be applied to other nonintonation-based speech techniques. However, these components are often not featured in the traditional therapeutic context.

How might MIT facilitate recovery and what do its unique elements contribute to the process? Functional imaging tasks targeting the perception of musical components that require a more global than local processing strategy (e.g., melodic contour, musical phrasing, and/or meter) tend to elicit greater activity in right than in left hemispheric brain regions. It has also been shown that tasks emphasizing spectral information over temporal information have shown more right than left hemispheric activation (Meyer, Alter, Friederici, Lohmann, & von Cramon, 2002; Zatorre & Belin, 2001). Further, patients with right hemisphere lesions have greater difficulty with global processing (e.g., melody and contour processing) than those with left hemisphere lesions (Peretz, 1990; Schuppert, Munte, Wieringa, & Altenmuller, 2000). Last, but not least, the right hemisphere might have increased sensitivity to slow temporal features in acoustic signals (Abrams et al., 2008; Zatorre & Gandour, 2008). Thus, it is possible that the melodic element of MIT engages the right hemisphere, particularly the right temporal lobe, more than therapies that do not incorporate use of pitch or melody.

The effects of the left hand tapping should be considered in the same context. Once the right temporal lobe is specifically engaged by the melodic intonation and contour, it is conceivable that the role of the left hand tapping could be the activation and priming of a right hemispheric sensorimotor network for articulation. Because concurrent speech and hand use occurs in daily life, and because gestures are frequently used during speech, hand movements, possibly in synchrony with articulatory movements, may have a facilitating effect on speech production, but the precise role of this facilitation is unknown (Benjamin, Towler, Garcia, Park, & Sudhyadhom, 2014; Meister, Buelte, Staedtgen, Boroojerdi, & Sparing, 2009; Rose, 2013). We hypothesize that tapping the left hand may engage a right hemispheric sensorimotor network that coordinates not only hand movements but also orofacial and articulatory movements, and may facilitate speech

production through rhythmic anticipation, rhythmic entrainment, or auditory-motor coupling (Benjamin et al., 2014; Lahav et al., 2007; Schlaug, Altenmuller, & Thaut, 2010; Thaut & Abiru, 2010; Thaut et al., 1999; Wan, Rüber, Hohmann, & Schlaug, 2010).

81.7 CONCLUSION

The clinical observation that patients with nonfluent aphasia are better at singing lyrics than they are at speaking the same words inspired the development of MIT. Despite several small case series, the efficacy of MIT, particularly with regard to untrained items or with regard to improvements in propositional speech, has not been substantiated. Neural correlates of the therapy have emerged in several studies, but differences between studies remain. Because of its potential to engage or unmask speech-motor regions in the unaffected right hemisphere, MIT appears to be well-suited for patients with large left hemisphere lesions whose only chance to recover is through recruitment of the right hemisphere. The observed brain changes after treatment indicate that MIT's engagement of predominantly right hemispheric brain regions (including the superior temporal region, primary sensorimotor and premotor cortices, as well as the IFG) and the connections between these regions (mainly through the AF) accounts for its therapeutic effect.

82.1 APHASIA THERAPY: RELEVANCE AND CLASSIC PARADIGMS

Aphasia is the most common language deficit attributable to neurological disease. It is most commonly caused by stroke. Approximately 1 out of 2,000 individuals suffer from poststroke aphasia (PSA), with a much higher prevalence in the elderly population (Dickey et al., 2010; Law et al., 2009). During the first year after stroke, during the acute and subacute stages, there is still a good chance that PSA will “spontaneously” improve. In the chronic phase (>1 year after onset), only minimal, if any, spontaneous improvement occurs (Kertesz, 1984). The traditional view was that language therapy delivered during the chronic stage does not lead to significant improvements, or that the evidence for such improvement is weak (Basso, Capitani, & Vignolo, 1979; Greener, Enderby, Whurr, & Grant, 1998; Holland & Wertz, 1986; Lincoln et al., 1984; Wertz et al., 1986). However, in 2001, a controlled clinical trial showed that this belief was incorrect and that patients with chronic PSA can improve their language performance over a short therapy interval of only 2 weeks (Pulvermüller et al., 2001). The main focus of this therapeutic approach was practicing behaviorally relevant language in an intensive way and administering language therapy tailored to the patients’ preserved abilities and communication needs. The new method, called Constraint-Induced Aphasia Therapy (CIAT), had been developed on the basis of theory and data in neuroscience (Taub, 1977, 1980) and in the neuroscience of language

(Pulvermüller & Berthier, 2008). The theories and neuroscience data behind this new therapeutic approach are introduced, the basic principles and methods of CIAT are addressed, and a summary of data concerning its efficacy is presented. Finally, two extensive methodological revisions of the original CIAT protocol, namely CIAT II (Johnson et al., 2014) and intensive language action therapy (ILAT) (DiFrancesco, Pulvermüller, & Mohr, 2012; Pulvermüller & Berthier, 2008) are described and their supporting preliminary data are discussed.

82.2 NEUROSCIENCE AND LANGUAGE EVIDENCE

82.2.1 Language Structure and Function in Aphasia Rehabilitation

CIAT was developed on the basis of two related methods of neurological rehabilitation. One is Constraint-Induced Movement Therapy (CIMT) (Taub et al., 1993; Taub, Uswatte, & Elbert, 2002; Taub, Uswatte, Mark, & Morris, 2006) and the other is pragmatic-linguistic or communicative aphasia therapy (CAT) (Aten, Caligiuri, & Holland, 1982; Davis & Wilcox, 1985; Pulvermüller & Berthier, 2008; Pulvermüller & Roth, 1991). These two therapeutic approaches target different neurological syndromes; CIMT is for limb paresis and CAT for language deficits. However, the two approaches have significant features in common. Most importantly, they put emphasis on the *behavioral relevance* of the actions performed during therapy. In CIMT, motor action relevant in

everyday life, such as pouring water from a pitcher into a glass, are targeted, although elementary finger movements may be practiced in preparation for the behaviorally relevant action (Taub, Uswatte, Bowman, et al., 2013). In CAT, linguistic utterances are used in action contexts where they carry similar functions as in everyday life, for example, requesting water from a communication partner; however, word and sentence repetition may be used as a springboard for such communicative actions (DiFrancesco et al., 2012; Pulvermüller & Schönle, 1993). This pragmatic aphasia therapy contrasts with other approaches to language therapy, where the emphasis is on the production or comprehension of linguistic forms (sounds, words, sentences, texts) rather than on the communicative functions these utterances carry in dialogues. The reasons why behavioral relevance and, in the specific case of language, communicative function play an important role is addressed. General findings in basic neuroscience research along with recent data from a large number of neuroimaging studies contributed to the further development and conceptual grounding of CIAT. In recent years, studies involving healthy participants as well as brain-damaged individuals demonstrate that the human brain's language and action systems are functionally linked and interdependent (Pulvermüller, 2005; Pulvermüller & Fadiga, 2010) and therefore cannot be viewed as having encapsulated functions, as once postulated by modularistic approaches (Newmeyer, 1988). For example, lesions in motor or sensory systems may lead to impairment in the semantic domain, for example, in processing words with specific action-related meaning (Bak, 2013; Kemmerer, Rudrauf, Manzel, & Tranel, 2012). It could even be demonstrated that stimulating the motor system facilitates specific language functions in healthy people (D'Ausilio et al., 2009; Pulvermüller, Hauk, Nikulin, & Ilmoniemi, 2005). These results not only show that the brain's language and action systems are functionally interwoven, as depicted in Figure 82.1, but also suggest that lesions to one of these systems may, in part, be compensated by supportive activity from the functionally linked system. In addition, brain imaging studies with healthy participants confirm that when the same utterances are used for *naming* exercises and for communicative speech acts such as *requesting*, the cortical motor system is activated by behaviorally relevant requesting, but not by naming (Egorova, Pulvermüller, & Shtyrov, 2014; Egorova, Shtyrov, & Pulvermüller, 2013). These studies show that everyday speech acts such as requesting engage both language and motor systems and, therefore, their putative synergistic between-systems links. From these and similar data, it seems evident that practicing *behaviorally relevant*, action-embedded language in social and communicative contexts in everyday life is important in aphasia therapy.

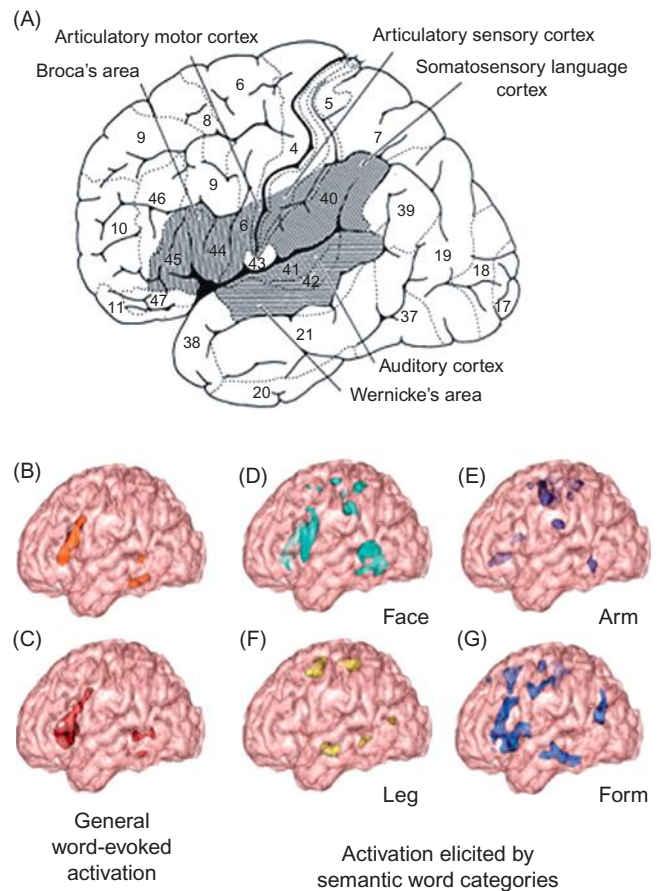

FIGURE 82.1 Brain areas involved in language processing. (A) The perisylvian language cortex, defined as the first convolution surrounding the Sylvian fissure, is indicated on a lateral view of the brain (shaded area). Broca's area and Wernicke's area are indicated along with the somatosensory language area. Lesions in left perisylvian areas typically cause aphasia. (B)–(G) Language processing involves a wide range of brain areas in addition to the left perisylvian areas. (B) and (C) Silently reading words activates the left inferior frontal and superior temporal areas and the left inferior temporal and fusiform gyri. Reading specific semantic word categories activates additional specific bilateral brain areas. (D)–(F) Action words related to the face, arm, and leg, such as “lick,” “pick,” and “kick,” activate the motor system in a somatotopic manner, together with specific foci in temporal cortex. (G) Some semantic word categories, for example, form words such as “square,” excite a wide range of fronto-parieto-temporal foci. Brain activity related to the processing of semantic information has been reported in both cortical hemispheres. 82.2.2 Guidance by Constraints

Originally, the CIMT model was thought to be applicable to PSA because of an apparent similarity in characteristics of the expressive deficit in aphasia and the motor deficit of the more affected upper extremity after stroke. CIMT is said to be efficacious for improving the motor deficit of the extremities, partly because it overcomes a learned inhibition of limb use, termed “learned nonuse,” that develops in the acute period

after substantial neurological injury takes place. When coordination of the movement of a limb is very poor, as is typical soon after injury, attempts to use that limb fail and, in behavioral terms, are thereby punished, reducing the frequency of future attempts to use that limb. Strategies to accomplish tasks that are successful, such as using the limb on the other side of the body or asking a family member to complete tasks for the patient, are rewarded and become more frequent. This learning process results, some time after injury, in greatly reduced real-world use of an extremity compared with the motor ability that the extremity can be shown to have in the laboratory by a test during which patients are requested to make their best possible effort. For example, a patient with hemiparesis primarily affecting the right arm would typically use the left arm for most activities as a compensatory strategy. Research involving animals and humans has shown that avoidance of use of the extremity affected by neurological disease can markedly reduce functional motor ability after central nervous system damage (Taub, Ellman, & Berman, 1966; Taub, Perrella, & Barro, 1973; Taub, Perrella, Miller, & Barro, 1975); (Taub, 1977, 1980; Taub et al., 2006). Based on these data, one of the key features of CIMT is the guidance of patients by constraints that are administered to overcome *learned nonuse*. One way to use constraints to target the negative effects of *learned nonuse* is to constrain the patient's unaffected arm by a sling or other restraining device so that the patient is "forced" to use the impaired arm in everyday activities as much as possible (Taub et al., 1993). Another way that is even more important for adult humans is intensive training of the more affected arm, especially by the behavioral technique termed shaping. Persistent use of the affected limb encouraged by these two techniques markedly reduced poststroke motor deficits. In fact, in the chronic stages after a stroke, dramatic improvements in purposive movements have been documented after intensive (several hours per day) CIMT (Taub et al., 1993; Taub, Uswatte, King, et al., 2006). These motor improvements have been shown to be accompanied by functional (Liepert et al., 2000) and structural changes in the brain (Gauthier et al., 2008; Sterling et al., 2013), especially in the sensorimotor cortices.

In a similar way, *learned nonuse* would appear to also occur when there is language impairment after neurological injury. Because of halting and slow verbal production and incomplete understanding, speech becomes effortful and often unsuccessful. The person compensates by remaining silent, by using gestures as a nonverbal means of communication, or by restricting himself/herself to words and (a)grammatical constructions easily available to them (Kolk & Heeschen, 1990). Moreover, caregivers often "speak for" the person

with aphasia to facilitate communication, thereby further suppressing the remaining verbal abilities of the patients (Croteau & Le Dorze, 2006; Croteau, Vychytil, Larfeuil, & Le Dorze, 2004). Given the likely similarity of the mechanism underlying part of the deficit of both the extremities and language, it seemed reasonable to attempt to improve speech after damage to the central nervous system (CNS) by developing a treatment for language parallel in as many respects as possible to CIMT. This was the conceptual basis of CIAT and its modifications (CIAT II and ILAT), which are described in more detail in this chapter.

In conventional aphasia therapy, it is standard practice to choose materials appropriate for the patient undergoing treatment. For example, in the naming context, pictures and language materials can be tailored to the needs of the patients. These constrain the patients' use of language in a drill-like exercise far from the context of behaviorally relevant communicative interactions. As already noted, the constraints in CIMT are given in contexts that are behaviorally relevant. The methods of CIAT, which are explained here, allow for constraining and guiding patients' language actions, exploiting their individual abilities and addressing their specific needs in social-interactive communication while at the same time providing language therapy in social-communicative contexts similar to everyday language use. To this end, so-called *language games* are used (Pulvermüller, 1990; Pulvermüller & Roth, 1991). Language games are schemas for communicative interaction defined by common goals using linguistic and nonlinguistic materials, including materials depicting action sequences. The concept of language games is derived from the work of the philosopher Ludwig Wittgenstein, who used them to illustrate the intrinsic relationship of language and action and, in the philosophic context, for semantic and conceptual analysis (Wittgenstein, 1953). In the context of language games, language carries its normal function as a tool in interaction—for example, when a builder asks a partner to bring him building blocks as part of an interactive building process. In CIAT, forms of interaction similar to Wittgenstein's language games are used to practice language use and communication with PSA patients. In this case, the communicative constraints—or guidance tools—include the game context and goals (language is used to obtain objects or object pictures from partners), the objects, and object pictures themselves (further features of the interaction setting are explained in this chapter). Another important feature of language games is that linguistic actions can be practiced repeatedly. Use of language games in the aphasia therapy context was adapted from CAT (Pulvermüller et al., 2001; Pulvermüller & Roth, 1991; Pulvermüller & Schönle, 1993). Note that language

games serve as models of behaviorally relevant everyday language interactions in which language is embedded into action contexts—both overt body actions (such as handing over something) and linguistic actions or speech acts (such as requesting or rejecting a request).

In essence, CIAT seeks to *constrain and guide* patients' language use by communicative settings that make it possible to tailor therapy to the individual's level of ability and communicative needs. For CIAT, it is essential that such guidance be made available in interactions that resemble communicative interactions in daily living. Moreover, this guidance is done by shaping, that is, by successive approximations of the desired behavior or communicative interaction. Even small improvements of language functions are continuously positively reinforced. In this way, language (re-)learning follows a behavioral scheme similar to the one used in CIMT.

82.2.3 Therapy Intensity and Frequency

One of the key features of CIAT is its high intensity or frequency. It has been demonstrated that the same amount of aphasia rehabilitation delivered in a short time period results in better outcomes than the same amount of therapy stretched over a longer period (Pulvermüller et al., 2001). In CIMT and CIAT, the standard is to provide therapy at least 3 h/day for at least 2 weeks or more. In the language therapy context, it has also been argued that “more helps more,” that is, independent of type of therapy, the frequency of the therapeutic exercises determines its success (Bhogal, Teasell, & Speechley, 2003). The principles of *maximal amount (in hours overall)* and *especially that of maximal frequency of therapy (in hours per day)* can be justified on the basis of well-known Hebbian learning principles (Kempster, Gerstner, & Van Hemmen, 1999; Tsumoto, 1992). Assuming that the controlled environment of language therapy can support correlations between linguistic utterances and their appropriate contexts, the Hebbian principle “what fires

together wires together” predicts that the crucial neuronal connections between linguistic and context representations strengthen. If therapy is applied with high frequency, then the time between consecutive therapy sessions is minimized. Between therapy, language contexts are not controlled and patients may therefore fail more frequently, so that the correlation between linguistic form and context is low. The anti-Hebb rule that “neurons out of sync delink” implies synaptic weakening of crucial language-context connections if linguistic signs appear in inappropriate contexts. Therefore, it is advantageous to provide the controlled environment of language therapy for as long as possible and to minimize the intervening time, thus resulting in high therapy frequency. The principles of *massed practice and high therapy frequency* are therefore important key features of CIAT.

82.3 CIAT: METHODS AND EFFICACY

82.3.1 CIAT Methods

CIAT uses interactive language game targeting requests. Requests or, more generally, directive speech acts represent one of the most common types of language use (Searle, 1979). Evidently, asking for assistance, asking for objects, or asking for actions by others are even more important for neurological patients than for healthy individuals. In natural communication, people make requests, for example, by asking for a beverage in a coffee shop, for apples in a grocery store, or for a specific dish to be served to them in a restaurant. Requests call for one out of a set of specific response actions by communication partners, for example, the delivery of the requested object, the rejection of the request (“We are out of tea, sorry”), or a request for clarification (“What did you say?”) (Fritz & Gloning, 1992).

These different options to act are built into the therapeutic language game (Figure 82.2). A therapist and a

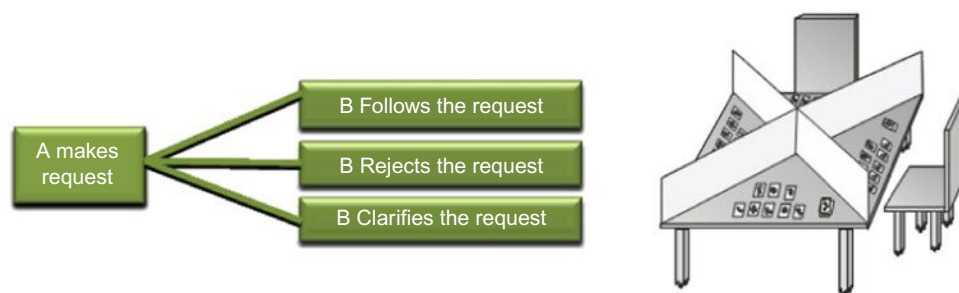

FIGURE 82.2 CIAT for chronic PSA. (Left) Action sequence structure of therapeutic language game used for CIAT. Participants are trained to make verbal requests and respond to requests by passing object cards or by rejecting or clarifying the request. (Right) Typical setting for the CIAT game. Barriers prevent the participants from seeing each other's cards, prompting them to communicate verbally. *Adapted with permission from Taylor & Francis Group © Pulvermüller and Berthier (2008).*

small group of patients sit around a table, with each having a set of picture cards depicting objects. Players are only permitted to see their own items; to this end, barriers are erected between players. Two copies of each item—object or picture card—are in the game, so that players can assume that any card in front of them has a copy that belongs to one of the other game participants. The aim of the game is to obtain items from the other participants by making verbal requests. A round of the game starts with one of the players (requester) directing a request for the twin of one of the cards in his/her hand to any of the other players (responders). If the selected target item is the picture of an apple, then the requester's utterance can be "apple," or "please give me an apple," or "might you possibly have a big red apple for me please," or perhaps "red round fruit," or even "a thing—well—sweet, red." The other player (responder 1) can then respond by handing over the requested object/picture. This requires responder 1 to have understood the request and to have the requested card/item. If this is not the case, then responder 1 would reject the request ("Sorry, no apple") or initiate a repair sequence ("I did not understand"). The requester can then address his/her request to another player (responder 2). The task of responder 2 is to help the requester by asking, "Do you mean yes or no," or by asking alternative questions referring to his/her own card set ("Would you like a pear?" "an apple?" "a knife?"). The round of the game is completed when one of the responders picks up the specific card in response to an appropriate request from the requester. Matching cards are then compared and shown to all players in the game to give feedback about communicative success. If the two cards are mismatched, then the round fails and the requester and responder take back their cards. In any case, it is the last responder's turn to make a new request (for more details, see [DiFrancesco et al., 2012](#)).

Typically, the game is played with four players, one therapist and three aphasic patients, but it is also possible to have one additional co-therapist present who is not a player but who assists patients when necessary ([DiFrancesco et al., 2012](#); [Pulvermüller et al., 2001](#)). If severely aphasic patients participate in therapy, then it might be better to decrease group size—or to work on a one-to-one basis ([Pulvermüller & Schönle, 1993](#)). However, it has been reported that including patients with global aphasia in CIAT groups with mixed performance levels can work well ([Sickert, Anders, Münte, & Sailer, 2014](#)). The therapist who is an active participant in the game acts as a model for the aphasic participants, shapes the actions of the patients, defines specific rules for each player, positively reinforces patients for making successful linguistic actions,

and selects and hands out card sets. The last three tasks can also be undertaken by a nonparticipating co-therapist.

Constraints are imposed by the game, for example, players cannot see the cards of the other players, nor can they see or easily make any manual gestures that communicate relevant information. In this way, verbal communication becomes the only method for achieving success. The therapist also successively shapes the patients' actions toward using spoken language by explicitly encouraging speech and discouraging non-verbal gestures. Still, manual gestures are only allowed as a means of communication when they are used to accompany appropriate verbal output ([DiFrancesco et al., 2012](#)). Further constraints or guidance are achieved by the design of the materials. A progression of difficulty levels in the game materials may increase the phonological, syntactic, lexical-semantic, or pragmatic complexity of the request that must be made. For example, we normally start using items that can be named by high-frequency words and then proceed to items with low word frequency, which are more difficult to process. Moreover, items from dissimilar semantic categories (e.g., animals and fruits) are used initially. With improved language use as the therapy progresses, items from the same semantic domain are used, which are more difficult to differentiate verbally (e.g., different mammals). Pragmatically, the game can first be a simple two-step process (request followed by handing over), progressing toward more complex interaction schemas. The rules and materials of the game are adjusted to the level of deficit of the aphasic players. If performance levels markedly differ between participants, then different rules can be established for different players within the same game. For example, a severely affected player may have few constraints placed on their performance, whereas better performers may be required to make requests using politeness formulas or whole sentences.

Problems in playing the linguistic card game may be encountered by including patients with severe attention or memory deficits, apraxia, visual agnosia, or other severe cognitive deficits. These problems therefore may be used as exclusion criteria. However, we recommend having prospective patients engage in a short practice game of low complexity to assess their ability to participate (for further details of the CIAT methods, please see [Berthier, Green, Juárez, Lara, & Pulvermüller, 2014](#); [DiFrancesco et al., 2012](#); [Neininger, 2002](#); [Pulvermüller & Berthier, 2008](#)).

Part of the card set used in the first CIAT trial is available on the Internet (<http://www.ub.uni-konstanz.de/kops/volltexte/2002/879/>), and a Spanish version is now published in book form, together with a complete set of pictures ([Berthier et al., 2014](#)).

82.3.2 Evidence: Is CIAT Effective?

Randomized controlled trials (RCTs) are the strongest form of evidence. The first RCT of CIAT was performed in 2001 (Pulvermüller et al., 2001). CIAT was delivered for 2 weeks for 3 h/week to patients with mild to moderate PSA who had a poststroke onset mean of 6 years. A control group received the same amount of conventional therapy distributed over several weeks. The CIAT group demonstrated significant improvements on clinical language tests and a communication questionnaire that elicited information about the use of language in the life situation termed the *communicative activity log* (CAL) (Pulvermüller et al., 2001); the control group did not show these improvements. The difference between the two groups was also significant. Meinzer, Djundja, Barthel, Elbert, and Rockstroh (2005) performed a further RCT comparing two versions of CIAT, the original and a version including training of written language. A similar improvement was found in both groups. Moreover, the improvement persisted over 6 months, indicating long-term benefits of CIAT. Berthier et al. (2009) performed a placebo-controlled RCT comparing CIAT therapy alone with CIAT plus *memantine*, a competitive dopamine inhibitor. The significant improvement after CIAT was found to be further amplified by the administration of memantine (Figure 82.3). Further studies involving single cases and small groups have provided additional support for the efficacy of CIAT, and some of these have suggested that it might be more efficacious than other methods of speech-language therapy (Breier et al., 2009; Breier, Maher, Schmadeke, Hasan, & Papanicolaou, 2007; DiFrancesco et al., 2012; Kirmess & Maher, 2010; Kurland, Pulvermüller, Silva,

Burke, & Andrianopoulos, 2012; Maher et al., 2006; Meinzer, Streiftau, & Rockstroh, 2007; Richter, Miltner, & Straube, 2008; Szaflarski et al., 2008).

Cochrane reviews have concluded that aphasia therapy is effective during the chronic stage (Brady, Kelly, Godwin, & Enderby, 2012; Kelly, Brady, & Enderby, 2010). Important evidence on which this conclusion was based is derived from the aforementioned RCTs on CIAT. However, CIAT is frequently described *only* as an intensive method of providing therapy. This ignores two of its other distinctive features, *behavioral relevance* and *guidance/constraint*. Whether the *high-frequency* principle alone can be sufficient for therapy success has been asked in a recent study in which single patients were treated with a traditional utterance-based approach in an intensive fashion comparable with CIAT (Barthel, Meinzer, Djundja, & Rockstroh, 2008). This study reports improvements comparable with those reported after CIAT, although the generality of the conclusions is limited because of the lack of a control group and the resultant possibility of a bias in patient selection. Furthermore, training was between a therapist and one patient only, so that therapy intensity per patient was greater in this study than in a typical CIAT group therapy. A recent RCT with early subacute PSA patients compared group therapy with CIAT delivered with somewhat reduced intensity (2 h/day) with an utterance-centered approach and found similar improvements with both methods (Sickert et al., 2014). Although the authors suggest that therapy intensity is an important factor and that other methodological differences might not be relevant, it is not possible to determine whether the improvements seen in their

FIGURE 82.3 Efficiency of CIAT. (Left) Language performance before and after 2 weeks of CIAT (30 h) compared with same amount of conventional PSA therapy. (Right) Effects of memantine, CIAT, and concomitant memantine and CIAT. Drug therapy is indicated by line color (blue, on drug; red, placebo; gray, off drug). The results show stronger improvement with CIAT than with conventional treatment, synergistic effects of drug treatment and CIAT, and long-term stability of CIAT, but no long-term stability for drug treatment. CIAT, constraint-induced aphasia therapy; WAB-AQ, Western Aphasia Battery Aphasia Quotient. Adapted with permission from American Heart Association © Pulvermüller et al. (2001) and from John Wiley and Sons, Inc. © Berthier et al. (2009).

study were a result of therapy *per se*, because the patients were in the subacute phase; therefore, improvements could have been attributable to spontaneous recovery independent of the treatment. Previous studies of the effect of pragmatic and CAT suggest that behavioral relevance alone can lead to a significant improvement in language performance in chronic PSA (Pulvermüller & Roth, 1991; Pulvermüller & Schönle, 1993), although no RCT is available to strongly support this suggestion.

82.4 VARIANTS AND EXTENSIONS OF ORIGINAL CIAT METHODS

The basic CIAT design has been modified in a number of studies. For example, the application of the standard CIAT methods is sometimes difficult in clinical settings for organizational reasons. Therefore, CIAT methods were applied with slightly reduced frequency, and the CIAT methods were also taught to communication partners of patients (Sickert et al., 2014). The unexpected outcome was that lay-person–led training yielded improvements that were similar to those of CIAT administered by professional speech therapists (Meinzer et al., 2007). There have also been attempts to include a wider spectrum of therapy methods in the basic CIAT protocol. In one study, training of written language use was included (Meinzer et al., 2005). Finally, the supplementary use of additional methods that might have a beneficial effect on language recovery was studied, for example, the application of pharmacological or magnetic and electric stimulation of the brain during the CIAT period. As mentioned, use of drugs can produce synergistic effects enhancing the improvements brought about by CIAT (Berthier et al., 2014; Berthier & Pulvermüller, 2011; Berthier, Pulvermüller, Davila, Casares, & Gutierrez, 2011).

82.4.1 ILAT: Widening the Scope of Communicative Actions and Linguistic Materials

ILAT is not just a new term introduced to highlight two (intensity and action-embedding) of the three key principles of CIAT (as opposed to only one highlighted by CIAT, i.e., constraint). The new label ILAT also indexes a move toward a broader spectrum of social-communicative actions, interaction schemes, and linguistic materials targeted (Berthier & Pulvermüller, 2011; Pulvermüller & Berthier, 2008). In the original form of CIAT, participants always ask for objects or picture cards and, although the requests practiced are of eminent importance in everyday life, there is a wide range of social-communicative speech acts that are also relevant but outside the scope of the original method.

Likewise, linguistically, CIAT's request game focuses on the use of nouns for objects, with other vocabulary types being somewhat underrepresented. New materials have been developed to also allow systematic coverage of adjectives (Berthier et al., 2014), but verbs and function words are typically difficult to integrate. ILAT overcomes these limitations by offering additional language games that now focus on further important linguistic actions such as planning, bargaining, making a proposal, rejecting or supporting a proposal, and arguing the pros and cons of a given possibility to act. For example, in the "joint planning" game (DiFrancesco et al., 2012; Pulvermüller, 1990), participants use action pictures and the aim is to propose and agree on an action to be performed collectively by the participants. This new method makes it possible to specifically target action verbs and function words relevant for argumentation (because, therefore, thus, since...) and therefore helps constrain therapy toward word types specifically impaired in some subtypes of PSA (Kemmerer et al., 2012; Miceli, Silveri, Villa, & Caramazza, 1984). Concordant with the broadening of communicative methods, ILAT materials have been extended by newly developed card materials covering a variety of individual or group actions ranging from leisure to work-related and household-related activities (Berthier et al., 2014; DiFrancesco et al., 2012). In a recent clinical trial, ILAT, including both request and planning games, was administered for 10 consecutive weekdays and led to significant improvements of language functions in a group of 14 patients with chronic mildly to moderately impaired PSA (DiFrancesco et al., 2012).

82.4.2 CIAT II: A Revision of the Original CIAT Protocol Bringing It Closer to the CIMT Model

The original CIAT protocol was a partial translation of the methods applied in CIMT (Taub et al., 1994; Taub, Uswatte, King, et al., 2006). Although CIAT produces significantly larger real-world improvements of language functions than conventional speech and language therapies, its outcome seems smaller compared with the results reported in CIMT studies. Therefore, as a further development of CIAT, the initial protocol was modified to more closely resemble the methods used in CIMT. This new protocol is termed CIAT II (Johnson et al., 2014). Modifications involved addition of new exercises, including a final exercise in which everyday verbal interactions were simulated and modeled. There was increased emphasis on the shaping of responses and the primary caregiver was trained as an alternate therapist, with training beginning in the laboratory but focused largely on the at-home practice of verbal behavior. In addition, a "transfer package" (TP)

parallel to that used in CIMT was introduced (Taub, Uswatte, King, et al., 2006; Taub, Uswatte, Mark, et al., 2013). The latter was probably the most important change in the CIAT protocol. The TP is a set of techniques designed to facilitate transfer of therapeutic gains from the treatment setting to life situations. The TP techniques consisted of behavioral contracts with the patient and caregiver to perform specified activities using only speech and not gestures or other means of communication, monitoring the amount of out-of-laboratory speech by daily maintenance of a verbal behavioral diary, daily administration of a structured questionnaire (Verbal Activity Log [VAL]) derived from the original CAL, problem-solving to circumvent apparent barriers to participation in speech in the life situation, home practice exercises, periodic phone contact after the end of treatment, and involvement of a caregiver in all phases of the treatment both in the laboratory and during home practice during formal treatment and after its end. These behavioral techniques, singly and in combination, have been used extensively for the treatment of a number of clinical conditions, including, for example, the outpatient treatment of cocaine dependence (Higgins, Budney, & Bickel, 1997), autism, and adherence to behavior modification training for parents of children with behavior problems (Eyberg & Johnson, 1974), and the control of obesity, smoking, and alcoholism.

To date, six patients have been treated with CIAT II. All patients showed significant improvements in the use of speech during life situations (measured by VAL) (Johnson et al., 2014). VAL data recorded an approximate 300% increase in spontaneous speech in the life situation compared with 30% reported by previous CIAT studies using the Communicative Aphasia Log. Data from the first study with CIAT II are presented in Figure 82.4. Interestingly, further improvements of verbal activity scores were found during the 6 months after the completion of treatment. This increase would appear to be attributable to the continuation of training by the caregivers in the real-world environment, a procedure that is part of CIAT II.

82.5 SUMMARY AND OUTLOOK

The development of CIAT and the consistently positive outcome in a large number of studies published during the past decade demonstrate that this therapy approach is successful in the treatment of PSA. Studies have shown that chronic and possibly also subacute patients greatly benefit from this therapy method, and that patients with a broad spectrum of symptoms can participate in the treatment and show significant improvements of language functions. The short

FIGURE 82.4 Changes in amount of participation in speech in life situations after CIAT II. Each line indexes results from one subject. The mean gain from pretreatment on the VAL Amount scale was significant after treatment. After treatment, there was an additional significant performance gain. Data in the graph are ipsitized (i.e., pretreatment scores are set to 0 for each participant and subsequent scores are reported as changes from pretreatment). Modified from Johnson et al. (2014).

duration and treatment intensity of CIAT, combined with its strong behavioral relevance in everyday communication, seem to be the factors that lead to the beneficial effects. However, it is not yet entirely clear which of these factors contribute most because they have been used in combination in CIAT. New developments of the original CIAT protocol include increased practice of behaviorally relevant language in everyday life, as applied in CIAT II, which is focused on translation of therapeutic gains achieved in the clinic to performance of spontaneous speech in everyday life activities. In ILAT, a greater focus on language–action relationships and a broadening of the repertoire of everyday communicative speech acts and vocabulary types has been implemented. As a next step, the positive preliminary findings of CIAT II and ILAT need to be confirmed in randomized controlled clinical trials with a larger number of aphasia patients. Moreover, it seems most promising to combine the newly developed techniques of CIAT II and ILAT to maximize treatment effects and transfer of newly acquired language skills in relevant daily communicative contexts.

Noninvasive Brain Stimulation in Aphasia Therapy: Lessons from TMS and tDCS

H. Branch Coslett

Department of Neurology, Perelman School of Medicine at the University of Pennsylvania,
Philadelphia, PA, USA

83.1 INTRODUCTION

Disorders of language are quite common in the context of brain dysfunction. It is estimated that approximately 33% of individuals who experience a left hemisphere stroke develop aphasia (e.g., [Dickey et al., 2010](#)). Impairments of language are also observed in traumatic brain injury as well as degenerative brain disorders, some of which are characterized by profound language deficits in the absence of generalized dementia.

Although speech-language therapy (SLT) is of proven benefit ([Kelly, Brady, & Enderby, 2010](#); [Robey & Dalebout, 1998](#)), remediation of aphasia has proven to be remarkably difficult. There are many potential reasons for this. First, variability in the severity and nature of an individual's language deficits may have important implications for the type of therapy that will prove most beneficial; at present, however, there is little information regarding the most effective mapping between type of SLT and aphasic performance. Second, there is considerable intersubject variability in factors such as the site and size of the lesion as well as other more difficult to quantify factors such as degree of atrophy, white matter burden, and number of lesions that are likely to be important determinants of recovery and response to therapy. Third, individual differences in genetic and developmental factors that underlie differences in the degree of lateralization of language and the capacity for reorganization after brain injury (one aspect of brain plasticity) are likely to significantly influence language recovery. Finally, access to SLT is limited for many people with aphasia. As conventionally delivered, SLT is resource-intensive; it has been estimated that maximal benefit for SLT requires

100 hours of therapy, whereas the average patient in the United States receives 30 hours of therapy.

In light of the urgent need for more effective forms of therapy, there has been substantial interest over the past decade in the use of noninvasive brain stimulation as a therapeutic intervention, often in combination with conventional SLT. This effort parallels the use of noninvasive brain stimulation as therapy for a wide range of disorders of brain function, including hemiparesis ([Ayache et al., 2012](#); [Khedr, Ahmed, Fathy, & Rothwell, 2005](#); [Khedr et al., 2013](#)), pain ([Pérez-Borrego et al., 2014](#)), and neglect ([Koch et al., 2012](#); [Mylius et al., 2012](#); [Sunwoo et al., 2013](#); see [Coslett & Hamilton, 2011](#)). In this chapter we review recent work exploiting two types of noninvasive brain stimulation—transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (tDCS)—that have shown promise in the treatment of aphasia. TMS and tDCS have been used in normal subjects to address questions regarding the functional architecture. This literature is outside the scope of this chapter; interested readers are referred to recent reviews of TMS ([Torres, Drebing, & Hamilton, 2013](#)) and tDCS (e.g., [Flöel et al., 2012](#)) studies of normal language.

83.2 TMS AS TREATMENT FOR APHASIA

83.2.1 Basics of TMS

TMS is a procedure in which a brief surge of current through a coil held near the skull induces a magnetic field that penetrates the skull and soft tissue of the head and ultimately generates a small electrical current in the brain (see [Jahanshahi & Rothwell, 2000](#); [Miniussi](#)

et al., 2008). The electrical current in the brain causes neurons in a circumscribed region of the brain to depolarize, thereby generating action potentials.

The effects of TMS are dependent on a number of parameters including stimulus intensity, the frequency with which the pulses are applied, the configuration of the coil, and the distance between the coil and the cortex. Stimulus intensity is most frequently expressed as a percentage of maximal machine output that is required to generate a measurable motor response from an intrinsic hand muscle (e.g., the first dorsal interosseus); this value is called the motor threshold (MT). Depending on the stimulus intensity, individual characteristics of the subject (e.g., skull thickness), and coil design, a TMS pulse is assumed to depolarize approximately 1 cm³ of brain tissue. It is important to note that although TMS directly influences only a small region of cortex, depolarization of neurons in one brain region may alter, by virtue of direct axonal connections to distant brain regions, function in multiple distal sites in the brain (George, Wassermann, & Post, 1996).

As the strength of the magnetic field induced by the current drops off sharply as a function of distance from the coil, TMS is most useful for stimulating cortex that is close to the skull. TMS may be administered as a single pulse or as a series of pulses, a paradigm termed repetitive TMS (rTMS). Whereas a single pulse produces only a very brief effect (e.g., 100 ms), rTMS produces effects that persist beyond the period of stimulation. With rTMS the frequency of the pulses determines the effect of the train of pulses. Low-frequency rTMS, usually administered at 1 Hz, causes a suppression of the activity of the underlying brain activity that has been likened to a “virtual lesion.” Stimulation at higher frequencies (typically >5 Hz) is associated with enhancement of brain function. Finally, theta-burst TMS (TBS) (Huang & Rothwell, 2004) is a pulse sequence in which brief trains of 50 Hz (theta frequency) pulses are delivered with variable interpulse intervals; “continuous” TBS is thought, like 1 Hz TMS, to be “inhibitory,” whereas “intermittent” TBS, like high-frequency rTMS, is thought to be “excitatory.”

The effects of rTMS are transient (typically minutes to an hour in the motor system) when administered in a single session; crucial for the present discussion, with appropriate stimulus parameters, a series of TMS sessions may induce alterations in brain function that far outlast the administration of the stimulation (Pascual-Leone et al., 1998). The use of TMS as a therapy for aphasia builds on this crucial observation.

83.2.2 TMS as Therapy for Aphasia

To date there have been 22 reports including more than 200 subjects describing the results of TMS as a

therapy for aphasia from stroke. Additionally, there is some literature describing beneficial effects of TMS for treatment of aphasia in the context of degenerative disorders of the brain such as Alzheimer’s disease (Cotelli et al., 2011; Cotelli, Manenti, Cappa, Zanetti, & Miniussi, 2008). This chapter focuses on the use of TMS in the treatment of aphasia resulting from stroke.

The first reports of therapeutic effects of TMS in aphasic subjects were provided by Naeser and colleagues (Martin et al., 2004, 2009; Naeser et al., 2005a, 2005b); because these investigations not only provided the initial evidence that TMS can be beneficial in this context but also have served as the model for most subsequent studies, the basic approach of Naeser and colleagues is described in some detail (see also Naeser et al., 2012).

The rationale for Naeser et al.’s approach and for much of the work with tDCS comes from accounts from the motor domain that attribute aphasia, at least in part, to transcallosal inhibition of the lesioned hemisphere by the contralesional hemisphere (Heiss & Thiel, 2006; Van der Knaap & van der Ham, 2011). Naeser et al. (2005b, 2012) reasoned that if chronic aphasia is characterized by an inhibition of left hemisphere language structures by an overactive right hemisphere, suppression of the right hemisphere would permit the left hemisphere language structures to function optimally, thereby improving language performance. To that end, Naeser and colleagues administered 1 Hz repetitive TMS, a procedure thought to inhibit underlying cortex, to the right frontal lobe. As they had no strong *a priori* hypothesis regarding the optimal site to stimulate, they used a “site finding” procedure (see also Hamilton et al., 2010; Medina et al., 2012) in which multiple sites in the RH including the mouth region of M1, pars triangularis, pars opercularis, and pars orbitalis were stimulated, in turn, to identify a location at which TMS would improve picture naming. Those subjects for whom a site at which 10 minutes of 1 Hz TMS lead to significant improvement in naming could be identified were subsequently treated with 20 minutes of 1 Hz TMS at 90% of motor threshold for 10 sessions over 2 weeks.

In a series of studies involving a small number of subjects, Naeser and colleagues (Martin et al., 2004; Klein et al., 2007; Naeser et al., 2004, 2005a, 2005b) demonstrated consistent benefit in naming from 10 sessions of 1 Hz TMS to the right pars triangularis. Additionally, we and others have demonstrated significant improvement in multiple measures of language function (e.g., Hamilton et al., 2010) in controlled studies using a partial cross-over design with sham stimulation (Medina et al., 2013) or vertex stimulation (Barwood et al., 2013). These positive findings provided the impetus for a number of additional studies

of the role of TMS in aphasia therapy that have used a wide range of experimental designs. In the following sections, we briefly review the more recent studies involving TMS as a therapy for aphasia.

83.2.3 Blinded, Controlled Studies in Subacute and Chronic Aphasia

As is typically the case when new therapies are under development, initial studies of TMS were “proof of principle” investigations in which small groups of people with chronic aphasia were enrolled and control conditions were not used (see [Table 83.1](#) for details). There is clear evidence from these studies that TMS may benefit subjects with chronic, nonfluent aphasia. To determine if therapy is of more general benefit, however, blinded studies with adequate controls are needed. Since 2011 there have been nine such studies, six of which included 10 or more subjects. Six of the studies used sham stimulation ([Cotelli et al., 2011](#); [Khedr et al., 2014](#); [Kindler et al., 2012](#); [Medina et al., 2012](#); [Seniów et al., 2013](#); [Waldowski, Seniów, Leśniak, Iwański, & Członkowska, 2012](#)), in some instances using a cross-over design so that all subjects eventually received active TMS; in three studies ([Abo et al., 2012](#); [Barwood et al., 2013](#); [Thiel et al., 2013](#)), subjects were randomized to RIFG or vertex stimulation.

Four studies enrolled people with chronic aphasia; three of these ([Barwood et al., 2012](#); [Medina et al., 2012](#); [Thiel et al., 2013](#)) involving a total of 46 subjects used a paradigm modeled on that of Naeser and colleagues: 1-Hz stimulation at 90% MT to the right IFG for several weeks. The three studies demonstrated a consistent and significant beneficial effect across a variety of tasks, including naming, picture description and a variety of other measures included in aphasia batteries such as the Aachen Aphasia Test. Although there is variability with respect to the magnitude of the benefit, many of the significant improvements were in the range of 20–30% relative to the pretest baseline. As in previous reports, benefit was observed at the final testing period, varying between 6 and 10 months after treatment ([Barwood et al., 2011](#); [Medina et al., 2012](#)). As is discussed, in many instances the improvement noted after therapy increased over the course of the follow-up period.

There have been four studies of subacute stroke ([Khedr et al., 2014](#); [Seniów et al., 2013](#); [Waldowski et al., 2012](#); [Weiduschat et al., 2011](#)) involving a total of 78 subjects.¹ Two of the larger studies, [Seniów et al. \(2013\)](#) with 38 subjects and [Waldowski et al. \(2012\)](#) with 26 subjects, demonstrated no main effect of

group; significant benefit was observed by [Weiduschat et al. \(2011\)](#) and [Khedr et al. \(2014\)](#). Subgroup analyses reported by [Seniów et al. \(2013\)](#) demonstrated that nonfluent and more severe cases derived the greatest benefit.

83.2.4 Variables Relevant to the Response to TMS

Although a number of studies have used the approach pioneered by Naeser and colleagues, multiple other approaches have been tried. An overall assessment of the efficacy of TMS therapy for aphasia is complicated by substantial variability between investigations with respect to a wide range of factors including aphasia type, aphasia chronicity, site of stimulation, TMS stimulation parameters, and the use of speech therapy in conjunction with TMS. We review the effects of these variables before attempting to synthesize the lessons from studies to date.

83.2.4.1 Effect of Aphasia Subtype, Severity, and Lesion Location

Most studies have not offered precise characterizations of the type of aphasia exhibited by participants. Most commonly, participants have been described as “fluent” or “nonfluent,” designations that offer little insight into the nature of the language processing deficits exhibited by the participants. Many studies included nonfluent subjects exclusively, but several more recent studies have included subjects with different types of aphasia (e.g., [Abo et al., 2012](#); [Khedr et al., 2014](#); [Kindler et al., 2012](#); [Seniów et al., 2013](#); [Szaflarski et al., 2011](#); [Thiel et al., 2013](#); [Waldowski et al., 2012](#); [Weiduschat et al., 2011](#)). Only one small study of two subjects ([Kakuda, Abo, Uruma, Kaito, & Watanabe, 2010](#)) has been restricted to people with chronic “sensory” aphasia.

Studies including people with nonfluent aphasia have, with one exception ([Kakuda, Abo, Kaito, Watanabe, & Senoo, 2010](#)), demonstrated improvement in language function. The exception was a small study of four subjects that differed from most other studies not only with respect to subject characteristics but also in that the stimulated site was selected on the basis of fMRI findings; therefore, it differed across subjects. Furthermore, [Waldowski et al. \(2012\)](#) and [Seniów et al. \(2013\)](#) demonstrated greater improvement in people with nonfluent aphasia as compared to people with fluent aphasia. Thus, there is considerable evidence that TMS benefits subjects with nonfluent aphasia, whereas evidence for benefit in fluent subjects is less

¹Note that the subjects reported by Waldowski et al. are included in the later Seniów et al. manuscript.

TABLE 83.1 Initial Proof of Principle Studies for TMS Treatment of Aphasia.

Author	Subjects	Time from stroke	Stimulated areas	Stimulus parameters	Number of sessions	Study design	Task	Speech therapy	Time of evaluation	Language effect
Martin et al., 2004	6 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture naming	No	2 months	Significant improvement
Naeser et al., 2005	1 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture naming	No	2 months	Significant improvement
Naeser et al., 2005	4 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture naming	No	8 months	Significant improvement
Martin et al., 2009	2 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture naming	No	2 months	Significant improvement
Naeser et al., 2011	1 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture naming, BDAE	No	6 months	Significant improvement in naming, auditory comp.
Martin et al., 2009	1 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture naming	Yes—CILT	No	Significant improvement
Kakuda, Abo, Kaito, et al., 2010	4 nonfluent	Chronic	Contralateral to area of max fMRI activation	1 Hz, 20 min, 90% MT	10 (6 days)	No control group/condition	Picture naming	No	NO	No benefit
Kakuda, Abo, Uruma, et al., 2010	2 fluent	Chronic	Post-STG	1 Hz, 20 min, 90% MT	10 (6 days), then weekly for 3 months	No control group/condition	Token test	Yes		“Modest” improvement
Hamilton et al., 2010	1 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	Picture description	No	10 months	Significant improvement
Kakuda et al., 2011	4 nonfluent	Chronic	R IFG	600 pulses 6 Hz, then 1 Hz, 20 min, 90%MT	18 (2 × /day for 9 days)	No control group/condition	SLTA, WAB	Yes		Modest improvement, no statistics, moderate better than mild aphasia
Weiduschat et al., 2011	10 multiple types	Subacute	R IFG, vertex	1 Hz, 20 min, 90% MT	10	Randomized: IFG or vertex	Aachen aphasia battery	Yes	4 months	Significantly greater improvement in IFG group than vertex (19.8 versus 8.5)
Cotelli et al., 2011	3 nonfluent	Chronic	L DLPFC	20 Hz trains, 2000 pulses, 90% MT	20 (50% sham, two subjects)	2/3 with sham TMS in cross-over design	Picture naming	Yes	Up to 48 weeks	Significantly better naming persisting to 48 weeks for trained and untrained but observed before TMS in two subjects; no delay between sham and real TMS

(Continued)

TABLE 83.1 (Continued)

Author	Subjects	Time from stroke	Stimulated areas	Stimulus parameters	Number of sessions	Study design	Task	Speech therapy	Time of evaluation	Language effect
Szaflarski et al., 2011	8 multiple types	Chronic	LH frontal defined by fMRI	Excitatory theta-burst	10	No control group/condition	Multiple measures	No	2 weeks	Significant improvement in semantic fluency
Barwood et al., 2012	7 nonfluent (6 from 2011)	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	No control group/condition	BDAE, BNT	No	8 months	Significant benefit across number of measures; global greatest increase
Waldowski et al., 2012	26 multiple types	Subacute	Right pars opercularis & triangularis	1 Hz, 30 min, 90% MT	10	Randomized, double blind, sham controlled	Naming, other	Yes	15 weeks	No main effect group; improvement in anterior lesions
Abo et al., 2012	24 multiple types (13 hemorrhagic)	Chronic	Contralateral to max fMRI; fluent at post-STG, nonfluent at IFG	40 min, 90% MT	10	No control group/condition	SLTA battery	Yes	4 weeks	Significant improvement in naming, comprehension, spontaneous speech; no major difference between fluent/nonfluent
Kindler et al., 2012	18 multiple types	Variable (0.5–57 months)	R IFG	Continuous thetaburst TMS	1	Randomized, sham-controlled, cross-over	Timed picture naming	No	Immediate	Modest effects but <6 months after better response
Medina et al., 2012	10 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	Randomized, cross-over, sham controlled	Picture description	No	2 months	Significant benefit from TMS
Thiel et al., 2013	24 multiple types	Chronic	R IFG, vertex	1 Hz, 20 min, 90% MT	10	Randomized, vertex active site	Aachen aphasia test	Yes	2 weeks	Significant improvement in AAT, including subtests
Seniów et al., 2013	38 multiple types	Subacute	R IFG, vertex	1 Hz, 30 min, 90% MT	15	Randomized, double-blinded, sham control		Yes		No main effect group but improved in severe and nonfluent aphasics
Barwood et al., 2013 (see also 2011)	12 nonfluent	Chronic	R IFG	1 Hz, 20 min, 90% MT	10	Randomized, blinded; vertex control	Language battery	No	12 months	Treated group improved in naming, comprehension, repetition, picture description
Khedr et al., 2014	30, multiple types	Subacute (mean, 5.3 weeks)	R IFG (500 at pars triangularis and opercularis), then L IFG (pars triangularis and opercularis)	1-Hz, 16.6 min, 110% MT (1000 pulses), then 10 trains 20-Hz for 5 seconds (1000 pulses)	10	Randomized, sham controlled	Language battery	Yes	2 months	Improvement in comprehension, naming, repetition and fluency noted in first post-stimulation session and sustained.

convincing. However, this is clearly an area in which much remains to be learned; future studies should address the role of linguistic factors in predicting response to therapy.

Because many “nonfluent” subjects are likely to have lesions that involve the frontal lobe, it is not surprising that there is some evidence that subjects with frontal lesions respond better to TMS. Weiduschat et al. (2011), for example, reported that subjects with lesions involving the IFG responded better than subjects whose lesion did not involve the IFG. Similarly, although no formal data are provided, Waldowski et al. (2012) reported that subjects with anterior lesions had a better response.

There has been little discussion in the literature about subjects who fail to respond. The single exception to this comes from a report by Martin et al. (2009), who reported detailed analyses of the lesion characteristics of two individual subjects, one of whom benefited from TMS whereas the other did not. Unfortunately, multiple differences in the extent of the lesion in brain regions thought to be crucial for naming such as the posterior superior frontal gyrus and middle temporal gyrus make the interpretation of the differences in response problematic.

Although systematic analyses are lacking, there is suggestive evidence that TMS may be most beneficial in subjects with severe but not profound deficits. Seniów et al. (2013) and Barwood et al. (2012) reported greater benefit in subjects with more severe deficits; it may also be relevant in this context that the only study that failed to find benefit in people with nonfluent aphasia (Kakuda, Abo, Kaito, et al., 2010) included subjects with very mild deficits. Although the evidence is limited, some data suggest that subjects with truly profound deficits (e.g., one-word phrase length) (Martin et al., 2009) fail to benefit from TMS.

83.2.4.2 Site of Stimulation

As noted, most studies have targeted the right IFG. However, even in those studies stimulating this region, a potentially important methodologic difference may be identified. Naeser and colleagues (2005a, 2005b, 2011) used a “site-finding” approach in which picture naming is assessed before and after rTMS in an effort to find the optimal site for stimulation as defined by a neuro-navigation system. We believe that identifying the optimal structure on an individual basis may be important; for example, we have reported that subjects differ substantially with respect to the specific location at which the best effects are elicited (see Figure 83.1). Whereas most of our subjects demonstrated best performance with sites in the pars triangularis, we often observed different effects from stimulation of nearby sites and even from different sites in the pars

FIGURE 83.1 A lateral view of the right hemisphere indicating the sites at which the best response in object naming was found after 1-Hz TMS in 10 subjects (see Medina et al., 2012).

triangularis. We also identified sites in the right IFG at which stimulation adversely affected performance (Hamilton et al., 2010; Medina et al., 2012). Random selection of a stimulation site in the IFG entails the risk that an inactive or even potentially deleterious site could be targeted.

Other investigators have taken a different approach to right IFG stimulation. For example, citing TMS evidence that the pars triangularis and opercularis were relevant to different aspects of language function (e.g., Devlin, Matthews, & Rushworth, 2003; Gough, Nobre, & Devlin, 2005), Waldowski et al. (2012) stimulated both of these regions in all subjects. Furthermore, as many investigators targeted the right IFG using external coordinate systems (e.g., the International 10/20 system) rather than on the basis of the individual’s anatomy, the precise site at which stimulation is delivered cannot be stated with certainty.

Still another approach to selecting the site to stimulate is to use fMRI activations to target TMS. Abo et al. (2012) stimulated the hemisphere contralateral to the hemisphere demonstrating the greatest fMRI activation on a language task; subjects with “fluent” aphasia were then stimulated in the posterior STG, whereas subjects with “nonfluent” aphasia were stimulated over the IFG of the hemisphere contralateral to the site of greatest BOLD activation. Kakuda, Abo, Kaito, et al. (2010) also identified the region of maximal fMRI activation on a naming task and stimulated over the homologous region of the contralateral hemisphere. Finally, Szaflarski et al. (2011) stimulated over the left frontal region, at which fMRI activation was greatest during a language task. There is mixed evidence regarding the efficacy of selecting the activation site on the basis of fMRI activation. Szaflarski et al. (2011) and Abo et al. (2012) reported improvement, but Kakuda, Abo, Kaito, et al. (2010) was the only group to fail to

find benefit from TMS in people with chronic nonfluent aphasia.

Finally, [Khedr et al. \(2014\)](#) reported a randomized, sham controlled study in which they stimulated the right pars opercularis (500 pulses) and pars triangularis (500 pulses) of inhibitory 1 Hz stimulation followed by excitatory stimulation of the same regions on the left. They reported benefit across a number of language parameters in patients with subacute aphasia.

In an attempt to address the issue concerning the relative benefit of the stimulation site, we calculated effect sizes for those studies for which data regarding picture naming were available. There were eight published studies ([Abo et al., 2012](#); [Barwood et al., 2013](#); [Heiss et al., 2013](#); [Kakuda, Abo, Momosaki, & Morooka, 2011](#); [Khedr et al., 2014](#); [Kindler et al., 2012](#); [Seniów et al., 2013](#); [Szaflarski et al., 2011](#)) and our unpublished picture naming data (see [Medina et al., 2012](#) for picture description data from these subjects). Effect sizes ranged from small (0.181) to moderately large (0.889), with an average of 0.379 (0.22, 0.54). Restricting the analysis to those studies using inhibitory right IFG stimulation (see [Table 83.1](#)) yielded a mean Cohen's D of 0.584.

83.2.4.3 Stimulus Parameters

Most studies have used 20 minutes of 1-Hz stimulation at 90% of motor threshold for 10 sessions. [Kakuda et al. \(2011\)](#) used a strategy of "pretreating" the right IFG with 600 pulses at 6 Hz prior to 20 minutes of 1-Hz stimulation. Reflecting the widely held perspective that the goal of TMS is to increase the efficiency and involvement of the remaining left hemisphere tissue, two groups have used theta-burst TMS to alter the balance of activity in the right and left hemispheres. [Szaflarski et al. \(2011\)](#) delivered excitatory (intermittent) theta-burst TMS to the left frontal lobe with beneficial effects, whereas [Kindler et al. \(2012\)](#) administered inhibitory (continuous) theta-burst TMS to the right hemisphere with little benefit. Finally, [Cotelli et al. \(2011\)](#) took a different approach entirely, delivering "excitatory" 20 Hz rTMS to the left dorsolateral prefrontal cortex. Because differences in stimulus parameters were often confounded by other dissimilarities in experimental design, the data do not demonstrate a clear best practice.

83.2.4.4 Does Concurrent Speech Therapy Make a Difference?

Ten studies, including the five largest studies, administered speech language therapy during the same period during which TMS was administered. The potential role of SLT in conjunction with TMS was not systematically investigated in any of these studies, however. The evaluation of the potential contribution

of concurrent speech therapy is complicated further by the fact that studies with and without concurrent SLT differed in a wide range of parameters. Thus, although there is a strong rationale for combining TMS with speech therapy, there is little convincing evidence that the presence of speech therapy is a significant determinant of response to therapy. This is an issue that warrants additional study.

83.2.4.5 Time Course of Benefit

A major weakness of many types of speech-language therapy is that the initial beneficial effect erodes over weeks to months. The beneficial effects of TMS in chronic aphasia stand in stark contrast to this general rule. In fact, one striking aspect of the data from TMS investigations is the finding that the benefit from TMS is typically not only sustained through the period of follow-up but also, at least in some instances, increases over time in the absence of ongoing therapy. For example, [Martin et al. \(2009\)](#) reported a subject with chronic aphasia whose performance at 16 months after therapy was significantly better than at 3 months. We reported a similar finding in a subject followed for 10 months ([Hamilton et al., 2010](#); see also [Naeser et al., 2005a](#) and [2005b](#)). Similarly, in an open-label case series involving 7 people with chronic aphasia tested at 1 week, 2 months, and 8 months after therapy, [Barwood et al. \(2012\)](#) found that subjects exhibited continued improvement; performance was better on 7 of 7 measures at 8 months as compared to 2 months after treatment.

Although the explanation for this finding remains unclear, we speculate that in the aftermath of a left hemisphere stroke residual components of the language circuits in the left and right hemispheres develop new patterns of interaction over weeks to months (see also [Devlin and Watkins, 2007](#); [Hamilton et al., 2010, 2011](#)). Improvement in performance during this interval may reflect the optimization of performance of an inefficient architecture. Based on a meta-analysis of functional imaging studies of aphasic subjects, [Turkeltaub et al. \(2011](#); see also [Hamilton et al., 2011](#)) identified a region in the right anterior pars triangularis that, unlike most regions of activation in the right hemisphere, was not homotopic with sites of activation in the left hemisphere; one potential account, then, is that this brain region is recruited during language recovery but that activation at this site is deleterious. If this is true, then inhibiting this right IFG site would be expected to improve language function. Thus, we speculate that the subsequent slow and sustained improvement in language function after TMS is attributable to suppression of this site that serves to "reboot" the language network, permitting new and more adaptive patterns of connectivity to emerge. It is interesting to note in this context that optimal sites

identified in our site finding studies of 10 aphasic subjects (Medina et al., 2012) were, in many cases, close to the site identified in the meta-analysis.

83.2.5 Summary of TMS Effects

In summary, multiple proof-of-principle studies as well as larger studies involving control conditions (e.g., sham or vertex stimulation) support the claim that TMS may improve picture naming and other indices of language function in people with aphasia. Although substantial differences in virtually all aspects of study design make it impossible to identify optimal procedures, there is compelling evidence that inhibitory stimulation to the right IFG produces reliable benefits in people with aphasia. Additional investigations will be necessary to determine whether aphasia type, chronicity, and severity are important predictors of response.

83.3 tDCS AS THERAPY FOR APHASIA

tDCS is a procedure in which a small current (e.g., 1–2 mA) is delivered to (usually) relatively large electrodes (e.g., 5 × 7 cm) on the scalp. Although much of the current is shunted from the anode to the cathode through skin, cerebrospinal fluid, and other tissues, the brain is subjected to tonic stimulation with, at least under some circumstances, polarity-dependent effects. Although the basic effects of small electrical currents applied to the cortex were first elucidated in the 1960s, electrical stimulation of the human brain with direct currents was largely ignored until approximately 2000, when groundbreaking work by Nitsche and Paulus (2000, 2001, Nitsche et al., 2003) demonstrated that the technique is capable of producing significant effects on behavior.

83.3.1 Basics of tDCS

Work in the 1960s with animals demonstrated that small positive and negative currents delivered to the cortex generated polarity-specific effects on resting membrane potentials; in particular, neurons near an anode exhibited lowered resting membrane potentials, thereby making neurons more likely to discharge; in contrast, the resting membrane potentials of neurons near the cathode were hyperpolarized, making neurons less likely to discharge (Purpura & McMurtry, 1965).

In a series of seminal reports, Nitsche and Paulus (2000) demonstrated polarity-dependent effects on brain function from small direct currents applied to the scalp. They demonstrated that direct current of 1 mA with the anode over the motor cortex and the

cathode over the contralateral supraorbital region for 12 minutes caused an increase in TMS-induced motor-evoked potentials, whereas reversing the electrode placement such that the cathode was over the motor strip caused a reduction in the motor-evoked potential. The effects of tDCS outlasted the stimulation by minutes to hours depending on the stimulation parameters.

Although much remains to be learned about the physiologic basis of tDCS effects, the persisting effects are thought to be caused by LTP and LTD-like processes, probably mediated by NMDA receptors and altered GABAergic activity (e.g., Nitsche et al., 2003; Stagg et al., 2009). The duration of tDCS effects is prolonged by combining stimulation with a task; this effect appears to be mediated, at least in part, by BDNF-dependent synaptic plasticity (Fritsch et al., 2010). There is substantial evidence that repeated administrations of tDCS produce effects that persist for weeks (e.g., Reis et al., 2009).

It is important to note that tDCS does not cause neurons to discharge but, by virtue of its effect on resting membrane potentials, it influences the rates at which neurons discharge. Because changes in firing rates may produce long-term effects by LTP and LTD-like mechanisms, the technique may have a disproportionate impact on circuits that are active during tDCS administration. For example, if neural circuits mediating language are active while tDCS is being administered, then anodal tDCS, which lowers resting membrane potentials, may increase the firing rates of the language-related neurons, thereby strengthening synaptic connections within the language circuits. For this reason, most of the investigations of tDCS as a therapy for aphasia have incorporated concurrent language therapy as part of the protocol.

There are a number of variables that determine the effect of tDCS. One crucial factor is electrode placement. In those instances in which there is reason to believe that enhancing neuronal activity is likely to be beneficial, the anode is typically placed near the brain region at which increased neuronal firing rate is desired and the cathode is often located at a site thought to be not relevant to task (e.g., supraorbital region) or off the head entirely (e.g., the shoulder). In those instances in which the goal is to decrease the firing rate of neurons in a specific brain region, the cathode is placed near the relevant tissue.

A second important variable is current intensity. Much of the pioneering work with tDCS in humans involved 1-mA currents; in recent years, many investigators have used larger currents (1.5–2 mA). Although it has been assumed that the effects of current intensity would be linear across intensities, recent data suggest that this is not true. Batsikadze et al. (2013) recently reported data from motor cortex stimulation with

2-mA currents for 20 minutes. They found that with the anode over the motor cortex, 2-mA stimulation produced the same enhancement of motor-evoked potential produced by 1-mA currents; surprisingly, however, reversing the placement of the electrodes so that the cathode was over the motor cortex generated effects that were quite different from those generated by 1-mA stimulation. Thus, with 2-mA currents, cathodal and anodal stimulation were indistinguishable in their effects on the motor cortex. Although the generalizability of this effect to different brain regions is not known, the findings of Batsikadze et al. (2012) complicate the interpretation of studies involving 2-mA stimulation. We return to this point later.

Finally, many investigators use sham stimulation as a control for nonspecific effects of the testing environment as well as subject expectations. Sham stimulation permits subjects and, in some instances, investigators to be blinded with respect to the type of stimulation (Kessler, Turkeltaub, Benson, & Hamilton, 2012). In most instances, sham stimulation involves a ramp-up of the current for 30–45 seconds to provide the tingling and local sensation associated with tDCS before extinguishing the current.

83.4 tDCS AS A TREATMENT FOR APHASIA

tDCS has proven to be beneficial in a number of clinical disorders such as epilepsy (Fregni et al., 2006), chronic pain (Bolognini, Olgiati, Maravita, Ferraro, & Fregni, 2013), major depression (Brunoni et al., 2011), and hemiparesis (Madhavan, Weber, & Stinear, 2011). In this section we review a total of 13 studies in which the effects of tDCS on aphasia have been reported. Studies have ranged in size from 3 to 37 subjects, with a total of approximately 140 subjects. As was the case with TMS investigations, there is substantial variability with respect to study design; indeed, no two studies used the same design. Nonetheless, certain commonalities in approach may be identified. We review the major variables in tDCS design and how they differ across studies before discussing the effectiveness of the intervention (see also de Aguiar, Paolazzi, & Miceli, 2015).

83.4.1 Electrode Placement

The most fundamental decision in the design of a non-invasive brain stimulation study is the electrode placement because this will determine the pattern of current flow and, ultimately, the brain regions that are stimulated. There has been striking variability with respect to electrode placement in the 13 studies reviewed here.

Nine tDCS studies were motivated by the same perspective that animated TMS studies—the conviction that excitation of the left hemisphere or inhibition of the right hemisphere will improve performance in chronic aphasia. However, the manner in which this goal was achieved differed. Many studies (see Table 83.2) attempted to enhance left hemisphere function with anodal stimulation of the left hemisphere and a “neutral” cathodal placement (e.g., supraorbital region, shoulder). Kang, Kim, Sohn, Cohen, and Paik (2011) took a different approach to altering the balance between right and left hemisphere function, using right hemisphere cathode stimulation to “inhibit” the right hemisphere. You, Kim, Chun, Jung, and Park (2011) used a left anode and right cathode (both with supraorbital reference) in separate conditions. Finally, Marangolo et al. (2014) used a simultaneous left anode and right cathode to the bilateral IFG to both potentiate the left and inhibit the right hemisphere (see Lindenberg et al., 2010).

Other investigators systematically investigated the role of the left and right hemispheres by applying anodal and cathodal stimulation to the same structure in different conditions. Thus, Monti et al. (2008) administered both anodal and cathodal stimulation to the left frontal region in separate conditions while Flöel et al. (2011) administered both anodal and cathodal stimulation to the right temporal/parietal region in separate conditions.

Not all studies were motivated by the desire to alter the balance between the hemispheres in favor of greater activation in the left hemisphere. In the largest study reported to date (37 subjects), Jung, Lim, Kang, Sohn, and Paik (2011) used cathodal stimulation to left frontal regions to down-regulate neural activity in the left hemisphere. Additionally, based on the assumption that Melodic Intonation Therapy relies on right hemisphere structures, Vines, Norton, and Schlaug (2011) administered anodal stimulation to the right IFG to enhance the value of this concurrently administered therapy.

Although most studies reported significant benefit, no definitive conclusion regarding the optimal electrode placement can be drawn from studies that used only one active montage. Five studies that contrasted the effects of different montages do, however, provide some important insights. Marangolo, Fiori, Calpagnano, et al. (2013) and Marangolo, Fiori, Di Paola, et al. (2013) contrasted the effects of left Broca and left Wernicke anodal stimulation (both with right supraorbital cathode) on verb naming (2013) and a variety of measures of speech production (2013); in both studies, they found significantly greater benefit from Broca area anodal stimulation, whereas Wernicke area anodal stimulation did not differ from sham.

Two studies speak to the hypothesis that activating the left hemisphere or inhibiting the right hemisphere

TABLE 83.2 Studies for the Use of tDCS in the Treatment of Aphasia.

Author	Subjects	Anode*	Cathode*	Design	Intensity and Duration	Task	Concurrent Speech Therapy?	Time at Testing	Effects
Monti et al., 2008	8 Chronic aphasics:	Condition 1: L frontal	Condition 1: R shoulder	Single session, 1 wk between sessions	2 mA/ 10 min	Picture naming	No	Immediately after stimulation	Cathode 33% better accuracy
	4 Broca	Condition 2: R shoulder	Condition 2: L frontal	6 Subjects assigned to both condition 1 and 2					
	4 Wernicke	Control: sham	Control: sham						
Baker et al., 2010	10 Chronic aphasics (> 12 months)	Condition 1: L perilesional (25 cm ²)	Condition 2: R shoulder (25 cm ²)	20 min of 1 mA tDCS; 5 days in each condition	1 mA/ 20 min	Spoken word-picture matching	Yes	Immediately after treatment and 1 week later	Improved naming with anodal tDCS for treated
		Control: sham	Control: sham						Marginal effect for untreated words
You et al., 2011	21 Subacute global aphasics	Condition 1: L superior temporal gyrus (CP5)	Condition 1: R supraorbital	Subjects randomized to 1 of 3 conditions; 10 daily sessions each condition	2 mA/ 30 min	Naming	Yes		Significant benefit of right cathodal stimulation versus anode and sham for aud comp.; no effect on other measures
Flöel et al., 2011	12 Chronic aphasics	Condition 1: R temp/par	Condition 1: L supraorbital (100 cm ²)	Randomized, double-blind cross-over with 3 conditions; 2 sessions/day for 3 days in each condition	1 mA/ 20 min	Picture naming	Yes	2 weeks after treatment	All conditions show >80% improvement, right anodal greatest and significantly better than sham
		Condition 2: L supraorbital (100 cm ²)	Condition 2: R temp/par						
		Control: sham	Control: sham						
Fiori et al., 2011	3 Chronic aphasics	Condition 1: L Wernicke's (CP5)	Condition 1: R supraorbital	Cross-over design	1 mA/ 20 min	Picture naming	Yes	1 and 3 weeks after therapy	Anodal 20% better than sham
		Control: sham	Control: sham	2 Conditions separated by 1 week					
Fridriksson et al., 2011	8 Chronic fluent aphasics with postcortical. or subcortical lesions	Condition 1: posterior margin of lesion at max fMRI activation	Condition 1: R supraorbital (100 cm ²)	Double-blind, cross-over with 5 sessions	1 mA/20 min	Spoken word-picture matching	Yes	3 weeks after	Anodal reduces RT for trained nouns relative to sham; no generalization
		Control: sham	Control: sham						

(Continued)

TABLE 83.2 (Continued)

Author	Subjects	Anode*	Cathode*	Design	Intensity and Duration	Task	Concurrent Speech Therapy?	Time at Testing	Effects
Kang et al., 2011	10 Chronic aphasics	Condition 1: L supraorbital Control: sham	Condition 1: R "Broca's" (F8) Control: sham	Double-blind, randomized, cross-over design; 20 min daily for 5 days in each condition	2 mA	Picture naming	Yes	Immediately after treatment	Significant improvement in naming after tDCS
Vines et al., 2011	6 Nonfluent chronic aphasics (> 12 months)	Condition 1: R IFG (16.2 cm ²) Control: sham	Condition 1: L supraorbital (30 cm ²) Control: sham	Double-blind, cross-over design; 3 sessions each condition	1.2 mA	Speech production time	Yes, melodic intonation therapy	Immediately after treatment	Anodal reduced production time
Jung et al., 2011	37 Aphasics, average: 27 <90 days after and 26 nonfluent	Condition 1: R supraorbital Control: none	Condition 1: L Broca's area Control: none	10 Sessions of 20 min over 2–3 weeks	1 mA	Korean WAB	Yes	Immediately after treatment	No effect of sham Significant improvement of 14.9% or 65.2% of baseline
Santos et al., 2013	19 Chronic aphasics	L supraorbital Control: none	R motor strip Control: none	10 Sessions of 20 minutes over 2 weeks	2 mA	Multiple measures	No	Immediately after treatment	Significant improvement in 3 of 18 measures, trend in another 4 measures
Volpato et al., 2013	8 Chronic mild or moderate aphasics	Condition 1: L Broca's area Control: sham	Condition 1: R supraorbital Control: sham	Cross-over design; 10 daily sessions over 2 weeks in 2 conditions	2 mA/ 20 min	Object and action naming	No	Immediately after treatment	No group effects on action or object naming
Polanowska et al., 2013	24 Subacute (2–24 weeks) nonfluent aphasics	L "Broca's area"	R supraorbital	Randomized, sham controlled. 15 sessions	1 mA/10 min	Picture naming	Yes	Immediately after treatment and 3 months later	No significant difference between groups
Marangolo, Fiori, Calpagnano, et al., 2013	7 Chronic "nonfluent" aphasics	Condition 1: L "Broca" area (F5) Condition 2: L "Wernicke" area (CP5)	Condition 1: R supraorbital Condition 2: R supraorbital	5 Daily sessions in each of three conditions for all subjects	1 mA/20 min	Verb naming	Yes	Immediately after treatment, 1 and 4 weeks later	Broca's stimulation significantly better than sham and Wernicke stimulation (these two did not differ)

(Continued)

TABLE 83.2 (Continued)

Author	Subjects	Anode*	Cathode*	Design	Intensity and Duration	Task	Concurrent Speech Therapy?	Time at Testing	Effects	
Marangolo, Fiori, Di Paola, et al., 2013	12 Chronic "nonfluent" aphasics	Control: sham	Control: sham	10 Daily sessions in each condition	1 mA/20 min	Content units in disclosure	Yes	Immediately after treatment	C-units, verbs, and sentences: Broca's area stimulation greater than Wernicke's and sham, which did not differ	
		Condition 1: L "Broca's" area (F5)	Condition 1: R supraorbital						2 weeks later	Benefit maintained at follow-up
		Condition 2: L "Wernicke's" area	Condition 2: R supraorbital							Effect seen in trained and untrained materials
Marangolo et al., 2014	7 Chronic "nonfluent" aphasics	Control: sham	Control: sham	10 Daily sessions	2 mA/20 min	Description of videotaped vignettes	Yes: "pragmatic therapy"	Immediately after therapy and 1 week later	Improved noun, verb, description relative to sham; average increase across 3 measures 16.3% versus 5.3%	
		Condition 1: left IFG	Condition 1: right IFG						Some generalization	
Campana, Caltagirone, and Marangolo, 2015	20 Chronic nonfluent aphasics	Control: sham	Control: sham	10 Daily sessions	2 mA/20 min.	Picture description, verb and noun naming	Yes	Before and after 10 day sessions	Significant improvement in all three measures	

will enhance performance. Thus, [Monti et al. \(2008\)](#) reported greater benefit from cathodal as compared to anode placement over the left frontal region (both conditions paired with right shoulder electrode). Similarly, [Flöel et al. \(2011\)](#) contrasted the effects of placement of the anode and cathode over the posterior right hemisphere (both paired with left supraorbital) and found that anodal stimulation of the right hemisphere provided significantly better performance.

Finally, Hamilton and colleagues (in press) adopted a “site finding” approach similar to that pioneered by Naeser et al. (2005) in TMS investigations. Reasoning that extant data did not provide a clear “best” approach, these investigators assessed naming under a total of five conditions. On separate days, all subjects were tested before and after 20 minutes of 2 mA tDCS in the following conditions: (1) anode over the left IFG and cathode over the right IFG; (2) anode over the right IFG and cathode over the left IFG; (3) anode over the left posterior STG and cathode over the right posterior STG; (4) anode over the right STG and cathode over the left STG; and (5) sham stimulation using the configuration described in (1). Subjects who demonstrated significant benefit in one of the conditions received therapy consisting of daily sessions of 20 minutes at 2 mA using the montage that provided the greatest benefit.

One additional point regarding electrode placement concerns the limitation in specificity of stimulation resulting from the large electrode size and patterns of current flow. As most studies have used large (5 × 7 cm) electrodes that cover brain regions larger than those typically hypothesized to be relevant to language function, claims regarding the site of stimulation should be interpreted with caution. Furthermore, efforts to model current distribution across the brain (e.g., [Datta et al., 2009](#); [Miranda, Lomarev, & Hallett, 2006](#)) suggest that effects are not likely to be restricted to the site of the electrode and may, in fact, be maximal at sites adjacent to rather than under the electrode. Although presently unsupported by empirical data, these simulations suggest that large swaths of regions between electrodes are subjected to current. Although the recent advent of “high-definition” tDCS using small and relatively closely spaced electrodes may afford substantially greater precision than has been available to date ([Datta, Bikson, & Fregni, 2010](#); [Suh, Lee, & Kim, 2012](#)), it is not possible to make strong statements regarding the role of specific brain regions in the genesis of the reported effects.

83.4.2 Control Conditions and Follow-up

A strength of tDCS studies to date has been the inclusion of multiple experimental conditions. As previously noted, tDCS affords the possibility of a sham

stimulation in which current is delivered at the start of the session, thereby inducing cutaneous symptoms of itching and/or burning before being extinguished. Several studies have demonstrated that, at least with current intensities of 1 mA, subjects cannot distinguish between real and sham conditions ([Kessler et al., 2012](#)). Eleven studies have used a sham condition. Four studies used two active conditions in addition to a sham condition to address hypotheses regarding the relative benefit of anterior versus posterior electrode placement ([Marangolo, Fiori, Calpagnano, et al., 2013](#)) or contrast the benefit of anodal or cathodal stimulation of the same ([Flöel et al., 2011](#); [Monti et al., 2008](#)) structure or homologous structures of the right and left hemispheres ([You et al., 2011](#)).

A shortcoming of the tDCS literature to date is the lack of long-term follow-up. Whereas many TMS studies report data from at least 4 months after stimulation, a significant number of tDCS studies report data only from testing immediately after the end of treatment. Only four studies reported data from 3–4 weeks after treatment, rendering it impossible to determine the long-term effects of the intervention.

83.4.3 Concurrent Treatment

As previously noted, tDCS is assumed to modulate neural activity. Therefore, it is not surprising that 14 of 16 tDCS investigations have paired stimulation with speech therapy. Although the small numbers of studies argue for caution in drawing conclusions, it is noteworthy that [Volpato et al. \(2013\)](#) demonstrated no benefit relative to a sham condition from stimulation with the anode over the left Broca’s area and the cathode over the right supraorbital region. [Santos et al. \(2013\)](#) reported modest effects, finding significant improvement in only 3 of 18 language measures. Thus, we believe that evidence to date argues for the inclusion of language therapy in future tDCS studies.

83.4.4 Outcomes

What can these studies tell us about who will benefit and the magnitude of that benefit? As with TMS studies, although striking differences between stimulation parameters and study designs confound attempts to draw generalizations from the investigations published to date, tentative conclusions may be drawn.

A closer look at the studies demonstrates that 2 of the 16 studies do not speak directly to the potential of tDCS as a therapy for aphasia. Subjects reported by [Monti et al. \(2008\)](#) received only one stimulation in each of three conditions and the only assessment was immediately after therapy. Additionally, [Jung et al.](#)

(2011) reported benefit in the largest series published to date ($n = 37$), but the absence of a control group in a population that included 73% subacute (less than 90 days poststroke) cases in subjects who would be expected to improve under any circumstances makes this finding interpretable. The fact that the subjects were receiving concurrent speech-language therapy further confounds efforts to discern effects of tDCS in this group.

Thirteen of the remaining 14 studies reported benefit on at least some measures. The only study that reported a negative result (Volpato et al., 2013) included many subjects with mild aphasia in whom beneficial effects could have been obscured by ceiling effects. There appears to be substantial variability with respect to the magnitude of the benefit, however. In some investigations, the effects are relatively modest. You et al. (2011), for example, reported a benefit in auditory comprehension in subjects treated with the cathode over the left hemisphere but no benefit in other measures; other investigators report improvement in naming accuracy on the order of 10–15% or less. In two studies (Fridriksson, Richardson, Baker, & Rorden, 2011; Vines et al., 2011), the beneficial effect was manifested as a modest reduction in speech production times.

Are the positive effects of tDCS clinically relevant? A definitive answer would require additional information regarding magnitude and duration of the benefit and the range of language processes that are influenced by the intervention. Although effect sizes are typically not reported, several studies (Baker, Rorden, & Fridriksson, 2010; Jung et al., 2011; Kang et al., 2011; Polanowska, Kesniak, Seniow, Czepiel, & Czlonkowska, 2013; Santos et al., 2013; Volpato et al., 2013; You et al., 2011) provide information regarding changes in accuracy and such a measure of effect size (Cohen's D) may be calculated. The effect sizes range from 0.175 (−0.76–1.11) (Volpato et al., 2013) to 1.064 (−0.31–2.44) (Baker et al., 2010), with a mean of approximately 0.489. As was the case with TMS studies, the effect size data must be considered preliminary because of differences in methods, small sample sizes, and other factors. Nonetheless, findings to date suggest that, at least in some instances, tDCS generates clear benefit.

Promising data regarding the range of language faculties influenced by tDCS are starting to emerge. Most early studies used only naming tasks to assess the effects of the intervention. You et al. (2011) reported data from a more comprehensive language assessment, the Korean version of the Western Aphasia Battery. The former demonstrated a benefit from auditory comprehension but, more generally, not the WAB Aphasia Quotient. More recently, Marangolo and colleagues

have reported studies that have extended the range of phenomena that are positively influenced by tDCS. For example, Marangolo and colleagues reported benefit from stimulation with the anode over Broca's area on verb naming (Marangolo, Fiori, Calpagnano, et al., 2013) and "content units" (Marangolo, Fiori, Di Paola, et al., 2013) in discourse. Most recently these investigators also reported data from seven "nonfluent" subjects with left IFG anode and right IFG cathode demonstrating improvements in speech elicited in attempts to describe videotaped vignettes (Marangolo et al., 2014). In both of the latter two studies there was some evidence of generalization to unpracticed clips. Interestingly, "traditional" measures of language function did not change with the interventions in two of these studies (Marangolo, Fiori, Di Paola, et al., 2013; Fiori, Cipollari, Caltagirone, and Marangolo, 2014; Marangolo et al., 2014). Thus, recent data extend the range of phenomena shown to be effected by tDCS to include language capacities that are of clear ecological significance. Furthermore, the evidence of generalization found by these investigators, while not robust, is promising.

A second issue pertaining to the clinical relevance of the intervention is that only short-term outcome data are available. Most studies have assessed tDCS effects either immediately or several weeks after stimulation. Only one study reports findings persisting for up to 1 month (Marangolo, Fiori, Calpagnano, et al., 2013). The lack of information about duration of effects limits the assessment of the clinical utility of the benefit of tDCS and should be addressed in future studies.

There are a number of other fundamental questions regarding subject selection and study design that have yet to be addressed. For example, does the duration of aphasia influence the response to tDCS? Most studies have involved patients with chronic aphasia; however, people with subacute aphasia have been included in several studies. In a study of 21 subacute patients, You et al. (2011) reported no main effect of tDCS and a relatively modest benefit on only one measure, auditory comprehension. As previously noted, Jung et al. (2011) reported data from 37 subjects, 73% of whom were subacute; although the subacute subjects improved more than the people with chronic aphasia, the absence of a control group clouds the interpretation of this finding. Finally, Polanowska et al. (2013) demonstrated no significant differences between real and sham-treated groups. Thus, limited evidence to date does not demonstrate the utility of tDCS in people with subacute aphasia. There is no *a priori* reason to believe that the technique should not be beneficial in this setting and further study seems warranted.

Another important issue about which relevant information is lacking is the importance of subject characteristics such as type of aphasia. Many studies are

heterogeneous with respect to aphasia subtype, whereas other studies report subjects only as “fluent” or “nonfluent,” a dichotomy that fails to capture a range of potentially relevant dimensions of language function. [Fridriksson et al. \(2011\)](#) reported benefit on a spoken word to picture matching task in people with “fluent” aphasia and multiple studies involving people with “nonfluent” aphasia have demonstrated benefit in that (heterogeneous) group. Therefore, at present, there is little information regarding aphasia subtype and the basis on which to select subjects for tDCS therapy.

The optimal electrode montage has not been established. One factor that seriously undermines efforts to identify optimal sites of stimulation is the inherent imprecision of tDCS when administered with the large electrodes used in the studies reviewed here. Tentative conclusions may be drawn regarding electrode placement, however. First, the data do not unambiguously support the hypothesis that stimulation of the left or inhibition of the right hemisphere will be of benefit. Although a number of left hemisphere stimulation and right hemisphere inhibition ([Kang et al., 2011](#)) studies have demonstrated benefit, studies involving right hemisphere stimulation ([Flöel et al., 2011](#); [Vines et al., 2011](#)) have also produced benefit. Furthermore, in a direct comparison of left frontal anodal and cathodal stimulation, [Monti et al. \(2008\)](#) reported that a single session of cathodal stimulation of the left frontal region produced significantly better performance on a naming task. However, because they were using 2-mA current, the interpretation of this finding is currently unclear.

Second, there is limited evidence regarding the effects of stimulation of the anterior as opposed to the posterior language cortices. Of greatest relevance in this context are the studies by [Marangolo, Fiori, Calpagnano, et al. \(2013\)](#) and [Marangolo, Fiori, Di Paola, et al. \(2013\)](#), in which the effects of anodal placement in the anterior and posterior regions and cathode over the contralateral forehead were directly contrasted. In both studies, anodal placement over the frontal lobe was associated with significant benefit, whereas performance with placement over the posterior regions did not differ from the sham condition.

83.5 GENERAL DISCUSSION

Data from more than 25 studies, many with appropriate control conditions, demonstrate that noninvasive brain stimulation may be of benefit in the treatment of aphasia. There is clear evidence that rTMS is of persistent benefit for people with subacute and chronic non-fluent aphasia with respect to a wide range of language tasks and what, at least in some instances, is

estimated to be a large effect size. However, there is also evidence of benefit from tDCS in well-controlled, randomized studies at present regarding the duration and range of the positive effects.

83.5.1 TMS and tDCS: Advantages and Disadvantages ([Wasserman, 1998](#))

As there is evidence for the effectiveness of both TMS and tDCS as treatments for aphasia, which one is preferable? Although there is no clear answer to this question, there are a number of factors that must be considered.

One crucial issue is safety. At this point, both techniques appear to be safe and well-tolerated. In particular, tDCS has an exemplary safety record. The technique has been investigated in several studies in normal subjects (e.g., [Kessler et al., 2012](#); [Lang et al. 2005](#)) with no major adverse effects noted and there has been no evidence of significant issues in the growing literature documenting its use in hundreds of subjects with brain pathology. It is not surprising, then, that no adverse effects have been demonstrated in any study involving aphasic subjects. Similarly, there have been no reports of adverse effects in the more than 200 subjects participating in TMS studies to date. We are also unaware of reports of subjects dropping out of TMS studies because of adverse effects. Although one might be more concerned about seizures in subjects with a neurologic condition such as stroke, which is known to be associated with seizures, it is noteworthy that no significant adverse effects have been reported in any TMS involving people with aphasia. Furthermore, TMS has been administered to the lesioned hemisphere using more aggressive stimulation parameters than those in most studies of people with aphasia in a variety of other rehabilitation settings without adverse effects (e.g., [Khedr et al., 2005, 2014](#)). At present, therefore, both tDCS and TMS appear to be safe in this setting.

A second parameter relevant to the decision to use tDCS or TMS is cost. tDCS is less resource-intensive in several respects. The apparatus is less costly and easier to administer. Whereas TMS often requires administration by two experimenters, tDCS can be administered by one person.

A third factor that may be relevant to a choice between TMS and tDCS is the ease with which the technique may be paired with speech-language therapy. The effects of TMS are substantially more intrusive and distracting than tDCS, making the latter much easier to combine with therapy. The import of this factor is not clear. For theoretical reasons discussed herein, concurrent therapy may be important for tDCS

but not for TMS, for which therapy immediately after stimulation may be adequate.

Finally, along with patient safety, the most important consideration regarding the decision to use tDCS or TMS is efficacy. Although there are no definitive data at this time, informal assessment of reported benefits suggest that TMS may be somewhat more effective, at least as judged by picture naming. Furthermore, there is evidence of sustained benefit from TMS, but the issue has not been addressed for tDCS.

83.5.2 NIBS and Mechanisms of Recovery

There has been controversy regarding the neural basis of the recovery of language function after stroke, at least since the initial report by Barlow (1877) of a patient who, after recovering from stroke-induced aphasia, became aphasic once again after a new right hemisphere stroke. In recent years there has been substantial debate regarding the anatomic basis of recovery, with some evidence suggesting that recovery is mediated by remaining left hemisphere tissue and other studies suggesting that the right hemisphere is crucial for recovery (Hamilton et al., 2010, 2011; Thiel et al., 2006; Turkeltaub et al., 2011; Winhuisen et al., 2007). The approach adopted by Naeser and many subsequent investigators using both TMS and tDCS has been motivated by the hypothesis that the right hemisphere adversely influences language performance, because of inhibition of remaining left hemisphere language structures, an increasing reliance on right hemisphere regions that are not optimized for language, or both. TMS studies involving “inhibitory” 1-Hz stimulation of the right hemisphere as well as “excitatory” stimulation of the left hemisphere are consistent with the predictions of this account. Furthermore, imaging data are in accord with this prediction. For example, Allendorfer et al. (2012) reported that excitatory theta-burst TMS to the left frontal cortex was associated with an increase in white matter connectivity as assessed by fractional anisotropy (FA) in regions near the stimulation site. However, as acknowledged by the authors, the interpretation of these data is complicated by the fact that other distant regions (e.g., right midbrain) also demonstrated increases or decreases in FA. Weiduschat et al. (2011) performed PET scans to measure blood flow during a verb generation task in 10 subacute stroke patients before and after TMS. They calculated a Laterality Index reflecting the difference between blood flow in language-related areas of the right and left hemispheres. They found that TMS to the left hemisphere was associated with a change in the LI reflecting greater blood flow in the left IFG (or preserved tissue

nearby), whereas no such change was observed in the sham group. Similar findings were reported by Naeser et al. (2009) and Thiel et al. (2013). However, not all data support the hypothesis that recovery after TMS is attributable to greater left hemisphere involvement. We (Turkeltaub et al., 2011) reported a patient who improved after receiving TMS to the right IFG but became acutely and permanently worse after a subsequent right hemisphere stroke. These data strongly suggest that, at least for some subjects, right hemisphere structures are crucial components of the distributed language system.

Data from tDCS studies are also not definitive. As noted, improvement in language function after tDCS has been observed with electrode montages that, on traditional assumptions regarding the role of anodal and cathodal stimulation, would be expected to stimulate or inhibit both the right and left hemispheres. Therefore, at this juncture, the data from noninvasive brain stimulation studies do not unambiguously address the relative contributions of the right and left hemispheres to language recovery. Rather, the data reinforce the view that multiple factors such as infarct size, location, and premorbid functional anatomy determine the composition of language networks mediating recovery from aphasia.

In conclusion, although much remains to be learned regarding the patient selection and optimal procedures, there is compelling evidence that both TMS and tDCS improve language function in aphasic subjects. Ultimately, a randomized, controlled clinical trial involving subjects with multiple aphasia types with comprehensive language assessments extending for at least 6 months will be needed to assess the relative efficacy of the techniques.

Imitation-Based Aphasia Therapy

E. Susan Duncan¹ and Steven L. Small²

¹Solodkin/Small Brain Circuits Laboratory, Department of Neurology, University of California, Irvine, Irvine, CA, USA;

²Department of Neurology, University of California, Irvine, Irvine, CA, USA

84.1 INTRODUCTION: REPETITION AND IMITATION IN APHASIA

In 1683, the German physician Peter Rommel was the first to write about repetition deficits in a patient with nonfluent aphasia (Benton & Joynt, 1963). Imitation has since been a key diagnostic and treatment tool for such acquired language disorders. All popular standardized instruments for the assessment of aphasia, such as the Western Aphasia Battery-Revised (WAB-R) (Kertesz, 2006), Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1983), and Aachen Aphasia Test (Huber, Poeck, & Willmes, 1984), include repetition ability in their classification scheme.

Imitation was fundamental to the nascent field of aphasia therapy at the turn of the 20th century, and it remains so today (Duffy, 1995). This chapter describes the neurobiological rationales for, and current implementations of, imitation in aphasia therapy. “Imitation” and “repetition” are used interchangeably, and modes of stimulus presentation are clarified as needed. Additionally, it should be noted that acquired apraxia of speech, a motor planning deficit frequently accompanying nonfluent aphasia (Duffy, 1995), is not specifically addressed in this chapter.

84.2 NEUROBIOLOGICAL APPROACHES TO LANGUAGE AND APHASIA

The earliest approaches were based on behavioral and educational principles, and this philosophy dominates aphasia therapy today (Small, 2004). Aphasia is a neurological impairment resulting from brain damage, typically stroke (Ellis, Dismuke, & Edwards, 2010), yet treatment programs are rarely biologically motivated. Since the end of the 20th century, studies in aphasia have

been relying less on applied psychology and linguistic models, instead seeking to link observed deficits to impairments in the underlying neural systems (Blumstein, 1997). Rehabilitation of the behavioral deficits of aphasia must target the plasticity and repair of affected biological systems. Two main biological models characterizing these systems are considered here, the human mirror system and the dual-stream hypothesis for speech.

84.3 MIRROR NEURON SYSTEM

84.3.1 Macaque

Mirror neurons were discovered serendipitously during single-cell recordings of hand motor representations in the macaque. Rizzolatti and colleagues found neurons firing in premotor cortex (area F5) in a motionless monkey during observation of the experimenter (Di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992). Individual neurons were active during observation and execution for hand and mouth movements (Ferrari, Gallese, Rizzolatti, & Fogassi, 2003; Gallese, Fadiga, Fogassi, & Rizzolatti, 1996). Additional mirror neurons possessing visuomotor properties were subsequently identified in the inferior parietal region of the macaque (Fogassi, Gallese, Fadiga, & Rizzolatti, 1998), primarily in subcomponents PF and PFG (Rozzi, Ferrari, Bonini, Rizzolatti, & Fogassi, 2008), which have strong anatomical projections to the ventral premotor cortex (F5). These findings led to the suggestion of a functional “mirror” network (Rozzi et al., 2006).

The existence of mirror neurons immediately prompted hypotheses about their role in action recognition (Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). Further support for this has been provided by the discovery that some mirror neurons in macaque F5 have auditory as well as visual and motor properties

(Kohler et al., 2002), firing in response to observation and execution of actions, and for sounds associated with those actions. This multimodal integration at the level of a single cell may form the basis for action understanding and motor learning (Jeannerod, 1994).

84.3.2 Human

Ethical considerations prohibit systematic human studies investigating individual mirror neurons. However, support for the existence of a human parieto-frontal mirror neuron system is converging from behavioral, neurophysiological, and brain imaging studies (Small, Buccino, & Solodkin, 2012). The “direct matching hypothesis” postulates that imitation is subserved by simple neural mechanisms mapping observed actions onto internal motor representations of the same action by neurons with mirror properties, which are more strongly activated for actions elicited by preceding observations (Iacoboni et al., 1999).

84.3.2.1 Behavioral

Behavioral studies demonstrate motor facilitation when action execution immediately follows observation, supporting the existence of a mirror system in humans. Finger movements are faster if the stimulus cue is a modeled finger movement compared to an unrelated symbol (Brass, Bekkering, Wohlschläger, & Prinz, 2000). Response speed further increases as the modeled movement more closely resembles the target, even when the stimulus image is flipped upside-down (Brass, Bekkering, & Prinz, 2001). Grasping response speed increases when subjects are shown a picture of a hand with optimal orientation for their own final hand position (Craighero, Bello, Fadiga, & Rizzolatti, 2002). On language tasks, response times for plausibility judgments are faster when the action response required is similar to the action described in the stimulus sentence (Glenberg & Kaschak, 2002).

84.3.2.2 Neurophysiology

Studies using electroencephalography (EEG) demonstrate a central mu rhythm in the alpha frequency range (8–13 Hz) present when the subject is at rest. This is suppressed during action observation, as was first described in 1954 (Cohen-Seat, Gastaut, Faure, & Heuyer, 1954). These findings have since been replicated for observation, imitation, and execution of actions with EEG (Altschuler et al., 2000; Cochin, Barthelemy, Roux, & Martineau, 1999). Responses measured via implanted subdural electrodes show a reduction in absolute power in the alpha band over primary motor cortex and Broca’s area for both observation and execution of finger movements (Tremblay et al., 2004).

Mu suppression is stronger for grasping than for movements that are not goal-oriented in adults (Muthukumaraswamy & Johnson, 2004) and in children (Lepage & Théoret, 2007). A precursor to the mu rhythm, with overlapping reduction for observed and executed grasping movements, is found in infants in the frequency range of 6–9 Hz (Marshall, Young, & Meltzoff, 2011). It is proposed that mirror neurons underlie early childhood imitation, language acquisition, and the development of other social and cognitive functions (Williams, Whiten, Suddendorf, & Perrett, 2001).

Magnetoencephalography (MEG) reveals a band of activity of 15–25 Hz in the precentral motor cortex during rest. Suppressing this activity via upper extremity median nerve stimulation allows study of its rebound in varying contexts. This rebound is extinguished during object manipulation after stimulation and is significantly reduced during passive observation of the same task (Hari et al., 1998).

Transcranial magnetic stimulation (TMS) manipulates cortical responses by either inducing or inhibiting action potentials. TMS-induced motor-evoked potentials (MEPs) demonstrate increased excitability when observing grasping actions and arm movements using the same muscles (Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995). These results have been replicated using observation of handwriting and arm movements compared to rest (Strafella & Paus, 2000).

These neurophysiological findings suggest the influence of mirror properties on the human motor system extends to primary motor areas, in addition to the postulated premotor homologues of the frontal regions where macaque mirror neurons have been identified. Greater extension still has been proposed. In single-cell recordings from subjects with medically intractable epilepsy, a significant number of neurons in the supplementary motor area (SMA) and the medial temporal lobe (MTL) respond to the observation and execution of a single action (Mukamel, Ekstrom, Kaplan, Iacoboni, & Fried, 2010). These regions, with clinical rather than theoretical determination of electrode placement, have not previously shown mirror properties. Additionally, some neurons responded with increased excitation for execution but suppressed firing rate for observation, unlike macaque studies. The authors propose that these findings may provide evidence of multiple mirroring systems in the brain, with reduced activity of some neurons during observation playing a role in suppressing socially inappropriate imitation.

84.3.2.3 Brain Imaging

Brain imaging studies permit greater spatial localization of mirror properties in humans. Early evidence

came from a positron emission tomography (PET) study contrasting object observation with action observation (Rizzolatti, Fadiga, Matelli, et al., 1996). Activation in response to action observation was found in Broca's area and left hemisphere temporal regions (middle temporal gyrus, superior temporal sulcus). Mirror properties have since been demonstrated via functional magnetic resonance imaging (fMRI) in two regions of the human brain active during both passive observation and imitation of finger movements, the left frontal operculum of Broca's area and the right anterior parietal region (Iacoboni et al., 1999).

Broca's area, the putative frontal oral-motor and speech area in localist language models, plays a role in hand motor representation (Binkofski et al., 1999) and is typically identified as the human homologue of macaque F5 in which mirror neurons have been recorded (Rizzolatti, Fadiga, Gallese, et al., 1996). However, the consistent finding of activation in response to observation of hand and arm actions (Decety et al., 1997; Grafton, Arbib, Fadiga, & Rizzolatti, 1996) in Broca's region, in combination with its long history in the neuroscience of language, has raised the question of whether this increased neural response is perhaps an epiphenomenal artifact of internal speech during these tasks.

fMRI investigation of responses to actions performed by the hand, foot, or mouth reveals a somatotopic organization of premotor cortex similar to that found in the primary sensory and motor cortices with ventral mouth movements and dorsal foot movements (Buccino et al., 2001). Similar organization is found in the posterior parietal lobe for object-related actions. These findings ground single neuron measures from macaque in a broader network of motor circuitry underlying both action observation and execution in humans.

Macaque mirror neurons fire for observation of grasping only in the presence of a graspable object, even if it is not visible (Umiltá et al., 2001). It has been suggested that this system is not encoding simple movements, but goal-oriented motor acts (Gallese et al., 1996). In human PET scans, left frontal and temporal regions are activated for meaningful, but not meaningless, actions (Decety et al., 1997). With fMRI, actions embedded in contexts show increased activation in the posterior inferior frontal gyrus (IFG) and ventral premotor cortex (vPM) compared to viewing either the action or the context alone (Iacoboni et al., 2005). This is especially pertinent to the discussion of language, in which we use our motor systems to transmit meaningful messages, with mirror neurons bridging the gap between "doing" and "communicating" (Rizzolatti & Arbib, 1998).

84.4 MIRROR NEURON SYSTEM AND LANGUAGE

Language, as a uniquely human property, lacks an ideal animal model, and biological theories of language cannot be directly tested. However, indirect evidence supports a role for the mirror neuron system in human language ability, both phylogenetically through evolutionary selection processes (Rizzolatti & Arbib, 1998) and ontogenetically in facilitating child language acquisition (Kuhl & Rivera-Gaxiola, 2008). It is suggested that mirror deficits may underlie developmental disorders of language and social interaction, notably autism (Williams et al., 2001), although such issues are controversial and beyond the scope of this text.

84.4.1 Perception and Production of Articulated Speech

fMRI reveals somatotopy in human frontal and parietal regions having mirror properties with ventral mouth activation compared to hands or feet, as in primary motor and somatosensory cortices (Buccino et al., 2001). The observation–execution or direct matching hypothesis suggests that action perception, including speech, depends on previous experience producing those actions or sounds (Iacoboni et al., 1999). One model of this is the "inverse-forward model pairs" (IFMPs) (Skipper, Nusbaum, & Small, 2006). These are mechanistic components of the mirror system, in which speech sounds, heard or observed, are transformed into corresponding articulatory gestures (inverse) and motor predictions (forward) with resultant sensory consequences affecting perception. These IFMPs operate in the multisensory contexts in which we experience language, consisting of acoustic signals and also the visual cues of oral, facial, manual, and body gestures, particularly when auditory information is distorted or ambiguous.

84.4.1.1 Neurophysiology

Listening to the lingual trill /r/ results in significantly increased amplitude in tongue muscle MEPs in neurologically intact participants compared to the non-lingual labiodental phoneme /f/ or thumb muscle MEPs (Fadiga, Craighero, Buccino, & Rizzolatti, 2002). This response is more pronounced for real words compared to pseudowords. Similarly, increased MEPs in oral muscles, but not finger muscles, are found during listening to connected speech and viewing silent video of speech-related lip movements (Watkins, Strafella, & Paus, 2003). This contrast is not found for nonspeech control conditions, including nonverbal sounds and

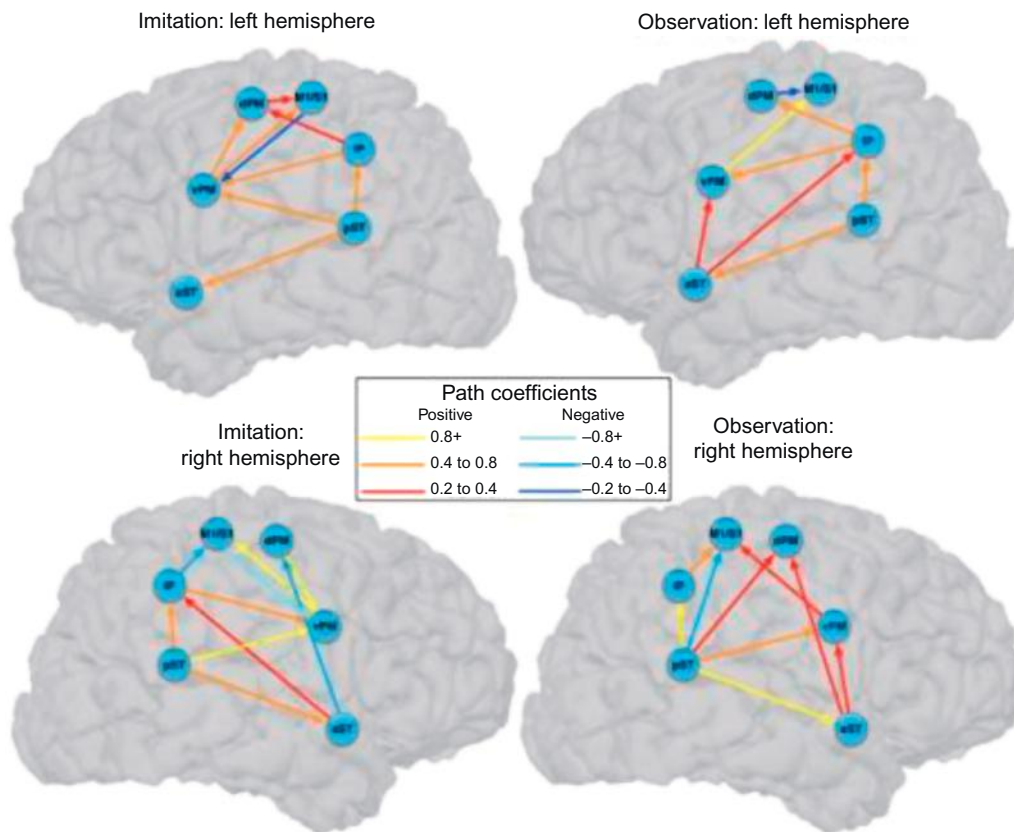

FIGURE 84.1 Weighted connections obtained from SEM of fMRI during observation (right) and imitation (left) of audiovisual syllables. Connections are shown for the left (top) and right (bottom) hemispheres. Both models share connections between pST, aST, IP, vPM, dPM, and M1/S1. Abbreviations are as follows: IP, inferior parietal lobule; M1/S1, primary motor/somatosensory cortex; pST, posterior superior temporal gyrus and sulcus; aST, anterior superior temporal gyrus and sulcus; vPM, ventral premotor cortex; dPM, dorsal premotor cortex; M1/S1, primary motor/somatosensory cortex. *Figure as originally published in Mashal et al. (2012).*

observation of eye movements. Consistent with widely accepted lateralization theories of speech and language, this follows stimulation of the left, but not the right, hemisphere.

84.4.1.2 Brain Imaging

84.4.1.2.1 MOTOR REGIONS ENGAGED DURING SPEECH PERCEPTION

Brain imaging studies provide indirect evidence of a relationship between speech observation and execution. Speech motor regions are engaged in response to audiovisual (Skipper, van Wassenhove, Nusbaum, & Small, 2007; Watkins et al., 2003), visual (Nishitani & Hari, 2002), and auditory (Fadiga et al., 2002; Tettamanti et al., 2005) speech perception. Figure 84.1 shows regions active during both syllable production and passive observation of audiovisual, visual, or auditory speech. Bilateral brain activation is present in premotor regions and Broca's area during silent lip-reading (Buccino et al., 2004), indicating that frontal motor cortices are activated in response to multimodal aspects of speech perception.

Structural equation modeling (SEM) shows common functional connections shared by observation and imitation of audiovisual syllables during fMRI, differing in connection strength but sharing the same essential structure (Mashal, Solodkin, Dick, Chen, & Small, 2012). Like imitation, speech observation engages dorsal and ventral premotor cortices and primary motor cortex.

84.4.1.2.2 TEMPORAL AND AUDITORY REGIONS ENGAGED DURING SPEECH PRODUCTION

Regions in posterior auditory cortex are active during speech production, including covert speech, as well as speech perception (Okada & Hickok, 2006; Papathanassiou et al., 2000). Further, posterior lesions of the left temporal cortex, as in Wernicke's aphasia, are associated with verbal expression and comprehension errors (Damasio & Geschwind, 1984). Temporal regions have classically been excluded from the putative mirror neuron system, because there has been no finding of motor activation in the temporal lobe in macaque studies (Keysers & Perrett, 2004). Still, the existence of individual mirror neurons remains poorly

defined in humans due to limitations of appropriately noninvasive methods. It is possible that their cortical distribution is more extensive than that in our primate cousins (Mukamel et al., 2010).

84.4.2 Comprehension of Action Language

The human mirror system operates in tandem with low-level sensorimotor aspects of speech and also higher-level language comprehension (Barsalou, 2008). Listening to sentences describing motor activity activates a broad left-lateralized network of frontal, temporal, and parietal regions, as do action observation and execution, which do not occur for sentences not encoding action (Tettamanti et al., 2005). Listening to or reading action-related language evokes somatotopic motor cortex activation consistent with the described effector (Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni, 2006; Hauk, Johnsrude, & Pulvermüller, 2004).

Theories proposing that cognition is grounded in (superimposed on) basic sensory and motor processes also apply to language. Priming effects are found for objects sharing affordances, such as a piano and a typewriter, even when the task does not address the object's use (Myung, Blumstein, & Sedivy, 2006). Subjects receiving verbal or visual cues to assume certain handshapes are faster to respond to the plausibility of action-object pairings congruous with the simulated grasp (Klatzky, Pellegrino, McCloskey, & Doherty, 1989). This difference disappears when a verbal response replaces the motor response, indicating that the interplay between language processing and the motor system confers the advantage, rather than the semantic relationship.

84.5 DUAL STREAMS FOR SPEECH

The dual-stream theory of vision has long been dominant (Mishkin, Ungerleider, & Macko, 1983), with a ventral "what" pathway for object identification and a dorsal "where" or "how" pathway for visuomotor integration (Goodale, 1993). More recently, two stream models have been identified in the study of audition (Rauschecker & Tian, 2000), speech perception (Hickok & Poeppel, 2004), speech production (Hickok & Poeppel, 2007), and sentence comprehension (Friederici, 2009). There is considerable debate among varying theories regarding specific functions, regions, connections, and the role of feedback. Broadly, however, the dorsal stream progresses from temporoparietal regions to frontal premotor areas, whereas the ventral stream progresses through temporal lobes to prefrontal cortex.

The present discussion only superficially describes the putative roles of the two streams to elucidate their role in imitation. The interested reader is referred to the original sources, including those described here, and the Large-Scale Models section of this book. The streams are typically discussed separately, as here, but it should be understood that this division is an artificial one for the sake of simplicity rather than accuracy. In actuality, the streams must be integrated for successful functioning, operating through "cooperative computation" (Fagg & Arbib, 1998). The strongest neurobiological models underpinning language processing in the brain presently comprise the dual-stream model and the mirror neuron system.

84.5.1 The Ventral Stream

The ventral pathway is conceived in terms of semantics, extracting meaning from the communicative signal (Saur et al., 2008). It is considered to be bilateral in some models (Hickok & Poeppel, 2007), whereas others identify ventral auditory language pathways only in the left hemisphere (Parker et al., 2005). In the temporal lobe, it includes anterior portions of the superior temporal gyrus and sulcus, the middle and inferior temporal gyri, and the temporal poles. In the macaque, these areas connect to frontal regions including orbitofrontal cortex and pars orbitalis via the uncinate fasciculus, and pars opercularis and pars triangularis via the extreme capsule (Petrides & Pandya, 2009).

Imitation of familiar and meaningful actions is positively correlated with ventral activity in the inferior temporal cortex (Decety et al., 1997). This is consistent with the object identification, or "what," role of the visual ventral stream, which may share connectivity analogous to that of the auditory ventral stream (Seltzer & Pandya, 1978). In contrast, dorsal parieto-occipital activation occurs with imitation of novel and meaningless actions (Rumiati et al., 2005).

Words and sentences, which can be conceived of as meaningful "gestures" or speech "objects," also represent a domain of the ventral stream. Consistent with this, temporal lobe atrophy is associated with semantic dementia, a variant of frontotemporal dementia characterized by progressive deficits in confrontation naming and single word comprehension, and loss of the concepts associated with the language (Mummery et al., 2000), whereas speech repetition remains intact (Gorno-Tempini et al., 2011). Although the role of the ventral stream in imitation may seem minimal, the stimuli to be repeated might engage regions and enhance connectivity patterns differently depending on semantic meaning and social relevance (Kilner, Marchant, & Frith, 2006), such as personal significance, ecological validity, and familiarity.

84.5.2 The Dorsal Stream and Parietal Cortical Connectivity

In contrast with the semantic role of the ventral stream, analogous to the “where” or “how” role of the visual dorsal stream, the dorsal stream for speech is proposed as a sensorimotor network mapping sounds onto motor plans for production (Hickok & Poeppel, 2007). Repetition, especially of meaningless pseudowords, is the prototypical task of dorsal stream function (Saur et al., 2008).

The dorsal stream projects from primary auditory regions to posterior superior temporal and inferior parietal regions, and then to more posterior regions of the frontal lobe (including pars opercularis of the IFG and premotor and motor cortices) compared with ventral stream projections (Skipper et al., 2006). At a gross anatomical level, temporal and parietal regions of the dorsal stream associated with speech and language functions are shared by the dorsal stream for vision. All of these regions show strong activation on fMRI during action observation, especially in the left hemisphere (Decety & Grèzes, 1999). These regions, specifically pars opercularis and inferior parietal cortex, are considered the human homologues of macaque F5 and PF/PFG in which mirror neurons have been identified (Rizzolatti, Fogassi, & Gallese, 2001; Rozzi et al., 2006). Some models consider the dorsal stream for speech to be strongly left-dominant (Hickok & Poeppel, 2007).

In conduction aphasia, the ability to repeat is disproportionately impaired. This is classically attributed to damage to the left arcuate fasciculus (Geschwind, 1965), traditionally thought to serve as the primary dorsal pathway (Anderson et al., 1999); however, this is debated due to recent anatomical work implicating the superior longitudinal fasciculus (Schmahmann & Pandya, 2006). Voxelwise lesion symptom mapping with perfusion and diffusion-weighted imaging shows damage involving the left supramarginal gyrus or underlying white matter is most strongly related to repetition deficits (Fridriksson et al., 2010). The temporoparietal region has been identified by other investigators (Buchsbaum et al., 2011) to be implicated in repetition impairment, supporting the critical role of the dorsal stream in repetition and the presence of mirror neurons within this functional network. This also suggests that the arcuate fasciculus may not serve the crucial role once suggested for the interconnection of Broca’s and Wernicke’s areas.

84.6 APHASIA THERAPY: SPEECH IMITATION AS THERAPEUTIC TOOL

Imitation has a long history in therapy for communication disorders, including aphasia, using visual

input to complement other sensory modalities and enhance the patient’s ability to produce accurate speech output (Duffy, 1995). Early approaches to aphasia therapy were developed prior to the fundamental work of the 20th century in learning theory and the unfortunate consequences of World War II, which produced many young veterans with head injuries, and often relied solely on repetition and drilling (Basso, 2003). Later researchers continued to use repetition in aphasia rehabilitation, but within a better-defined theoretical framework. For example, in the Helm Elicited Language Program for Syntax Stimulation (Helm-Estabrooks, 1981) designed to treat agrammatism, increasingly more complex syntactic forms are introduced by imitation at level A before the same forms are elicited in context at level B.

Love and Webb (1977) found imitation to elicit the most accurate picture naming in patients with severe Broca’s aphasia. Repetition is often the simplest level of a cueing hierarchy (Linebaugh, Shisler, & Lehner, 2005). Although imitation is sometimes promoted as a technique to be used only when no other prompts cue correct responses, its ability to facilitate speech output make it inherently error-reducing. Thus, it is a useful tool and desirable starting point in errorless learning designs, in which every response, regardless of accuracy, is viewed as self-reinforcing, and the therapy environment is structured to produce the greatest possible successes (Sigurðardóttir & Sighvatsson, 2006). However, the benefit of errorless learning remains debated in aphasia rehabilitation (Fillingham, Sage, & Lambon Ralph, 2005).

Many aphasia therapies used in research do not cite imitation as a rationale for their use or theorized effectiveness, yet they still rely heavily on imitation or choral reading (online imitation) in their implementation. Semantic Feature Analysis (SFA) seeks to improve word retrieval by targeting conceptual connections of individually trained words, using modeling and repetition of the target word and its semantic associations when these are not produced independently (Boyle & Coelho, 1995). Melodic Intonation Therapy (MIT), recommended for patients with non-fluent aphasia and poor repetition, uses melody and rhythm to increase speech output, relying on choral productions of intoned targets before progressing to imitation and more naturalistic contexts (Helm-Estabrooks, Morgan, & Nicholas, 1989). Conversational script training introduces scripts to be learned via online and delayed imitation (Youmans, Holland, Munoz, & Bourgeois, 2005). Choral reading and imitation are also paired with written stimuli in some therapy programs, such as Oral Reading Treatment (Orjada & Beeson, 2005) and Oral Reading for Language in Aphasia (Cherney, 2004).

FIGURE 84.2 Logical conjunction analyses from fMRI of production and perception of the same syllables. Orange indicates regions of activation overlap between production and perception (thresholded at $p < 0.05$). Blue indicates regions active during passive perception but not during production (thresholded at $p < 0.05$). Stimuli for speech perception were audiovisual (A), visual only (B), or auditory only (C). Reproduced with permission from Oxford University Press from Skipper et al. (2007).

84.7 MIRROR NEURON SYSTEM AND REHABILITATION

Given evidence for motor system activation during action observation (Buccino et al., 2001), and given identification of neural circuits active during observation–execution of oral movements (Ferrari et al., 2003), there is a sound biological basis for speech imitation as an aphasia rehabilitation technique. Connections between inferior parietal and ventral premotor regions are active during observation and imitation of syllables, as seen in Figure 84.2, and may represent a human mirror neuron network for speech (Mashal et al., 2012). Although the most straightforward implication of engaging this system may be for the direct motor act of speech production, the role of this network in speech perception (Möttönen & Watkins, 2012) and comprehension of action language (Tettamanti et al., 2005) could result in a broader impact on more general aspects of language rehabilitation (Small et al., 2012).

A similar approach undertaken in hand motor rehabilitation following stroke comprises viewing videos of daily actions followed by therapist-assisted performance of observed actions with the impaired upper extremity (Ertelt et al., 2007). Patients demonstrate significant improvement following therapy compared to baseline performance or controls, with maintenance of at least 8 weeks after intervention. Increased activation during object manipulation was found with fMRI in contralateral supramarginal gyrus and bilateral ventral premotor cortices, SMA, and superior temporal gyri, consistent with human correlates of the macaque mirror neuron system (Small et al., 2012).

84.8 APHASIA THERAPY: SPEECH IMITATION AS THERAPEUTIC THEORY

84.8.1 IMITATE

IMITATE (Intensive Mouth Imitation and Talking for Aphasia Therapeutic Effect) is a novel computer-based aphasia therapy program to improve communication skills in aphasia by repetition of audiovisual words and phrases, motivated by neurophysiological findings in human and nonhuman primates (Lee, Fowler, Rodney, Cherney, & Small, 2010). The stimuli are presented by video featuring a view of the speaker's head and shoulders. The therapy is intense and uses ecologically valid stimuli presented by a variety of human talkers, and difficulty increases are graded overall yet are variable within a level.

The control therapy, REPEAT, uses similar principles but audio-only stimuli with a still image of the talker. This therapy also varies the stimulus presentation, such that subjects hear a single presentation by a single talker before each cued repetition, in contrast with the IMITATE group, which hears six consecutive talkers present each stimulus before repeating the target word or phrase several times. Each group hears the same overall number of stimuli and the same number of presentations.

Nineteen subjects completed a 6-week course of therapy (9 h weekly). The IMITATE group made significant gains in the Aphasia Quotient composite score of the WAB-R but the REPEAT group did not, although there were no significant differences between groups (Duncan, Schmah, & Small, in prep).

In a sleep study, high-density electroencephalographic (EEG) recordings were taken for 13 subjects

with aphasia on two consecutive nights, before and after participating in a single, highly intensive 3.5-h session of IMITATE (Sarasso et al., 2014). Findings indicate a significant increase in slow wave activity (SWA), associated with synaptic plasticity (Huber, Ghilardi, Massimini, & Tononi, 2004), in regions active during observation–execution of speech in healthy controls (Mashal et al., 2012) in the right (intact) hemisphere. A positive correlation was found between increased SWA over the left ventral premotor cortex and improvement on the Repetition subtest of the WAB-R. This finding is of interest due to premotor cortex involvement in imitation and the inclusion of this region in the lesion extent of most of the participants.

84.8.2 Speech Entrainment

Citing previously mentioned findings of activation in left frontal speech-motor areas when visual observation accompanies auditory speech, Fridriksson et al. (2009) hypothesized that better performance would be elicited when a computer-based naming treatment for patients with nonfluent aphasia included audiovisual compared to auditory-only stimuli. Findings indicated statistically significant gains for audiovisual treatment only, including trained and untrained items.

Fridriksson et al. (2012) coined the term “speech entrainment” to describe the ability of some subjects with nonfluent aphasia to produce more fluent speech with an audiovisual model compared to spontaneous speech. Subjects performed online imitation of scripts, which are heard while viewing the speaker on an iPod screen. Only the speaker’s mouth is visible to emphasize visual perception of the speech act. This therapy resulted in production of twice as many words during entrainment for 13 patients with Broca’s aphasia. Significant increases in word variety were maintained for 1 week after treatment for production of practiced scripts during entrainment and spontaneous speech. Generalization to entrainment of untrained scripts remained significantly improved for 6 weeks.

Using fMRI to explore the neural mechanisms underlying behavioral findings, Fridriksson et al. (2012) found greater activation in left BA 37 and bilateral anterior insula/BA 47 for the speech entrainment condition compared to spontaneous speech. Imitation of speech may facilitate word retrieval (BA 37) and visceral speech support (anterior insula/BA 47) for rapid, online lexical processing and/or airflow modification or for lexical prediction and anticipation of respiratory demands. Broca’s area may be an internal temporal gating device, which, although injured, can be compensated for by external temporal gating offered by

real-time imitation of an observed speaker, entraining the requisite regions to again function as part of a coordinated network.

84.9 APHASIA THERAPY: NONSPEECH MOTOR OBSERVATION AND IMITATION

Speech is a motor activity and gestures are a rich aspect of human communication, whether for independent information transmission or to supplement spoken language (Goldin-Meadow, 1999). Verbal communication among humans may have evolved on top of existing gestural communication systems relying on the observation–execution matching system (Rizzolatti & Arbib, 1998). Gesture has thus been targeted as a means of treatment for aphasia.

Visual Action Therapy is a nonverbal therapeutic intervention for global aphasia, using real and drawn objects in a hierarchy (Helm-Estabrooks, Fitzpatrick, & Barresi, 1982). Manipulation of real objects or associated pantomimed gestures is imitated by the subject, with the ultimate goal of producing a pantomimed action to represent an unseen object. The rationale is that gestures, requiring unilateral gross motor control compared to speech, may be used symbolically (Helm-Estabrooks et al., 1982). Although Visual Action Therapy is not a contemporary subject of research, similar gesture-based therapies continue to be investigated in aphasia rehabilitation.

Patients with nonfluent aphasia improve in verb retrieval abilities after training of gesture labeling when observing or imitating the target gesture, but not when they observe a gesture and produce a meaningless movement (Marangolo et al., 2010). There is no significant difference between therapies using observation or meaningful imitation, with improvement maintained for 2 months. These findings may support a bilateral distribution of frontoparietal connections engaged in action observation and execution given the damage to regions associated with the human mirror neuron network of the left hemisphere (Aziz-Zadeh, Koski, Zaidel, Mazziotta, & Iacoboni, 2006). Action observation alone engages this network, but addition of a meaningless gesture interferes with this process, eliminating the beneficial result of observation and the resultant therapeutic gains in verb retrieval.

Observation therapy only improves verb production for actions within the human motor repertoire, such as dancing compared to printing (Marangolo, Cipollari, Fiori, Razzano, & Caltagirone, 2012). fMRI findings also demonstrate differences between activation resulting from observation of actions within the realm of human behavior, even when performed by non-humans (e.g., a dog biting), compared to those that are

not (Buccino et al., 2004). These findings further reinforce the role of a mirror neuron network implicated in action observation and execution that subserves language production.

84.10 CONCLUSION

Although aphasia is a biological disorder resulting from neurological damage, aphasia rehabilitation has traditionally neglected biological approaches to treatment in favor of behavioral and educational models. However, increasing understanding of the neurobiology underlying language is shifting the discourse toward biological mechanisms.

The two main biologically based models with empirical support at this time are the human mirror neuron system and the dual-stream hypothesis. These models support imitation as a powerful tool to rehabilitate the speech and language deficits of aphasia. Action observation engages the mirror properties of the same neural networks that are activated during execution, which is as true for speech and oral motor actions as for the grasping behaviors for which they were initially discovered. Higher-level language skills are also grounded in motor systems. Both observation and imitation of speech engage a similar network including components of the dorsal and ventral pathways for language.

Imitation has long been, and continues to be, used in many aphasia interventions. More recently, several researchers have developed neurophysiologically motivated aphasia therapy programs targeting online or delayed imitation as a strategy to improve speech output and language function. Some aphasia therapies have also used nonspeech imitation of actions to enhance gestural communication and production of action labels.

Pharmacotherapy for Aphasia

Daniel A. Llano¹ and Steven L. Small²

¹Department of Molecular and Integrative Physiology, University of Illinois at Urbana-Champaign, Champaign, IL, USA; ²Department of Neurology, University of California at Irvine, Irvine, CA, USA

85.1 INTRODUCTION

Aphasia is one of the most common consequences of stroke, and it is also one of the most feared. Approximately 10–30% of stroke victims suffer from a language deficit after stroke (Bersano, Burgio, Gattinoni, Candelise, & P.S.G., 2009; Pedersen, Stig Jørgensen, Nakayama, Raaschou, & Olsen, 1995; Wade, Hewer, David, & Enderby, 1986), and recovery from a stroke-related language deficit is highly variable and dependent on a range of factors. For example, lesion-related variables, such as the size and location of the stroke, and patient-related variables, such as the patient's age and history of strokes, are likely major determinants in recovery from stroke (Caplan, Hildebrandt, & Makris, 1996; Heiss & Thiel, 2006; Kertesz, Harlock, & Coates, 1979; Lazar & Antonello, 2008) and are essentially unmodifiable in the postacute setting. Other aspects important in the long-term language recovery of patients, such as prevention of future strokes, design and implementation of a language therapy plan, and pharmacologic therapy, can all be points of successful intervention by the clinician.

In this chapter, we review the literature on pharmacologic approaches to aphasia recovery. Specifically, we attempt to integrate a body of literature on motor stroke recovery in animal models with clinical data examining the effects of drug interventions on aphasia recovery. Herein, we argue that a primary focus for the rehabilitation of patients with aphasia should be pharmacological enhancement of reorganization of neural circuits rather than simply the development of compensatory strategies. As such, we adopt a medical model to the treatment of stroke whereby the therapeutic aim is to guide plasticity with behavioral therapy and to facilitate this plasticity with pharmacological intervention.

85.2 MAJOR CHALLENGES

It is worth noting early in this chapter that there are two significant challenges to making progress in the area of aphasia recovery: limited clinical trial data and lack of animal models for language. Compared with other neurological diseases for which the underlying disease processes may be more homogeneous across subjects and the outcome measures have been validated to be sensitive to pharmacologic intervention, aphasia recovery is in a somewhat disadvantageous position. Strokes are highly variable in location, size, and even etiology. In addition, the term “aphasia” is quite broad and can include difficulties ranging from dysfluency to patients who are highly (or overly) fluent but with difficulties in the understanding and formulation of language. Such heterogeneity in language deficits likely reflects heterogeneity in lesion location, size, and etiology. The latter point is important because the term “stroke” may encompass a range of underlying pathophysiological mechanisms, such as large-vessel atherosclerotic disease, cardioembolic disease, small vessel disease, venous thrombosis, and intracranial hemorrhage. It is likely that stroke-related deficits caused by different underlying pathophysiological mechanisms will have different time courses of recovery and different sensitivities to pharmacological therapy. Similarly, although there are many different rating scales available to evaluate the severity of aphasia (Shewan & Kertesz, 1980; Strauss, 2006), the underlying heterogeneity in aphasia types and etiologies and the lack of validation of such scales for sensitivity to drug manipulations create challenges for the use of a single instrument to evaluate the efficacy of drug therapies for aphasia. These factors have contributed to the relatively small number of clinical trials performed to examine the

potential for drugs to treat aphasia. For example, a recent (July 2013) search on www.clinicaltrials.gov revealed four studies actively recruiting subjects for drug interventions for aphasia. When evaluating the clinical literature on aphasia drug therapies, these challenges make it difficult to apply the same criteria as those for diseases that are more amenable to study using standard clinical trial approaches.

Another factor affecting progress in this area is the lack of adequate animal models. Animal models serve as a proving ground for putative new therapies and have been shown to be indispensable for the development of drug therapies for epilepsy, multiple sclerosis, and Parkinson disease (Dauer & Przedborski, 2003; Gold, Lington, & Lassmann, 2006; McNamara, 1985), and have led to great insights to the underlying pathophysiology of other diseases such as Alzheimer disease (Price & Sisodia, 1998). Currently, however, there are no established animal models for language—at least language as humans experience it. Although this is a topic that has been hotly debated in the literature (Hauser, Chomsky, & Fitch, 2002), and although the details of this are well beyond the scope of this chapter, it is safe to say that there are no established models with a high enough throughput to allow the vetting of potential drug therapies. Instead, the field has relied on animal models of motor stroke. Here, the literature is quite mature, many approaches to inducing stroke exist (middle cerebral artery ligation, photothrombosis, etc.) (Carmichael, 2005), and the outcome measures of motor recovery are highly quantifiable. Therefore, for the current discussion we assume that at least some of the mechanisms of repair and reorganization of neural structures involved in recovery from motor stroke are similar to those involved with language recovery, although more work is greatly needed in this area to validate this assumption.

Despite the challenges described, it is worth noting that now, more than ever, we are strategically positioned for great advances in the development of drug therapy for aphasia. Human and animal imaging technologies have advanced to the point that the impact of drug and/or behavioral therapy on neural networks can be studied in humans and animals using very similar imaging technologies, facilitating comparisons of the pharmacodynamics of putative therapies across species (Bifone, Gozzi, & Schwarz, 2010; Rumble et al., 2013). Therefore, the impact of drug and behavioral interventions, both on task-related activation patterns and resting states, as well as structural imaging of gray and white matter (Jang, 2011; Schwarz et al., 2011) can be assessed and compared. It is hoped that this chapter will serve as a starting point to initiate future mechanistic studies in this area.

85.3 MECHANISMS OF RECOVERY AND PHARMACOTHERAPY

There is a substantial body of work documenting the natural history and the impact of pharmacological modulation of stroke recovery in animal models. Most of this research has involved lesions of the motor cortex and has used motor output as its focus for efficacy. Once a small area of cortex is lost, a host of short-range and long-range mechanisms are engaged to facilitate reorganization of cortical function (Hermann & Chopp, 2012; Murphy & Corbett, 2009). These mechanisms are activity-dependent and include axonal sprouting (Dancause et al., 2005; Overman et al., 2012), which can extend distances >1 cm across the adult primate cortex, elaboration of dendritic spines (Brown & Murphy, 2008; Ueno et al., 2012), migration of subventricular stem cells to the infarction zone (Danilov, Kokaia, & Lindvall, 2012; Kahle & Bix, 2013; Lichtenwalner & Parent, 2005), and modulation of the strength or excitability of existing synapses (Di Filippo et al., 2008; Jaenisch, Witte, & Frahm, 2010; Yao et al., 2005). Because such mechanisms are likely to be differentially sensitive to pharmacological manipulation, one might postulate that different etiological mechanisms of infarction would require different forms of intervention. It is also possible that some forms of modulation of synaptic strength may be maladaptive (Costigan, Scholz, & Woolf, 2009; Di Filippo et al., 2008) and therapeutic modalities, appropriately targeted and timed, may be used to interfere with such forms of pathological plasticity.

Several concepts have arisen from the animal literature on stroke recovery (and lesion recovery more generally) that may inform our review of the literature on drug therapy for aphasia. First, it is clear that maximal benefit is derived not from drugs or rehabilitation approaches on their own, but with *combination* therapy. There are many studies supporting the idea that synaptic plasticity, which is presumed to be the dominant mechanism underlying synaptic rewiring responsible for stroke recovery, is greatly facilitated when neurotransmitter manipulations are accompanied by behavioral training (Bao, Chan, & Merzenich, 2001; Kilgard & Merzenich, 1998; Schultz, 2002). Further, many of the classes of drugs discussed within this review have been explicitly modeled to help support and strengthen neural networks being modified by behavioral training (Korchounov & Ziemann, 2011), such that their efficacy in the absence of behavioral training may be greatly reduced. Taken further, one might even speculate that drugs that support synaptic plasticity, when used in the absence of targeted behavioral therapy, may actually reinforce maladaptive

patterns of neuronal activity. In addition, it is of high clinical relevance that the cerebral cortex undergoes plastic changes for at least *months* after stroke, and that these adaptive changes occur not only in the tissue immediately surrounding the lesion but also in areas remote from the site of injury (Jenkins & Merzenich, 1987; Nudo & Friel, 1999; Nudo, Wise, SiFuentes, & Milliken, 1996; Xerri, Merzenich, Peterson, & Jenkins, 1998). Finally, the animal studies suggest that certain classes of drugs commonly used in clinical practice, particularly sedating drugs such as benzodiazepines, can *diminish* the reorganization of brain networks after injury (Goldstein, 2000; Larson & Zollman, 2010). Given the emerging recognition of poststroke depression and anxiety (Aben et al., 2003; Barker-Collo, 2007) and the relatively high incidence of seizures after stroke (Lossius, Rønning, Mowinckel, & Gjerstad, 2002; Olsen, 2001), both of which may be treated with benzodiazepines, these data indicate that non-sedating alternatives may be more appropriate to avoid interference with poststroke recovery mechanisms.

85.3.1 Animal Studies: Catecholamine-Based Therapy

There is a rich history of the use of catecholamine augmentation as adjunctive therapy to enhance stroke recovery. Catecholamines are a natural target for stroke therapeutics because it has long been known that there are significant alterations in brainstem and cortical catecholamine levels in the acute and subacute periods after stroke (Brown, Carlson, Ljunggren, Siesjö, & Snider, 1974; Cohen, Waltz, & Jacobson, 1975; Robinson, Shoemaker, & Schlumpf, 1980; Robinson, Shoemaker, Schlumpf, Valk, & Bloom, 1975). In addition, lesions to the noradrenergic afferents from the locus ceruleus have been shown to impair recovery of animals with contralateral sensory-motor cortical injuries (Goldstein & Bullman, 1997), and pharmacological antagonism of alpha adrenergic receptors with phenoxybenzamine delays spontaneous recovery from cortical damage (Feeney & Westerberg, 1990).

A number of neurophysiological mechanisms are postulated to underlie the beneficial effects of catecholamine enhancement of stroke recovery. Norepinephrine and dopamine modulate multiple forms of synaptic plasticity, including long-term potentiation and long-term depression, and spike timing-dependent plasticity (Carey & Regehr, 2009; Clem & Haganir, 2013; Dommett, Henderson, Westwell, & Greenfield, 2008; Edelmann & Lessmann, 2013; Ghanbarian & Motamedi, 2013; Gu, 2002; Wolf, Mangiavacchi, & Sun, 2003). These data would suggest

that the impact of catecholamine modulation on recovering neural circuits would be highly activity-dependent, which is consistent with the data presented. Other studies have shown that catecholamines may enhance neural regeneration (Hiramoto, Ihara, & Watanabe, 2006; Lloyd, Balest, Corotto, & Smeyne, 2010; Spiegel et al., 2007) or axonal sprouting (Papadopoulos et al., 2009). Overall, these data suggest that catecholamine augmentation may function to alter neuronal plasticity on several different temporal and spatial scales.

The paradigm for the study of catecholamine-based therapy was established by early work demonstrating that administration of a single dose of dextroamphetamine (D-amphetamine, which causes the release of stored norepinephrine, dopamine, and, to a lesser degree, serotonin) can facilitate recovery of beam-walking behavior after lesion of motor cortex (Feeney, Gonzalez, & Law, 1982). Importantly, drug effects on recovery were only seen when drug administration was coupled with the promotion of physical activity. This basic finding of the dependency between active training and catecholamine augmentation for maximum motor recovery has been reproduced in animals several times in several stroke models (Barbay et al., 2006; Beltran, Papadopoulos, Tsai, Kartje, & Wolf, 2010; Papadopoulos et al., 2009; Ramic et al., 2006; Rasmussen, Overgaard, Hildebrandt-Eriksen, & Boysen, 2006). For example, in the visual system, bilateral visual cortex lesions in cats leading to deficits in depth perception can be ameliorated with a combination of visual experience and dextroamphetamine administration (Feeney & Hovda, 1985). No benefit was seen when either the drug or behavioral training were given independently of each other.

The receptor pharmacology of the beneficial effects of D-amphetamine is not yet entirely clear. The effect of D-amphetamine on motor recovery can be blocked by the haloperidol (Feeney et al., 1982), a D2 antagonist, which also has weaker antagonism at the alpha1 adrenoceptor. In addition, as described, alpha1 receptor blockade impaired spontaneous recovery (Feeney & Westerberg, 1990) and treatment with intraventricular norepinephrine, but not dopamine, and reproduced the beneficial effect of D-amphetamine (Boyeson & Feeney, 1984). Further, findings in animals that have recovered from brain trauma that show that alpha adrenergic antagonists, such as phenoxybenzamine, can cause the recrudescence of lesion-related deficits long after functional recovery has occurred (Feeney, De Smet, & Rai, 2004) and suggest that a long-standing and tonic increase in norepinephrine is needed to restore function in certain neural networks. Most recently, motor recovery in a rat stroke model

was facilitated by atipamezole and alpha-2 blocker, which elevates synaptic norepinephrine levels, with little effect on dopamine (Beltran et al., 2010; Gobert, Billiras, Cistarelli, & Millan, 2004). These data suggest that norepinephrine, acting on alpha adrenergic receptors, is the primary driver of functional recovery in these models. However, it has been suggested, primarily based on data from levodopa-enhanced word-list learning in normal humans and the low rates of conversion of levodopa to norepinephrine (~5%), that dopamine may also play a significant role (Breitenstein et al., 2006). The mixed clinical picture surrounding drugs like amphetamine and levodopa, which activate multiple receptor types, suggests that there is a need to more precisely define the mechanism of action of these drugs to target the efficacious mechanisms.

85.3.2 Animal Studies: Cholinergic Mechanisms

Luria postulated that enhancement of acetylcholine levels via the natural cholinesterase inhibitor galanthamine (precursor to modern Alzheimer's drug, galantamine), may promote functional language recovery after stroke (Luria, Naydyn, Tsvetkova, & Vinarskaya, 1969). In general, these agents have been particularly relevant to the treatment of Alzheimer disease, for which there is a cholinergic model that relates atrophy in the nucleus basalis of Meynert (the source of all cerebral cortical acetylcholine) to the pathophysiology of Alzheimer disease (Whitehouse, Price, Clark, Coyle, & DeLong, 1981). Acetylcholine is thought to be involved in a number of aspects of cognition, including sensory perception, selective attention, associative learning, and memory, as well as experience-dependent plasticity (Baskerville, Schweitzer, & Herron, 1997; Yu & Dayan, 2002). Very suggestive evidence for the potential for acetylcholine augmentation to be used as a therapeutic modality to enhance plasticity is derived from findings in the auditory cortex, where experience-dependent alterations of sensory maps were greatly enhanced when sensory stimulation was coupled with stimulation of cholinergic fibers from the basal forebrain (Kilgard & Merzenich, 1998). Notably, map reorganization parameters were directly related to the specific training stimuli used, emphasizing the importance of understanding the interactions between specific speech and language therapies with pharmacologic intervention. One view is that cholinergic neurons from the basal forebrain serve a modulatory function by *marking* behaviorally salient stimuli (Kilgard & Merzenich, 1998). This experience-dependent and acetylcholine-dependent map reorganization learning is probably

mediated by muscarinic cholinergic receptors, rather than nicotinic receptors, because this learning can be blocked by scopolamine, a muscarinic antagonist (Thiel, Friston, & Dolan, 2002).

Despite the well-recognized role for acetylcholine in activity-dependent plasticity, there are comparatively little data supporting enhancement of cholinergic activity for motor stroke recovery in animal models. A study using galantamine in a motor stroke model did not show efficacy (Zhao, Puurunen, Schallert, Sivenius, & Jolkkonen, 2005), whereas the data for nicotine administration are mixed (Gonzalez, Gharbawie, & Kolb, 2006; Lim, Alaverdashvili, & Whishaw, 2009). It is interesting to note that the muscarinic blocker scopolamine has been shown to have some *beneficial* effects in early recovery in animal models of traumatic injury (Lyeth et al., 1992), possibly by reducing cholinergic neuronal activation (Saija et al., 1988), but the window for such an advantage is very short (15 min) (Hamm, O'Dell, Pike, & Lyeth, 1993). This is similar to what has been seen with several "neuroprotective" agents, such as NMDA(N-methyl-D-aspartate)-receptor antagonists (Villmann & Becker, 2007) and gamma-amino butyric acid (GABA)-potentiators (Green, Hainsworth, & Jackson, 2000), reinforcing the idea that the *timing* of intervention will play a critical role in the development of aphasia treatment strategies.

85.3.3 Animal Studies: Serotonin and Brain-Derived Neurotrophic Factor

Serotonin regulates some forms of cortical map reorganization (Gu & Singer, 1995; Jitsuki et al., 2011; Vetencourt, Tiraboschi, Spolidoro, Castrén, & Maffei, 2011) and adult neurogenesis in the hippocampus (Daszuta, 2011; Li et al., 2009), although the evidence supporting a role for serotonin in promoting neural reorganization in the chronic stroke setting is relatively sparse. More attention has been given to the ability of serotonin to enhance the expression of the ubiquitously expressed Brain-Derived Neurotrophic Factor (BDNF). Rodent studies have shown that BDNF increases both locally and remotely after the induction of stroke (Béjot et al., 2011), and that inhibition of BDNF using antisense oligonucleotides impair stroke functional recovery from motor cortex stroke (Ploughman et al., 2009). This study also revealed a synergistic interaction between physical therapy and BDNF expression. Other rodent work has demonstrated that exogenous BDNF administration facilitates motor recovery from acute stroke (Schabitz et al., 2007). Despite the suggestive findings regarding BDNF and stroke, there are major hurdles to the translation

of this therapy to the clinic. Delivery of such a large molecule to the central nervous system (CNS) poses a problem, particularly in the chronic phase of stroke when the blood–brain barrier has reconstituted. This provides an opportunity to drive BDNF expression indirectly via serotonin augmentation (e.g., through the use of selective serotonin reuptake inhibitors [SSRIs]). It is not clear, however, whether serotonin augmentation through SSRIs is sufficient to drive BDNF expression to sufficient levels to promote recovery because SSRI studies in chronic stroke have had a mixed track record (Boyeson, Harmon, & Jones, 1994; Windle & Corbett, 2005). It may be that extrasynaptic serotonin is necessary to promote BDNF expression, or that only specific serotonin receptor subtypes are responsible for BDNF expression (there are at least seven subtypes of the serotonin receptor) and should be targeted more specifically. There is another unanswered question regarding the ability of BDNF to promote recovery in the chronic phase of stroke. BDNF has neuronal protectant properties (Marini et al., 2004), and most studies to date have been performed in the acute phase.

85.3.4 Animal Studies: GABAergic Mechanisms

Another agent that has received attention in animal studies is GABA. GABA is particularly interesting because its action on neurons is primarily inhibitory (Hendry, Schwark, Jones, & Yan, 1987). Augmentation of GABAergic neurotransmission, either via benzodiazepines or via barbiturates, has been a popular drug development strategy to promote neuronal protection during the acute phase of stroke, presumably by limiting neuronal metabolic demand during periods of high metabolic stress (Green et al., 2000). In the chronic phase, there is little evidence that GABA potentiation promotes reorganization after stroke. For example, intracortical infusion of GABA exacerbates the hemiparesis produced by a small motor cortex lesion in rats (Schallert et al., 1992). In addition, the short-term administration of diazepam (a benzodiazepine and indirect GABA agonist) permanently impedes sensory cortical recovery from neocortical injury (Schallert, Hernandez, & Barth, 1986). Furthermore, the GABA potentiator phenobarbital also interferes with recovery from brain injury (Hernandez & Holling, 1994; Montanez, Kline, Gasser, & Hernandez, 2000). Another approach involves removal of GABAergic inhibition, which may promote cortical map reorganization, for which there is some evidence (Jacobs & Donoghue, 1991). However, such an approach would pose a challenging translational strategy because blockade of

GABA significantly lowers seizure threshold (Seger, 2004) and chronic stroke patients have a risk of seizure that is higher than baseline (Asconapé, 1991; Lossius et al., 2002; Olsen, 2001).

85.3.5 Animal Studies: Extracellular Matrix-Based Mechanisms

Stroke induces the expression of a number of extracellular molecules that are potentially hostile to axonal outgrowth. These include myelin-associated extracellular molecules, such as Nogo-A, myelin-associated glycoprotein, and oligodendrocyte-myelin glycoprotein, and extracellular matrix proteins, such as tenascin and chondroitin sulfate proteoglycans (Carmichael, 2006). Among these, the Nogo-A system has been well-characterized, and inhibitors of this system have moved forward into clinical trials of spinal cord injury and are under consideration for stroke. In animal models of subacute motor cortical stroke, inhibition of Nogo-A activity via passive immunization resulted in enhanced recovery of motor function in several studies (Brenneman et al., 2008; Papadopoulos et al., 2009; Tsai et al., 2007). Of potential relevance for the therapy of aphasia are the findings that intraventricular administration of anti-Nogo antibodies promoted recovery in a rodent model of hemispatial neglect (Brenneman et al., 2008) and poststroke spatial memory deficit (Gillani et al., 2010), suggesting that Nogo inhibition may ameliorate cognitive dysfunction. No studies of anti-Nogo therapy, to our knowledge, have been performed during the late chronic phase of stroke. However, because the studies referenced have not demonstrated any alteration in infarct size after anti-Nogo therapy, anti-Nogo therapy may promote neural reorganization rather than neuronal protection. This supposition suggests that anti-Nogo therapy represents at least a feasible path forward for studies of chronic stroke patients.

One potential concern with the body of rat literature documenting the benefits of anti-Nogo therapy is that in both the motor stroke studies (Papadopoulos et al., 2009; Tsai et al., 2007) and at least one of the “cognitive” stroke studies (Brenneman et al., 2008), recovery was in large part mediated by activation of contralesional structures. This suggests that anti-Nogo therapy may promote sprouting of long-range axons of contralesional origin rather than remaining ipsilateral axons. Because recovery in human motor stroke (Fridman et al., 2004), aphasia (Heiss et al., 1997; Karbe et al., 1998; Szaflarski, Allendorfer, Banks, Vannest, & Holland, 2013), and neglect (Corbetta, Kincade, Lewis, Snyder, & Sapir, 2005) is likely optimally mediated by ipsilesional structures, promotion of sprouting of contralesional axons may not be an optimal recovery

strategy. It is not known if the preference for the contralesional structures is specific to anti-Nogo therapy or to rodent stroke recovery in general.

85.3.6 Animal Studies: Combining Drug and Behavioral Therapy

A feature common to most pharmacotherapy for chronic stroke is the requirement that physical therapy must be used to materialize the benefits of drug administration. By extension, speech and language therapy (SLT) may have a similar role in the pharmacotherapy for aphasia. Because certain forms of neuronal plasticity can be maladaptive (Costigan et al., 2009; Di Filippo et al., 2008), it is crucial that alterations of synaptic strength or number are not haphazard. In addition, because most drugs uniformly bathe the brain without the ability to specifically modify damaged circuitry, SLT is necessary to target particular areas for synaptic modification. As such, drug therapy likely plays a permissive role in stroke recovery. There may be exceptions to this. For example, stem cell therapy may be able to target specific areas of the brain that overexpress molecular factors in damaged areas (see Chapter 86 on cell-based therapies). It is unknown whether these molecular targets are sufficiently specific to allow neural repair without the guidance of behavioral training. It will be important to clarify this issue in animal models because it has therapeutic implications. For example, for patients unable to participate in rehabilitation, it may very well be counterproductive to offer permissive drug therapy, such as catecholamine augmentation, because these drugs may reinforce inappropriate circuitry. However, such patients may be candidates for therapies that can target damaged circuitry, such as stem cell therapy. Continued exploration of the combination of drug therapy and physical therapy in animal models will assist in guiding these decisions.

85.4 HUMAN STUDIES: PHARMACOTHERAPY FOR APHASIA

There is a long history of attempts at aphasia pharmacotherapy (Bergman & Green, 1951; Linn, 1947; Sarno, Sarno, & Diller, 1972; West & Stockel, 1965) (for a review of these studies, see Small, 1994 or Small, 2001). The outcomes of these studies were generally negative, likely related to inadequate scientific rationales or poor study design (e.g., underpowered studies, poor dose selection, inappropriate outcome measures). The animal data would suggest that the most promising targets for pharmacotherapy for

aphasia would be accentuation of norepinephrine and dopamine levels coupled with behavioral therapy. Fortunately, this hypothesis lends itself to direct clinical translation because of the existence of several approved drugs that increase brain catecholamine levels (D-amphetamine, levodopa, etc.). Regarding study design, in general, the optimum study design to establish that a pharmacological agent promotes brain reorganization to enhance language processing would be a double-blind, placebo-controlled, adequately powered, parallel-group study that contains at least one outcome measure that is assessed after drug washout to ensure that any benefit observed is due to plastic changes in the brain. Unfortunately, very few studies have had this type of design. In addition, much of the literature utilizes heterogeneous outcome measures and many studies provide few details regarding the results, making meta-analyses very challenging. This section reviews the existing literature on drug therapy of aphasia. To our knowledge, there have been a total of 18 prospective, double-blind studies involving patients with subchronic or chronic stroke that used a language metric as a primary outcome measure, and we review these studies here. The attention here is restricted to small-molecule therapy in the subacute and chronic phases of aphasia due to stroke.

85.4.1 Human Studies: Noradrenergic Agents

The animal data tell a compelling story that enhancement of catecholamine levels, coupled with physical therapy, can promote neural reorganization and functional recovery even during the chronic phase of motor stroke. The two most highly studied catecholamines for stroke recovery are dopamine and norepinephrine. Dopamine and norepinephrine poorly cross the blood–brain barrier and are therefore rarely administered in these studies. Instead, other drugs such as D-amphetamine, which indirectly elevates synaptic catecholamine levels, or related compounds are administered. Other approaches have been to block the reuptake of norepinephrine and dopamine with methylphenidate. None of these drugs permit the isolation of noradrenergic from dopaminergic effects, although it has been argued that dopamine may play a dominant role in language recovery.

We are aware of four prospective, placebo-controlled, double-blind studies that examine the effects of D-amphetamine on language function in aphasic patients. The largest and most frequently cited study is that by Walker-Batson et al. (2001). In this study, subjects with subacute stroke were treated with D-amphetamine or placebo, and treatment was coupled with traditional speech therapy over a 5-week period.

A greater percentage of active subjects demonstrated improvement on the Porch Index of Communicative Ability (PICA) scale at the 6-week time point than their counterparts who received placebo (83% vs. 22%); improvement was assessed 1 week after the last dose of drug. There was a nonsignificant trend for a persistent benefit at 6 months after dosing. This study was confounded by differences in age (D-amphetamine patients were 9.5 years younger) and amount of therapy received (D-amphetamine patients received 21% more therapy time). The authors found that significant differences were maintained after adjusting for baseline age; unfortunately, there was no adjustment performed for therapy time. A more recent study by Whiting, Chenery, Chalk, and Copland (2007) using a double-blind, placebo-controlled, crossover design in two patients with chronic aphasia from stroke also demonstrated improvements in language function associated with D-amphetamine administration. In this study, naming improved in both patients (but reached statistical significance in only one patient) during periods when they received D-amphetamine plus language therapy compared with periods when they received placebo plus language therapy. This benefit persisted 1 month after cessation of drug and language therapy. Clearly, a crossover study with a behavioral outcome such as this study is potentially compromised by a period effect because of learning by the patient, the investigator, or both, over the course of the trial. These two small studies, each with design inadequacies, are at least suggestive of signals of efficacy for D-amphetamine when coupled with SLT for chronic aphasia.

Two earlier placebo-controlled studies did not show a benefit of D-amphetamine therapy. McNeil et al. (1997) conducted a crossover, multiple-baseline study that examined the effects of D-amphetamine or selegiline, with and without lexical-semantic activation inhibition therapy (L-SAIT), in two patients with chronic aphasia from stroke. Both patients responded well to L-SAIT, but there was not consistent improvement across several language measures when L-SAIT was combined with pharmacotherapy. Darley, Keith, and Sasanuma (1977) examined the effects of 3 days of 20 mg of daily methylphenidate administration on performance on PICA in 14 subchronic or chronic aphasia patients. The trial was a crossover design with no washout period, and no SLT was given. The subjects also underwent 3 days of daily 20-mg chlordiazepoxide administration. The absence of a washout period and the inclusion of traumatic brain injury patients in this study make this study particularly difficult to interpret.

In addition to the data on aphasic subjects, D-amphetamine coupled with SLT has been shown to improve language performance and alter the activation of language-related networks in the brain of healthy

nonaphasic subjects. Breitenstein et al. (Breitenstein et al., 2004) taught 40 healthy subjects an artificial vocabulary of 50 words via word–picture matching and coupled this training with D-amphetamine or placebo administration. They found that D-amphetamine enhanced learning of the artificial words in the active group compared with placebo, and that this difference persisted 1 month after drugs, suggesting that enhanced performance was not simply a nonspecific effect of arousal. In a similar study, Whiting, Chenery, Chalk, Darnell, and Copland (2007) found that amphetamines enhanced new word learning in healthy subjects, and that there was no correlation between word learning and attention, mood, or cardiovascular arousal that would suggest a specific effect of D-amphetamine on the trained networks. Supporting the idea that D-amphetamine specifically influences the activity of behaviorally activated networks are two pharmacological MRI studies. Uffring et al. (2001) demonstrated that D-amphetamine specifically increased activation in auditory cortical regions during tone discrimination tasks and enhanced activation of motor cortical areas during motor tasks. Similarly, Sommer et al. (2006) found that D-amphetamine administration during verb generation and semantic decision task (using a conjoint analysis) increased overall left hemispheric activation and increased activation of Broca's areas, the right homolog of Broca's area, and left supramarginal gyrus, but it did not significantly increase activation of multiple other volumes of interest. These data suggest that D-amphetamine can act to potentiate activity and plasticity of behaviorally activated networks rather than nonspecifically promoting arousal.

Of importance, and in concordance with the animal model studies (Feeney et al., 1982; Feeney & Hovda, 1985), the studies showing beneficial effects of sympathomimetics (on motor or language) (Crisostomo, Duncan, Propst, Dawson, & Davis, 1988; Grade, Redford, Chrostowski, Toussaint, & Blackwell, 1998; Walker-Batson, Devous, Curtis, Unwin, & Greenlee, 1991; Walker-Batson, Smith, Curtis, Unwin, & Greenlee, 1995) share the common feature of evaluating D-amphetamine as an adjunct to behavioral or physical therapy rather than alone. This is consistent with the view espoused at the outset regarding the role of behavior in modifying neural circuits and the notion that, without training, even extensively reorganized or remodeled neural circuits are not likely to improve performance.

Although not reviewed here in detail, it is worth noting that after early promising trials, D-amphetamine has failed to show improvement in several more recent well-designed, appropriately powered trials of recovery of motor function after stroke in humans

(Gladstone et al., 2006; Platz et al., 2005; Sonde & Lökk, 2007; Sprigg et al., 2007). It is difficult to predict whether D-amphetamine for aphasia would meet a similar fate if tested in larger trials. One factor that differs between motor and language studies, and across language studies, is the type and magnitude of behavioral therapy given to patients. Might some forms of behavioral therapy be more amenable to drug facilitation than others? The constraint-induced movement therapy typically used in modern stroke motor recovery trials may promote plasticity near or around damaged neural networks, whereas other forms of therapy may be more likely to promote reorganization of different compensatory neural networks. Given the paucity of efficacious drug therapy for chronic aphasia, the good safety profile of D-amphetamine and the promising data from Walker-Batson et al. and Whiting et al., larger trials are merited. It may be interesting to independently vary the type of SLT offered to D-amphetamine patients to probe the drug–behavior interactions mentioned.

Although most of the basic and clinical literature has been directed toward the investigation of the benefits of sympathomimetic compounds as described, an additional report has been published documenting the effect of propranolol, a beta1/beta2 adrenergic antagonist, on language function (Beverdorf et al., 2007). In this double-blind crossover study, four chronic Broca's aphasic patients were administered single 40-mg doses of propranolol or placebo and had language assessed via performance on the Boston Naming Test (BNT) across three separate drug trials. The authors found consistent small increases in naming performance (average BNT before drug = 26.3, after drug = 29.0). This report is consistent with a previous abstract demonstrating benefit of propranolol on language performance (Porch, Wyckes, & Feeney, 1985). The authors speculate that the benefits of beta antagonism may be related to suppression of background activity (as discussed by Hasselmo, Linster, Patil, Ma, & Cekic, 1997) or, less likely, in their view, to the anxiolytic properties of propranolol.

85.4.2 Human Studies: Dopamine Agonists and Levodopa

Several studies have examined the role of dopamine in aphasia recovery by either providing bromocriptine, a D2 agonist, or levodopa, the precursor to dopamine, with a peripheral decarboxylase inhibitor to prevent peripheral conversion of levodopa to dopamine. These drugs have a long track record with a good safety profile and less abuse liability than D-amphetamine. We have found six prospective, double-blind, placebo-controlled studies of these drugs in chronic aphasia.

Bragoni et al. (2000) studied the effects of high-dose bromocriptine (up to 30 mg three times per day) on 11 chronic nonfluent aphasics. They utilized a single cohort study, and each subject was compared with his/her own baseline. They found that bromocriptine plus SLT for 60 days improved performance on several language metrics over SLT alone. The benefit was sustained after a 60-day washout of the drug for several metrics but was only statistically significant for reading comprehension. As suggested by the Whiting et al. (2007) study of D-amphetamine, a single cohort study such as this is potentially compromised by a period effect. A recent study by Seniów, Litwin, Litwin, Lesniak, and Czlonkowska (2009) utilized a parallel design of 39 patients with subacute stroke randomized to receive either 100 mg levodopa or placebo. Drug therapy was timed to precede five-times-weekly SLT by 30 min and was continued for 3 weeks. The Boston Diagnostic Aphasia Examination (BDAE) was used as the primary outcome measure. They found improvement on all metrics, but this only reached statistical significance for verbal fluency, repetition of phrases and sentences, and repetition of words. Washout performance was not assessed. Levodopa patients were younger than placebo subjects by 6.3 years, potentially confounding the analysis, but the investigators found that age was not associated with BDAE outcome.

Several other studies of dopamine-based therapy did not show efficacy. Ashtary, Janghorbani, Chitsaz, Reisi, and Bahrami (2006) examined the impact of bromocriptine, 10 mg daily, started during the acute phase and continued for 4 months; 19 active patients and 19 placebo patients were enrolled. SLT was not required during this study, and it is not clear if any of the subjects received SLT. The investigators did not find any benefit of bromocriptine administration on a standardized Persian language test. Sabe, Salvarezza, García Cuerva, Leiguarda, and Starkstein (1995) reported the results of a crossover study of seven subjects with chronic nonfluent aphasia who received up to 60 mg daily of bromocriptine for 6 weeks. There was no requirement for SLT. The authors found similar performance during both the bromocriptine periods and the placebo periods. Unfortunately, their randomization scheme placed all subjects into the drug arm first, raising the possibility that a practice effect benefited the placebo period. In a similarly designed study, Gupta, Mlcoch, Sclaro, and Moritz (1995) studied the effect of up to 45 mg of bromocriptine over 10 weeks in patients with chronic aphasia. There was no requirement for SLT. This study had a more balanced randomization scheme than that of Sabe et al., and the authors found no influence of bromocriptine over a wide range of language metrics. Most recently, Leemann et al. observed no benefit of 2 weeks of

levodopa plus benserazide versus placebo when coupled with intensive computer therapy in the subacute period after stroke (Leemann, Laganaro, Chetelat-Mabillard, & Schneider, 2011).

It is notable that the two studies that demonstrated efficacy for dopamine therapy explicitly coupled dopamine therapy with SLT, whereas three out of four studies that did not show efficacy had no requirement for SLT. This is consistent with the animal literature described previously. These data are also consistent with much of the data from the human motor recovery literature, where levodopa, when coupled with physical therapy, has improved motor outcomes (Rösler et al., 2008; Scheidtmann, Fries, Müller, & Koenig, 2001). As recently noted (Gill & Leff, 2014), a relatively narrow range of dopaminergic agents and doses has been explored in these studies. The totality of the data, although incomplete, suggests that bromocriptine or levodopa therapy, coupled with SLT, may hold promise for aphasia treatment.

85.4.3 Human Studies: Cholinergics and Anticholinergics

Acetylcholine-augmentation as a therapeutic approach is supported by findings that there might be a relative lateralization of cholinergic projections (Bracco, Tiezzi, Ginanneschi, Campanella, & Amaducci, 1984) and that methylscopolamine, an anticholinergic drug, can impair phonological and lexical processing in normal adults (Aarsland, Larsen, Reinvang, & Aasland, 1994). Despite these findings and the body of neurophysiological data on the role of cholinergic projections in modulating neural plasticity and the neuropsychological data documenting its role in learning and memory described, there have been relatively few attempts to modulate this system for the treatment of aphasia. Inhibitors of acetylcholinesterase have widespread use for Alzheimer disease and, in general, have good safety and tolerability profiles. There have been several open-label pilot studies that showed signals of efficacy (Berthier, Hinojosa, Martin Mdel, & Fernandez, 2003; Pashek & Bachman, 2003; Tanaka, Miyazaki, & Albert, 1997; Tsz-Ming & Kaufer, 2001). One single case study involved a patient with a small subcortical lacunar infarction. Dopamine agonist therapy was ineffective, but donepezil led to a significant improvement in fluency (Hughes, Jacobs, & Heilman, 2000).

We are aware of one randomized controlled trial that examined the utility of cholinesterase therapy for stroke-related aphasia. Berthier et al. (2006) studied the effect of 16 weeks of donepezil (up to 10 mg daily) in patients with chronic aphasia. This was a parallel

study design with 13 individuals in each group, and all patients received standard SLT. The subjects were well-matched at baseline. The investigators found that the donepezil group improved significantly on the Western Aphasia Battery (WAB), the Communicative Activity Log, and the picture-naming subtest of the Psycholinguistic Assessment of Language Processing in Aphasia test. There were trends for improvement regarding spoken word–picture matching and spoken sentence–picture matching. The improvements noted at week 16 were not present at week 20, suggesting that the benefits of donepezil are not related to neural reorganization. This lack of persistent benefit is similar to what has been seen with the effects of donepezil on the improvement of patients with Alzheimer disease (Rogers, Farlow, Doody, Mohs, & Friedhoff, 1998). Given these short-term improvements, it would be interesting to determine if the improvements on language tests are related to an overall improvement across multiple domains of cognition, which has been seen with donepezil, or whether they are specific to language. If so, then that would imply that the benefits of donepezil may not be dependent on SLT and therefore may become a therapeutic option for those patients who may not have access to SLT. These data are consistent with a more recent open-label study demonstrating efficacy of another cholinesterase inhibitor, galantamine, relative to control subjects, for the treatment of chronic poststroke aphasia (Hong, Shin, Lim, Lee, & Huh, 2012).

85.4.4 Human Studies: Piracetam

Piracetam is a derivative of GABA and has a range of effects on the CNS. Piracetam facilitates cholinergic and excitatory amine neurotransmission (Giurgea, Greindl, & Preat, 1983; Vernon & Sorkin, 1991), increases regional cerebral blood flow (Jordaan, Oliver, Dormehl, & Hugo, 1996), and alters neuronal membrane properties (Müller, Eckert, & Eckert, 1999). It has been claimed that this agent improves learning and memory, but it is not clear which of its biological effects (e.g., neuroprotective, circulatory, or others) are responsible for the purported cognitive benefit (Malykh & Sadaie, 2010). Piracetam is currently available as a nutritional supplement in the United States and is approved for the treatment of myoclonus in Europe.

The data on piracetam for aphasia are mixed. One large multicenter trial (n = 927) aimed to treat all stroke patients within 12 h and used a variety of outcome measures, including assessment of aphasia. This study showed no effect on the primary outcome measure of neurological status (Barthel Index and

Orgogozo scale) at 4 weeks (De Deyn, Reuck, Deberdt, Vlietinck, & Orgogozo, 1997). A post hoc analysis of an "early treatment subgroup" (defined prospectively as within 6 h, but retrospectively as within 7 h) showed some benefit of piracetam. This was particularly true in the moderate to severe subgroup (De Deyn et al., 1997; Orgogozo, 1999). Of these patients, approximately one-third ($n = 373$) were aphasic, and aphasia recovery at 12 weeks was better in the piracetam group than in the control group, particularly for the early treatment subgroup (Huber, 1999; Orgogozo, 1999).

In postacute and chronic aphasia, several randomized controlled trials have been performed. Enderby et al. observed significant improvements on a multivariate analysis of Aachen Aphasia subtest scores relative to baseline in favor of piracetam ($P = 0.02$) at 12 weeks. This effect was no longer present at 24 weeks (Enderby, Broeckx, Hospers, Schildermans, & Deberdt, 1994). A later double-blind, placebo-controlled study involving chronic aphasia showed trends for improvements across all subsets of the Aachen Aphasia Test, which only reached statistical significance written language (Huber, Willmes, Poeck, Van Vleymen, & Deberdt, 1997). Integrating functional imaging measures into a treatment trial, another study showed an increase in task-related blood flow in several left hemisphere regions generally associated with language over the course of the treatment period; more increase in blood flow in the treatment group than the placebo group. The piracetam group improved on six language measures and the placebo group improved on three (Kessler, Thiel, Karbe, & Heiss, 2000). Most recently, Güngör, Terzi, and Onar (2011), in a single-blind design, examined the impact of 6 months of piracetam given after ischemic stroke causing aphasia and found no benefit across any of the primary language or disability outcome measures, although subjects receiving piracetam showed improvement in auditory comprehension ($P = 0.023$). Thus, there were signals for efficacy in three out of four trials, three of which were relatively small (less than 25 active subjects each) and were thus likely underpowered to see small differences between groups.

85.4.5 Human Studies: Memantine

Memantine is a noncompetitive NMDA-receptor antagonist currently approved for the treatment of Alzheimer disease. A single trial has been performed examining the efficacy of memantine to treat chronic aphasia due to stroke. Berthier et al. (2009) found that 20 mg daily of memantine for 16 weeks, in the absence of SLT, produced enhanced performance on the WAB. Incorporation of constraint-induced aphasia therapy (CIAT) for 2 weeks produced further separation of the

memantine group from the placebo group. After a 4-week washout, the memantine group's WAB performance declined substantially, but it was slightly better than that of the placebo group ($P = 0.041$). This study is suggestive of an effect of memantine in the absence of SLT, although evidence for a synergistic relationship between CIAT and memantine is weakened by the differences in WAB scores at the onset of CIAT. Given the good efficacy and tolerability profile of combination use of donepezil and memantine for Alzheimer disease (Tariot et al., 2004), and given the positive studies for both drugs and aphasia described here, it would be interesting to examine the effects of combination therapy on aphasia recovery.

85.4.6 Human Studies: Zolpidem

Zolpidem is a short-acting nonbenzodiazepine hypnotic that potentiates GABA. Although its hypnotic effects are similar to those of the benzodiazepines, it is classified as an imidazopyridine and is molecularly distinct from the classical benzodiazepine molecule. It binds to the alpha1 subunit of the type A GABA receptor, which is preferentially localized to the middle cortical layers of the neocortex when compared with other GABA A-receptor subtypes (Akbarian et al., 1995). There have been case reports documenting substantial clinical improvements in patients with deficits in arousal or awareness after receiving zolpidem (Clauss, Güldenpfennig, Nel, Sathegke, & Venkannagari, 2000; Thomas, Rasclé, Mastain, Maron, & Vaiva, 1997). One recent double-blind, placebo-controlled report of one patient with akinetic mutism documented enhanced motor and language performance after the patient received 20 mg of zolpidem. This patient improved from having no speech output with placebo to having limited naming and repetition ability during the zolpidem period. The rCBF study of this patient using $H_2^{15}O$ positron emission tomography demonstrated increased blood flow to the anterior cingulate and orbital frontal cortices during the naming tasks (Brefel-Courbon et al., 2007). Another single, open-label case study reported the improvement in language function in an aphasic patient with a single dose of zolpidem (Cohen, Chaaban, & Habert, 2004). In this case report, an individual with nonfluent aphasia and a lesion in the left insula, putamen, and superior temporal gyrus had mild insomnia and was prescribed zolpidem, which led to sudden and unexpected improvement in her speech and naming ability. This remitted when the zolpidem wore off and was reproducible. An electroencephalography (EEG) failed to show any changes after zolpidem administration. Technetium-99 SPECT scanning demonstrated an increase in blood flow to Broca's area, left

middle frontal gyrus, left supramarginal gyrus, and the bilateral orbitofrontal and mesial frontal cortices. The commonality of increases in blood flow to the orbitofrontal cortices in both patients that had improved language ability under zolpidem administration raises the possibility that zolpidem influenced the planning or motivational aspects of language behavior in these patients. It is worth noting that these reports are reminiscent of the very early literature on aphasia pharmacotherapy, in which many single cases were reported, mostly involving sedative hypnotics (e.g., amobarbital) (Linn, 1947), suggesting cures of aphasia (see Small, 1994). As yet, no large-scale studies of zolpidem have been reported.

85.4.7 Human Studies: Vasopressin

Vasopressin is produced in the hypothalamus, is released by the posterior pituitary, and is thought to be important in mediating social behavior (Donaldson & Young, 2008) as well as behavior in multiple cognitive domains (Born, Pietrowsky, & Fehm, 1998; Kovacs & De Wied, 1994). Tsikunov and Belokoskova (2007) examined the effects of intranasal desmopressin (a V2-receptor agonist) administration in 26 patients with chronic stroke-related aphasia. This was a single cohort crossover design, and comparisons were made between active treatment periods and placebo periods that always preceded the active periods. The authors observed “good” responses (improvements on at least 3 out of 10 language tests) for 13 out of 26 subjects. SLT was not incorporated into this trial. Because placebo periods always preceded drug periods, this study is subject to a period effect. Review of their Figure 1 shows no improvement between the baseline and placebo periods, but improvement during the drug periods, suggesting minimal period effect. These data are promising and should be studied in a confirmatory trial. One intriguing factor here is the fact that V2 receptors (the probable target for desmopressin) are sparse in the adult human brain. Therefore, it is not clear if the beneficial effects seen here are due to desmopressin interacting with V1 receptors (which are expressed in the brain) or if a peripheral effect of desmopressin (e.g., hyponatremia) is responsible for the benefits. If desmopressin is, in fact, acting in the brain, and given the speculation of the role of vasopressin in social behavior, then it would be interesting to determine the degree to which the improvements in language function correlate with indices of social functioning in these patients. If vasopressin-based recovery has a different mechanism of action than “traditional” neurotransmitter-based therapy, this approach holds promise in being a nonredundant form of pharmacotherapy for subjects receiving one of these classes of drugs.

85.4.8 Drugs to Avoid

If certain pharmacological manipulations have the potential to improve language outcomes in aphasic patients, then it is likely that other manipulations may worsen or delay recovery. Early studies of the inadvertent pharmacological interference with aphasia recovery suggested that haloperidol and hydrochlorothiazide diuretics were associated with worse language outcomes after aphasic stroke (Porch & Feeney, 1986; Porch et al., 1985). Another early report noted that several drugs that impair recovery in experimental stroke (e.g., drugs that affect catecholamine or GABA systems) are commonly given to stroke patients for coincident medical problems (Goldstein, 1993). This led to a formal retrospective (chart review) study of patients using these specific drugs at the time of their strokes (Goldstein, 1995). A total of 96 patient records were reviewed and patients were grouped regarding whether they were using one or more of the following drugs: clonidine, prazosin, any dopamine receptor antagonist (e.g., neuroleptics), benzodiazepines, phenytoin, or phenobarbital. Statistical analysis revealed that although patient demographics and stroke severity were similar between groups, motor recovery time was significantly shorter in the group not using one of these drugs.

Several other drugs have been associated with language difficulties of one type or another and in one context or another. Certainly, the effects of anticholinergic medications on memory function (Koller et al., 2003; Sherman, Atri, Hasselmo, Stern, & Howard, 2003; Taffe, Weed, & Gold, 1999) would suggest avoiding agents with these effects. Anticonvulsant medications, notably vigabatrin and topiramate, have potentially serious cognitive effects, including causing or exacerbating aphasia (Gil & Neau, 1995; Jambaqué, Chiron, Kaminska, Plouin, & Dulac, 1998; Wong & Lhatoo, 2000). Topiramate appears to occupy a unique niche in its ability to produce cognitive disturbances, often manifesting as aphasia. Mula, Trimble, Thompson, and Sander (2003) found word-finding difficulty in 7.2% of more than 400 patients with epilepsy while using topiramate, and a case study demonstrated reversible focal left frontal hypoperfusion and motor aphasia in a seizure patient using topiramate (Cappa, Ortelli, Garibotto, & Zamboni, 2007). Language disturbances have been observed in migraine patients using topiramate as well. Coppola et al. (2008) reported that 26.7% of migraine patients in their clinic who were treated with topiramate had some form of language disturbance compared with 0% for patients using other prophylactic therapy (and matched for headache syndrome severity). These studies do not specifically address the ability for

topiramate or other anticonvulsants to alter the recovery from a lesion in the language network. Given the importance of SLT on language recovery, it is likely that topiramate would interfere with the ability of patients to optimally participate in SLT, and therefore it should be avoided.

85.5 CONCLUSION

Existing studies on pharmacological approaches to the treatment of aphasia do not yet paint a clear picture to guide current therapy. Nonetheless, there are increasingly reliable data suggesting a potential beneficial effect potentiation of catecholaminergic transmission on animal motor recovery and aphasia rehabilitation. The data are also promising for drugs that potentiate acetylcholine, as well as for compounds in which the scientific rationale and mechanisms are less clear, such as memantine, and vasopressin. Importantly, cholinesterase inhibitors and memantine have a long track record of safe use in elderly populations with cardiac comorbidities, suggesting few safety concerns about the use of these drugs. It is important to note that despite some of the encouraging data in the aphasia trials, the effect sizes are generally small, and there are few data demonstrating an impact of drug therapy on quality of life or functional outcome measures. Further, despite the common practice in most chronic diseases to use multidrug therapy to attack different pathophysiological pathways, there have been no randomized trials of combination therapy for aphasic stroke therapy. In addition, different etiological forms of aphasia probably have different natural histories and, therefore, different sensitivities to pharmacotherapy, and this has not yet been explored in any depth.

In most cases, drug efficacy has only been seen when coupled with active SLT, which was strongly predicted by the animal literature. SLT is likely the "behavioral engine" that drives pharmacological responses (Nadeau & Wu, 2006). Therefore, pharmacotherapy should not be used as a substitute for speech therapy, and any biological intervention should be used only in concert with individually tailored behavioral therapy, preferably carefully designed adaptive learning approaches. In addition, it is likely that different forms of drug therapy are likely to interact optimally with different forms of SLT, and this should be explored. Further, aphasic patients have a host of comorbidities, such as hypertension, depression, seizures, behavioral disturbances, and others, and they are often using other medications for these. To ensure maximal recovery of language function, it will be important to balance the need for each of these

medications with their potential to worsen or delay language recovery and to seek alternatives when they exist. Finally, it should be noted that advances in imaging technology in both animals and humans will make it easier to directly translate findings from rodent studies into human study design, permitting development of novel therapeutics in the future.

86.1 INTRODUCTION

Aphasia is a consequence of injury to brain language networks. Many different forms of pathology can produce aphasia, including ischemia, degenerative disease, infection, and trauma, with the most common cause being ischemic stroke; approximately 1 in 4 patients with stroke have some degree of aphasia on acute presentation (Rathore, Hinn, Cooper, & Tyroler, 2002). The natural course of aphasia varies with the pathogenesis. When the cause is an ischemic stroke, some degree of spontaneous behavioral recovery is often seen. However, this is generally incomplete, and aphasia remains an important source of human disability.

A number of training and compensation strategies are available to reduce aphasia-related deficits, as reviewed elsewhere in this book. However, although some data suggest the potential for pharmacotherapy to improve outcomes (Allen, Mehta, McClure, & Teasell, 2012; and reviewed elsewhere in this book), there are no convincing data that any drugs improve speech, language, and communication; therefore, no drugs have been approved for this indication (Dobkin & Dorsch, 2013; Klein & Albert, 2004; Small, 1994). There are a number of possible reasons for this. For example, specific challenges that arise in studying therapies that target aphasia include the large number of languages and patterns of communication across our species, the paucity of directly relevant preclinical models of aphasia, current limitations in use of drugs to modulate restorative brain events in a targeted way, and the enormous heterogeneity by which aphasia presents clinically.

Increasing evidence suggests the potential for stem cell therapies to improve outcome after neural injury such as stroke. However, there has been very little research published examining stem cell therapies specifically in relation to aphasia. A review of potential stem cell therapies and general consideration of issues surrounding translation of stem cell therapy therapies in humans are presented.

86.2 STEM CELL THERAPIES: INTRODUCTION

Stem cells are found in all multicellular organisms across animal and plant kingdoms and can be defined on the basis of two key features. The first is self-renewal; cell division produces an additional stem cell as well as a differentiated cell. The second is potency, meaning that stem cells can become many different cell types. The extent of potency varies between different types of stem cells. Stem cells are normally present across the lifespan, from embryo to adult, and in healthy subjects are found within many different tissues, including the brain (Gonzalez-Perez, 2012).

These stem cells may be isolated and grown in culture for use as a therapeutic agent. Many variations are undergoing study, such as stem cell therapies that include gene modification, transformation *in vitro* such as by exposure to selected chemicals, or addition of a bioscaffold. Stem cell therapies have been examined in relation to a vast number of different diseases. This includes numerous neurological disorders and specific neurological deficits. The stage of development for

stem cell therapies ranges from preclinical to phase III trials, and at least some cell-based therapies have been approved in selected western countries (De Feo, Merlini, Laterza, & Martino, 2012; Eckert et al., 2013; Mankikar, 2010; Savitz, 2013). Numerous routes of stem cell administration have been advocated, from intravenous to highly invasive. Many different mechanisms of action have been described across the many formulations of stem cell therapy. In the brain, stem cell therapies generally promote repair through local or sometimes systemic pathways. In some non-neurological conditions, stem cell therapy can also be used to replace disease-affected tissue; however, to date, actual replacement of injured or dead neural cells by stem cell therapy has been suggested in only a very restricted set of conditions (De Feo et al., 2012). The current review focuses on classes of stem cells that have received a relatively greater amount of study in relation to neurological diseases such as stroke, and thus are the stem cells that may be of greatest relevance to treatment of aphasia.

86.3 HUMAN NEURAL STEM CELLS

Various types of human neural stem cells (hNSCs) have been proposed for cell replacement therapy in a number of neurological conditions, including traumatic injuries to the brain or spinal cord injury, stroke, multiple sclerosis, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis, and Alzheimer's disease (Cummings et al., 2005; Gold et al., 2013; Karussis, Petrou, & Kassis, 2013; Keirstead et al., 2005; Pluchino et al., 2003). These hNSCs or neural derivatives are isolated from the donor human organism at different developmental stages and are classified according to their specific origin or the potential of what they can become. Many different types of endpoint have been studied for hNSC and their neural derivatives, ranging from a goal as simple as synthesis of a vital protein to the complex goal of establishing synaptic connections and integrating with host circuitry.

86.4 ADULT/FETAL hNSCs

hNSCs can differentiate into neurons and glia and are multipotent cells, meaning that they can differentiate into multiple different types of cells, but not all types of cells found in the body. An important issue for therapeutic applications is that hNSCs obtained later in development, such as those harvested from the central nervous system (CNS) of a human fetus or adult, are likely to have cell fate restrictions that could

limit what they can become. In some cases, cell fate restriction is more desirable and may reflect a lower tendency to form tumors or non-neural cell types. This inherent characteristic of fetal and adult hNSCs may be appealing to regulatory agencies and might have contributed to these cells having been approved for clinical trials for several neurological conditions. Ironically, the potential benefits of such hNSC populations can be limiting, mainly because their inherent fate restriction does not permit the realization of their full potential. Critically, fetal or adult hNSCs harvested at different developmental periods or from specific CNS regions are likely to yield specific neural progenitors or cell types that have therapeutic utility for a certain condition or CNS region. Accordingly, hNSCs that have been harvested from the late-stage fetal period or from the adult CNS mainly differentiate into astrocytes, whereas those harvested from an earlier stage of fetal development mainly differentiate into neurons (Nguyen et al., 2014). Furthermore, the fate restriction observed for fetal/adult hNSCs often coincides with a decrease in cell expansion potential, making it more difficult to scale-up production for human patients. In some instances, advances have been made to increase the expansion potential of fetal/adult hNSCs via the selection of the "stemness" marker CD133 (Wang, O'Bara, Pol, & Sim, 2013). However, cells selected in this manner are limited regarding the number of times that they can divide under culture conditions, and thus repeated hNSC cell division can, in the long-term, affect their differentiation potential as well as their chromosomal stability, issues common to many forms of stem cell therapy.

86.5 HUMAN EMBRYONIC STEM CELLS AND NEURAL DERIVATIVES

Human embryonic stem cells (hESCs) are harvested from the inner cell mass of a blastocyst and retain several inherent characteristics that permit long-term expansion. These cells are pluripotent, meaning that they have the capacity to become any of the specialized cell types that comprise the human body (Nichols & Smith, 2012). hESCs may be a limitless source for generating hNSCs and hNSC derivatives such as neurons or glia. This could represent a major potential advantage for human stem cell therapy applications (Brunt, Weisel, & Li, 2012). However, the tendency for hESCs and their derivatives to form tumors in the CNS has been a major concern for cell replacement. hESC-derived hNSCs and derivatives are heterogeneous and are often thought to consist of undifferentiated cells with retained tumor tendency. In an effort to prevent tumor formation, a number of neuralization

protocols have been established whereby hESCs are differentiated into more neural-restricted derivatives. These neural derivatives have the potential to differentiate into astrocytes and neurons (Denham & Dottori, 2009; Zhang & Zhang, 2010), as well as specific neural progenitors that can give rise to motoneurons (Chambers et al., 2009; Ebert et al., 2009; Erceg et al., 2008; Li et al., 2005), dopaminergic neurons (Schwartz et al., 2012; Swistowski & Zeng, 2012; Zhang & Zhang, 2010), or oligodendrocytes (Erceg et al., 2010; Hatch, Nistor, & Keirstead, 2009; Okamura et al., 2007); note that neural derivatives generated from these protocols can have variable neural cell fate and expansion potential. Moreover, the resulting neural precursors are typically exposed to undefined factors from mouse feeder cells and bovine serum. In fact, recent advances for cell differentiation into hNSCs and specific neural progenitors or cell types have been made predominantly from cells maintained under conditions containing undefined animal-derived products, which can increase the risk of host immune responses, graft rejection, or infection by nonhuman pathogens (Cobo et al., 2005; Martin, Muotri, Gage, & Varki, 2005; Skottman & Hovatta, 2006). Furthermore, animal-derived products may have added unknown effects on cell characteristics (e.g., proliferation and differentiation), whether the exposure is *in vitro* or *in vivo*. Hence, establishing xeno-free (XF), or more defined, cell culture conditions and protocols for neuralization represents an important step to further the development of therapeutically relevant cell lines.

Several factors have been defined that have established value for differentiating hESCs into neural derivatives (e.g., motoneurons, dopaminergic neurons, or oligoprogenitors), including retinoic acid, sonic hedgehog, and the bone morphogenetic protein and/or signaling inhibitors such as noggin (Chiba, Lee, Zhou, & Freed, 2008; Li et al., 2005; Sundberg et al., 2011; Wada et al., 2009). One attractive feature of using such factors to establish neural derivatives is that they appear to reduce risks of transplant rejection and infection by nonhuman pathogens. However, the practicality of these factors to generate neural derivatives or hNSCs for the clinical human population may depend on their ability to induce neural differentiation while maintaining chromosomal stability of cell lines. A recent study has reported increased incidents of aneuploidy in retinoic acid–treated hESCs (Sartore et al., 2011); hence, the practical use of some of these factors may be limited and more research is needed to better assess the effect of long-term exposures of these factors. Alternatively, growth factors such as those normally found in humans (e.g., epidermal growth factor, basic fibroblast growth factor, and leukemia inhibitory factor) can induce efficient neural differentiation and

therefore have been used successfully to generate neuralized spheres and adherent hNSCs under defined or XF conditions (Ebert et al., 2013). These neural derivatives are highly proliferative, retained normal karyotype and have the potential to differentiate in neurons, astrocytes, and/or oligoprogenitors. Overall, recent advances have demonstrated the feasibility of neural differentiation under defined or XF conditions that are attractive to cell replacement therapy for human patients. However, more work is needed to further characterize and test the safety and translational feasibility of these defined or XF neural derivatives, particularly of how they behave in an animal system and how they respond to the cues and toxicity of the brain or spinal cord after trauma or disease.

86.6 HUMAN-INDUCED PLURIPOTENT STEM CELLS AND NEURAL DERIVATIVES

Reprogramming technology has elevated excitement for cell replacement therapy because its advances have allowed somatic cells of the adult human body, such as fibroblasts derived from skin, to be modified *in vitro* into hESC-like stem cells referred to as human-induced pluripotent stem cells (hiPSCs). Like hESCs, hiPSCs can, in principle, become any cell type of the body, providing unprecedented access to *in vitro* human models and thus new opportunities (e.g., to study human genetic diseases or response of patient-specific cells to selected pharmacological compounds) (Bellin, Marchetto, Gage, & Mummery, 2012; Yamanaka, 2012). The hiPSCs also have the potential for autologous transplantation (i.e., use of cells derived from a patient's own body). In contrast with allogeneic transplantation (i.e., use of cells derived from a different organism but of the same species), autologous transplantation generally avoids the need for immunosuppression and therefore avoids the many complications associated with immunosuppression (Morizane et al., 2013).

Therapies using hiPSCs have many potential advantages such as ease of availability and of individualizing therapy. However, the properties of these cells have been incompletely characterized; therefore, concerns remain in relation to translation of hiPSCs for cell replacement therapy. Critics of hiPSC note that some lines are not fully reprogrammed, which might potentially cause mutations. Accordingly, some hiPSC lines previously generated have shown high variation in gene expression, DNA methylation, immunogenicity, and pluripotent potential (Yamanaka, 2012). In some cases, hiPSCs and their neural derivatives have shown an increased tendency to form tumors after cell

transplantation (Miura et al., 2009), a finding that has been attributed to selected features of cell reprogramming and culture conditions. Recent advances include generating integration-free hiPSCs through induction methods that include plasmids, small molecules, and synthesized RNAs and proteins. An advantage of such approaches is that they do not involve vector integration into the host genome.

The potential benefits of using hiPSCs as a means to provide a patient-specific therapy remain attractive and contribute, in part, to the continued high level of research activity focused on hiPSCs for regenerative medicine and disease-specific cell model systems.

86.7 MESENCHYMAL STEM CELLS

Mesenchymal stromal cells (MSCs), also known as marrow stromal cells and marrow stem cells, are a form of cellular therapy that have received considerable attention, in part because they are found in many different body tissues (e.g., bone marrow or adipose) and are relatively easy to isolate. MSCs are also immunoprivileged; therefore, concomitant immunosuppression is not required. MSCs are multipotent (i.e., can differentiate into a limited number of cell types, for example, osteoblasts, adipocytes, and chondroblasts) (Dominici et al., 2006). Exogenously administered MSCs are selectively attracted to sites of injury, where they transform and provide benefit through multiple parallel processes, including paracrine delivery of growth factors, immunomodulation, reduced apoptosis, and promotion of cellular remodeling.

86.8 ISSUES RELATED TO CLINICAL APPLICATION OF STEM CELL THERAPIES

A number of issues arise when evaluating stem cell therapies in the treatment of neurological diseases such as those causing aphasia. Some are important across many classes of restorative therapy, whereas others are more specific to cell-based therapies.

Whatever efficacy is ultimately found for stem cells, this will be compared with any additional therapies also proposed for the same clinical indication. There are some unique challenges to providing stem cell therapy, and these are included in any cost-benefit analysis. For example, manufacture and storage of stem cells require very specific laboratory conditions that can be expensive to maintain (Chase et al., 2012; Ilic et al., 2011; Murdoch et al., 2012). For many stem cell therapies, the protocol calls for invasive methods of cell introduction; therefore, the risk of the stem cell therapy is determined

by the combined risk of the cells themselves as well as the invasive procedure (Savitz, Cramer, & Wechsler, 2014). Similarly, for any stem cell therapy that requires concomitant immunosuppression, the risk must be measured as that of the stem cells combined with that of the immunosuppressive regimen, a consideration that increases in significance when the target disease is associated with an immunosuppressed state, as has been described early after stroke (Vogelgesang & Dressel, 2011). Many forms of stem cells persist in the body for months or longer, in contrast to most pharmacological compounds that are largely excreted within hours or days. As a result, the period of time needed to reasonably assess the true safety profile of a cell-based therapy may be measured in years. Some types of stem cells have an increased risk for tumor formation, adding to the potential cost and complexity of such a therapeutic approach (Hess, 2009).

A number of issues exist that are of broad importance across clinical investigation of many types of restorative therapies targeting neurological disease. Clinical trials must be carefully designed to enroll a population in which any treatment effect, if present, can be identified. This might be informed by preclinical studies or by careful mechanistic human studies. Studies enrolling patients who lack the substrate necessary for the effects of cell therapy are unlikely to identify a treatment effect. Dose-response studies are critical to translation of restorative therapies and are no less critical when the intervention is cell-based (Benowitz & Carmichael, 2010; Cramer, 2008; Cramer et al., 2011; Savitz et al., 2014). Stroke, the most common cause of aphasia, is a very heterogeneous condition, and methods for selecting or stratifying patients are critical to detecting treatment effects (Cramer, 2010). Efforts to reduce the many sources of potential inter-subject variance are critical to insure adequate study power (Barak & Duncan, 2006; Bath et al., 2012). A related issue is the need for clinical trials of stem cells to use as outcome measure tests that have established validity and reliability (Bath et al., 2012).

The outlook for cell-based therapies in the treatment of aphasia is uncertain at this time. Several factors suggest that stem cells may be found useful for improving language function. For example, several types of cell therapy appear promising in preclinical studies of diseases that affect language, such as stroke, and they are being evaluated in early phase human translational studies. A large body of evidence documents the many forms of behaviorally useful neural plasticity that occur in the human language system in response to neurological disease (Heiss & Thiel, 2006; Lubrano, Draper, & Roux, 2010; Naeser et al., 1998; Rosen et al., 2000; Vandenbulcke, Peeters, Van Hecke, & Vandenberghe, 2005), suggesting the capacity of the

language network to undergo remodeling in support of improved language function, at least in some patients. Furthermore, other classes of restorative therapy might also have the potential to improve language function in selected cases and, when combined with a cell-based therapy, might provide further options (Bhagal, Teasell, & Speechley, 2003; Liepert, 2008; Naeser et al., 2005; Shah, Szaflarski, Allendorfer, & Hamilton, 2013; Small & Llano, 2009; Thiel et al., 2013). Other points temper enthusiasm at this time. There are no approved drugs to improve language function, increasing the challenges of identifying an effective cell-based therapy. Many language functions rely on eloquent cortex, and when such brain regions are critically devastated by disease, plasticity can be of limited value to behavioral status. Although the region of the brain that can contribute to language function in humans is broad and variable (Ojemann, Ojemann, Lettich, & Berger, 1989), the key areas needed to be functional in language might actually subtend a rather restricted distribution (Fridriksson, 2010; Hillis et al., 2006). Many of the more advanced stem cell therapeutic applications are based on the cells performing a specific action, such as immune system modulation or paracrine release of neurotrophins. If aphasia recovery requires regrowth of a new area of six-layered cortex with proper white matter connections, then the goal may be elusive in the near future.

Neural repair occurs on the basis of experience-dependent brain plasticity. As a result, it is critical to ensure that behavioral reinforcement is provided concomitant with a restorative therapy such as stem cell therapy (Kleim & Jones, 2008). As an extension of this principle, the amount of therapy provided outside of therapy (e.g., as part of standard of care) must be carefully measured to understand behavioral effects of stem cell therapy (Cramer, 2011).

Processing Tone Languages

Jackson T. Gandour and Ananthanarayan Krishnan

Department of Speech Language Hearing Sciences, Purdue University, West Lafayette, IN, USA

87.1 INTRODUCTION

Speech perception is important because it provides multiple windows along the auditory pathway into the cerebral cortex regarding how continuous, acoustic signals are transformed into representations on which computations are based at different levels of the brain. Pitch is one of the most important information-bearing components of speech. Tone languages offer advantages for investigating neural mechanisms underlying pitch at different levels of processing because of their phonemic status at the word level (Yip, 2002).

With respect to tonal processing in the brain, almost all experiments performed since 2000 have focused on speech perception or recognition using techniques of functional brain imaging (positron emission tomography [PET]; functional magnetic resonance imaging [fMRI]) and neurophysiology (electroencephalography [EEG]; magnetoencephalography [MEG]). This review focuses primarily on the articles published within that time frame that address four topics related to lexical tone. We evaluate the effects of the phonological status of pitch information on pitch processing in the brain. These experiments tease apart sublexical tonal processing from other cognitive processes involved in speech perception, especially lexical semantic processing. Experimental findings reveal patterns of cortical activation that may vary as a function of acoustic features associated with types of phonological units (i.e., tone versus subsyllabic and segmental units, e.g., consonants and vowels). Because pitch is multidimensional, it is important that we evaluate the effects of pitch features in addition to tonal categories. Those experiments using methods with high temporal resolution reveal the role played by pitch features at early, preattentive stages of processing. There are other suprasegmental units besides tone. The question arises whether common or distinct neural substrates underlie the

processing of different suprasegmental units (e.g., intonation, rhythm). Experimental findings to date support the view that speech prosody perception involves a dynamic interplay among widely distributed regions not only within a single hemisphere but also between the two hemispheres, and even different levels of the brain (e.g., midbrain). Moreover, it becomes clear that the time window is pivotal for revealing how hemispheric laterality patterns may reflect higher-level and lower-level stages of auditory processing.

This review on tonal processing in the brain extends previous surveys that have covered dichotic listening (Gandour, 2007; Wang, Behne, Jongman, & Sereno, 2004; Wang, Jongman, & Sereno, 2001), tonal breakdown in production and perception after brain damage (Gandour, 1987, 1994, 1998a, 1998b; Wong, 2002), brain mapping of speech prosody (Gandour, 2006a, 2006b; Zatorre & Gandour, 2008), meta-analysis of lesion literature of linguistic and emotional prosody perception (Witteman, van Ijzendoorn, van de Velde, van Heuven, & Schiller, 2011), and communication disorders in speakers of tone languages (Wong, Perrachione, Gunasekera, & Chandrasekaran, 2009).

87.2 TONE LANGUAGES OF EAST AND SOUTHEAST ASIA

This review focuses exclusively on *lexical tone* languages, that is, those in which the pitch of a word can change the meaning of a word. They are distinguished from *pitch accent* languages (e.g., Japanese), which have a smaller number of contrasting tones, narrower word distribution, and co-occurring syllable structure constraints (Yip, 2002, pp. 1–4). Mandarin Chinese (Beijing), hereafter referred to as Mandarin, has four contrastive tones: *ma*¹ “mother,” *ma*² “hemp,” *ma*³ “horse,” and *ma*⁴ “scold.” Tones 1 to 4 are high-level (M1), high-rising (M2),

low-falling–rising (M3), and high-falling (M4) (Xu, 1997). Cantonese (Hong Kong) has six contrastive tones: ji^1 “cure,” ji^2 “chair,” ji^3 “opinion,” ji^4 “son,” ji^5 “ear,” and ji^6 “two.” Tones 1 to 6 are high-level (C1), high-rising (C2), mid-level (C3), low-falling (C4), low-rising (C5), and low-level (C6) (Zee, 1999). Thai (Bangkok) has five contrastive tones: $khaa^M$ “stuck,” $khaa^L$ “galangal,” $khaa^F$ “kill,” $khaa^H$ “trade,” and $khaa^R$ “leg”. Tones 1 to 5 are mid-level (T1), low-falling (T2), high-falling (T3), high-rising (T4), and low-rising (T5) (Tingsabath & Abramson, 1999). Voice fundamental frequency (f_0) contours provide the dominant cue for tone recognition (Gandour, 1994).

87.3 LEXICAL VERSUS SUBLEXICAL UNITS

With technological advances in functional brain imaging and auditory neurophysiology at the turn of the century, the aim of the research agenda was to establish that the processing of pitch information in the brain could vary depending on its functional status (linguistic versus nonlinguistic). At that time, it was already well-known that nonlinguistic pitch perception was mediated by neural mechanisms in the right hemisphere (RH) (Zatorre, Belin, & Penhune, 2002, review).

Almost all functional imaging studies of lexical tones have been performed on Thai and Mandarin. Subjects were required to make active judgments (same–different, word recognition) involving later stages of cognitive processing (working memory, decision-making). In discrimination judgments of Thai tones embedded in real words, Thai natives activated the left inferior frontal gyrus (IFG), but Mandarin-speaking Chinese and English did not (1: Gandour et al., 2000; Gandour, Wong, & Hutchins, 1998).¹ This leftward asymmetry in the Thai group is not restricted to a phonemic contrast in tone. Vowel length (/bat^{low}/ “card,” /baat^{low}/ “monetary unit”) is phonemic in Thai. When asked to discriminate pitch and timing patterns in Thai pseudowords and nonlinguistic hums (4: Gandour et al., 2002), Thai natives, but not Chinese, similarly activated the left IFG. Chinese natives, however, activated the left IFG when presented with Mandarin tones (3: Klein, Zatorre, Milner, & Zhao, 2001); in contrast, homologous regions in the RH were activated by English (2: Hsieh, Gandour, Wong, & Hutchins, 2001). To isolate processing of lexical tone, Chinese and English listeners were presented with Mandarin tones embedded in actual Mandarin words and in English pseudowords (5: Wong, Parsons,

Martinez, & Diehl, 2004). When Chinese listeners were asked to discriminate Mandarin tones embedded in Mandarin words, the left anterior insula was the most active; when embedded in English pseudowords, the right anterior insula was the most active. English listeners activated the right insula and IFG regardless of whether the pitch patterns were embedded in Mandarin or English words. This finding is strengthened by an experiment in which English-speaking adults were trained to use Mandarin tones (M1, M2, M4) to signal lexical meaning on English pseudosyllables (7: Wong, Perrachione, & Parrish, 2007). Good English learners of Mandarin tones showed increased activity in the left posterior superior temporal gyrus (STG); poor learners showed increased activity in the right STG and IFG. Thus, pitch processing engages the left hemisphere (LH) when the pitch patterns signal lexical meaning; otherwise, they are lateralized to the RH.

To isolate sublexical tonal processing, hybrid stimuli were created by superimposing Thai tones onto Mandarin syllables (*tonal chimeras*) and Mandarin tones onto the same syllables (Mandarin words) (6: Xu, Gandour, Talavage, et al., 2006). The tonal chimeras were nonwords in both Mandarin and Thai. In a comparison of native versus nonnative tones, overlapping activity between Mandarin and Thai listeners was identified in the left planum temporale (PT). In this area, a double dissociation between language experience and neural representation of pitch occurred such that stronger activity was elicited in response to native as compared with non-native tones. This neural activity arguably reflects sublexical, phonological processing and is consistent with the view that neural responses to acoustic stimuli can be modulated by their linguistic function (Griffiths & Warren, 2002). Converging evidence that the left PT plays a role in tonal processing comes from an fMRI study in which Chinese listened *attentively* to normal and pitch-flattened sentences (8: Xu, Zhang, Shu, Wang, & Li, 2013). Pitch-flattened sentences elicited greater activation in the left PT compared with normal sentences. Moreover, this activation began to increase and reach its peak earlier than activations in other areas responsible for lexical semantic processing (right PT activation for passive listening to pitch-flattened German sentences; Meyer, Alter, Friederici, Lohmann, & von Cramon, 2002; Meyer, Steinhauer, Alter, Friederici, & von Cramon, 2004). The time course of activation suggests that access to lexical meaning in pitch-flattened sentences is accomplished by the recovery of long-term tonal representations.

¹The *number*: notation preceding a citation indicates its location in Table 87.1.

TABLE 87.1 Selected References on the Neurobiology of Tonal Processing (2000–2013)

LEXICAL VS. SUBLEXICAL UNITS					
Study	Year	Stimuli	Tasks	Methods	Conclusions
1: Gandour	2000	THA: word, hum; onset consonant, tone	Same–different	PET	Activity in left IFG (frontal operculum) varies depending on linguistic status of pitch
2: Hsieh	2001	MAN: word sequences, hum; onset, rime, tone	Same–different	PET	Leftward asymmetry in inferior frontal cortex for pitch processing depends on its language functions
3: Klein	2001	MAN: word, silence; tone	Same–different	PET	Hemispheric specialization for pitch varies as a function of its linguistic relevance
4: Gandour	2002	THA: pseudowords, hum; tone, vowel length	Same–different	fMRI	Thai group shows more activity in left inferior frontal cortex than Mandarin for processing tone and vowel length in nonlexical contexts
5: Wong	2004	ENG: pseudosyllable; MAN: tones m1, m2, m4	Same–different	PET	Activity in anterior insula indexes whether stimulus is a word (LH) or nonword (RH) in the Mandarin group, but not English group
6: Xu	2006	MAN: word; tonal chimera: MAN syllable + Thai tones	Same–different	fMRI	Double dissociation in the left PT reflects stronger activity to native (Mandarin or Thai) than nonnative tones
7: Wong	2007	ENG, MAN: pseudowords with m1, m2, m4	Same–different	fMRI	Good English learners of Mandarin tones show increased activity in the left posterior STG; poor learners, in the right STG and IFG
8: Xu	2013	MAN: normal, pitch-flattened sentences	Active listening	fMRI	Pitch-flattened sentences elicit greater activity than normal in the left PT, reflecting its role in automatic tonal decoding
TONAL VS. SEGMENTAL UNITS					
9: Gandour	2003	MAN: word	Same–different	fMRI	Activity is greater for rimes versus onsets and tones in left posterior middle frontal gyrus, tones versus onsets and rimes in posterior IFG bilaterally
10: Li	2003	MAN: word	Auditory probe	fMRI	Tone extraction relative to the syllable elicits activity in dorsal frontoparietal areas of the LH
11: Liang	2004	MAN: word	Identification tone, vowel	Aphasia	Differential breakdown of vowels (spared) and tones (impaired) in spoken word production of Chinese aphasic supports a dissociation of tonal and segmental processing
12: Schirmer	2005	CAN: word	Passive oddball	N400	Tonal and segmental information play comparable roles for word processing in Cantonese
13: Luo	2006	MAN: word	Passive oddball	MMN	Opposite laterality for onsets (LH) and tones (RH) indicates acoustic basis for hemispheric dominance at early stage of processing
14: Liu	2006	MAN: word	Naming	fMRI	Tones elicit more activity than vowels in the right IFG in spoken word production
15: Li	2010	MAN: word	Auditory probe	fMRI	RH asymmetry in frontoparietal areas for tones versus onsets or rimes supports role of RH in speech prosody processing
16: Zhao	2011	MAN: word	Passive oddball	N400	Rimes, tones, and syllables equally modulate the amplitude and time course of N400
17: Malins	2012	MAN: word	Match picture	N400	Tonal and phonemic (onsets, rimes) information, not syllabic, constrain spoken word recognition
18: Hu	2012	MAN: word	Semantic congruity	N400	N400 and LPC support functional dissociation of vowel and tone processing in spoken word recognition

TABLE 87.1 (Continued)

Study	Year	Stimuli	Tasks	Methods	Conclusions
TONAL FEATURES					
19: Chandrasekaran	2007	MAN: m1/m3, m2/m3	Passive oddball	MMN	Language experience (M > E) influences early, preattentive cortical processing of pitch
20: Chandrasekaran	2007	MAN: m1/2, m1/3	Passive oddball	MMN	Language-dependent weighting of specific, perceptual features of tone may influence its early cortical processing
21: Chandrasekaran	2007	MAN: m1/2, m1/3, m2/3	Passive oddball	MMN, MDS	Effects of language experience vary depending on specific pitch dimensions (height, contour)
22: Kaan	2007	THA: word; t1/t2, t1/t4	Passive oddball	MMN	English and Mandarin listeners, respectively, are sensitive to pitch height and pitch contour of Thai tones
23: Tsang	2011	CAN: c6/1, c6/3, c1/2, c6/2	Passive oddball	MMN, P3a	Change in pitch contour (P3a) and height (MMN) indicate that both tonal attributes are important to tonal processing
TONAL PROCESSING IN THE BRAINSTEM					
24: Swaminathan	2008	MAN: nonspeech; m1, m2, m3, m4	Passive listening	FFR	Pitch representation in the brainstem is sensitive to specific features across speech/nonspeech contexts
25: Krishnan	2009	MAN: nonspeech; m2, m2 inverted, m2 linear, m2 trilinear	Passive listening	FFR	Brainstem pitch encoding is sensitive to time-varying perceptually salient features of pitch patterns
26: Krishnan	2009	MAN: nonspeech; m1, m2, m3, m4	Passive listening	FFR	Degree of acceleration is a critical variable that influences pitch extraction in the brainstem
27: Krishnan	2010	MAN: click trains; m2	Passive listening	FFR	Mandarin listeners' pitch encoding advantage extends to higher acceleration rates beyond the speech domain
28: Krishnan	2011	MAN: m2, m2i; [œ]	Passive listening	FFR	Functional ear (a)symmetries in the brainstem vary depending upon the linguistic status of pitch contours
CATEGORICAL PERCEPTION OF TONE					
29: Xi	2010	MAN: m2, m4	Passive oddball	MMN	Acoustic and phonological information is processed in parallel within the MMN time window
30: Zhang	2011	MAN: m2, m4	Passive oddball	fMRI	Across-category deviants elicit stronger activity in the mid portion of the left middle temporal gyrus; within-category deviants in the right Heschl's gyrus and STG
31: Zheng	2012	MAN,CAN: m1, m2 and c1, c2	Active detection of deviants	P300	Cantonese (not Mandarin) show strong categorical perception effect in P300 amp that may reflect differences in tonal inventories between the two tone languages
TONE VS. OTHER SUPRASEGMENTAL UNITS					
32: Gandour	2004	MAN: pseudosentences; tone, sentence meaning (statement, question)	Same–different	fMRI	Speech prosody perception is mediated primarily by the RH, but is left-lateralized to task-dependent regions when language processing is required beyond the auditory analysis of the complex sound
33: Tong	2005	MAN: sentence focus (initial, final); intonation (statement, question)	Same–different	fMRI	Speech prosody perception involves a dynamic interplay among widely distributed regions not only within a single hemisphere but also between the two hemispheres

(Continued)

TABLE 87.1 (Continued)

Study	Year	Stimuli	Tasks	Methods	Conclusions
34: Gandour	2007	MAN, English: sentence focus (initial, final); intonation (statement, question)	Same–different	fMRI	Phonetic discrimination of functionally equivalent prosodic contrasts in Mandarin and English by unequal Chinese/English bilinguals reveals essentially a unitary neural system that can adapt to stimulus-specific and task-specific demands for processing a lower-proficiency second language
35: Fournier	2010	RD: rd1, rd2; statement, question	Active listening	MMNm	Lateralization of pitch processing is condition-dependent (tone, LH; intonation, RH) in the Roermond Dutch tone dialect group only, suggesting that language experience determines how processes should be distributed between hemispheres according to the functions available in the grammar
36: Zhang	2010	French: CV sequences; intonation, rhythm	Passive oddball	fMRI	Both rhythm and intonation activated a common area in the right mid portion of the STG for Mandarin listeners, whereas intonation elicited additional activation in the right anterior STS

t5	Thai Tone 5, low rising

87.4 TONAL VERSUS SEGMENTAL UNITS

Linguistic theory informs us that the onset and rime of a syllable contain segmental units. They differ in their duration and the order in which their information unfolds in time over the duration of a syllable. Rimes and tones, however, overlap substantially in the order in which their information unfolds in time. Tones are suprasegmental; they are mapped onto (morpho) syllables.

Depending on task demands, tones elicit effects that differ from those of segments. The time course and amplitude of N400 (a negative component associated with lexical semantic processing that peaks approximately 400 ms after the auditory stimulus) were the same for consonant, rime, and tone violations in Cantonese (12: Schirmer, Tang, Penney, Gunter, & Chen, 2005). Their findings were replicated in Mandarin, but syllable violations elicited an earlier and stronger N400 than tone (17: Malins & Joanisse, 2012; cf. 16: Zhao, Guo, Zhou, & Shu, 2011). This separation of tone from its carrier syllable was also reported in an auditory verbal recognition paradigm in which subjects selectively attended to either the syllable or the tone (10: Li et al., 2003). In a spoken word recognition paradigm, tones elicited larger late positive event-related potential (ERP) component than vowels (19: Hu, Gao, Ma, & Yao, 2012). In a left brain-damaged Chinese aphasic, vowels were spared and

tones were severely impaired (11: Liang & van Heuven, 2004). These findings together support a functional dissociation of tonal and segmental information.

It is well-known that hemispheric specialization may be driven by differences in acoustic features associated with segments. The question is whether hemispheric specialization for tone can be dissociated from segments. Tones induce greater activation in the right posterior middle frontal gyrus (MFG) for English speakers when compared with consonants or rimes (9: Gandour et al., 2003). This area has been implicated in pitch perception (Zatorre et al., 2002). Their increased activation is presumably due to their lack of experience with Chinese tones. Using a tone identification task, the right IFG was found to be activated in English learners of Mandarin tone only *after* training (Wang, Sereno, Jongman, & Hirsch, 2003). This finding demonstrates early cortical effects of learning a second language that involve recruitment of cortical regions implicated in tonal processing. Focusing on hemispheric specialization for tone production (14: Liu et al., 2006), Mandarin tones elicited more activity in the right IFG than vowels. This rightward preference for tonal processing converges more broadly with the role of the RH in mediating speech prosody (Friederici & Alter, 2004; Glasser & Rilling, 2008; Wildgruber, Ackermann, Kreifelts, & Ethofer, 2006).

As measured by the mismatch negativity (MMN), a fronto-centrally distributed cortical ERP that indexes a

change in auditory detection, it is well-known that language experience may influence the automatic, involuntary processing of consonants and vowels (Naatanen, 2001, review). Therefore, one would expect language experience to modulate the automatic cortical processing of lexical tones. Tones evoked stronger MMN in the RH relative to the LH, whereas consonants produced the opposite pattern (13: Luo et al., 2006). An fMRI study showed that Mandarin tones, relative to consonants or rimes, elicited increased activation in right frontoparietal areas (15: Li et al., 2010). Taken together, these data suggest the balance of hemispheric specialization may be modulated by distinct acoustic features associated with tonal as compared with segmental units.

87.5 TONAL FEATURES

The notion that a phonetic segment can be decomposed into a set of features is universally accepted among linguists. Tone, a suprasegmental unit, has also been characterized as being made up of features (Wang, 1967; Yip, 2002, pp. 39–64). Their ontological status in tone perception is well-established (Gandour, 1983; Gandour & Harshman, 1978) and confirmed in more recent studies of tone perception (Huang & Johnson, 2011; Khouw & Ciocca, 2007) and tone learning (Chandrasekaran, Sampath, & Wong, 2010; Francis, Ciocca, Ma, & Fenn, 2008). The brain, however, is a neurophysiological apparatus. Features, however, are not to be confused with neural mechanisms.

How they are implemented in the brain depends on the anatomical level to which they are being applied and their functional status in a particular language. Using nonspeech homologues of Mandarin tones (19: Chandrasekaran, Krishnan, & Gandour, 2007a), native Chinese exhibited larger MMN responses than English in response to a deviant representing a natural *curvilinear* rising pitch contour representative of M2, but not in response to a *linear* rising ramp that is a crude approximation of M2 that does not occur in natural speech. This finding demonstrates that experience-dependent plasticity is sensitive to the shape of pitch contours. To further probe the stimulus attributes that trigger these language-dependent effects (20: Chandrasekaran, Krishnan, & Gandour, 2007b), two passive oddball conditions were presented to Mandarin and English listeners. One contained two tones that are acoustically dissimilar to one another (M1/M3); the other contained two tones that are acoustically similar (M2/M3). MMN responses of Chinese listeners were larger than those of English for the high dissimilarity condition only (M1/M3). An explanation based on tonal categories does not tell us

why MMN amplitude is reduced for one condition but not the other. All three stimuli exhibited pitch contours exemplary of their tonal category. Language group differences may be attributed to the relative saliency of perceptual features. To test the hypothesis of separate neural processing of pitch dimensions, another oddball condition (M1/M2) was added. A multidimensional scaling analysis of pairwise dissimilarities of MMN responses to Mandarin tones revealed that Chinese listeners, relative to English, are more sensitive to pitch contour than pitch height (21: Chandrasekaran, Gandour, & Krishnan, 2007). Thus, MMN may serve as a neural index of the relative saliency of underlying features of pitch that are differentially weighted by language experience.

In Cantonese (23: Tsang, Jia, Huang, & Chen, 2011), MMN and P3a (an automatic attention shift induced by the detection of deviant features in the passive oddball paradigm) were elicited from two Cantonese tonal pairs: one differing in pitch height (height-large, C6/C1; height-small, C6/C3) and the other differing in pitch contour (contour-early, C1/C2; contour late, C6/C2). The size and latency of MMN were sensitive to the size of pitch level change, whereas the latency of P3a captured the presence of pitch contour change. Their findings confirm that pitch contour and pitch height are important tonal features in early lexical tone processing. Most importantly, MMN and P3a are revealed to be independent neural components that are differentially sensitive to pitch height and contour, respectively. In another study (22: Kaan, Wayland, Bao, & Barkley, 2007), two oddball conditions were presented to Mandarin and English listeners to assess the effects of perceptual training of Thai tones as a function of language background. One condition contained two tones that are acoustically dissimilar (T1/T4), mid versus high-rising; the other contained two tones that are acoustically similar (T1/T2), mid versus low-falling. After training, the high-rising deviant (T4) elicited a larger MMN amplitude for English listeners in contrast to a later MMN latency for Mandarin listeners. Their findings suggest that English listeners are more sensitive to early differences in pitch height, whereas Mandarin Chinese are more sensitive to later rapid changes in pitch contour.

87.6 TONAL PROCESSING AT THE LEVEL OF THE AUDITORY BRAINSTEM

Pitch processing may also be subject to experience-dependent effects at the level of the brainstem before the auditory signal reaches the cerebral cortex. Electrophysiological responses to tonal features may emerge no later than 5 to 8 ms from the time the

auditory signal enters the ear (Krishnan & Gandour, 2009, review). The frequency following response (FFR) reflects sustained phase-locked activity in a population of neural units within the brainstem and is characterized by a periodic waveform that follows the individual cycles of the stimulus waveform (Chandrasekaran & Kraus, 2010; Krishnan, 2007, tutorials). Experience-dependent pitch encoding mechanisms in the brainstem are especially sensitive to the *curvilinear* shape of pitch contours that occur in speech and nonspeech contexts (24: Swaminathan, Krishnan, & Gandour, 2008). Linear approximations of Mandarin tones (M2, M4) fail to elicit a language-dependent effect (25: Krishnan, Gandour, Bidelman, & Swaminathan, 2009; Xu, Krishnan, & Gandour, 2006).

Neural mechanisms in the brainstem show enhanced language-dependent pitch encoding in response to particular time-varying acoustic properties within tonal *subsections*. Using nonspeech homologues of Mandarin tones (26: Krishnan, Swaminathan, & Gandour, 2009), pitch strength (magnitude of the normalized autocorrelation peak) of 40-ms subsections revealed that Chinese listeners, relative to English, exhibit more robust pitch representation of those subsections containing rapid changes in pitch. This heightened sensitivity to rapid changes in pitch by Chinese listeners was maintained even in severely degraded stimuli (Krishnan, Gandour, & Bidelman, 2010a). This experience-dependent enhancement of pitch encoding may transfer to other tone languages. Pitch strength of tonal subsections containing moderate rises in pitch were most important in distinguishing tonal (Mandarin, Thai) from nontonal language (English) groups (Krishnan, Gandour, & Bidelman, 2010b). Neuroplasticity for pitch processing in the brainstem is not necessarily limited to the domain in which the pitch contours are perceptually relevant. Mandarin listeners had an advantage over English not only in response to a click-train homologue of M2 but also in response to scaled variants with increasingly higher acceleration rates that fall proximal to or outside the boundary of natural speech (27: Krishnan, Gandour, Smalt, & Bidelman, 2010). Moreover, changes to the acoustic periodicity of a stimulus directly influence brainstem encoding and its corresponding perceptual responses to pitch (Krishnan, Bidelman, & Gandour, 2010). Neural pitch strength in the brainstem and perceptual pitch salience, as reflected by f_0 difference limen estimates, improved systematically with increasing temporal regularity of the M2 stimulus. This strong correlation between neural and behavioral measures supports the view that pitch encoding at a subcortical sensory level of processing plays an important role in shaping tone perception.

Hemispheric asymmetries in the cerebral cortex are predictable based on low-level, spectrotemporal

features of stimuli, but they can also be modulated by their linguistic function (Meyer, 2008; Poeppel, Idsardi, & van Wassenhove, 2008; Wildgruber et al., 2006; Zatorre & Gandour, 2008, reviews). It is also well-known that there are fixed, structural asymmetries in the auditory pathway. Whether *ear asymmetries* at the level of the brainstem can be modulated by functional changes in pitch is an open question. Using two synthetic speech stimuli (native M2; nonnative flipped variant of M2), magnitude of the f_0 component in the FFR (amplitude of the spectral component at f_0) was obtained from a perceptually salient portion of M2 that exhibits rapidly changing pitch (28: Krishnan, Gandour, Ananthakrishnan, Bidelman, & Smalt, 2011). The native tone (M2) evoked a comparatively larger degree of rightward ear asymmetry in pitch encoding than the non-native pitch pattern. In response to left-ear and right-ear stimulation, the FFR evoked by M2 was larger than its flipped variant with right ear stimulation only. On an absolute scale, asymmetry favoring left ear stimulation was evoked by the non-native pitch contour. These differences in ear asymmetry may reflect an emerging functional separation of periodicity and spectral representations at the midbrain level.

87.7 CATEGORICAL PERCEPTION OF TONE

Categorical perception is believed to reflect fundamental aspects of the processing of speech sounds (Harnad, 1987, review). It refers to the phenomenon whereby a specific step along a continuous sensory dimension may signal the boundary between separate categories. The bulk of research has focused on consonants and vowels (tones; Francis, Ciocca, & Ng, 2003; Peng et al., 2010; Xu, Gandour, & Francis, 2006). An ERP study of the categorical perception of Mandarin tones provides a window to the interplay between phonetic and phonological processing (29: Xi, Zhang, Shu, Zhang, & Li, 2010). Xi et al. created an 11-step f_0 continuum with M2 (high-rising) and M4 (high-falling) as the endpoint stimuli in both speech and nonspeech conditions. Using a passive oddball paradigm, both within-category and across-category deviants elicited larger MMNs in the RH sites; however, at the same time, larger MMNs were elicited by across-category than by within-category deviants in the LH. Given their low spatial resolution and methodological constraints that limit unambiguous interpretation of hemispheric dominance of ERPs based on scalp topographical maps, it was necessary to use a method with high spatial resolution to clearly identify cortical activation in different brain regions. In a companion fMRI study (30: Zhang et al., 2011), brain areas activated by

acoustic variation within tonal categories were located in the dorsal and posterior-lateral STG bilaterally, especially the right middle STG. In contrast, brain areas activated by phonological variation across tonal categories, as compared with within-category acoustic variation, were located in the left middle temporal gyrus (MTG). These findings are consistent with the view that the dorsal STG and lateral mSTS/MTG are responsible for acoustic analysis and phonological processing, respectively. Superior regions of the temporal lobe are known to be responsible for initial stages of auditory analysis, whereas the superior temporal sulcus (STS) and MTG have been implicated in higher-level phonological processing (Hickok & Poeppel, 2004, 2007; Liebenthal, Binder, Spitzer, Possing, & Medler, 2005; Liebenthal et al., 2010). A cross-language ERP study focused on the influence of language experience (Mandarin, Cantonese) on categorical perception of a three-step f_0 continuum consisting of rising pitch contours common to both tone languages (31: Zheng, Minett, Peng, & Wang, 2012). Deviant responses were measured by the P300 amplitude, a voluntary attention-switching response elicited by an *active* oddball paradigm (Polich, 2007). As reflected by P300 amplitude, Cantonese listeners discriminated the tonal stimuli better than Mandarin. Zheng et al. speculate that Cantonese listeners make finer distinctions in f_0 height and slope because the Cantonese tonal space (six contrasts) is more dense than that of Mandarin (four contrasts).

87.8 TONE VERSUS OTHER SUPRASEGMENTAL UNITS

There are other suprasegmental units of speech besides tone (Lehiste, 1996). In comparison with tone, we are especially interested in those units that may also be signaled by variations in pitch (e.g., stress, intonation, sentence focus). In tone languages, pitch variations can be used to signal differences in the meaning of sentences as well as words. In an fMRI study of Mandarin tone and intonation (32: Gandour et al., 2004), Chinese listeners exhibited greater activity than English in the left ventral aspects of the inferior parietal lobule regardless of the level of prosodic representation. Both language groups, however, showed activity within the right STS and MFG (Ren, Yang, & Li, 2009). This right-sided preference may reflect shared mechanisms underlying early processing of complex pitch patterns irrespective of language experience (Zatorre, Mondor, & Evans, 1999). The LH activity in the inferior parietal lobule is likely to reflect higher-level, language-dependent phonological processing (Jacquemot, Pallier, LeBihan, Dehaene, & Dupoux, 2003).

In tone languages, pitch variations can be used to signal differences in the meaning of sentences as well as words. The MEG study of tone and intonation in Roermond Dutch provides an account of a tonal dialect that unambiguously encodes both contrasts phonologically (35: Fournier, Gussenhoven, Jensen, & Hagoort, 2010). That is, Roermond has two lexical tones that are phonetically distinct in statements and questions. When asked to listen *attentively* to oddball sequences, native Roermond listeners showed a stronger MMNm (150–250 ms) over the left temporal cortex for tone and a predominantly RH response for intonation. Non-native listeners showed a stronger response over the left temporal cortex irrespective of prosodic unit. Using a *passive* oddball paradigm, the MMN (120–240 ms) yielded RH dominance in Mandarin for both word-level (tone) and sentence-level (intonation) prosodic functions (Ren et al., 2009). These conflicting findings between Roermond Dutch and Mandarin are likely due to task demands (attentive versus preattentive) rather than the lack of a prosodic function in their phonological system.

Mandarin and English differ structurally in their use of prosody at the word level. However, both languages exploit prosody at the sentence level to distinguish focus and discourse meaning. A cross-language fMRI study of the perception of Mandarin sentence focus and intonation demonstrated that Mandarin listeners exhibited greater activity in the left supramarginal gyrus and posterior MTG than English across conditions (33: Tong et al., 2005). This leftward specialization is consistent with the notion of a dorsal processing stream that emanates from auditory cortex, projects to the inferior parietal lobule, and ultimately projects to frontal lobe regions, and with a ventral processing stream that projects to the posterior MTG (Hickok & Poeppel, 2007). Rightward preferences were observed in the middle portion of the MFG for both language groups, implicating more general attention and working memory processes associated with pitch perception. Because both sentence-level phenomena occur in Mandarin and English, it is also possible to compare the processing of the same prosodic contrasts in late-onset Chinese/English bilinguals' first (Mandarin) and second languages (English). Any differences in neural activity associated with auditory processing of the same prosodic contrast in the bilinguals' native language and second language may serve as an index of whether the neural substrates are shared or segregated for the two languages. Chinese/English bilinguals displayed overlapping activation between Mandarin and English stimuli in frontal, parietal, and temporal areas regardless of language (34: Gandour et al., 2007). The sentence focus task, however, elicited greater activation for English stimuli than Mandarin in

the bilateral anterior insula and MFG. This is presumably attributable to differences in the way sentence focus is signaled phonetically in the two languages (Xu, 2006). Increased computational demands for the lower-proficiency language lead to greater activation in frontal areas implicated in attention (Shaywitz et al., 2001) and working memory (Smith & Jonides, 1999).

Another suprasegmental feature of speech is rhythm (pattern of timing variations over phrases). Both rhythm and intonation (pattern of pitch variations over phrases) span a number of segments over a relatively long time interval and, therefore, are expected to be preferentially processed in the RH (Poehppel, 2003). The question is whether overlapping or distinct regions of the RH are involved in the processing of rhythm and intonation. Using a passive listening task, a common area in the right middle portion of the STG was activated by Mandarin listeners for both rhythm and intonation conditions (36: Zhang, Shu, Zhou, Wang, & Li, 2010). Compared with rhythm, intonation elicited additional activation in the right anterior STS. This isolation of a particular brain region in the processing of intonation suggests that it is responsive to specific acoustic features associated with dynamic variations in pitch (Humphries, Love, Swinney, & Hickok, 2005; Lattner, Meyer, & Friederici, 2005).

87.9 CONCLUSION

Language experience shapes processing of pitch information at both cortical and subcortical levels. Tones play a role comparable with that of segments in word processing. Whereas both engage the LH in attention-modulated, task-dependent processing, tones show a distinctive rightward asymmetry relative to segments, especially at early stages of processing. Pitch is a multidimensional perceptual attribute that affords us an opportunity to investigate pitch features. Tonal processing reveals experience-dependent sensitivity to specific features that are linguistically relevant at the level of the cerebral cortex and the brainstem. Specific cortical regions may index whether variation in pitch contour falls within or between tonal category boundaries. Neural representations of pitch information are already extracted by early preattentive sensory level processing in both the brainstem and auditory cortex. Neural substrates of tone and other units of speech prosody that are manifested by variations in pitch share widely distributed cortical regions in common. However, when compared directly with a unit of speech prosody based primarily on timing variations (e.g., rhythm), segregated brain regions appear that are responsive to acoustic features associated with dynamic variations in pitch.

The importance of pitch features in gaining a fuller understanding of tonal processing in the brain cannot be overemphasized. We argue that it is necessary to develop a neural response specific to pitch features and, moreover, one that is capable of indexing dynamic variations in pitch that are ecologically representative of those that occur in natural speech (Krishnan, Bidelman, Smalt, Ananthakrishnan, & Gandour, 2012; Krishnan, Gandour, Ananthakrishnan, & Vijayaraghavan, 2014). With respect to speech perception, each pitch feature is defined by an auditory pattern that triggers its detection (Poehppel et al., 2008, pp. 1082–1082, review). Their precise definition, however, varies depending on the level of brain structure, time window, and functional representation in speech perception.

We hasten to acknowledge that the fundamental elements of linguistic theory are not easily reduced to or matched up with the fundamental biological units identified by neuroscience (Poehppel & Embick, 2006). The challenge is to formulate hypotheses about linguistic computations that underlie *real-time* tonal processing at different levels of biological structure in the brain.

The Neurocognition of Prosody

Silke Paulmann

Department of Psychology, Centre for Brain Science, University of Essex, Colchester, UK

88.1 INTRODUCTION

Verbal communication is often a question of “tone.” Modulating parameters such as vocal pitch (high/low), loudness (loud/silent), tempo (fast/slow), or voice quality (clear/harsh) allows us to give the correct meaning to what we are saying and help the listener to interpret a message correctly. This is true not only when expressing how we feel (e.g., angry, nervous, happy) but also when conveying nonemotional information. For instance, by raising (or not raising) our voice when articulating a string of words, we can alter the interpretation of an utterance (e.g., changing from a statement such as *You finished writing the chapter.* to a question *You finished writing the chapter?*). Suprasegmental parameters of speech (prosody) can also be used to convey lexical meanings (e.g., *hot dog* vs. *hot dog*) or discourse information (e.g., new information is often accented while old information is de-accented; prosodic phrasing guides syntactic sentence interpretation) while expressing emotions and attitudes (e.g., often a raised voice is associated with an angry speaker, whereas a lowered voice might indicate that the speaker feels sad). Thus, prosody serves several linguistic and nonlinguistic (emotional) functions; however, it is often an undervalued component of spoken language and brain-based models that take into account the role prosody plays in dynamic speech comprehension are still rare (but see [Friederici & Alter, 2004](#)) and controversially discussed. In fact, much of the controversy around the neural basis of prosody is probably attributable to the fact that it fulfils several communicative functions (often at once); thus, the question that has been driving past research is whether the different prosodic functions are independent or interdependent. This chapter reviews past research on each function and outlines our current

understanding of the neurocognitive architecture underlying prosody.

88.2 BRAIN MAPPING OF PROSODY

Historically, investigations into the cerebral representation of prosody aimed to specify whether one hemisphere dominates control over linguistic and/or emotional prosody processing by examining lesion data. These early *simple hemispheric models* ([Sidtis & Van Lancker Sidtis, 2003](#)) resulted in three main hypotheses:

1. Prosody, irrespective of communicative function (e.g., linguistic, emotional), is lateralized to the right cerebral hemisphere. Interactions with other linguistic information such as syntactic or semantic information are mediated through the corpus callosum ([Friederici & Alter, 2004](#); [Klouda, Robin, Graff-Radford, & Cooper, 1988](#)).
2. Emotional prosody is processed in the right hemisphere (RH) ([Blonder, Bowers, & Heilman, 1991](#); [Ross, 1981](#)).
3. Linguistic prosody is processed in the left hemisphere (LH), whereas emotional or affective prosody processing can be linked predominantly to the RH (known as Functional Lateralization Hypothesis) ([Van Lancker, 1980](#)).

Although it has since been shown that a simple cortical hemispheric distinction is not substantiated by the available data (for reviews see [Baum & Pell, 1999](#); [Sidtis & Van Lancker Sidtis, 2003](#)), the effect of these proposals can still be felt when scanning through the more recent literature. Many researchers base their hypotheses about the brain network underlying prosody processing on the premise that linguistic and emotional prosody are fully distinct

entities in the language system and that these processes are (each) fully lateralized to one cerebral hemisphere (but see Seddoh, 2002, arguing why emotional and linguistic prosody should not be considered distinct categories). However, an alternative to simple hemispheric models was put forward by Van Lancker and Sidtis (1992): hemispheric lateralization is based on physical features. Pitch is preferably processed by right hemispheric brain structures, whereas duration and intensity are primarily processed by left hemispheric structures (known as the Cue or Physical Feature–Dependent Hypothesis).

An additional problem with the early simple hemispheric models is that they neglect the role that subcortical brain regions play during prosody processing. However, accumulating evidence from lesion patients showed that impaired prosody processing is often associated with damage to structures such as the caudate nucleus, putamen, and/or globus pallidus (i.e., the basal ganglia [BG]) (Breitenstein, Daum, & Ackermann, 1998; Cancelliere & Kertesz, 1990; Paulmann, Pell, & Kotz, 2008, 2009). Hence, a fifth hypothesis posits that prosody processing is heavily mediated by subcortical brain regions without a strong hemispheric lateralization.

In an attempt to consolidate the different hypotheses, Sidtis and Van Lancker Sidtis (2003) proposed a Neurobehavioral Approach to Dysprosody. This framework suggests that prosody processing is not driven by one single mechanism, but instead relies on a complex conglomerate of motor, perceptual, and more cognitively based functions. Thus, a widespread, bilateral brain network might be implicated in prosody processing and discrepancies across lesion studies are probably due to the fact that dysprosody can materialize after disruption to any of the involved mechanisms linked to different brain regions.

More recently, similar working models, that is, frameworks that suggest a highly differentiated brain network underlying *emotional* prosody processing, have been put forward by researchers who based their hypotheses primarily on evidence obtained from neuroimaging studies instead of data from the lesion approach (Brück, Kreifelts, & Wildgruber, 2011; Kotz & Paulmann, 2011; Schirmer & Kotz, 2006; Wildgruber, Ethofer, Grandjean, & Kreifelts, 2009). Moreover, some of these models also hypothesized the temporal dynamics of emotional prosody processing. For instance, Kotz and Paulmann (2011) suggest that an initial extraction of acoustic cues (e.g., fundamental frequency, loudness, voice quality) takes place within 100 ms of stimulus onset. This process is argued to be mediated by primary and secondary auditory cortices (bilaterally). Once acoustic properties have been accessed, derivation of emotional salience/meaning

(established through integration of emotionally relevant acoustic cues) occurs within 200 ms after stimulus onset. This process has been linked to the right anterior superior temporal sulcus/superior temporal gyrus. Finally, more elaborate processes (e.g., integration of information from prosody with semantics or broad context) could start approximately 400 ms after stimulus onset. These higher cognitive processes are presumed to be mediated by inferior frontal and orbitofrontal cortex (bilaterally). Thus, researchers moved away from the assumption that prosodic processing is one single mechanism and instead suggest that different emotional prosody processing stages are subserved by different brain areas. Ideally, future models on the neural circuitry regulating emotional and linguistic prosody will be able to integrate findings from both lesion and imaging fields of the literature.

The following review aims to show how results from clinical and empirical neuroscience studies have helped shape our understanding of prosody processing. To provide an integrative view of key findings, evidence from important past and more recent studies are discussed, followed by a summary of how available evidence supports prosody processing models.

88.3 THE NEURAL BASIS OF LINGUISTIC PROSODY PROCESSING

88.3.1 Clinical Evidence

Initially, scientists predominantly relied on the lesion approach to specify which brain regions might underlie prosody processing. For instance, one of the earlier studies to explore the contribution of the RH to linguistic prosody processing was conducted by Weintraub, Mesulam, & Kramer (1981). They tested RH patients and healthy controls (HCs) and assessed their ability to discriminate between phonemic (e.g., DARK room versus dark ROOM) and sentential stress (e.g., STEVE drives the car versus Steve drives the CAR). Patients were found to be outperformed by controls on these tasks, prompting the authors to suggest that the RH plays a strong role in linguistic prosody perception. At approximately the same time, Baum, Daniloff, Daniloff, and Lewis (1982) investigated phonemic and sentential stress comprehension in LH patients and HCs. Their results showed that LH patients *also* suffer from difficulties on these tasks, challenging the view that the RH alone is involved in linguistic prosody perception. Heilman, Bowers, Speedie, and Coslett (1984) thus tested performance of *both* LH and RH patients on linguistic prosody processing in one study. The authors reported

difficulties in identifying the modality (question, statement, command) of filtered sentences by both LH and RH patients when compared with HCs. Again, these results challenged the view that the RH is solely responsible for linguistic prosodic processing and instead point to a possible additional involvement of the LH during linguistic prosody perception. In fact, evidence from a subsequent study comparing LH and RH patient performance on phonemic stress identification suggests that LH patients can be even more strongly impaired than RH patients (Emmorey, 1987). However, only 2 years later, conflicting evidence emerged when Bryan (1989) reported results from a range of tasks (e.g., sentential and phonemic stress identification, discrimination, and identification of sentence modalities) that showed that RH patients were outperformed by LH patients on most of the tasks administered. Although generally better than RH patients, LH patients performed poorly on the majority (but not all) of the tasks when compared with HCs, suggesting that both RH and LH patients show impairments for linguistic prosody processing. The importance of task effects was further examined years later. Pell and Baum (1997) asked RH and LH patients as well as HCs to either identify or discriminate between different sentence modalities (interrogative, declarative, imperative). Both patient groups performed comparable with the HC group when discriminating between different prosodic patterns. However, when examining the identification task, patients performed significantly worse than HCs. These data point to the possibility that linguistic prosody is processed bilaterally in the brain, and they also show that severity of impairment might depend on task instructions.

In the years that followed, researchers continued to obtain conflicting results when exploring the influence of the LH and RH on linguistic prosody processing. Borod and colleagues (1992) reported findings obtained from LH and RH patients and HCs. Nonsense syllable strings (e.g., pa-da-ka) that were intoned in three different ways (declarative, interrogative, emphatic) had to be discriminated by participants using multiple-choice response cards. Results showed that RH patients made significantly more errors than LH patients and HCs who did not differ from each other. In contrast, Breitenstein et al. (1998) report data from LH and RH patients who performed comparably with HCs when discriminating between sentence modality pairs. Yet again, Pell (1998) showed that LH patients are worse at identifying emphatic stress patterns than RH patients or controls. Similarly, Walker, Daigle, and Buzzard (2002) showed that LH patients performed significantly worse than RH patients and HCs when identifying lexical or

sentential stress. In addition, LH patients also suffered from difficulties in prosodic phrasing. As outlined, task differences (e.g., instructions, complexity) between studies are likely to affect results; however, discrepancies between findings from clinical research can also likely be linked to differences in patients' lesion locations and size as well as to differences in their speech and language abilities (see Baum & Pell, 1999; Kotz, Meyer, & Paulmann, 2006, for similar observations). Thus, Amebu Seddoh (2006) subdivided his LH patient population into three subgroups: Wernicke's aphasia patients, Broca's aphasia patients, and global aphasia patients. Their ability to identify the sentence modality (question versus statement) was assessed. Results confirmed that Wernicke's aphasia patients had no difficulties with the task, whereas Broca's aphasia patients suffered from difficulties in identifying questions and global aphasics suffered from difficulties in identifying statements and questions. Results suggest once more that the LH can be critically tied to linguistic prosody processing, but they also support the view that patients' lesion locations need to be controlled for better than by LH/RH distinctions. The latter conclusion is also underpinned by recent data by Rymarczyk and Grabowska (2007), who subdivided RH patients into three groups (patients with lesions to frontal, temporo-parietal, or subcortical brain structures). They looked at the performance of identifying as well as discriminating between sentence modalities and discriminating between empathic stress patterns. Although all patient groups perform significantly worse than HCs on all three tasks, results confirm the importance of controlling for lesion location because patients with lesions to temporo-parietal sites performed worse than the two other groups. The idea that we need to examine patients whose lesion delineation is comparable was followed-up by Kho et al. (2008). They looked at RH and LH patients who underwent anterior temporal cortex resection. The authors reported no differences between RH and LH patients when detecting word or contrastive stress, or during sentential discrimination.

Taken together, the evidence elaborated here clearly shows that clinical evidence provides very little convergent evidence that linguistic prosody is processed solely by one hemisphere. Moreover, the evidence from lesion patients that suggests that not only cortical but also subcortical brain structures play a critical role during prosody processing (Brådvik et al., 1991; Cancelliere & Kertesz, 1990; Ross & Mesulam, 1979; Rymarczyk & Grabowska, 2007; Starkstein, Federoff, Price, Leiguarda, & Robinson, 1994) also challenges all simple hemispheric models, although the idea that prosody is primarily mediated by subcortical structures is also clearly not

substantiated. In short, although telling, clinical evidence alone has not helped to provide support for either of the original hypotheses. This conclusion is supported by a recent activation likelihood estimation (ALE) meta-analysis by [Witteman, van Ijzendoorn, van de Velde, van Heuven, and Schiller \(2011\)](#), who reported that lesions to the LH or RH have similar detrimental effects on linguistic prosody perception.

88.3.2 Brain Imaging Evidence

Over the past two decades, fMRI and PET techniques have become popular tools for observing normal brain function. Motivated by the heterogeneous results from clinical studies, several investigations have been conducted to further delineate the brain network underlying prosody processing. However, in contrast to emotional prosody, imaging studies on linguistic prosody processing have been rare. It is likely that the limited number of imaging studies on linguistic prosody are linked to the problem that linguistic prosody is an umbrella term that refers to studies exploring a variety of processes linked to suprasegmental changes including (but not limited to) sentence type, phrase boundary, word stress, and pitch contour processing. Some of the existing research is summarized to show that despite using more fine-grained methodologies, the brain network underlying linguistic prosodic processing is still not fully specified.

In an early PET study, [Gandour et al. \(2000\)](#) investigated pitch perception of one-syllable Thai words in speakers of tone and nontone languages (Thai, Chinese, English). Their results suggest that neural mechanisms underlying pitch perception differ depending on linguistic relevance of stimuli. Specifically, left frontal operculum activity was found for Thai speakers when discriminating between pitch patterns, but the same activity was not found for English speakers. Also, Thai speakers failed to show the same left-lateralized activation when discriminating pitch patterns of nonspeech stimuli, suggesting that “linguistic relevance” might modulate lateralized activation patterns. This hemispheric laterality effect was confirmed in an fMRI study a few years later ([Gandour et al., 2004](#)) when brain activity of Chinese and English speakers was measured. Participants had to discriminate between one- and three-syllable-long utterances and four different Chinese tones. Chinese (i.e., the tone language group), but not English, participants showed left-lateralized activation in inferior parietal and posterior superior temporal, anterior temporal, and frontopolar brain regions. Both English and Chinese participants showed right-lateralized activation hot spots in parts of the superior temporal sulcus as well as the middle frontal gyrus.

Similar to the previous study ([Gandour et al., 2000](#)), the authors interpreted their results to suggest that linguistic relevance/knowledge can influence brain activation patterns for prosody. In particular, the tone language group is argued to have an implicit understanding about the relationship between acoustic cues and internal representations of suprasegmental sentence information. In contrast, listeners from nontone language backgrounds cannot possess the same higher-order prosodic representations. Thus, it was argued that LH lateralization is linked to higher-order prosodic processing, whereas RH lateralization might represent lower-order acoustic feature processing ([Gandour et al., 2004](#)).

Imaging studies looking at sentences rather than syllables or words often report RH dominance for linguistic prosodic processing. For instance, [Meyer, Alter, Friederici, Lohmann, and von Cramon \(2002\)](#) investigated the neuroanatomical correlates of slow prosodic modulations. They presented participants with delexicalized (i.e., stimuli that contain no lexical-semantic information) and normal speech. When comparing stimuli from both conditions, the authors found increased activation in the right superior temporal brain region as well as in the fronto-opercular cortex for filtered speech, suggesting a strong RH involvement during linguistic prosodic speech processing (and slow pitch movements in particular). Similar RH dominance in response to prosodic stimuli was reported by [Plante, Creusere, and Sabin \(2002\)](#), who also explored the neural correlates of sentential prosody. Participants were again presented with low-pass filtered (i.e., delexicalized speech) and normal speech and had to perform tasks high (remember and recognize words) or low (no task) in memory load. When comparing hemodynamic responses for prosodic speech with responses to unfiltered speech in the “no task” condition, the authors found a stronger bilateral activation within the superior temporal gyrus for prosodic speech. Moreover, when looking at frontal lobe activation patterns, results showed that the tasks high in memory load affected processing of filtered and unfiltered speech differently: although both speech stimuli resulted in bilateral activation of the frontal lobes, processing filtered stimuli resulted in stronger RH activation than processing unfiltered stimuli.

Influence of task instructions on prosodic processes was also reported by other authors who looked at sentence material ([Geiser, Zaehle, Jancke, & Meyer, 2008](#); [Wildgruber et al., 2004](#)), albeit they failed to confirm a strongly right-lateralized network for linguistic prosodic processes. Instead, they showed that participants who focus on linguistic prosodic aspects of stimuli exhibit greater activation in the LH. Specifically, in their fMRI study, [Wildgruber et al. \(2004\)](#) showed right-lateralized activation of the dorsolateral frontal cortex and bilateral activation of thalamic and temporal regions in contrast

to a rest condition for stimuli that were synthetically manipulated to exhibit different sentence foci (second word versus final word focus). However, when participants were asked to focus on linguistic characteristics of stimuli, activation of the left inferior frontal gyrus was reported (as opposed to activation of bilateral orbitofrontal areas when the task focus was emotional). Similarly, Tracy et al. (2011) reported that processing pitch information from lexical stimuli predominantly recruits left-lateralized structures, including the cingulate gyrus and middle temporal and superior temporal gyri, whereas pitch processing from tone sequences relies on right frontal and temporal cortices.

Taken together, data from neuroimaging studies clearly suggest that a complex neural network spanning both hemispheres underlies linguistic prosodic processing. Findings further imply that various factors can impact lateralization of effects. Specifically, it has been shown that lateralization of prosody can depend on task focus (linguistic/nonlinguistic, active/passive; Wildgruber et al., 2004), task demands (high/low; Plante et al., 2002), language background/experience (tone/nontone language; Gandour et al., 2000), acoustic cue (pitch/duration; Van Lancker & Sidtis, 1992), and stimulus type (syllable/word/sentence; Gandour et al., 2004; Meyer et al., 2002), as well as on methodological factors, including design (event-related/ blocked; Kotz et al., 2006) and contrast/comparison conditions (rest/alternative prosodic function).

88.3.3 ERP Findings

In addition to exploring the brain structures involved, research has also tried to specify the time course of linguistic prosody using event-related brain potentials (ERPs). The temporal online dynamics of prosody are of particular interest because information might consolidate the different proposals on how prosody is represented in the brain considering that research suggests that *emotional* prosodic processing is a multistage process (Kotz & Paulmann, 2011; Schirmer & Kotz, 2006; Wildgruber, Ackermann, Kreifelts, & Ethofer, 2006; Wildgruber et al., 2009) with each stage linked to different brain areas. It is likely that a similar multilayered mechanism applies to linguistic prosody processing.

Several ERP components with different onset latencies have been described. For instance, Steinhauer, Alter, and Friederici (1999) explored how prosody helps listeners to establish a syntactic structure during language comprehension. They were the first to report that the so-called closure positive shift (CPS) is elicited quickly after prosodic phrase boundaries (which usually coincide with syntactic boundaries). This marker of

prosodic boundary processing is also found in delexicalized speech (Steinhauer & Friederici, 2001), as well as during implicit prosodic processing situations (e.g., reading; Hwang & Steinhauer, 2011). Generally speaking, the CPS is elicited rapidly (between -100 and 0 ms) after the offset of a preboundary word and is thus argued to be triggered by preboundary syllable lengthening (Pauker, Itzhak, Baum, & Steinhauer, 2011). A slightly later prosody-related component was recently reported by Li et al. (2011), who observed a fronto-centrally distributed negative ERP between 270 and 510 ms in response to prosodic prominence manipulations. Responses to prosodic boundary violations resulted in a longer negative ERP effect lasting from 270 to 660 ms. For a similar time window, Böcker, Bastiaansen, Vroomen, Brunia, and Gelder (1999) found that extraction of metrical stress from bi-syllabic words can be linked to the N325, which is elicited under active (discrimination) and passive (listening) tasks.

In addition, processing of prosodic contour expectancy violations has been studied. For instance, Paulmann, Jessen, and Kotz (2012) recently violated linguistic prosodic expectancy by merging the beginning of a declarative sentence with the end of a question. Results revealed a frontally distributed Prosodic Expectancy Positivity (PEP) 620 ms after the onset of prosodic violations irrespective of task focus (linguistic/emotional), suggesting that listeners can detect an abrupt change in prosodic contour and that discrepancies in contours are quickly reanalyzed (Paulmann et al., 2012). Similar late positivities were found by Astésano, Besson, and Alter (2004), who reported a P800 for similar prosodic expectancy violations, and by Eckstein and Friederici (2006), who reported a P600 response to prosodic incongruity of the final word of a sentence.

These findings lend support to the assumption that participants not only use prosody to build information about the sentence structure and modality but also realize quickly if the expectation is not fulfilled. However, these prosodic processes can sometimes be influenced by task focus, because the P800 in the study by Astésano et al. was only observed when participants focused on the prosody, whereas the positivity reported by Paulmann et al. (2012) was found even without participants' explicit focus on prosody. In sum, ERP results confirm that prosody interfaces with other language functions such as semantics (Paulmann et al., 2012) and syntax (Eckstein & Friederici, 2006; Steinhauer et al., 1999) during online language comprehension. Given the different distributions of prosody-related ERP effects and their differing temporal dynamics, it seems reasonable to assume that linguistic prosody processing not only is multifaceted but also at least partly hinges on differing neural mechanisms depending on the precise function that could recruit brain structures from both hemispheres.

88.4 THE NEURAL BASIS OF EMOTIONAL PROSODY PROCESSING

88.4.1 Clinical Evidence

Emotional prosody has long been of special interest to researchers exploring hemispheric specialization of brain processes, probably because this type of prosodic function cannot easily be associated with pure emotion (historically linked to the RH; Borod, Cicero, et al., 1998; Borod, Bloom, & Santschi-Haywood, 1998) or pure language (historically linked to the LH; Friederici, 2002) processing. Instead, emotional prosody is at the intersection of both domains. Early research on how emotional prosody is anchored in the brain was performed by Heilman, Scholes, and Watson (1975). They asked patients with right and left temporo-parietal lesions to identify the emotional tone a speaker used when intoning semantically neutral sentences. Results revealed that RH patients performed significantly worse on the task than LH patients, suggesting that emotional prosody is primarily processed in the RH, although the lack of a HC group posits a problem to this conclusion. Thus, a few years later, the same group (Heilman et al., 1984) investigated the comprehension of emotional prosody in RH and LH patients and this time compared their performance with that of HCs. Results confirmed a deficit for RH patients when compared with LH patients and HCs. Similarly, Bowers, Coslett, Bauer, Speedie, and Heilman (1987) reported that RH patients performed significantly worse than LH patients and HCs when discriminating between emotional categories of prosodically and semantically emotional congruent and incongruent sentences as well as low-pass filtered sentences. This once more indicated an important role for the RH in emotional prosody perception. Results from Blonder et al. (1991) also revealed that RH patients have difficulties discriminating among different emotional categories for emotionally intoned neutral sentences when compared with LH and HCs. Although subsequent evidence has often confirmed the RH involvement in emotional prosody perception (Blonder et al., 1991; Borod, Cicero, et al., 1998; Borod, Bloom, et al., 1998; Lalande, Braun, Charlebois, & Whitaker, 1992; Ross & Monnot, 2008; Rymarczyk & Grabowska, 2007), there is some clinical data that question the unique role of the RH (Breitenstein et al., 1998; Cancelliere & Kertesz, 1990; Schlanger, Schlanger, & Gerstman, 1976; Starkstein et al., 1994).

For instance, Schlanger et al. (1976) described no differences between LH and RH aphasic patients for identifying the emotional tone of a speaker, suggesting that LH brain structures can also play a role during emotional prosody perception. Van Lancker and

Sidtis (1992) asked LH and RH patients to identify emotional prosodic speech samples by matching them to facial expressions and emotional labels. They also fail to report differences between groups with respect to emotional prosody perception, indicating that emotional prosody perception is mediated through a bilateral network of brain structures. Support for this hypothesis comes from recent work by Kho et al. (2008), who showed that both RH and LH temporal lobe epilepsy patients were impaired on emotional prosody recognition when compared with HCs. Similarly, Starkstein et al. (1994) report that both LH and RH patients displayed emotional prosody comprehension difficulties; however, it should be noted that more detailed analyses also showed that RH patients with lesions in the BG and tempo-parietal cortex were most severely affected. Corroborating findings that subcortical brain structures are implied in an emotional prosodic network, Cancelliere and Kertesz (1990) report emotional prosody processing difficulties in patients with LH and RH lesions involving the BG. Paulmann et al. (2008) also report emotional prosody recognition deficits in patients with LH lesions in the BG (for a detailed review on the role of the BG in emotional prosody processing, see Kotz, Hasting, & Paulmann, 2013), rendering it unlikely that emotional prosody perception is uniquely mediated through RH cortical regions. In fact, in an attempt to illuminate how the LH and RH might contribute differently to emotional prosody recognition, Van Lancker and Sidtis (1992) explored whether patients with lesions in either hemisphere made similar errors in an emotional prosody identification task. Their findings suggest that patients used acoustic cues differently when judging the emotional tone of the speaker (Van Lancker & Sidtis, 1992). Specifically, a discrimination analysis on error patterns revealed that patients with lesions in the LH relied on pitch information to infer emotionality of stimuli, whereas patients with lesions in the RH seemed to predominantly use durational cues to infer emotionality. These data were argued to support the physical feature-dependent hypothesis; however, following the same methodology, Pell and Baum (1997) failed to find differences between LH and RH patients in their misclassifications of stimuli.

In short, results from clinical studies do not support simple hemispheric models, but instead suggest that emotional prosody processing recruits a broad network of cortical and subcortical brain regions possibly slightly more right-lateralized than left-lateralized. The modestly bigger RH involvement is corroborated by a recent meta-analysis (Witteman et al., 2011). When comparing results from studies testing RH and LH

patients directly, findings implied that damage to the RH results in more severe problems for emotional prosody perception than damage to the LH. Finally, task focus, stimuli differences, differences in experimental paradigms, and, most critically, differences in patients' lesion size and location can heavily impact findings and therefore might contribute to equivocal findings.

88.4.2 Brain Imaging Evidence

In line with the studies reviewed, neuroimaging findings also tend to reveal that emotional prosody perception is mediated by a complex bilateral network involving both cortical and subcortical brain structures, with some studies suggesting a slightly more right-lateralized network. For instance, an early PET study explored emotional prosody categorization of sentences (George et al., 1996). Results revealed significant blood flow changes in the right prefrontal cortex. Similarly, Buchanan et al. (2000) asked participants to listen to emotionally intoned words while either detecting the emotionality of the speaker (emotion task) or detecting a probe word (nonemotion task). They report right-lateralized frontal lobe and right-lateralized anterior auditory cortex activation for emotionally intoned words when comparing the emotion task with the nonemotion task; however, a bilateral activation is reported for emotionally intoned words when comparing the emotion task to a rest baseline. Also, Mitchell, Elliott, Barry, Cruttenden, and Woodruff (2003) reported right-lateralized activation of superior and middle temporal gyri when participants listened to emotional sentences spoken in different emotions. A right-lateralized network for emotional prosody perception was also confirmed by Beaucousin et al. (2007), who reported greater activation in the right temporal lobe for emotional prosody processing when comparing emotional speech with text-to-text speech lacking emotional attributes. Similarly, Wildgruber et al. (2005) outline that recognition of emotionally intoned and semantically neutral sentences resulted in right-lateralized activation of the posterior superior temporal sulcus, as well as dorsolateral and orbitobasal frontal areas when participants engaged in an emotional identification task. However, when comparing activation patterns for the emotional recognition task with a rest baseline, frontal, temporal, and parietal brain areas were activated bilaterally, again demonstrating that task effects (and/or condition comparisons) play a crucial role when looking at brain activation patterns for emotional prosody comprehension.

In fact, as is expected based on neuropsychological findings, bilateral brain activation is also reported

frequently. For instance, Kotz et al. (2003) compared sentences spoken in an emotional tone of voice with filtered sentences that contained only prosodic information. Comparisons revealed a bilateral frontal and subcortical (BG) activation pattern for the emotional prosodic condition. In addition, Sander et al. (2005) compared angry and neutral prosody processing in a dichotic listening paradigm. Irrespective of whether participants attended to or ignored the meaningless angry speech stimuli, right amygdala and bilateral superior temporal sulcus activation was reported. However, the same stimuli elicited greater bilateral activation in the orbitofrontal cortex and the cuneus (in the medial occipital cortex) when participants paid attention to presented stimuli as opposed to when they ignored them. Moreover, greater bilateral activation of mid-superior temporal sulcus has been reported for angry in contrast to neutral prosody (Grandjean et al., 2005). Also, Wiethoff et al. (2008) investigated activation for emotionally arousing prosody during passive listening. Specifically, they looked at happy, erotic, fearful, and angry prosody, and thus included stimuli of both positive and negative valence. The authors report greater activation for arousing prosody in the right primary auditory cortex, the mid-superior temporal gyrus, and the left temporal pole, as well as in the hypothalamus. Leitman et al. (2010) tried to compare stimuli that were either rich or low in emotional acoustic cue saliency (i.e., stimuli that are easily recognizable by a single acoustic parameter such as fundamental frequency or intensity). They reported greater activation for emotional prosodic stimuli that are rich in cue saliency for the planum temporale, posterior superior temporal, and middle gyri (i.e., superior temporal cortex), as well as the amygdala, whereas participants engaged in an emotional sentence identification task. In contrast, greater activation was found in inferior and temporo-frontal areas when participants processed stimuli with less salient or dominant acoustic cues. Interestingly, their results indicate that lateralization can depend on the specific emotion investigated, because stronger left-lateralized activation patterns were found for angry prosody in contrast to more right-lateralized hot spots for fearful and happy prosody.

In addition to exploring the influence of individual acoustic cues (or their saliency) on activation patterns, more recent research has also tried to illuminate the role of task effects in neural responses linked to emotional prosody processing. For instance, Bach et al. (2008) compared activation patterns for emotionally intoned pseudowords while participants had to decide either which gender the speaker voice was or which emotion the speaker was trying to convey. They found bilateral activation of the amygdala, left superior

temporal sulcus, and right parietal areas when participants judged the gender of the speaker, whereas activation for left inferior frontal gyrus, bilateral parietal, anterior cingulate, and supplemental motor cortex was found when participants focused on the emotionality of the stimuli. Moreover, when comparing emotional with neutral prosody, neural activity was found in right superior temporal gyrus and left inferior frontal gyrus, as well as in the anterior cingulate (bilateral), the insula, and the putamen (bilateral). Interestingly, subcortical brain activation was particularly strong when participants focused on the emotionality of the stimuli, once again leading to the impression that task effects can critically impact activation patterns. Finally, [Ethofer, Van De Ville, Scherer, and Vuilleumier \(2009\)](#) presented words spoken in an angry or neutral prosody to participants while they engaged in a valence discrimination or a word classification task. Activation in response to angry prosody was found not only in voice-sensitive areas of temporal cortices but also in the amygdala, insula, and mediadorsal thalami, irrespective of the task in which participants engaged. However, when comparing the valence discrimination with the word classification task, [Ethofer et al. \(2009\)](#) found stronger activation in the right middle temporal gyrus as well as in the orbitofrontal cortex (bilateral), suggesting that evaluation of emotional aspects activates these areas in particular.

In sum, neuroimaging data generally confirm that emotional prosody processing involves a bilateral temporo-frontal brain network, with some studies describing activation of subcortical structures. Activation hot spots between studies seem to differ depending on task focus and stimuli quality on activation patterns. Latter acoustic cue influence is confirmed in a meta-analysis by [Witteman, Van Heuven, and Schiller \(2012\)](#), who advocated that higher activation likelihood of the RH might stem from lateralized activation of primary and secondary auditory cortices (i.e., sensory cue processing).

88.4.3 ERP Findings

The time course underlying emotional prosody processing has been explored in recent electrophysiological studies. Several ERP components have been of special interest. The N100 is generally assumed to reflect processing of frequency (e.g., pitch) and loudness information (i.e., it is linked to the extraction of acoustic cues). This early component is followed by the P200, a fronto-centrally distributed component peaking 200 ms after stimulus onset (i.e., far before a sentence is completed), and that has been shown to be responsive to emotional prosodic ([Paulmann et al.,](#)

[2008; Schirmer, Chen, Ching, Tan, & Hong, 2013](#)) and arousal ([Paulmann, Bleichner, & Kotz, 2013](#)) attributes of stimuli. Specifically, it has been outlined that different emotional prosodies can be distinguished from one another ([Paulmann et al., 2013](#)) and from neutral ([Paulman & Kotz, 2008; Schirmer et al., 2013](#)) within 200 ms of stimuli onsets. Although the sensitivity of the P200 to pitch ([Pantev, Elbert, Ross, Eulitz, & Terhardt, 1996](#)) and loudness ([Picton, Woods, Baribeau-Braun, & Healey, 1977](#)) variations has been demonstrated, research on emotional prosody implies that listeners rely on more than just one acoustic parameter when detecting emotional salience from auditory stimuli. However, which specific acoustic cues (configurations) are needed to detect the valence or even one particular emotion from speech still needs further clarification. Although the P200 is elicited under attentive processing conditions (albeit irrespective of implicit or explicit emotional tasks), the mismatch negativity has been linked to emotional category change detection under preattentive processing conditions ([Schirmer, Striano, & Friederici, 2005](#)). Both components have repeatedly been linked to early emotional salience detection ([Kotz & Paulmann, 2011; Paulmann & Kotz, 2008; Schirmer & Kotz, 2006](#)).

This early emotional evaluation or appraisal of vocal expressions is followed by more elaborated stimulus evaluations. In particular, meaning evaluation or access to (emotional) memory representations have been linked to later ERP components such as the P300 ([Wambacq & Jerger, 2004](#)), N300 ([Bostanov & Kotchoubey, 2004](#)), N400 ([Schirmer & Kotz, 2003; Schirmer, Kotz, & Friederici, 2002; Schirmer et al., 2005; Paulmann & Pell, 2010](#)), and the late positive complex (LPC) ([Schirmer et al., 2013; Paulmann, Bleichner, & Kotz, 2013](#)). For instance, [Bostanov and Kotchoubey \(2004\)](#) assessed how emotional meaning is extracted from exclamations such as “Wow” and “Oooh” by presenting participants with emotionally congruent or incongruent stimuli. They reported an enhanced N300 in response to incongruous exclamations, suggesting that emotional prosodic meaning is extracted approximately 300 ms after stimulus onset. Similarly, larger N400 amplitudes were found for prosodically/semantically incongruent emotional words (e.g., “happy” spoken in an angry voice; [Schirmer & Kotz, 2003](#)). To explore how *much* prosodic information is needed to infer emotional meaning, [Paulmann and Pell \(2010\)](#) presented participants with emotionally intoned sentence fragments that were either 200 or 400 ms long. Sentence fragments served as primes and were followed by emotionally matching or mismatching facial expressions. N400-like priming effects were found for faces that were preceded by emotionally mismatching sentence fragments, although priming

from shorter fragments led to a reversed effect. The findings nicely showed that listeners can extract emotions from both short and somewhat longer sentence fragments, supporting the view that 200 ms is sufficient to build emotional context (see P200 results) and that emotionally relevant cues are extracted rapidly. Moreover, the N400-like priming effects are in line with studies proposing that emotional meaning is processed at approximately 300 to 400 ms after stimulus onset. Finally, two recent studies report differently modulated LPCs in response to sentences differing in emotional tones, suggesting continued exhaustive processing of emotional prosodic information at late processing stages (Paulmann et al., 2013; Schirmer et al., 2013). Moreover, Schirmer et al. (2013) further showed that P200 modulations can predict modulation of subsequently elicited LPCs, suggesting that successful early emotional salience detection goes hand-in-hand with later more in-depth processing of emotional prosody. Arguably, the latter step is necessary to ensure appropriate social behavior.

Finally, to investigate how far specific brain areas can be linked to individual emotional prosody processing steps, ERP lesion studies have been performed (Paulmann et al., 2008, 2009; Paulmann, Seifert, & Kotz, 2010). In a nutshell, these studies revealed that early emotional prosodic appraisal as reflected in the P200 component does not seem to be critically tied to the BG or orbitofrontal cortex. In contrast, later meaning-related processes (as reflected in the PEP and N400-like components) seem to be affected by lesions to the BG (Paulmann et al., 2008, 2009) and later emotional prosody recognition processes (as reflected in behavioral responses such as emotion recognition rates) are affected by lesions to the BG (Paulmann et al., 2008, 2009) and the orbitofrontal cortex (Paulmann et al., 2010). These findings highlight the potential of ERP lesion studies because they allow exploration of the function of specific brain areas with methodologies that have excellent temporal resolution, thereby helping to illuminate which processing stages might be modulated via specific neural structures. This methodology can thus help to consolidate conflicting findings from lesion and neuroimaging findings because the latter two lack the high temporal resolution of ERPs.

The studies reviewed in this section confirm that emotional prosodic processing includes processes such as rapid early emotional appraisal as well as comprehensive emotional meaning processing, that these processes occur irrespective of directed attention of listeners, and that different functions can be linked to different underlying brain areas. Moreover, comparing findings described in this section (emotional prosody) and the previous one (linguistic prosody), it also seems

as if the two processes generally elicit different ERPs (with different onset latencies). When exploring the comparative nature of the time course linked to the two functions, results from a recent ERP study (Paulmann et al., 2012) revealed that emotional prosodic expectancy violations are detected approximately 150 ms earlier than expectancy violation of linguistic prosody and that both violations resulted in different PEP distributions. Linguistic PEPs were elicited predominantly at anterior electrode sites, whereas emotional PEPs were most dominant at posterior electrode sites, suggesting that at least partly different neural mechanisms are at play during emotional and linguistic prosody processing. Taken together, and similar to the imaging literature reviewed, differences in ERP studies (e.g., ERP polarity and latency) seem to be influenced by stimuli (e.g., words/sentences, normal/filtered/pseudo-speech), tasks (e.g., implicit/explicit emotional evaluation), and designs (e.g., blocked/randomized). However, despite methodological differences across studies, electrophysiological research has helped delineate the time course underlying emotional prosodic processing, clearly supporting the idea that emotional prosody processing comprises different subprocesses.

88.5 SUMMARY

Years of research have shown that initially advocated simple hemispheric models fail to adequately describe brain mechanisms underlying prosody processing. Research has revealed that neural mechanisms of prosody are vulnerable to external influences, such as task demands, stimulus quality, and experimental design, thereby explaining some of the discrepant literature reports. Given the functional complexity of linguistic prosody processing, its neural specifications seem to be less clearly delineated than neural structures for emotional prosody. However, clinical and imaging results seem to suggest that both functions of prosody cover different subprocesses that are each anchored in different parts of the brain. Future development of brain-based language models requires that the field continues to move away from understanding prosody as a holistic concept and focuses instead on portraying each function as multilayered.

Acknowledgments

I thank Rick Hanley for helpful comments on a previous version of this chapter.

89.1 WHAT ARE ENVIRONMENTAL SOUNDS?

An environmental sound is historically defined by what it is not. An environmental sound is not speech. Nor is it a decontextualized sine tone or white noise burst often used in psychoacoustics experiments. But any other sound is fair game.¹ As Ballas and Howard (1987) commented, such a definition by exclusion is not very satisfying. This is particularly true given that perceiving environmental sounds is presumably the primary job of the vertebrate auditory system. Thus, by understanding more about environmental sounds, we should arrive at a better understanding of the auditory system that evolved to perceive them—a system parasitized in our own species by spoken language.

What, then, are some general characteristics of environmental sounds? Until recently, the acoustical character of environmental sounds was determined by interactions between solids, liquids, and gases (Gaver, 1993a), thereby intrinsically binding the sounds to their physical sources. Thanks to modern computers and sound synthesizers, this no longer needs to be the case. Nonetheless, because of the tight correspondence between a sound and its generating substance, environmental sounds can be thought of as a naturally occurring “auditory icon” for that object (Gaver, 1993b). Alternatively, an environmental sound can be conceived of as an auditory pointer to a physical referent, one that might convey meaning to the

hearer. However, it is important to keep in mind that with the exception of some nonhuman vocalizations, human nonspeech sounds, or alert sounds, environmental sounds are not intentional communicative signals. Moreover, spoken language has a fairly rigid temporal frame in which to convey action concepts, whereas environmental sounds vary hugely, with semantic identity unambiguously conveyed extremely quickly (a cork pop) to quite slowly (buttering toast).

As with visual objects and arrays, a useful means of characterizing environmental sounds is to partition them along acoustical, perceptual, and conceptual dimensions. Such an exercise can provide a rough guide of what type of information can and cannot be derived from environmental sounds, what the “grain” of that information is, and how it is distributed across sounds.

The acoustical and semantic space that environmental sounds inhabit has been mapped out by various groups over the past few decades, primarily by asking participants to perform similarity or overt category ratings on a set of recorded sounds and also by measuring a sizeable number of acoustic characteristics of the rated sounds. These studies tend to focus on one main class of environmental sounds often called “auditory objects”—a term that remains amorphous and controversial in equal measures (Giordano, McAdams, Zatorre, Kriegeskorte, & Belin, 2012; Griffiths & Warren, 2004; Lewis, Talkington, Tallaksen, & Frum, 2012; Wightman & Jenison, 1995). These

¹Although music and nonhuman vocalizations are often used as environmental sounds (Leaver & Rauschecker, 2010; Lewis, Talkington, Puce, Engel, & Frum, 2011; Talkington, Rapuano, Hitt, Frum, & Lewis, 2012), both are described in depth in other parts of this volume and therefore will not be discussed here.

auditory objects are often naturally occurring,² short *auditory events* and can have definable and reasonably obvious beginning and ending points. Moreover, as stated by Lewis et al. (2012), “auditory pattern analyses should allow for perceptual categorization and auditory objects should be separable by perceptual boundaries.” For example, the sound of a lead crystal wine glass smashing on a marble floor might begin with the main impact of the base of the glass and end when all of the glass shards have stopped bouncing. If asked to identify or name the sound, the typical English-speaking listener will name the source or material from which that the sound emanates, often along with a verb indicating what is happening with that source (e.g., “cow mooing,” “glass breaking”).

However, many, if not most, auditory objects have a more ambiguous event structure. Take the seemingly simple case of the sound of someone typing on a computer keyboard. A single keystroke might constitute an auditory object or event. Unless the sound recording is of the most hesitant of typists, keystrokes usually play out in clusters, and even in long sequences of bursts if the keyboardist is inspired (or under a tight deadline). Somewhat akin to speech, the sound of each keystroke will often blend with the subsequent one; with reasonably speedy typists, the sound of the release of one key will overlap in time with the sound of another being depressed. Thus, the “auditory object” becomes less straightforward to identify—is it the keystroke, a cluster of keystrokes, or the entire sequence of keystrokes that begins and ends with a prolonged silence?³ Even in the seemingly more straightforward case of the wine glass shattering, the event itself can be considered (and artificially reconstructed) as multiple overlapping repetitions of glass shards hitting the floor (Warren & Verbrugge, 1984).

This iterative repetition of a basic event (or waveform)—but over an indefinitely long period of time—is the acoustic signature of some very familiar auditory objects, such as a helicopter hovering or a diesel truck engine idling. These sounds could be considered boundary cases between auditory objects and the other major division of environmental sounds, *auditory scenes*. Some of these scenes can be acoustically quite simple and repetitive ambient human-created

environments such as the distant sound of highway traffic, the buzz of an electrical transformer, or the aforementioned idling diesel engine. They also include complex natural *textures* or “*soundscapes*” (Gygi & Shafiro, 2011; Turner, 2010) such as waves crashing on the shore, wind blowing through leaves, a crackling fire, or gentle rain falling on tarmac. Remarkably, many of these natural soundscapes can be generated by combining “atomic elements” of sounds in different combinations (McDermott, Wroblewski, & Oxenham, 2011; Turner, 2010). These simple scenes or soundscapes are also distinguished by their *lack* of event structure in that nothing particularly noteworthy happens or changes over a long period of time. Instead, soundscapes provide a particular auditory *context*—something we return to later.⁴

More complex auditory scenes or *backgrounds*—such as the ambient sounds of a busy park, a quiet office, or tropical rainforest—may contain several of these more basic soundscape features along with repeating, shorter auditory objects embedded in the scene.⁵ In natural scenes, the probability that a given *category* of auditory object will be heard is partly contingent on the type of soundscape—a contextual property to which listeners are sensitive (Gygi & Shafiro, 2011; Krishnan, Leech, Aydelott, & Dick, 2013; Leech, Gygi, Aydelott, & Dick, 2009; discussed in more depth later). However, these scenes typically have no real event structure in that there is a reasonably uniform temporal probability that auditory objects will appear within the (indefinitely long) soundscape.

These relatively static auditory backgrounds contrast with *dynamic auditory scenes* in which the probability of an auditory event occurring at a particular time is *contingent* on what has been heard previously. A classic example of such a scene is a car crash sequence in an action movie (Humphries, Willard, Buchsbaum, & Hickok, 2001), where the sounds of a car racing is followed by squealing brakes and tires, crinkling metal and glass, and—depending on the director’s penchant for drama—the whoof of igniting gasoline that precedes a death-dealing explosion. Needless to say, the temporal contingencies in such dynamic scenes are entirely dependent on the “real-world” event structure. Therefore, they are a physical

²An increasing number of auditory objects and events are completely artificial (with the most obvious being the novel alerts and “auditory icons” that accompany daily computing and telephone use. In addition, many people now have their only experience with natural sounds via recordings or synthesized examples, rather than with the animal or environment itself.

³A typical label from an English speaker for *any* of these keyboard sounds might be “typing.”

⁴Lewis et al. (2012) have noted that mechanical sounds classified by listeners as auditory objects (a clock or fax machine) tend to be size-delimited, whereas auditory scenes depict things that are large relative to the size of the observer (wind, rain, etc).

⁵These scenes are ubiquitous in radio plays, TV shows, and the movies, with vast numbers of prerecorded scenes available from the BBC and other studios.

reflection of the changing state of the world as opposed to language's more abstract representation of it, one whose surface form might change ("The car hit the post" versus "The post was hit by the car") but whose semantic content remains very similar. These cases highlight a clear difference between what is conveyed by environmental sounds and spoken language, namely the directness and invariability of the mapping between the information-carrying acoustic signal and the semantic content and/or event structure that is conveyed by that signal.

89.2 PERCEPTUAL, COGNITIVE, AND NEURAL PROCESSING OF ENVIRONMENTAL SOUNDS

Because the academic field studying spoken language is so much larger and more established, it has been natural for the study of environmental sound to mirror the study of language, and for the general subtopics (e.g., perceptual, cognitive, and neural factors) implicated in processing environmental sounds to be similar to those for language research. One consequence of this homologous organization is that it enables comparisons between language and environmental sounds. Therefore, what follows is structured around theoretical and methodological themes that roughly parallel ones in the psycholinguistics literature. We first summarize results from a number of environmental sound norming studies (somewhat similar to picture naming; Bates, D'Amico, et al., 2003) that give an idea of the perceptual and semantic characteristics and categories that seem to underlie environmental sounds recognition. In studies that roughly parallel some in the spoken word recognition literature, we examine how environmental sounds recognition and identification develops and changes over the lifespan. We then turn to the literature on perceptual and semantic priming with environmental sounds using unimodal, cross-modal, and cross-domain priming paradigms. We finally examine context effects—both acoustic and "real-world knowledge"-based—on environmental sound recognition.

In the second section on the neural bases of environmental sound comprehension, we begin with a brief overview of the historical literature comparing hemispheric asymmetries for environmental sounds and language processing, and then proceed to a more extensive review on auditory agnosias and the effect of brain damage on environmental sound comprehension,

and how these effects compare with those on language processing. We finish with an in-depth look at the neuroimaging literature on environmental sounds, with particular emphasis on comparisons with language and on regional neural biases for particular acoustical or semantic characteristics.

89.3 SECTION ONE: PERCEPTUAL AND COGNITIVE FACTORS IN PROCESSING ENVIRONMENTAL SOUNDS

89.3.1 Identification and Categorization of Environmental Sounds

As has been carried out with corpora of meaningful visual objects such as pictures (Bates, Burani, D'Amico, & Barca, 2001; Bates, D'Amico, et al., 2003; Cycowicz, Friedman, Rothstein, & Snodgrass, 1997; Szekely et al., 2004) as well as words (Balota et al., 2007), several groups have undertaken norming studies of environmental sound recordings to establish baseline characteristics such as discriminability, identifiability, nameability, and imageability (Ballas, 1993; Fabiani, Kazmerski, Cycowicz, & Friedman, 1996; Giordano, McDonnell, & McAdams, 2010; Gygi, Kidd, & Watson, 2004; Hocking, Dzafic, Kazovsky, & Copland, 2013; Marcell, Borella, Greene, Kerr, & Rogers, 2000; Saygin, Dick, & Bates, 2005; Schneider, Engel, & Debener, 2008; Shafiro, 2008; Shafiro & Gygi, 2004). These norming studies tend to use similar experimental paradigms in which participants listen to one of X sounds, press a key as soon as they think they know its identity, and then type or choose a verbal label. In some cases, participants are also asked to give alternative labels and perform a number of rating tasks on the sound. Among other results (comprehensively laid out in Hocking et al., 2013; Marcell et al., 2000), these ratings have shown: (i) imageable sounds are more identifiable; (ii) the more imageable a sound is, the faster participants will name it (and the more confidence they will have in their judgments about the sound); and (iii) familiar sounds are more identifiable and are also more pleasurable.

One useful metric derived in several of these studies is the "causal uncertainty" or Hcu⁶ (Ballas, 1993) associated with a sound. Although its definition varies slightly across studies, the Hcu is essentially a measure of the number of potential sound sources associated with a given sound, as indexed by the number of semantically distinct labels for a sound that are

⁶As defined by Ballas, the Hcu or causal entropy of a given sound is calculated as follows: for each label provided for the sound, multiply the probability that the label was used by the binary log of that probability and then sum these products, e.g., $Hcu = \sum p_{ij} \log_2 p_{ij}$. A similar metric has been used in picture-naming studies (Snodgrass & Vanderwart, 1980).

provided by participants. For instance, highly distinct and identifiable sounds like a doorbell would have a low Hcu, whereas the sound of a light switch—which in the study of Ballas (1993) was confused with a stapler or ballpoint pen—would have a higher Hcu. Perhaps unsurprisingly, a sound's Hcu is strongly correlated with the time it takes to identify and name it.

A major lacuna in all environmental sounds norming studies (and of environmental sounds studies more generally) is an estimate of a sound or sound category's frequency of occurrence—in psycholinguistics, word frequency is a fundamental variable of interest (Balota et al., 2007; Bates, D'Amico, et al., 2003; Roland, Dick, & Elman, 2007). To our knowledge, the only published frequency-of-occurrence data on environmental sounds are in the work by Ballas (1993).⁷ Here, undergraduate volunteers were prompted (via timers and pagers) to write down what sound(s) they were hearing at different times over the course of a normal day. Ballas (1993) used these survey data to predict behavior in a subset of the sounds used in the norming studies and showed that more frequently occurring sounds were more identifiable (and identified more quickly) and had lower causal uncertainty. The exceptions to this trend were alert sounds and signals, which had shorter reaction times (RTs) and were more identifiable than would be expected from their low frequency of occurrence.

Another challenge and conundrum in environmental sounds studies is how to account for sound length—again, word or phrase length is a very important psycholinguistic property. As Marcell et al. (2000) write regarding their own stimuli, “[we edited] each sound to a duration that we believed allowed the ‘sound event’ or ‘auditory object’ [...] to unfold naturally [...] this was clearly more of an artistic than empirical endeavor.” This ambiguity is reflected in the variability in sound duration across (and even within) norming studies, with durations varying by more than two orders of magnitude, ranging from consistently short or medium duration (Ballas, 1993, all sounds <625 ms; Fabiani et al., 1996, average duration ~330 ms; Hocking et al., 2013, all sounds set to 1,000 ms) to highly variable (Saygin et al., 2005, ~500–4,500 ms; Marcell et al., 2000, ~500–6,000 ms). This is the equivalent in duration of comparing single short spoken words to sentences with 20 or more words (a considerable potential difference in

informativeness!)—yet duration does not appear to be correlated with recorded sounds' identifiability (either in accuracy or in response latency), familiarity, or confidence with which listeners identify the sound (Marcell et al., 2000).

A primary goal of many of these studies is to uncover the acoustical, perceptual, and cognitive category structure of environmental sounds. Explicit categorization tasks (Gygi, Kidd, & Watson, 2007; Hocking et al., 2013; Houix, Lemaitre, Misdariis, Susini, & Urdapilleta, 2012; Marcell et al., 2000) have revealed fairly consistent category groupings, for instance, Hocking et al. (2013) found that participants could reliably classify sounds as: (i) animal; (ii) human; (iii) nature; (iv) household/tool/accessory; (v) recreational; (vi) transport; (vii) weapon; (viii) alarm/signal; or (ix) musical instruments.⁸ A somewhat more detailed category structure was captured in a free classification task by Marcell et al. (2000) (see Table 89.1).

When this category space is compared with that associated with visual objects (Huth, Nishimoto, Vu, & Gallant, 2012), it is striking how much more limited, sparse, and clumpy the semantic space is that is covered by environmental sounds (at least recognizable recorded ones). This may be due to a fundamental property of sound itself. As Wightman and Jenison (1995) noted, “In the case of vision the physical features of environmental objects map directly to patterns of stimulation on the retina [...] In contrast, hearing offers no direct peripheral representation of environmental

TABLE 89.1 Environmental Sounds Categories (in Alphabetical Order) Provided by Participants in Marcell et al. (2000)

Accident	Ground transportation	Pet	Household
Air transportation	Human	Reptile/amphibian	Machine
Bathroom	Hygiene	Sickness	Paper
Bird	Insect	Signal	Weapon
Farm animal	Kitchen	Sleep	Weather
Four-legged animal	Musical instrument	Tool	
Game/recreation	Nature	Water/liquid	

⁷Cummings et al. (2009) conducted a survey of infants' and toddlers' parents to try to establish frequency-of-occurrence norms for everyday sounds; however, there was little consistency in parents' reports, which may reflect a problem in the survey instrument or true variability in children's exposure to environmental sounds.

⁸In their fMRI studies of “action sounds,” Lewis et al. (2012) have suggested a division into human, animal, mechanical, and environmental sounds, based on acoustical, perceptual, and cortical organization grounds.

objects.” In other words, visible light will reflect off almost any surface and therefore create a “signal” that tells us about almost any surface or object. In contrast, for us to receive an acoustic signal from an object, it must *actively* emit vibrations that can travel in the air far enough to be detected, or it must interact with air movement and turbulence in a distinctive way (i.e., the vibrations induced by wind flowing through dry leaves versus chimes). This means a more restricted number of objects/situations create sounds, severely limiting the category space of the auditory objects and scenes relative to vision.

The perceptual and categorical similarity space of environmental sounds has been extensively characterized in a series of studies by Gygi et al. (2004, 2007). By using participants’ pairwise similarity ratings for 50 sounds along with a large number of acoustic measures, they found that sounds tended to fall into three major acoustical categories—harmonic, discrete impact, and continuous sounds—and that the different underlying sound sources tended to cluster together in the multidimensional scaling (MDS) space. They also found that ordering of the sounds along different dimensions of the MDS space was associated with linear combinations of acoustic variables, such as harmonicity, amount of silence, and modulation depth.⁹

89.3.2 Environmental Sounds Comprehension Over the Lifespan

In a comprehensive study of children ages 5 to 16, young adults, older adults, and patients with Alzheimer’s dementia, Fabiani et al. (1996) showed that with few exceptions (such as video game sounds), people across the lifespan generally categorize environmental sounds very similarly. However, older participants and those with Alzheimer’s tended to be less accurate and consistent in their identification of sounds and often used superordinate categories to name sounds. This was true even in the case of animal vocalizations, which tend to be quite specific and easy to identify for younger adults. It is important to note that while there is general consistency in environmental sounds identification, there can be very significant regional and cultural differences in exposure to different sounds, which can have a real impact on causal uncertainty. For example, when norming our own set of environmental sounds in different cities (Dick et al., 2007), there were some sounds (such as cutting crusty bread and lighting a gas stove) that were easily recognizable by residents of Rome, but that flummoxed San Diegans. As Giordano et al. (2010) (p. 9) note, it is

important to account for these effects because “uncontrolled differences in identification performance between environmental subcategories might be sufficient to produce patterns of neural selectivity.”

In *Childhood*, a series of studies using behavioral picture–sound matching paradigms has shown that environmental sounds and spoken language comprehension generally go hand-in-hand over development. Cummings, Saygin, Bates, and Dick (2009) tested 60 infants (ages 15–25 months) listening to environmental sounds or spoken phrases in a preferential looking paradigm, where infants were presented with two photographs side by side and then heard an environmental sound or spoken phrase corresponding to one of the objects; their looking time to the correct picture was the dependent measure. Infants’ looking accuracy for environmental sounds was correlated with that for spoken language after taking into account the effects of age. Regression analyses showed that environmental sounds comprehension improvements were associated with chronological age, whereas spoken phrase comprehension was associated with productive vocabulary as measured by the MacArthur-Bates Communicative Development Inventory. Using a match-to-sample sound–picture paradigm (Saygin et al., 2005) with children 6 to 18 years of age, Dick, Borovsky, Cummings, Trauner, and Saygin (unpublished data) found that RTs to environmental sounds and spoken phrases were tightly correlated, even after accounting for age-related decreases. Using the same behavioral paradigm, Saygin et al. (2005) found that RTs for the two domains were only marginally correlated in early and later adulthood. Nonetheless, studies involving adults with cochlear implants (or who were hearing simulated cochlear implant input) have shown that training with environmental sounds can generalize to language and speech comprehension to a surprising degree (Loebach & Pisoni, 2008; Shafiro, Sheft, Gygi, & Ho, 2012), suggesting that there are shared processing resources underlying the two domains.

89.3.3 Semantic and Conceptual Priming with Environmental Sounds

As shown by these recognition and identification studies, even very young listeners can extract consistent meaningful information from environmental sounds. A number of behavioral and electroencephalography (EEG)/ERP studies have asked how this semantic, conceptual, or “real-world” information conveyed by environmental sounds is processed and integrated with subsequently encountered information.

⁹Lemaitre, Houix, Misdariis, and Susini (2010) reported that “sound experts” (musicians, sound engineers, and so forth) tended to weight such acoustic properties in their sound categorization ratings somewhat more heavily than everyday listeners.

Many of these studies have also asked how similar or distinct semantic and conceptual processing of environmental sounds might be to that observed in spoken language comprehension. Typically in these studies a standard semantic priming paradigm is used in which a target word (written or spoken) is preceded by a prime stimulus that varies in terms of its semantic relationship with the target. A half-century of psycholinguistics research has shown that targets that are semantically related to the prime should show faster RTs and higher accuracy than unrelated (or less-related) targets. In the ERP literature, the N400, a negative wave peaking at approximately 400 ms post-stimulus onset, is commonly used as an indicator of semantic integration of the incoming word with the foregoing content: the more explicit the expectation for the next word, the larger the N400 amplitude for words violating the expectation (Kutas & Federmeier, 2000). The N400 can also be elicited by mismatching meaningful stimulus pairs: two words, a sentence and word, two pictures, or a picture and a word.

In general, priming and particularly ERP studies have shown very similar semantic effects with environmental sounds, alone and when directly compared with language stimuli. RT measures have shown that environmental sounds can prime semantically related words (Chiu & Schacter, 1995; Frey, Aramaki, & Besson, 2014; Orgs, Lange, Dombrowski, & Heil, 2006; van Petten & Rheinfelder, 1995) and pictures (Chen & Spence, 2011; Schneider et al., 2008), and may also prime other semantically related sounds (Stuart & Jones, 1995, but see Chiu & Schacter, 1995; Frey et al., 2014; Friedman, Cychowicz, & Dziobek, 2003). Written words (Orgs et al., 2006; Pizzamiglio et al., 2005) and pictures (Schneider et al., 2008) have also been reported to prime related environmental sounds (but see Chiu & Schacter, 1995; Schön, Ystad, Kronland-Martinet, & Besson, 2010). Using a masked visual word prime and environmental sound target, Galati et al., (2008) showed that cross-domain priming between words and environmental sounds can be highly semantically specific in that RTs to an identity prime (the masked word “laugh” followed by the sound of laughing) are faster than both within-category pairs (“whistle” followed by laughing) and across-category pairs (“boiling” followed by laughing).

Among ERP studies that use environmental sounds, there are quite consistent effects of semantic or

conceptual relatedness on the N400. An “N400 effect” (more negative-going N400 waveform for a target that is conceptually unrelated to a context or prime compared with a related target) has been observed in several combinations. N400 semantic relatedness effects have been observed for short environmental sound targets preceded by pictures (Cummings, Ceponiene, Dick, Saygin, & Townsend, 2008; Cummings et al., 2006; Plante, van Petten, & Senkfor, 2000), longer environmental sounds (Schirmer, Soh, Penney, & Wyse, 2011), visually presented words (Orgs et al., 2006; Orgs, Lange, Dombrowski, & Heil, 2007; Schön et al., 2010; van Petten & Rheinfelder, 1995; Wu, Athanassiou, Dorjee, Roberts, & Thierry, 2012), and spoken words (van Petten & Rheinfelder, 1995, but see Frey et al., 2014). N400 relatedness effects with environmental sounds as primes have also been observed for target spoken words (Frey et al., 2014; Plante et al., 2000; Van Petten & Rheinfelder, 1995) and visually presented words (Orgs et al., 2006).¹⁰

Direct comparisons between environmental sound-evoked and language-evoked N400s have tended to show very similar overall N400 profiles (see Figure 89.1, adapted from Cummings et al., 2006) but with a somewhat earlier onset and more anterior distribution of the N400 effect for semantically unrelated environmental sounds targets compared with words (Cummings et al., 2006; Orgs et al., 2006; but Schön et al., 2010; van Petten

FIGURE 89.1 Matching and mismatching ERP responses to words, environmental sounds, and nonmeaningful sounds. Redrawn from Cummings et al. (2006) with permission from the publisher.

¹⁰Other ERP components have also been investigated with environmental sounds—for results and review, see Cummings et al. (2006), Schirmer et al. (2011), and Frey et al. (2014), among other studies. In addition, environmental sounds have been shown to evoke repetition priming effects in EEG and fMRI studies (Bergerbest, Ghahremani, & Gabrieli, 2004; Murray, Camen, Spierer, & Clarke, 2008). EEG with environmental sounds has also shown quite early discrimination of sounds derived from living versus human-made objects (Murray, Camen, Gonzalez Andino, Bovet, & Clarke, 2006) and differential localization of mouth-related and hand-related sounds (Pizzamiglio et al., 2005).

& Rheinfelder, 1995).¹¹ Some studies have found differential lateralization of N400 responses to environmental sounds and words (Plante et al., 2000; van Petten & Rheinfelder, 1995), but others have not (Cummings et al., 2006; Orgs et al., 2006; Schirmer et al., 2011). N400 effects with both linguistic and environmental sound stimuli are also similarly modulated by task demands (Frey et al., 2014; Wu et al., 2012).

There has been some question about whether such cross-domain similarities might be driven by covert naming of environmental sounds. However, this explanation does not have much empirical support. As mentioned, participants show longer RTs when asked to covertly name sounds during a sound–picture matching task, suggesting that this is not a default strategy for most participants (Dick, Bussiere, & Saygin, 2002). In addition, synthesized nonlinguistic sounds that are not easily associated with verbal labels evoke very similar N400 effects (Schön et al., 2010). Even novel cross-modal associations between “jagged” and “smooth” sounds and shapes can evoke a small N400-like effect (Cummings et al., 2006).

In contrast to results with typically developing individuals, some ERP studies with language-impaired (LI) and autistic children have shown cross-domain differences in N400 effects on spoken language and environmental sounds. Cummings & Ceponiene (2010) found that children with LI showed typical N400 effects of semantic incongruity for environmental sound/picture mismatches, but showed a delayed N400 latency to spoken phrase/picture mismatches when compared with typically developing age-matched children. McCleery et al., 2010 used a very similar paradigm with young highly functioning autistic children (ages 4–7) and found an even more striking difference: autistic children showed a typical N400 effect with environmental sound/picture mismatches but no discernible N400 effect with spoken word/picture mismatches.¹² Thus, there is some indication that in certain developmental disorders, language and environmental sounds processing can become detoggled—a result that contrasts with much work with acquired language disorders such as aphasia.

89.3.4 Context Effects in Environmental Sounds Processing

Linguistic context affects performance in phoneme monitoring, lexical decision, and naming tasks (reviewed in Aydelott, Leech, & Crinion, 2010). In the

speech perception literature, the effects of context are more obvious when ambiguity is present or when the target stimuli are impoverished. Ballas and Mullins (1991) investigated the effects of “semantic” contexts on the identification of ambiguous environmental sounds. They conducted a series of experiments where listeners were played nearly homonymous sounds (for instance, a fuse burning and food frying) and found that these sounds were more accurately identified when presented in isolation or embedded in consistent contexts (food frying in the context of kitchen sounds) relative to when context was biased toward the other alternative (food frying in a “fireworks” context).

The effects of competing backgrounds have also been extensively studied in speech perception and are often referred to as the cocktail party effect. Environmental sound identification also occurs in the presence of similar competing sounds and backgrounds. In everyday listening situations, listeners do not identify environmental sound targets in isolation, but from within a background of multiple competing sound sources. As demonstrated by Ballas and Mullins (1991), listeners are aware of the likelihood of certain sounds occurring in certain contexts because of their everyday listening experience, for instance, cow moos are likely to occur in the context of a barnyard than in an office.

When these more naturalistic listening conditions are simulated, the detection and identification of familiar unambiguous environmental sounds are enhanced in the presence of contextually *incongruent* environmental scenes in adults (Gygi & Shafiro, 2011; Leech et al., 2009) and school-age children (Krishnan et al., 2013). Gygi and Shafiro (2011) showed that the advantage for contextually incongruent sounds was level-dependent and interacted with the listener’s familiarity with the sounds and the background. Congruent backgrounds might produce greater interference by increasing the uncertainty about the separation of target from background in a manner not dissimilar from speech. For example, listeners are adversely affected by competing speech in their native language (Van Engen & Bradlow, 2007).

In vision, some studies suggest that a contextual pop-out effect also occurs when viewing natural scenes, that is, inconsistent objects pop-out in these scenes (Underwood & Foulsham, 2006). However, other researchers have suggested that these differences can be accounted for by low-level visual perception (Vö & Henderson, 2011). Leech et al. (2009) investigated the low-level acoustic and perceptual features that may play a role in identifying environmental sounds within

¹¹Interestingly, a developmental ERP study by Cummings et al. (2008) showed that this earlier latency for environmental sound–related N400 effects slowly emerges with increasing age, with latencies decreasing from young school-age children through adolescence to early adulthood.

¹²This is in contrast to results from behavioral results from the study by van Lancker et al. (1988) involving autistic children who showed similar performance on the two domains in a sound-to-picture matching task.

a context. In addition to experimenter-defined factors of congruence or incongruence, they found that spectral measures, such as the mean, standard deviation, and range of the sound's pitch, as well as temporal autocorrelation measures were significant predictors of the advantage for incongruent over congruent sounds. The results of these studies indicate that the identification of environmental sounds in context involves the integration of perceptual, attentional, and real-world knowledge.

89.4 SECTION TWO: NEURAL FACTORS IN PROCESSING ENVIRONMENTAL SOUNDS

89.4.1 Behavioral Studies on Hemispheric Asymmetries in Environmental Sounds Comprehension

Before exploring the literature on brain damage and environmental sound comprehension, we briefly review early studies on dichotic listening, ones that have been instrumental in establishing our notions regarding hemispheric differences for processing different aspects of meaningful sounds, both linguistic and nonlinguistic. The logic of these experiments is based on preferential projections from the cochlea to the contralateral hemisphere. In an important early study, [Curry \(1967\)](#) compared recall of words and environmental sounds in left-handed and right-handed English speakers. He presented triplets of spoken word or nonword pairs, with each word in a pair presented to only one ear; after listening to the word pairs, subjects had to list all the words that they recalled. They also listened to dichotically presented pairs of short sounds and wrote down the names of the sounds they heard. Curry found that right-handed individuals showed a significant right ear advantage (REA) for words (and an even more sizeable one for nonwords), with a significant left ear advantage (LEA) for identifying environmental sounds. This suggested that meaningful sounds were preferentially processed in the left hemisphere if they were linguistic and preferentially processed in the right if nonlinguistic. Complicating the story slightly, he also showed that left-handed individuals showed a weak but significant REA for words and no significant ear advantages for either nonwords or environmental sounds.¹³

When might these differential ear advantage effects for spoken language and environmental sounds emerge over development? [Knox and Kimura \(1970\)](#)

conducted a comprehensive set of dichotic listening studies with large samples of children ages 5 to 8 years. Here, children listened to dichotically presented digit pairs, environmental sound pairs, and animal sounds pairs, as well as performed two word–picture match-to-sample tasks with minimal pairs, with one word presented to each ear. For all language tasks, children showed a considerable advantage in recalling or perceiving words presented to the right versus the left ear. By contrast, environmental sound identification showed a weak but significant LEA, with no real lateralization when listening to animal sounds. These data suggest that a hemispheric division of labor emerges for processing meaningful sounds by the beginning of the school years. However, as seen in neuropsychological and neuroimaging studies, hemispheric differences are less cut-and-dried than one might be led to believe from these dichotic listening studies.

89.4.1.1 Effects of Brain Damage on Environmental Sounds Processing

A specific deficit in recognizing environmental sounds is often termed *nonverbal auditory agnosia*. It (like word deafness) is a very rare phenomenon usually associated with bilateral ([Albert, Sparks, Stockert, & Sax, 1972](#); [Kazui, Naritomi, Sawada, Inoue, & Okuda, 1990](#); [Spreen, Benton, & Fincham, 1965](#)) and, rarely, with unilateral left ([Saygin, Leech, & Dick, 2010](#)) or right hemisphere ([Fujii et al., 1990](#)) lesions. Experimental studies with larger groups of patients ([Saygin, Dick, Wilson, Dronkers, & Bates, 2003](#); [Schneider, Benson, Alexander, & Schneider-Klaus, 1994](#); [Varney & Damasio, 1986](#)) have shown that dissociations between verbal and nonverbal domains are the exception rather than the norm.

Two forms of nonverbal auditory agnosia have been proposed: (i) *perceptual-discriminative*, with patients failing to identify whether two consecutive sounds are identical and (ii) *associative-semantic*, with patients being impaired at audiovisual matching or naming. Early work did not reveal clear lesion correlates of these agnosia types. Bilateral lesions have been implicated in severe discriminative disorders ([Albert et al., 1972](#); [Kazui et al., 1990](#); [Lechevalier et al., 1984](#); [Mendez & Geehan, 1988](#); [Motomura, Yamadori, Mori, & Tamaru, 1986](#); [Rosati et al., 1982](#); [Taniwaki, Tagawa, Sato, & Lino, 2000](#); [Vignolo, 1982](#)). Unilateral right hemisphere lesions can lead to normal association with impaired discrimination ([Eustache, Lechevalier, Viader, & Lambert, 1990](#); [Vignolo, 1982](#)), deficient association with normal discrimination ([Spreen et al., 1965](#)), or deficient association and deficient discrimination ([Fujii et al., 1990](#)). Unilateral left hemisphere

¹³The right ear advantage for listening to linguistic sounds may not hold cross-linguistically, at least in some circumstances ([Hatta & Dimond, 1981](#)).

lesions have been linked to deficient association (Saygin et al., 2003) and normal discrimination (Vignolo, 1982), although in most studies with this sample discrimination was not tested on left hemisphere–injured patients because of a focus on language processing (Saygin et al., 2003; Varney, 1980; Varney & Damasio, 1986). Vignolo, Spinnler, and Faglioni reported disturbances of environmental sound recognition after unilateral hemispheric damage in a group of patients (Faglioni, Spinnler, & Vignolo, 1969; Spinnler & Vignolo, 1966). They noted that right hemisphere–damaged (RHD) patients tended to perform significantly worse than controls on perceptual tests involving environmental sounds and that left hemisphere–damaged (LHD) patients performed significantly worse on associative or semantic tests.

Several studies have directly compared environmental sounds and spoken language comprehension after stroke. In 1980, Varney used environmental sounds to examine both verbal and nonverbal comprehension deficits in the same aphasic patients and found that impairments in environmental sound recognition were seen only in subjects with impaired verbal comprehension, and that aphasic patients with intact verbal comprehension also performed well on sound recognition. There were some patients who were impaired in verbal comprehension, but not in sound recognition. More recently, Schneider et al. (1994) observed that both LHD and RHD patients performed significantly worse than a group of normal controls on an environmental sound recognition test. They found no significant differences in the performances of the two patient groups; however, the pattern of errors appeared to differ across groups. LHD patients made more semantically based errors, whereas RHD patients and control subjects made almost exclusively acoustic errors. For all patients, accuracy in recognizing environmental sounds correlated with language comprehension as measured by the Western Aphasia Battery (Kertesz, 1979). Lesion behavior correlations showed that LHD patients with impaired environmental sound recognition tended to have damage to the posterior superior temporal gyrus (pSTG) and the inferior parietal lobe.

Although these studies support a link between aphasia and nonverbal auditory agnosia, none of these were precise comparisons between verbal and nonverbal auditory processing in the same patients and did not control for factors such as stimulus frequency and identifiability or the relationship between the auditory and visual stimuli. In a large neuropsychological and lesion-mapping study, our group addressed these gaps in knowledge and assessed the relationship between verbal and nonverbal comprehension of complex, meaningful information in the

auditory modality by examining aphasic patients' abilities to match environmental sounds and corresponding linguistic phrases to associated pictures (Saygin et al., 2005; Saygin et al., 2003). Task demands, stimulus characteristics, and semantic features were all carefully controlled to reduce confounds and to focus on the relationship between verbal and nonverbal domains. Results from 30 LHD and 5 RHD patients (along with 21 neurologically intact age-matched control subjects) showed that RHD patients were only mildly impaired in the task, performing similarly to mild (anomic) aphasic LHD patients but significantly worse than controls. Patients with more severe aphasia (LHD) were impaired to the same extent in comprehending speech and environmental sounds, as measured by both accuracy and RT measures. Performance within the task between the two domains went hand-in-hand, with a strong correlation between accuracy and RT for speech and environmental sounds, suggesting that the two domains utilize some shared perceptual and neural mechanisms. Both lesion overlays (Saygin et al., 2003) and Voxel-Based Lesion-Symptom Mapping (Bates, Wilson, et al., 2003) demonstrated that damage to posterior regions in the left middle and superior temporal gyri and damage to the inferior parietal lobe were predictors of deficits for both speech and environmental sounds. Brodmann's area 22 and the surrounding middle temporal and inferior parietal regions (encompassing Wernicke's area) were also implicated in environmental sound processing. In fact, Wernicke's area itself, in the pSTG, was more strongly associated with performance in the nonverbal domain than in the verbal domain (Saygin et al., 2003).

It is not just within the stroke literature that impairments in spoken language and environmental sounds (ES) have been shown to be comorbid. Recent studies with neurodegenerative disorders (e.g., primary progressive aphasia and semantic dementia) have also revealed concomitant deficits in verbal and nonverbal meaningful sound processing (Bozeat, Lambon Ralph, Patterson, Garrard, & Hodges, 2000; Goll et al., 2010; Hsieh, Hornberger, Piguet, & Hodges, 2011).

Although an association is the norm between speech and nonverbal sounds, dissociations in neuropsychology can also be informative, even when rare (Bates, Appelbaum, Salcedo, Saygin, & Pizzamiglio, 2003; Bates, Saygin, Moineau, Marangolo, & Pizzamiglio, 2005). Varney (1980) had reported deficits in nonverbal comprehension only in patients who also exhibited deficits in verbal comprehension, but they did not find dissociations in the opposite direction. Clarke, Bellmann, De Ribaupierre, and Assal (1996) reported a patient who was deficient in the nonverbal auditory domain but had no diagnosed verbal

comprehension deficits (although formal testing was not reported). When both the task and stimuli were closely matched across domains, as we have done, deficits in the two domains were largely associated with each other.

We assessed dissociations between environmental sounds and verbal comprehension both quantitatively and statistically (Bates, Appelbaum, et al., 2003; Bates et al., 2005) in the large patient sample of Saygin et al. (2003). Doing so, we found three outliers, of which only one, Patient M, showed dissociation between the two domains. M, a right-handed individual who suffered a left hemisphere stroke, had persistent difficulty with environmental sound comprehension but had recovered language function to within normal levels (Saygin et al., 2010). Detailed behavioral assessment verified that the patient exhibited persistent and severe auditory agnosia for nonverbal sounds in the absence of verbal comprehension deficits or peripheral hearing problems. Acoustical analyses suggested that his residual processing of a minority of environmental sounds might rely on his speech processing abilities. In the patient's brain, contralateral (right) temporal cortex as well as perilesional (left) anterior temporal cortex were strongly responsive to verbal, but not to nonverbal, sounds, a pattern that stood in marked contrast to the data of the controls, suggesting a selective reorganization of auditory processing for speech but not environmental sounds processing.

In summary, performance in verbal and nonverbal domains is, in general, highly correlated after brain injury. However, not only is it possible to identify patients who perform worse in the verbal domain (i.e., the expected result based on an aphasic sample; Varney, 1980) but also we can reliably identify patients who perform worse in the nonverbal domain, an unexpected and rarely reported outcome (Saygin et al., 2010). It is possible that these dissociations are due to variation between individuals' premorbid brain organization for these functions, as well as nonuniform poststroke recovery patterns across patients and across domains.¹⁴

89.4.2 Functional Neuroimaging of Environmental Sounds

Neuropsychological and lesion symptom mapping approaches are extremely useful for understanding what brain regions are necessary for processing environmental sounds, as well as for characterizing how plastic the brain's organization for understanding meaningful

sounds may be after injury and subsequent learning and retraining. Complementary functional neuroimaging studies can tell us which brain networks are *involved* in environmental sounds (and shared with spoken word) comprehension. Equally, neuroimaging provides much finer-grained information about how these networks change in response to task demands and stimulus properties, allowing us to investigate how the brain decomposes and represents acoustical, perceptual, and cognitive dimensions of environmental sounds.

89.4.2.1 "Passive" Listening Neuroimaging Studies

In the simplest neuroimaging studies, participants were asked to listen to a series of single unordered environmental sounds without making any behavioral responses or covert judgments, with activation compared with rest. An early positron emission tomography (PET) regional cerebral blood flow (rCBF) study by Engelien et al. (1995) revealed bilateral but slightly right-lateralized perisylvian activation in the STG, superior temporal sulcus (STS), anterior insula/frontal operculum, and inferior parietal cortex. Using event-related fMRI, Specht and Reul (2003) also showed bilateral but more right-lateralized activation in primary and secondary auditory cortices, the superior temporal sulcus, and the lingual gyrus, and bilaterally in the supplementary motor area and precentral gyri. In a block-design study, Leech and Saygin (2011) showed bilateral but somewhat *left-lateralized* activation all along the temporal plane. Humphries et al. (2001) had participants passively listen to longer, artificially created auditory "events" (like the sound of a gun followed by the sound of fading footsteps) and found extensive bilateral activation in the middle and posterior portions of the STG/STS, along with the inferior frontal gyri. Engelien et al. (2005) compared PET rCBF for passive listening to environmental sounds that were presented either intact or temporally "scrambled" but with their overall spectrum and amplitude envelope intact, thereby rendering the sounds meaningless and unfamiliar. Temporally scrambled sounds evoked almost entirely right STG/STS/inferior frontal gyrus (IFG) activation, whereas the comparison of intact (meaningful/identifiable) minus scrambled sounds showed more left anterior STG/STS, IFG, and anterior parahippocampal gyrus activation, along with right anterior STG and mid-orbito-frontal gyrus activation.

Several of these passive listening paradigms also compared environmental sounds with spoken language activation, showing largely overlapping systems

¹⁴Dissociations have also been observed for different classes of environmental sound. Pazzaglia, Pizzamiglio, Pes, and Aglioti (2008) found that patients with buccofacial or limb apraxia showed deficits in environmental sounds comprehension related to their apraxia subtype, with buccofacial apraxics having somewhat greater difficulties with mouth-related sounds than limb-related sounds, and limb apraxics showing the converse pattern of deficits.

but with regional relative increases for either ES or spoken language. Specht and Reul (2003) compared the environmental sounds activation described with that of one- to two-syllable words spoken by a single talker (as well as with single tones). This revealed different graded activation profiles with: (i) the left orbital IFG and posterior STS and bilateral mid-STS/middle temporal gyrus (MTG) showing activation for words greater than environmental sounds and (ii) the left and right transverse gyri and planum temporale showing the opposite profile, with environmental sounds greater than spoken words. Humphries et al. (2001) compared their environmental sound sequences to sentential descriptions of the sequences and found more activation for sentences *bilaterally* in the anterior and mid-STS, as well as in the left inferior frontal and prefrontal gyri. Environmental sounds only showed more activation than sentences in the left inferior central sulcus and the right IFG. Leech and Saygin (2011) compared their environmental sound blocks to matched spoken phrases and also showed greater speech than environmental sound activation in bilateral STG/STS/MTG, as well as left anterior orbital IFG. In contrast to Humphries et al., they found more activation for environmental sounds than spoken phrases in medial auditory cortex. Leech and Saygin (2011) compared this simple subtraction-based analysis to a multivariate pattern analysis, which showed that finer-grained patterns of activation and deactivation within much of the left and right perisylvian cortex can disambiguate which class of sounds the listener is hearing, even if there is no overall activation advantage for one class within the region. Furthermore, these distributed patterns of activation to environmental sounds and language tend to be quite different across individuals. A promising model for understanding such differences—and what they might tell us about the functional organization cortex—might have been the approach of Charest, Kievit, Schmitz, Deca, and Kriegeskorte (2014), who showed that individual differences in visual representational structure in ventral inferior temporal regions was related to participants' individual interactions and associations with the represented objects.

89.4.2.2 “Active”/Task-Based Listening Neuroimaging

To our knowledge, all other PET and fMRI studies of environmental sounds use “active” tasks, whereby participants make a decision or judgment during scanning. Patterns of environmental sounds activation are strongly influenced by task and cognitive demands, even quite subtly different ones, although the trade-off is that this makes it more difficult to disambiguate “pure” sound processing from a range

of metacognitive and attentional factors involved in performing the task. An early demonstration of this was in the Engelien et al. (1995) PET study, where a comparison of the passive listening task with one where participants performed covert categorization of the sounds showed strongly left-lateralized increases during categorization in left prefrontal and frontal regions, along with categorization-related left-lateralized activation in inferior parietal and middle temporal regions. Lewis et al. (2004) compared activation for forward and reverse environmental sounds while participants pressed buttons to indicate whether they had recognized the sound (without any visual stimulation). They showed extensive perisylvian activation for environmental sounds and considerably greater activation for forward than for backward sounds in highly left-lateralized IFG, posterior STS, and anterior fusiform regions along with right posterior STS and right orbital IFG (see also Lebrun et al., 2001). Lewis et al. (2004) compellingly demonstrated that the greater activation for forward versus backward sounds are related to perceptual rather than acoustic properties because comparing recognized to unrecognized *forward sounds* showed the same pattern of activation differences as forward versus backward sounds. Moreover, there were no significant differences between *unrecognized forward and backward sounds* in these regions. Using overlays of cognitive and visual activation from other studies, Lewis et al. (2004) also showed that environmental sound recognition involves multiple inferior and prefrontal, inferior parietal, and posterior middle/superior temporal regions that are involved in high-level spoken word semantics (Figure 89.2). Hocking, McMahon, and De Zubicaray (2011) showed that environmental sound activity in these regions is differentially modulated by quite specific types of category judgments. For instance, the anterior fusiform was selectively activated by making more visually based judgments (again without any systematic visual stimulation), and activation in the angular gyrus and retrosplenial cortex was modulated by making semantic judgments (i.e., whether the sound was generated by animals who live in Australia).

89.4.2.3 “Active” Tasks Comparing Environmental Sounds and Language

A number of studies using active tasks without a visual component have directly compared environmental sound and language-related activation. An early PET study by O'Leary et al. (1996) compared healthy participants' rCBF with consonant–vowel–consonant (CVC) words, CVC nonwords, and short environmental sounds. They showed no quantitative differences between activations in these conditions, but they did demonstrate that attending to input from one ear

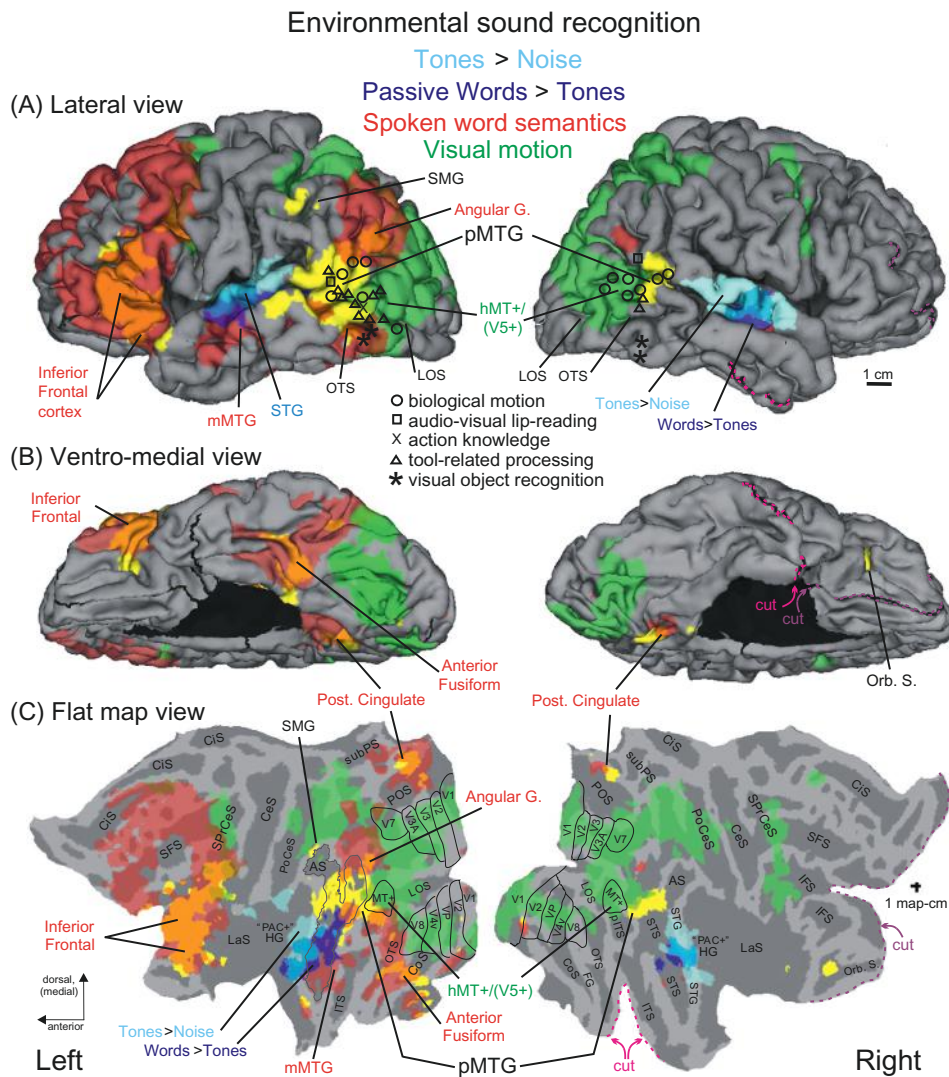

FIGURE 89.2 A comparison of environmental sound activation (yellow) with other tasks reported in the literature. Blue hues indicate early acoustic processing, including passive listening to tones versus white noise (light blue) and spoken words versus tones (dark blue). Red indicates semantic processing of spoken words (animal names). Green indicates visual motion processing of coherent versus random dot displays. Regions of overlap are indicated by intermediate colors. Symbols indicate previously reported activation centroids in Talairach coordinates (projected to the outer cortical surface for visibility). Reprinted with permission from Lewis et al. (2004).

substantially affects activation lateralization across domains. For instance, attending to the left ear when either environmental sounds or nonword CVCs are presented evoked very similar right-lateralized activation in the anterior STG/STS. Overlapping activation for environmental sounds and language activation was also reported by Visser and Lambon Ralph (2011). This fMRI study asked participants to perform a living/nonliving categorization task on diverse environmental sound and language stimuli (compared with low-level control conditions) and showed remarkably similar activity in both domains in the left and right anterior STG/STS, similar to the results of Engelien et al. (1995), but more activation for language than environmental sounds in a left anterior ventral temporal area known to be affected in semantic dementia.

In a PET study using a spoken recognition or verification task with environmental sounds, words, and meaningless syllables, Giraud and Price (2001)

showed generally overlapping perisylvian networks, but they found that words and syllables evoked more activation than environmental sounds in the left aSTG and pSTG and very posterior STS. Building on these results, Thierry, Giraud, and Price (2003) used similar stimuli as Humphries et al. (2001), whereby participants listened to constructed sequences of environmental sounds or phrases that would or would not make sense conceptually depending on their order of presentation (e.g., the sequence of events in a car crash). Participants performed two different tasks. In the “easy” task they indicated if there was an animal in the sequence; in the “hard” task, they indicated whether the entire sequence made sense. As with previous studies, Thierry et al. found activation overlap for verbal phrases and sounds in the left IFG, cerebellum, and all along the left STG, right STS, and right cerebellum. Comparison across domains showed more activation for language than environmental sound in

the left STS/STG, with the opposite pattern in right posterior STG. The authors performed a direct comparison with the Giraud and Price (2001) data and showed that the right hemisphere environmental sound greater than language activation was much more prominent in the sequence-judgment paradigm than in the single sounds recognition paradigm of Giraud and Price. Thierry et al. (2003)'s environmental sounds greater than language pattern was in the same right pSTG/STS region where Giraud and Price (2001) showed more activation for words than environmental sounds.

Cross-modal paradigms have also been used to compare environmental sound and language-related activation. Dick et al. (2007) used a picture–sound matching paradigm very similar to that of Saygin et al. (2003), whereby participants saw two semantically unrelated pictures and heard either an environmental sound or a short Italian phrase corresponding to one of the pictures; subjects pressed a button to indicate which picture matched the sound or phrase. Relative to the control condition (a simple match-to-sample task with nonsense shapes and tones), both environmental sounds and language stimuli evoked significant bilateral activation in the inferior frontal gyri, superior temporal gyri (anterior/transverse/posterior), and posterior middle and inferior temporal and fusiform gyri. Here, language stimuli evoked more activation than environmental sounds in the middle left MTG/STS/STG, the anterior left and right STG, and right-lateralized lateral fusiform gyrus. Environmental sounds evoked more activation than did language stimuli in patches along the right planum temporale, anterior, and superior-most extent of the right supramarginal gyrus, and the right IFG.

Dick et al. also analyzed relative lateralization for both domains across a number of language-associated perisylvian regions. Language-evoked activation was significantly L > R in all region of interests (ROIs) except the angular and supramarginal gyri, the transverse gyri, and the opercular part of the IFG. Unlike language, environmental sounds showed significant L > R activation only in the inferior temporal gyrus (ITG). However, environmental sounds did *not* show any significant lateralization effects in the opposite (R > L) pattern. Finally, using data derived from the lesion-mapping study of Saygin et al. (2003), Dick et al. (2007) also found that the more consistent the mapping between environmental sounds behavioral deficit and lesion was in a given left hemisphere region, the more environmental sounds activation they observed in typical participants. Notably, this held true not only *within* but *across* domains—that is, lesion maps associated with environmental sound behavioral deficits predicted degree of fMRI activation for matched verbal phrases sounds in healthy controls.

89.4.2.4 fMRI Studies of Cross-Modal Priming with Environmental Sounds

In an fMRI cross-modal and cross-domain priming paradigm that paralleled the behavioral and ERP/EEG studies reviewed, Noppeney, Josephs, Hocking, Price, and Friston (2008) presented participants with written words or pictures, and then with sounds or spoken words that were semantically congruent or incongruent with the visual display. To engage semantic processes, subjects made weight judgments about the sound source. Both spoken words and environmental sounds showed increased activation in the left inferior frontal sulcus and pre-supplementary motor area (pre-SMA) when semantically incongruent with the preceding written word or picture. Domain-specific effects were found in the left STS, where semantic incongruity effects were greater for spoken words than for environmental sounds, whereas the opposite effect was found in left posterior parietal cortex (environmental sounds >> words). These results contrast somewhat with those of Galati et al. (2008), who found action sound–specific increases for *congruent* versus *incongruent* written-word/environmental sound pairs in the left inferior frontal sulcus (IFS) as well as in the left ventral inferior frontal gyrus. It is possible that these results may be due to the particular stimuli used by Galati et al. (2008), who used highly somatotopically specific classes of environmental sounds. In addition to their semantic congruency effects, they found that “hand-related” sounds like clapping showed more activation than mouth-related vocalization-type sounds in the left inferior frontal sulcus, whereas the converse held true in bilateral STG/STS, where mouth-related sounds were greater than hand-related sounds. Gazzola, Aziz-Zadeh, and Keysers (2006) also demonstrated that mouth motor and somatosensory regions showed fMRI BOLD activation for mouth-related sounds than hand-related sounds, whereas hand movement–related somatomotor areas show activation for hand-produced sounds over mouth-produced sounds.

89.4.2.5 Categorical Representations of Sound Categories

The representation of sound category—particularly with reference to the body part involved in generating the sound—has been of particular interest in environmental sound research, given the relevance to “mirror neurons” (Rizzolatti, Luppino, & Matelli, 1998) and theories of embodiment in cognition (Glenberg & Robertson, 2000). In an influential fMRI study, Lewis, Brefczynski, Phinney, Janik, and DeYoe (2005) asked healthy participants to listen to a series of animal-related and tool-related sounds with their eyes closed and to respond silently in their heads regarding

whether the likely sound source was a tool or an animal. They found that animal sounds (primarily vocalizations) evoked significantly stronger activity than tool sounds along middle portions of the STG bilaterally (similar to the results of Galati et al., 2008), whereas tool sounds preferentially activated multiple left motor and somatosensory regions (mIFS, vPMC, iPS, AIP) along with the right pMTG/STS.¹⁵ By comparing the sound activation results with those of a “virtual tool use” functional localizer with a subset of the same participants, Lewis and colleagues (Lewis et al., 2005; Lewis, Phinney, Brefczynski-Lewis, & DeYoe, 2006; Lewis et al., 2011) showed that these tool sound activations overlapped extensively with regions engaged with virtual tool manipulation, that the lateralization of the tool sound activations corresponded closely to the handedness of the individual, and that these activation patterns can be tuned by training. Moreover, they showed that animal sounds *misperceived* as tools showed “tool-like” activation, suggesting that it is the *percept* of tool use and not the acoustics driving this effect. In contrast, activation patterns of miscategorized animal vocalizations were very similar to those for correctly perceived animal vocalizations (with more activation in mSTG); therefore, this animal sound response preference is likely to be due to acoustic rather than perceptual processing (a question more thoroughly analyzed in Lewis et al., 2012).

Direct analyses of the effect of different environmental sound semantic and acoustic properties on activation patterns has been investigated by Giordano et al. (2012) and Lewis et al. (2012), who showed that acoustics of sound objects appear to be coded in different temporal regions. Giordano et al.’s multivariate pattern classification results with different acoustical properties of auditory objects suggested that lateral Heschl’s and mid-STG regions tend to code for cross-object similarity in median pitch, with perceived loudness also preferentially encoded in left lateral Heschl’s STG and with right anterior STG particularly sensitive to structure in the flux of an auditory object’s spectral centroid. Giordano et al. (2012) also suggest that some categorical information about auditory objects—for instance, whether they are generated by living or non-living objects, or by human/nonhuman agents—is represented in lateral pSTG. The combination of acoustical and informational analyses toggled with high-resolution fMRI and multivariate pattern analysis (MVPA) of environmental sounds have also been very useful in unveiling fundamental coding principles of human auditory cortex (Moerel, De Martino, &

Formisano, 2012; Moerel et al., 2013). One promising avenue for future research is to use parametric variation of different perceptual dimensions inherent in environmental sounds to characterize the informational divisions that might underlie auditory functional organization (for an example of this approach, see Lewis et al., 2011).

In summary, the functional neuropsychological and neuroimaging findings converge on several key results. Both environmental sound and spoken language processing largely share neural resources centered on classical language and auditory processing regions. Functional neuroimaging suggests a bilateral temporal-parietal auditory system with a slight bias toward more right-lateralized processing for environmental sounds. However, there are circumstances when the two dissociate, which is accentuated by the specific auditory or cognitive task required. The neural organization of environmental sound processing is particularly dependent on cross-modal processes, such as somatosensory and visual information, and is dependent on actions associated with the sounds. More generally, the neural organization of environmental sounds processing in auditory and auditory association regions, such as those in the lateral STG, reflects basic acoustical properties of the sound.

89.5 CONCLUSION

Many of the processes involved in processing environmental sounds are highly similar to those for spoken language. Behaviorally, we see that, across the lifespan, we are experts at identifying environmental sounds, and that individual variability in performance on environmental sounds can resemble that observed in word comprehension. Further, factors such as frequency, length, and imageability affect ES comprehension as they do word comprehension. Equally, semantic and contextual factors are major determinants in ES comprehension. From a neural perspective, although much has been made of differences between spoken language processing and environmental sound processing (e.g., a right-lateralized bias for ES), the similarities are more striking. Well-controlled studies of patient groups suggest that, in the majority of cases, language and environmental sound processing breakdown together. Most neuroimaging studies reveal a shared bilateral network of regions for spoken language and environmental sounds, with within-environmental sound variability in activation often greater than the

¹⁵Using an fMRI adaptation paradigm, Doehrmann, Naumer, Volz, Kaiser, and Altmann (2008) showed a somewhat different pattern of tool and animal response preference, where adaptation to animal sounds was shown in bilateral anterolateral STG and transverse gyri, whereas adaptation to tools was most prominent in several patches in the left insula.

difference between environmental sound and spoken language networks.

These similarities in the neural “territory” for both environmental sounds and language are interesting given the considerable differences between environmental sounds—which are highly iconic, source-bound, and acoustically variable—and spoken language—with its complex syntactic organization, almost obligatory communicative content, and more abstract sound-to-meaning mapping. It is an exciting challenge for the neurobiology of language to understand how highly overlapping brain networks are able to learn and represent such disparate domains.

 Grammar of a language, 156
 Grammatical encoding, 210–211
 production models of, 210–211

- Grammatical processing, influence of AoA on, 412–415
- Granger causality (GC) method, 811–812
advantages, 812
connectivity of bilateral temporoparietal areas (TPAs), analyses, 812
reading network example, 812
- Granger causes, 811
- Graphemes, 791
- Grapheme-to-phoneme process, 792
- Graph theory, 400–401
- Graph theory method
advantages, 813
reading network example, 813
- Gray matter density, 384
across age, 408
- Gross deficits in language development, 879
- Grounded cognition, 647–648
- Grounding problem, 777–778
- ## H
- Habit learning, 846
- Haloperidol, 91
- Hand-action-verb processing, 782–783
- Hebbian learning, 311
- Hemianopic alexia, 794
- Hemingway, Ernest, 661
- Hemispheric asymmetries in human speech perception, 291
- Hemispheric specialization in phoneme perception, 457–458
- Hereditary ataxia, 77–78
- Heschl's gyrus (HG), 49, 287–288, 482–483
- H&H Theory, 186
- Hierarchical processing, 289
- Hierarchical State Feedback Control (HSFC)
model, 733–736, 734f
advantage of, 736
basic planning unit, 735
somatosensory target map in, 735
speech production, 735
vs DIVA model, 735
- Higher-order association cortices, 778
- High-N nonwords, 259–260
- High-resolution functional brain imaging, 4
- Hippocampus, 842, 954–955
and acquisition of language, 848–849
- Hub-and-spoke hypothesis, 765–766, 766f, 771
- Human auditory cortex
cortical field maps, 49–50
cortical organization in, 51–52
cortical periodotopic responses, 53
tonotopy, 50
- Human brain, 6–7
- Human cerebellum
contributions to motor control, 76–77
phoneme-boundary effect, 81–82
speech, 77–80
contributions to nonmotor functions, 80–82
speech and nonspeech auditory perception, 81–82
macroscopic and microscopic anatomy of, 73–76, 74f, 75f
afferent systems, 75
cerebrocerebellar circuitry, 74–75
cortex of, 75
functional compartmentalization, 75–76
inferior peduncle, 73
medial peduncle, 73
pontine nuclei, 74–75
Purkinje cells, 75
superior peduncle, 73–74
perspectives on size and composition, 76
- Human embryonic stem cells (hESCs), 1086–1087
- Human genome, 13
- Human-induced pluripotent stem cells (hiPSCs), 1087–1088
- Human motor cortex, 65–67
Broca's area, 65–66
human M1, 65
mirror mechanism of, 66
involved in imitation, 66–67
motor-evoked potentials (MEPs), 66–67
observation/execution condition, 67
"observation/execution" condition, 67
somatotopic organization of areas in, 66
posterior clusters, 65
primary motor cortex, 65
- Human neural stem cells (hNSCs), 1086
adult/fetal, 1086
- Human speech perception, 287. *See also*
Speech perception
neural basis of, 288
- Huntington's chorea, 88
- Huntington's disease (HD), 85, 89–90, 532
- Hypokinesia, 90, 986–987
- Hypophonia, 90
- ## I
- IFGpo, 693–694
- Imitation learning, 66–67
cortical activations in, 67
parsing and sensory motor transformation, 67
two-step model of, 67
- Immediate serial recall (ISR) task, 856
- Impaired phonological processing, 327
- Impaired semantics, 783
- Implicit learning, 211–214
phonotactic learning, 213–214
structural priming, 212–213
of words and phrases, 211–212
- Independent component analysis (ICA), 40–41, 751–752, 754–756, 758–759, 760f, 806
reading network example, 806
- Indexical information in speech, 247–248
- Inferior cerebellar circuit, 986
- Inferior frontal gyrus (IFG), 25, 27, 325, 330–333, 349–350, 353–354, 408–409, 455–456, 599, 663, 694, 702, 729, 805–806, 817, 900, 903, 913–914, 1015, 1057
posterior part of, 25–27
response to gestures, 391
semantic relation between gesture and speech, 391–392
statistical information processing, role of, 531
ventral pathway, 354
- Inferior frontal-occipital fasciculus (IFOF), 132, 330
cortical terminations of, 133
DES of, 133
in verbal and nonverbal semantic processing, 133
- Inferior parietal lobe (AG/SMG), 663
- Inferior parietal lobule (IPL)
connectivity of
with human, 38
with monkey, 38–39
functions and functional connectivity
language and speech, 39–41
motor functions and interaction with objects, 41–42
spatial functions, 42–43
gross anatomy of, 35
neural activity in caudal, 40
organization of between humans and monkeys, 39
parcellations of, 35–37, 39
cytoarchitectonic characteristics, 37
in human, 35–37, 36f
in monkey, 37
rostro-caudal tripartition of, 35–36
scheme of Vogt and Vogt, 35–36
- Inferior temporal gyrus (ITG), 544
- Informational masking, 494–495
- Information contingent processing, 198
- Information theory, 528
- Information-density sensitivity, 216–217
monitoring and adjusting, 217
predictability of phonetic output, 216
syntactic flexibility, 216–217
- Information-processing model of reading, 792, 792f
- Insular aphasia, 122
- Insular cortex
behavior and, 120–121
functional relationships, 120
prominent networks for, 120–121
connectivity, 118–120, 119f
cytoarchitectural parcellations of, 115–117, 117f
VENs, 117, 118b
gross anatomy, 115
insula, 116f
anterior/inferior/posterior/superior portions, 115, 118
anterior insular gyrus (IAIG), 115
anterior IS (AIS), 115
anterior peri-IS (ApIS), 115
central insular sulcus (CIS), 115
long posterior IG (lPIG), 115
posterior peri-IS (PpIS), 115
short anterior IG (sAIG), 115
short middle IG (sMIG), 115
short posterior insular gyrus (sPIG), 115
transverse insular gyrus (TIG), 115
trapezoidal, 115
vasculature of, 117–118

- involvement in interoception and salience networks, 124–125
 speech-language production and, 122–125
- Insular infarction, 117–118
- Integrated state feedback control (SFC)
 model of speech production, 306f
- Intensive language action therapy (ILAT), 1025, 1031
- Intention processing network (IPN), 676–679, 677f
 communicative comprehension and, 681
 in comprehending communicative intentions, 679
 levels of communicative processes, 680
 as a neural substrate for pragmatic comprehension, 679
 neuroimaging studies, 677–678
 in social intention recognition and comprehension, 677
- Interactive processing, 258–259
- International Phonetic Alphabet (IPA), 141–142
 charts for American English (A) consonants and (B) vowels, 142f
- Intonation-based speech therapy.
See Melodic intonation therapy (MIT)
- Intraparietal sulcus (IPS)
 anterior part of, 37
 connectivity of
 with human, 38
 with monkey, 38–39
 functions and functional connectivity
 language and speech, 39–41
 motor functions and interaction with objects, 41–42
 spatial functions, 42–43
 gross anatomy of, 35
 within posterior parietal cortex, 35
- Invasive electrophysiological methods, 479–482, 480f
 advantages, 482
 future of, 487
 high-frequency oscillations, 481
 limitations of, 481–482
- Inverse-forward model pairs (IFMPs), 1057
- Irrelevant nonspeech presentation, 858
- Irrelevant sound effect, 866
- Irrelevant speech presentation, 858
