Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication

We would like to dedicate Neurobiology of Language to all researchers and clinicians who spend their careers trying to understand human language, its neurobiological basis, and/or its neurological breakdown and rehabilitation. We would also like to thank our families for their support of our own careers that have aimed to understand all three of these aspects.

SECTION A

INTRODUCTION

1. The Neurobiology of Language

STEVEN L. SMALL AND GREGORY HICKOK

1.1 History	3
1.2 Lesion Analysis	3
1.3 From Neuropsychology to Cognitive Neuroscience	4
1.4 The Neurobiology of Language	5
1.5 Some Common Fallacies	5
1.6 Humans in Particular	6
1.7 Cognition and the Neurobiology of Language	7
1.8 Brain Disease, Treatment, and the Neurobiology of Language	7
1.9 Summary	8
References	8

SECTION B

NEUROBIOLOGICAL FOUNDATIONS

2. A Molecular Genetic Perspective on Speech and Language

SIMON E. FISHER

2.1 Introduction	13
2.2 The Discovery of <i>FOXP2</i>	14
2.3 <i>FOXP2</i> Mutations in Speech and Language Disorders	15
2.4 Functions of <i>FOXP2</i> : The View from the Bench	16
2.5 Insights from Animal Models	17
2.6 <i>FOXP2</i> in Human Evolution	20
2.7 Conclusions	20
References	21

3. The Ventrolateral Frontal Region

MICHAEL PETRIDES

3.1 Cytoarchitectonic Areas of the Ventrolateral Prefrontal Cortex	27
3.2 Parietal and Temporal Cortico-Cortical Connection Patterns of the Language Production Areas in the Ventrolateral Frontal Region	28
3.3 Functional Implications	30
3.4 Non-Ventrolateral Prefrontal Areas and Their Possible Role in Language	31
Acknowledgments	32
References	32

4. On the Neuroanatomy and Functional Role of the Inferior Parietal Lobule and Intraparietal Sulcus

FERDINAND CHRISTOPH BINKOFSKI, JULIANE KLANN AND SVENJA CASPERS

4.1 Gross Anatomy of the IPL and IPS	35
4.2 Modern Parcellation of the IPL and IPS	35
4.3 Connectivity of the IPL and IPS	38
4.4 Anatomical Differences Between Humans and Monkeys	39
4.5 Functions and Functional Connectivity of the IPL and IPS	39
4.6 Summary	43
References	43

5. Human Auditory Cortex

BRIAN BARTON AND ALYSSA A. BREWER

5.1 Introduction	49
5.2 Cortical Field Maps	49
5.3 Tonotopy: The First Dimension of AFMs	50
5.4 Cortical Organization of the Monkey Auditory System	50
5.5 Cortical Organization of the Human Auditory System	51
5.6 Periodotopy: The Second Dimension of AFMs	52
5.7 Similarities to AFM Organization in the Human Visual System	53
5.8 "Clover Leaf" Clusters Across Senses	55

5.9 Conclusion	55	9.6 Models of Thalamus and Language	109
References	56	9.7 Summary and Conclusions	110
		Acknowledgments	112
		References	112
6. Motor Cortex and Mirror System in Monkeys and Humans			
GIACOMO RIZZOLATTI AND STEFANO ROZZI			
6.1 Introduction	59	10. The Insular Cortex	
6.2 Anatomy of the Monkey Motor Cortex	59	JESSICA D. RICHARDSON AND JULIUS FRIDRIKSSON	
6.3 The Human Motor Cortex	65	10.1 Gross Anatomy	115
6.4 Motor System and Communication	67	10.2 Cytoarchitecture	115
6.5 Conclusion	68	10.3 Vasculature	117
Acknowledgment	69	10.4 Connectivity	118
References	69	10.5 Insular Cortex and Behavior	120
		10.6 Association with Speech—Language Behavior	122
		References	125
7. Cerebellar Contributions to Speech and Language			
HERMANN ACKERMANN AND BETTINA BRENDEL			
7.1 Introduction	73	11. White Matter Pathways in the Human	
7.2 Macroscopic and Microscopic Anatomy of the Human Cerebellum	73	HUGUES DUFFAU	
7.3 Comparative Anatomic Perspectives on Size and Composition of the Cerebellum	76	11.1 Introduction	129
7.4 Cerebellar Support of Motor Control in Humans: Upper Limb Movements	76	11.2 Projection Pathways	130
7.5 Contributions of the Cerebellum to Speech Motor Control	77	11.3 Long-Distance Association Pathways	131
7.6 Engagement of the Cerebellum in Nonmotor Functions	80	11.4 Implication of a Hodotopical View of Brain Organization in Humans: Rethinking the Connectivity of Language and Its Relationships with Cognition	133
7.7 Conclusion	82	11.5 The Limiting Role of Axonal Connectivity in Brain Plasticity	134
References	82	11.6 Conclusion	135
		References	135
8. The Anatomy of the Basal Ganglia			
KATE E. WATKINS AND NED JENKINSON			
8.1 Introduction	85	SECTION C	
8.2 Historical Background	85	BEHAVIORAL FOUNDATIONS	
8.3 Overview of Basal Ganglia Anatomy	86	12. Phonology	
8.4 The Role of the Basal Ganglia in Speech Motor Control	90	WILLIAM J. IDSARDI AND PHILIP J. MONAHAN	
8.5 The Role of the Basal Ganglia in Language	91	12.1 Introduction	141
8.6 Segregated Functional Loops for Speech and Language	92	12.2 Speech Sounds and the MAP Loop	141
8.7 Summary	92	12.3 Features or the Internal Composition of Sounds	145
References	92	12.4 Local Sound Combinations and Chunking	147
		12.5 Nonlocal Sound Combinations	148
		12.6 Summary	149
		References	149
9. The Thalamus and Language			
DANIEL A. LLANO			
9.1 Overview of Thalamic Organization	95	13. Morphology	
9.2 Defining the Role of the Thalamus in Language	96	ALEC MARANTZ	
9.3 A Thalamic “Locus” for Language?	103	13.1 Introduction	153
9.4 Imaging of the Thalamus in Language Tasks	105	13.2 Why Morphology?	154
9.5 Thalamic Circuitry and Physiology	107	13.3 What Makes Morphology, Morphology	156

13.4 Types of Morphemes, Types of Morphologies, Types of Morphological Theories	157	17.3 Adaptive Processing and Perceptual Learning	198
13.5 The View from Above	160	17.4 Empirical Evidence for Active Processing in Talker Normalization	200
13.6 Words and Rules: The Modern Consensus on Decomposition	161	17.5 Toward an Active Theory of Contextual Normalization	201
Acknowledgments	163	17.6 Neurobiological Theories of Speech Perception	202
References	163	17.7 Subcortical Structures and Adaptive Processing	204
14. Syntax and the Cognitive Neuroscience of Syntactic Structure Building		17.8 Conclusion	205
JON SPROUSE AND NORBERT HORNSTEIN		Acknowledgments	206
14.1 Introduction	165	References	206
14.2 A Brief History of Syntactic Theory	166	18. Successful Speaking: Cognitive Mechanisms of Adaptation in Language Production	
14.3 Two Concrete Examples of Syntactic Structure-Building Computations	168	GARY S. DELL AND CASSANDRA L. JACOBS	
14.4 Additional Properties of Syntactic Theories That One Would Expect from a Theory of Cognitive Computations	170	18.1 Language Production	209
14.5 The Collaboration Necessary to Engage in This Program	171	18.2 Long-Term Speaker Tuning: Implicit Learning	211
14.6 Challenges to This Research Program	172	18.3 Short-Term Speaker Tuning	214
14.7 Conclusion	173	18.4 Conclusion	218
References	173	Acknowledgments	218
15. Speech Perception as a Perceptuo-Motor Skill		References	218
CAROL A. FOWLER		19. Speech Motor Control from a Modern Control Theory Perspective	
15.1 Introduction	175	JOHN F. HOUDE AND SRIKANTAN S. NAGARAJAN	
15.2 Research Findings	177	19.1 Introduction	221
15.3 Conclusion	181	19.2 The Role of the CNS in Processing Sensory Feedback During Speaking	221
References	182	19.3 The CNS as a Feedforward Source of Speech Motor Commands	222
16. Speech Perception	185	19.4 Current Models of the Role of the CNS in Speech Motor Control	224
ANDREW J. LOTTO AND LORI L. HOLT		19.5 The Concept of Dynamical State	224
16.1 Introduction	185	19.6 A Model of Speech Motor Control Based on State Feedback	225
16.2 Effects of Auditory Distinctiveness on the Form of Speech	186	19.7 SFC Models Motor Actions as an Optimal Control Process	226
16.3 Effects of Auditory Interaction on the Form of Speech	187	19.8 Speaking Behaves Like an Optimal Control Process	227
16.4 Effects of Learnability on the Form of Speech	189	19.9 SFC Explains the Task-Specific Role of the CNS in Speech Feedback Processing	230
16.5 Moving Forward	191	19.10 Is SFC Neurally Plausible?	230
References	192	19.11 SFC Accounts for Efference Copy Phenomena	231
17. Understanding Speech in the Context of Variability		19.12 Neural Substrate of the SFC Model	232
SHANNON HEALD, SERENA KLOS AND HOWARD NUSBAUM		19.13 Conclusion	234
17.1 Speech and Speakers	195	References	234
17.2 The Lack of Invariance Problem	197		

20. Spoken Word Recognition: Historical Roots, Current Theoretical Issues, and Some New Directions

DAVID B. PISONI AND CONOR T. MCLENNAN

20.1 Introduction	239
20.2 Historical Roots and Precursors to SWR	239
20.3 Principle Theoretical Issues in SWR	240
20.4 SWR and the Mental Lexicon	246
20.5 Some New Directions and Future Challenges	248
20.6 Summary and Conclusions	249
Acknowledgments	249
References	249

21. Visual Word Recognition

KATHLEEN RASTLE

21.1 The Architecture of Visual Word Recognition	255
21.2 Orthographic Representation	256
21.3 Processing Dynamics and Mechanisms of Selection	258
21.4 Visual Word Recognition and the Reading System	260
21.5 Conclusion	262
Acknowledgment	262
References	262

22. Sentence Processing

FERNANDA FERREIRA AND DERYA ÇOKAL

22.1 Sources of Information for Sentence Processing	265
22.2 Theoretical Controversies	268
22.3 Classes of Models of Sentence Processing	270
22.4 Conclusion	272
References	272

23. Gesture's Role in Learning and Processing Language

ÖZLEM ECE DEMIR AND SUSAN GOLDIN-MEADOW

23.1 Gesture Not Only Reflects Thought, It Can Play a Role in Changing Thought	275
23.2 Role of Gesture in Language Learning	276
23.3 Role of Gesture in Language Processing	279
23.4 Implications for the Neurobiology of Language	281
References	281

SECTION D

LARGE-SCALE MODELS

24. Pathways and Streams in the Auditory Cortex

JOSEF P. RAUSCHECKER AND SOPHIE K. SCOTT

24.1 Human Speech Perception	287
24.2 Where Is "Wernicke's Area"?	287
24.3 Dual Processing Streams and Hierarchical Organization in the Auditory Cortex of the Monkey	288
24.4 Dual Processing Streams in the Auditory Cortex of Humans	290
24.5 Conclusions: A Common Computational Function for the Postero-Dorsal Stream?	293
Acknowledgments	294
References	294

25. Neural Basis of Speech Perception

GREGORY HICKOK AND DAVID POEPEL

25.1 Introduction	299
25.2 The Dual Route Model of Speech Processing	299
25.3 Clinical Correlates of the Dual Stream Model	307
25.4 Summary	307
References	308

26. Brain Language Mechanisms Built on Action and Perception

FRIEDEMANN PULVERMÜLLER AND LUCIANO FADIGA

26.1 Introduction	311
26.2 Phonemes	312
26.3 Signs	314
26.4 Meaning	314
26.5 Combinations and Constructions	317
26.6 Speech Acts and Social-Communicative Interaction	318
26.7 Outlook: Key Issues in Brain Language Research	319
Acknowledgments	321
References	321

27. The Dual Loop Model in Language

CORNELIUS WEILLER, TOBIAS BORMANN, DOROTHEE KUEMMERER, MARIACHRISTINA MUSSO AND MICHEL RIJNTJES

27.1 Patients	327
27.2 Neuropsychology	328

27.3 Functions of the Dual Loop Model	329
27.4 Anatomy, Hubs, Divisions	329
27.5 Development	333
References	334

28. MUC (Memory, Unification, Control):
A Model on the Neurobiology of Language
Beyond Single Word Processing

PETER HAGOORT

28.1 Introduction	339
28.2 Memory, Unification, and Control	339
28.3 The Network Topology of the Language Cortex	340
28.4 The Empirical Evidence for the MUC Model	342
28.5 A General Account of the Role of LIFC in Language Processing	343
28.6 The Dynamic Interplay Between Memory and Unification	344
28.7 Attentional Control	345
28.8 Beyond the Classical Model	345
Acknowledgments	346
References	346

29. The Neuroanatomical Pathway Model
of Language: Syntactic and Semantic
Networks

ANGELA D. FRIEDERICI

29.1 Introduction	349
29.2 From Dorsal and Ventral Streams to Fiber Tracts	349
29.3 The Neuroanatomical Pathway Model of Language	350
29.4 Conclusion	354
Acknowledgments	354
References	354

30. The Argument Dependency Model

INA BORNKESSEL-SCHLESEWSKY AND MATTHIAS SCHLESEWSKY

30.1 Introduction	357
30.2 A Brief History of the Development of eADM	357
30.3 Design Principles	358
30.4 The Model Architecture	360
30.5 Evidence for the Model	364
30.6 Consequences for Electrophysiology	366
30.7 Outlook	366
Acknowledgments	367
References	367

SECTION E

DEVELOPMENT, LEARNING, AND PLASTICITY

31. Language Development

FREDERIC DICK, SALONI KRISHNAN, ROBERT LEECH AND
SUZANNE CURTIN

31.1 Precursors to Language	373
31.2 First Words	376
31.3 Individual Variability, Developmental Trajectories, and the Vocabulary “Burst”	377
31.4 Early Language and Its Relationship to Nonlinguistic Abilities	378
31.5 Relationship Between Early Development and Later Language Abilities	379
31.6 The Relationship Between Vocabulary and Grammar	379
31.7 The Nature of Children’s Early Grammar	381
31.8 Language Development in Older Children	381
31.9 Neural Measures of Language Development	382
31.10 Conclusion	384
Acknowledgments	384
References	384

32. The Neurobiology of Gesture and Its
Development

ANTHONY STEVEN DICK AND IRIS BROCE

32.1 Exploring Gesture and Its Development at the Behavioral Level	389
32.2 Gesture and Its Development in the Context of a Broader Neurobiology of Language	390
32.3 The Neurobiology of Gesture: Electrophysiology	390
32.4 The Neurobiology of Gesture: Functional Imaging	391
32.5 The Neurobiology of Gesture Development	395
32.6 Conclusion	395
References	395

33. Development of the Brain’s Functional
Network Architecture

DEANNA J. GREENE, CHRISTINA N. LESSOV-SCHLAGGAR
AND BRADLEY L. SCHLAGGAR

33.1 What Is a Network and How Can We Study Brain Networks?	399
33.2 Organization of the Brain’s Functional Network Architecture	401
33.3 Is There a Language Network?	401
33.4 Development of Brain Networks	403

33.5 Implications of Development of Brain Networks to Language-Related Brain Regions	404
33.6 Future Directions	405

55. Neurobiology of Speech Production: Perspective from Neuropsychology and Neurolinguistics

SHEILA E. BLUMSTEIN AND SHARI R. BAUM

55.1 Introduction	689
55.2 Historical Perspective: Speech Production Deficits in Aphasia	689
55.3 Phonological Processes in Speech Production	690
55.4 Phonetic Processes in Production	692
55.5 Summary	696
Acknowledgments	697
References	697

56. Word Production from the Perspective of Speech Errors in Aphasia

MYRNA F. SCHWARTZ AND GARY S. DELL

56.1 Speech Errors in Aphasia: The Neurological Tradition	701
56.2 Two Stages of Lexical Access in Production	703
56.3 Model-Inspired Lesion Analysis of Semantic Errors	705
56.4 Summation Dual-Route Model of Repetition	707
56.5 Implications for Neurocognitive Models of Language	710
56.6 Conclusion	711
Acknowledgments	712
References	712

57. Motor-Timing and Sequencing in Speech Production

SONJA A. KOTZ AND MICHAEL SCHWARTZE

57.1 Formal and Temporal Prediction: Fundamentals in Speech Processing	717
57.2 A Synchronized Speech Processing Mode	718
57.3 Timing Speech: Subcortico-Cortical Interactions	720
57.4 Conclusion	722
References	723

58. Neural Models of Motor Speech Control

FRANK H. GUENTHER AND GREGORY HICKOK

58.1 Introduction	725
58.2 The Planning of Speech Movements	726
58.3 Brain Regions Involved in Speech Articulation	727
58.4 Neurocomputational Models of Speech Production	727
58.5 The DIVA Model	728
58.6 The GODIVA Model of Speech Sound Sequencing	733
58.7 The HSFC Model	733
58.8 Future Directions	736
Acknowledgments	737
References	737

59. Neurobiology of Speech Production: A Motor Control Perspective

PASCALE TREMBLAY, ISABELLE DESCHAMPS AND
VINCENT L. GRACCO

59.1 Introduction	741
59.2 Neurobiology of Speech Motor Control	741
59.3 Speech Movement Execution	744
59.4 Feedback Processing and Sensory-Motor Integration	745
59.5 Conclusion	746
Acknowledgments	746
References	747

60. Sentence and Narrative Speech Production: Investigations with PET and fMRI

RICHARD J.S. WISE AND FATEMEH GERANMAYEH

60.1 Introduction	751
60.2 What Have We Learned from Meta-Analyses of Language Studies	754
60.3 Narrative Speech Production	756
60.4 Functional MRI Studies of Sentence Production	758
60.5 Conclusion	760
References	761

CONCEPTUAL SEMANTIC KNOWLEDGE

61. The Hub-and-Spoke Hypothesis of Semantic Memory

KARALYN PATTERSON AND MATTHEW A. LAMBON RALPH

61.1 Introduction	765
-------------------	-----

61.2 The Importance of the Spokes and the Regions from Which They Emanate	766	64.5 Conclusions	813
61.3 The Insufficiency of the Spokes and Their Sources: Why We Need a Hub	767	References	813
61.4 Why Should the Hub Be Centered on the ATL?	769	65. Developmental Dyslexia	
61.5 Evidence for and Possible Reasons for a Bilateral ATL Hub	770	GUINEVERE F. EDEN, OLUMIDE A. OLULADE, TANYA M. EVANS, ANTHONY J. KRAFNICK AND DIANA R. ALKIRE	
61.6 The Graded Hub Hypothesis	772	65.1 Introduction	815
61.7 Concluding Comment	773	65.2 Functional Anatomy of Reading	816
References	773	65.3 Neuroanatomical Bases of Dyslexia	816
62. What Does It Mean? A Review of the Neuroscientific Evidence for Embodied Lexical Semantics		65.4 Neurofunctional Bases of Dyslexia	817
OLAF HAUKE		65.5 Genetic and Physiological Mechanisms in Dyslexia	819
62.1 Introduction	777	65.6 Neurobiology of Reading Interventions	820
62.2 Models of Embodied Semantics	777	65.7 Cause Versus Consequence?	821
62.3 Methods for Neuroscientific Research on Embodied Semantics	780	65.8 Important Variables in Studies of Dyslexia	821
62.4 Review of the Empirical Literature	780	65.9 Conclusion	822
62.5 The Influence of Task, Context, and Individual Experience	784	Acknowledgments	822
62.6 Conclusion	785	References	822
References	786

The Neurobiology of Language

Steven L. Small¹ and Gregory Hickok²

¹Department of Neurology, University of California, Irvine, CA, USA; ²Department of Cognitive Sciences, Center for Language Science, Center for Cognitive Neuroscience, University of California, Irvine, CA, USA

1.1 HISTORY

For many centuries, the biological basis of human thought has been an important focus of attention in medicine, with particular interest in the brain basis of language sparked by the famous patients of Pierre Paul Broca in the mid 19th century (Broca, 1861a,c). The patient Louis Victor LeBorgne (Domanski, 2013) presented to the Hôpital Bicêtre in Paris with severe difficulty speaking, purportedly only uttering the syllable “tan,” sometimes as a pair “tan, tan,” and often accompanied by gestures (Domanski, 2013). The diagnosis was not clear until autopsy, when Broca found on gross inspection that some neurological process (he reported a resulting collection of serous fluid) had destroyed a portion of the left posterior inferior frontal gyrus (Broca, 1861c) (Figure 1.1). A subsequent patient, LeLong, had a similar paucity of speech output (five words were reported) with a lesion not dissimilar to that of LeBorgne (Broca, 1861a). Given the ongoing debates at the time about brain localization of language, including attribution of the “seat of language” to the frontal lobes (Auburtin, 1861; Bouillaud, 1825; Gall & Spurtzheim, 1809)—which led Broca to investigate this case in the first place—he presented this patient with “aphémie” (LeBorgne) to the Société d’Anthropologie de Paris in 1861 (Broca, 1861b). These brains remain preserved to this day, and brain imaging studies have confirmed the original findings and extended them to demonstrate lesions to deeper structures (Signoret, Castaigne, Lhermitte, Abelanet, & Lavorel, 1984) and to white matter underlying the original descriptions (Dronkers, Plaisant, Iba-Zizen, & Cabanis, 2007).

1.2 LESION ANALYSIS

The era of brain localization for language blossomed after this, with the famous doctoral dissertation of

FIGURE 1.1 The exterior surface of the brain of LeBorgne (“tan”).

Wernicke (1874), the diagram-making of Lichtheim (1885) (Figure 1.2) and Grashey (1885), the anatomy of Déjerine (1895), and of course many other contributors. In the past century, Norman Geschwind recapitulated and added to the language “center” models that preceded him and presented a reconceptualized “connectionist” view of the brain mechanisms of language (Geschwind, 1965, 1970). Whereas the 19th century investigators relied on simple views of behavior and postmortem brain pathology, those of the mid to late 20th century were able to take advantage of significant advances in both the study of behavior (information processing psychology and formal linguistic theory), allowing much more robust characterizations of language performance than had been possible previously (Caramazza & Berndt, 1978; Chomsky, 1965), and the technology of structural brain imaging with computed tomography and magnetic resonance imaging (MRI), permitting the elucidation of brain pathology *in vivo* (e.g., Cappa & Vignolo, 1983; Metter et al., 1984). These advances led to a blossoming of brain lesion analysis (neuropsychological) studies in the second half of the

FIGURE 1.2 Lichtheim's model. Note the emphasis on brain anatomy.

20th century (for reviews, see [Damasio & Damasio, 1989](#); [Kertesz, 1983](#); [Shallice, 1988a](#)). Recent advances in image analysis (e.g., [Ashburner & Friston, 2000](#); [Bates et al., 2003](#)) have improved the lesion analysis method, and it continues to be a valuable method for biological inquiries in language.

By their very nature, lesion analysis studies tend to relate single foci of brain injury to single psychological or linguistic phenomena. The goal of the enterprise is to “double dissociate” functions and brain regions, such that an underlying focal substrate of brain can be tied unequivocally to a single function (and not another) (e.g., [Damasio & Tranel, 1993](#)) or to a specific “locus” in a cognitive or linguistic model (e.g., [Garrard & Hodges, 2000](#); [Shallice, 1988b](#)). Although not without its controversy (e.g., [Plaut, 1995](#)), this approach has been quite successful in giving insights into the neurobiology of language, that is, attributing functions to aspects of the brain (in this case, brain areas damaged by vascular lesions—or sometimes other types of lesions).

1.3 FROM NEUROPSYCHOLOGY TO COGNITIVE NEUROSCIENCE

The advent of high-resolution functional brain imaging in the past decade of the 20th century (e.g., [Fox, Raichle, & Thach, 1985](#); [Raichle, Martin, & Herscovitch, 1983](#)), its initial applications to the study of language ([Petersen, Fox, Posner, Mintun, & Raichle, 1988, 1989](#)), and its widespread acceptance for the study of brain/cognition relations in the early part of this century have dramatically changed the conduct of studies of

brain and behavior. Although the earliest functional anatomical studies were conducted with positron emission tomography, the most recent work uses functional magnetic resonance imaging (fMRI), a noninvasive approach that does not require intravenous administration of radioactive agents. These methods permit the investigation *in vivo* of brain regions that participate in the performance of any type of task that can be performed inside of an imaging machine. By contrast, task-dependent electroencephalography (EEG), more commonly known as “event-related potentials” (ERP), permits the characterization of temporal aspects of task performance. An important, if less commonly used, method for analyzing task-dependent brain function is magnetoencephalography (MEG), which can have finer spatial resolution than EEG and higher temporal resolution than fMRI, and thus can play a particularly important role in characterizing brain processing over time. Besides these methods of activating the brain, the method of transcranial magnetic stimulation (TMS) can be used to create “reversible lesions” in the brain. The majority of contemporary research in brain–behavior relations for language uses either the older method of lesion analysis or one of these newer methods of functional activation (fMRI, ERP, MEG) or ablation (TMS). Intracranial electrical recordings in humans undergoing elective brain surgery, including both surface (electrocorticography) and deep, are becoming more commonplace. A host of other less prevalent methods also play valuable roles.

Approximately 20 years ago, the burgeoning use of these brain measurement techniques to study psychological and linguistic processes led to the creation of a new field of cognitive neuroscience. During its existence, this field has evolved into an important discipline, with the majority of top cognitive programs (and some neuroscience programs) incorporating cognitive neuroscience as an important component of curriculum and, in some cases, degree-granting status. Importantly, the evolution of this discipline has focused more on using biological methods than on asking biological questions, for example, addressing linguistic or psychological questions by measuring brain responses constitutes a significant portion—if not the majority—of scientific studies in this area. In other words, the fraction of studies that develop and test “linking hypotheses” between neural and computational systems is smaller than one would hope for in a field that targets an understanding of the *relation* between mind and brain. Addressing biological issues is far less common in this field, and most practitioners of this discipline neither study biology nor concern themselves with biological questions. Students in this area are typically not required to study cellular and molecular neuroscience, and only a portion study systems neuroscience, neuroanatomy, neurophysiology, or neurology/neuropsychology. Of course, it is also true that from the

biological side, students and researchers are not typically required to study linguistics or experimental psychology. Despite this high prevalence of nonbiological studies of cognition using brain measurement, it has become increasingly clear that the new methods of functional brain imaging, along with other methods of human and animal neuroscience, provide new avenues to investigate the actual biological substrate and computations for human language.

1.4 THE NEUROBIOLOGY OF LANGUAGE

Thus, a neurobiology of language is now possible. Until several years ago, this term was barely used, if at all, with most research focusing on neuropsychology, cognitive neuroscience, or vaguely “brain and language.” We define “neurobiology of language” as the biological implementation and linking relations for representations and processes necessary and sufficient for production and understanding of speech and language in context. Biological disciplines that are highly relevant to the neurobiology of language include the anatomy and physiology of the human brain, the network connectivity of the brain, and the multiple roles of different brain areas (relevant cognitive areas are discussed later). We also note that the basic scientific findings in this area will necessarily lead to a physiological approach to therapy for speech and language disorders (Small, Buccino, & Solodkin, 2013).

Importantly, we define the neurobiology of language as a subfield of neuroscience, requiring substantial knowledge of psychology and linguistics, sharing in its primary assumptions, methods, and questions. By way of explanation, whereas psychology is the scientific study of the human mind and its functions, especially those affecting behavior in particular contexts, and linguistics is the scientific study of language and its structure, including the study of morphology, syntax, phonetics, and semantics, neurobiology is the study of the biology of the nervous system. Whereas cognitive neuroscience emphasizes experimental psychology and brain measurements, the neurobiology of cognition emphasizes cellular and molecular neuroscience, systems neuroscience, and other biological bases of language, such as genetics. We believe that both cognitive neuroscience and the neurobiology of cognition must address the *links* between cognitive and neuroscience data, although they come from different directions. Although the neurobiology of language is primarily a field involving human subjects—and has benefited from the novel and highly robust methods of brain measurement discussed—it must also adopt the central tenets of modern biology, including the evolutionary imperative

that the human brain evolved from that of nonhuman primates, and thus the study of other species plays an important role in the investigations of the neurobiology of language (Bornkessel-Schlesewsky, Schlesewsky, Small, & Rauschecker, 2015).

A number of brain imaging methods are used for the neurobiology of cognition but do not play a significant role in cognitive neuroscience. An enormous amount of information about the neurobiology of language has been gleaned from high-resolution quantitative structural imaging of both gray matter and white matter. For the gray matter, it is possible to measure precisely and accurately whole brain and regional volumes, and for white matter, we can measure accurately anisotropic diffusion (and several other diffusivity characteristics). In both cases, the anatomical measures can be related to behavior or to functional imaging measures. At a network level, white matter pathways can be reconstructed from the diffusivity data and can be related to regional correlations of gray matter characteristics or functional brain activations. These relations between structural connectivity and functional connectivity are leading to a preliminary understanding of brain circuits for language processing.

It is also possible to make direct measurements of human neural cells when medically indicated, as in people with intractable epilepsy who are undergoing ablative brain surgery. Early work demonstrated that direct cortical stimulation could lead to alterations in language performance in humans *in vivo* (Ojemann, Ojemann, Lettich, & Berger, 1989; Penfield & Roberts, 1959). Although this technique remains viable (e.g., Duffau, 2008), recent work has used cortical recording (electrocorticography) to begin to elucidate cellular and circuit features of language representations at the level of small neuronal populations (e.g., Chang et al., 2010; Flinker et al., 2015). Many additional biological techniques, such as genetic mapping, single cell recording, pharmacological manipulation, molecular imaging, and others, are beginning to be viable for human neuroscience research.

1.5 SOME COMMON FALLACIES

From a philosophical point of view, several assumptions commonly made in contemporary research in brain–behavior relations related to language are problematic. We identify four such assumptions, which we call the (i) methodological fallacy; (ii) theoretical fallacy; (iii) uniqueness fallacy; and (iv) the mind/brain fallacy. These fallacies relate to research assumptions by investigators in the cognitive sciences that lead to inappropriate biological conclusions from otherwise well-conducted studies in cognition (not

infrequently accompanying perfectly interesting and valid cognitive conclusions). We explain these in turn.

The *methodological fallacy* assumes that if a brain measurement technique is used in a study, that study is a study of the brain. Such an assumption essentially focuses on the method that is used, for example, if a research study uses EEG or MRI, then it is a neurobiological study. This is not the case. Among the most common uses of ERP is to distinguish one linguistic or psychological model from another, and fMRI is used very commonly to distinguish individuals with one condition (medical or psychological) from another. In neither case would an understanding of the biology be necessary to achieve the goals of the study. However, it is important to note that some EEG/MEG research does aim to understand the relation between neural network rhythms and cognitive processes, and much fMRI research also addresses neural computations. In summary, studies of this sort do not address linking hypotheses, although data from these studies could be used to inform linking relations.

The *theoretical fallacy* assumes that a theoretical model developed exclusively from assumptions about linguistic data or cognitive processing explains brain function. Such an assumption essentially ignores data from neuroscience while focusing on theoretical aspects of the legal utterances (linguistics) or processes (psychology) in one or more (or even “all”) languages. Even if a theory accounts for all legal utterances in all languages but does not say how brain structures actually compute them, it is not a theory of the biology of language. Of course, if a biological theory ignores the *linkages* between the neurobiology and cognition, it also is not a theory of the neurobiology of language.

The *uniqueness fallacy* is perhaps the most important because it ignores evolution, which is one of the most important principles of modern biology. This fallacy typically arises in the form of arguments that human language is so unique and so special that it is not computationally intertwined with other systems. But we know that language systems of the brain are fundamentally and inherently intertwined with those that process motor function, sensation, emotion, affect, and other aspects of human experience, and that the human brain—including those parts of the brain that participate in language processing—had to evolve from the brains of species (i.e., nonhuman primates) that do not use language. The evolutionary principles of phylogeny and ontogeny apply to the human brain as with other organ systems, and thus language representations in the brain have necessarily co-opted neural structures with evolutionary history. Relevant examples include auditory object perception, motor sequence control and planning, action understanding, and social interaction, all of which are found in other species.

In summary, we are concerned with the notion that linguistic computations are so unique that they bear no evolutionary resemblance to other systems. However, we acknowledge that language uniqueness cannot be ignored. Language ability is certainly unique to our species, suggesting an evolutionary process in which language computations developed on a framework of other computational structures in the brain. It is thus critical that we take the biology seriously and search for both computational commonalities and differences between language and nonlanguage systems within our species and in our cousin species.

Finally, the most common of all the fallacies is the *mind/brain fallacy*, which argues that all studies of human psychology are *ipso facto* studies of the brain, because the brain is the biological organ that subserves thought. Of course, this is perfectly correct, to a point, and the Society for Neuroscience includes human behavior among its disciplinary mandates. However, it is completely possible—even commonplace—for studies of human behavior to completely ignore the constraints placed on the behavior by the physical aspects of the brain or the plausibility of the behavioral conclusions in the context of brain structure and function. Among the most common examples in language research are explanations of experimental data in the form of “conceptual” or “cognitive” or “mental” models that could not possibly be implemented in brain hardware.

We certainly have no objection to cognitive models and indeed value them, whether or not they make immediate contact with neural implementation. These models help us think about information flow (and/or dynamics) and computational descriptions of the process. As such, they can sometimes generate testable hypotheses related to the brain as well as provide prospective points of contact for descriptions that relate brain to behavior. If we tried to build a neurobiology of language without linguistics or psychology, as the classical neurologists were forced to do, we would not have been able to transcend the 19th century models (e.g., characterizations such as “auditory word images”). But an important point here (for the cognocentric among us) is that the constraints must work *both* ways. Knowledge of biology must constrain our models of cognitive and linguistic function, just as knowledge of cognition must constrain our biological interpretations. Both are obviously critical in the development of linking hypotheses.

1.6 HUMANS IN PARTICULAR

There is no question that the human brain is unique in its capacity to manage speech understanding and production, in addition to their evolutionarily younger derivatives, reading and writing. That the human brain

can do this and other animal brains cannot is something that must be explained in a way that preserves the basic tenets of biology. Certainly, humans have vocal communication skills of very high complexity, and these depend on a large and complex variety of sensory and motor skills, memory capacities, and learning abilities, as well as the capability to represent and process intricate messages of many types. Although it is not clear exactly what changed between nonhuman primates and humans to effectuate this, the expansion of the cerebral cortex increased the human capacity for learning, remembering, and executing motor sequences, complex perceptions, and recursive processing (e.g., theory of mind, syntax) (Hauser, Chomsky, & Fitch, 2002; Yoshida, Dolan, & Friston, 2008). It remains to be elucidated just how the processes of language work in the human brain, and through this—perhaps with concomitant work in nonhuman primates to test their limits—we should find the answer to why humans have language and other species do not.

1.7 COGNITION AND THE NEUROBIOLOGY OF LANGUAGE

The neurobiology of cognition will only be elucidated by direct investigation of how the brain works, that is, the detailed implementation of understanding and producing speech in the hardware that is unique to the human brain. At the same time, such direct investigation must be informed by scientific evidence about the nature of cognition. For the neurobiology of language, this entails understanding the nature of languages and its processing, that is, investigations in linguistics and experimental psychology. The first step must involve spoken language, because that is the evolutionary basis on which the brain architecture for written language sits.

Understanding the nature of human languages is crucial, particularly research into the wide variety of different types of languages and how they express thoughts (e.g., MacWhinney & Bates, 1989). There is nothing in the basic brain structure of people born to parents who speak Basque, Farsi, or Navaho to distinguish them from speakers of English, Italian, or German. Yet, most research studies relating brain and language have been conducted in the latter three languages (and now, increasingly, Mandarin as well), and rarely in the other approximately 7,000 languages of the world (Lewis, Simons, & Fennig, 2009), some of which have properties that are quite different from those of the most commonly studied languages. Thus, it is important in characterizing the biological basis of language to know just what needs to be accounted for both in terms of variation of language forms and the computational mechanisms used to process them.

The study of linguistics is therefore critical to a successful neurobiology of language.

Equally important is characterizing the nature of speech production and understanding in processing terms. Without detailed knowledge about what people can understand, in what contexts, and under what constraints, we cannot develop a solid neurobiology of understanding. The same is true for production, that is, we need to know what people can produce at a given time and place, particularly with memories, emotions, and goals. Such investigations are the purview of experimental psychology and, as such, research in such areas as psycholinguistics and the psychology of memory has fundamental importance to inform investigations in the biological aspects of language.

1.8 BRAIN DISEASE, TREATMENT, AND THE NEUROBIOLOGY OF LANGUAGE

There are many diseases and/or types of injury to the human brain that lead to language disturbances, and these are important to our enterprise for two reasons: (i) helping to understand the basic neurobiology and (ii) advancing knowledge useful for development of treatments for conditions that affect language. Both of these endeavors have considerable importance to the field.

By understanding the nature of disease processes, it may be possible to gain insight into the fundamental neurobiology of language itself. For example, the cellular and molecular biology of language has been given a first hearing with the distinct pathological markers that differentiate the types of primary progressive aphasia (Gorno-Tempini et al., 2011). The entire history of research in the biological basis of language has depended significantly on inferences from individuals with ischemic stroke (e.g., Mohr, 1976). Patients surviving herpes simplex encephalitis, a multifocal disease, have provided important fodder for inferences about semantic representations in the brain (Warrington & Shallice, 1984). Language problems arising in people with dementia, tumors, Parkinson's disease, schizophrenia, and many other diseases—combined with the nature of the pathology specific to that disease (particularly in the context of the pathology of each individual involved)—are highly informative with respect to the neurobiology of language. Additionally, people undergoing surgery for diseases such as epilepsy and brain tumors, even when they do not affect language, have generously allowed investigators to study their language intraoperatively.

Of course, a very important purpose in understanding the biology underlying language is to develop new therapies (Small et al., 2013; Small & Llano, 2009). Novel treatments including pharmacotherapy, electrical and

magnetic stimulation, and even behavioral (speech-language therapy) interventions, have been developed based on rationales that come from a better understanding of brain anatomy and physiology.

1.9 SUMMARY

In summary, investigation into the neurobiology of language has a long history, beginning even before the seminal work of the 19th century neurologists, who associated brain lesions in certain focal areas (but not others) with language impairments. However, recently, this field has had a resurgence due to the advent of extraordinary new technologies that allow *in vivo* imaging of brain structure, structure/functional relations, and temporal processing features. Although lesion analysis remains quite important—and even more valuable in conjunction with advanced imaging—the current era is marked by a predominance of investigations using brain imaging technologies (broadly speaking). These methods can be used to advance our understanding of linguistics or psychology, thus contributing in a different way to the neurobiology of language, or to advance our knowledge of the anatomy, physiology, pharmacology, and even cellular and molecular biology of language directly. Such direct investigations of the brain in conjunction with investigations into the representations and computations behind language processes represent basic prerequisites in building the future of this discipline.

The two editors of this book—without a consensus on all issues—have come to the many common understandings of the field articulated here. We are in agreement that it is important to have “theoretically precise, computationally explicit, biologically grounded explanatory models of the human brain’s ability to comprehend and produce speech and language” (Poeppel & Hickok, 2004). We are also in agreement that the basic evolutionary biology of the brain must play an important role in such a theory, for example, by understanding the relation between computational implementations of sensory and motor functions (among others) to linguistic computations (Skipper, Nusbaum, & Small, 2005). By linking biological and cognitive hypotheses into well-designed studies, it is now possible to build a true neurobiology of language.

The reviews in this book reflect a combination of articles on the neurobiology of language *per se* and on the supporting knowledge from the neurosciences and from the cognitive sciences (including cognitive neuroscience) that neurobiologists of language require to accurately characterize the neural structures and functions that implement language. Ultimately, we hope that this reference book will encourage and support

the efforts of practicing scientists and their students to delve directly into this challenging field.

A Molecular Genetic Perspective on Speech and Language

Simon E. Fisher

Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen, the Netherlands;
Donders Institute for Brain, Cognition, and Behaviour, Radboud University, Nijmegen, the Netherlands

2.1 INTRODUCTION

For decades there has been speculation about the potential contribution of inherited factors to human capacities for speech and language. Arguments for a genetic basis have drawn from an array of diverse fields and approaches, marshaling threads of evidence taken from formal linguistics, child development, twin studies, biological anthropology, comparative psychology, and so on. In recent years, through advances in molecular biology techniques, it has become possible to move beyond these indirect sources and let the genome speak for itself (Graham & Fisher, 2013). In particular, by studying neurodevelopmental disorders that disproportionately disturb speech and language skills, researchers started to identify individual genes that may be involved in the relevant neurobiological pathways.

Rather than being seriously rooted in biology (Fisher, 2006), much of the prior debate on genetic foundations of spoken language has treated genes as abstract entities that can mysteriously yet directly determine linguistic functions. Accounts that depend on “genes for grammar” and other such magic bullets are simply untenable in light of all that is known about molecular and cellular processes and how these processes are able to impact development and function of brain circuitry. The human genome comprises approximately 20,000 different protein-coding genes. Each such gene is a string of G, C, T, and A nucleotides, the specific order of which is used by the cellular machinery to thread together a specific polypeptide sequence of amino acid residues taken from 20 different types of amino acids that are available as building blocks. (Linguists might enjoy the fact that this is a discrete

combinatorial system with the potential to yield an infinite number of different amino acid strings.) The sequence of amino acids in a protein determines the way that it folds into a three-dimensional shape, and the protein’s shape determines the function that it will have in cells and in the body. In this way, the different DNA sequences of different genes are able to specify a plethora of distinct cellular proteins—enzymes, structural molecules, receptors, signaling factors, transporters, and others. Some of these proteins play roles in the ways that cells of the nervous system proliferate, migrate (move to their final position), differentiate, and form connections with each other during development; some might be important neurotransmitters or other factors that help strengthen or weaken synapses during learning. Overall, intricate webs of genes and proteins acting through complicated sequences of developmental events and via continual interactions with the environment lead to assembly of complex networks of functioning neural circuits, and it is the latter providing the behavioral and cognitive outputs of the system that we call the human brain.

Based on this, we should never expect simple direct connections between DNA and language, but this does not mean that we cannot track down genes that are most relevant to our human capacities. To the contrary, by pinpointing crucial genes (e.g., those for which mutations lead to language impairments) it is possible to gain entirely novel entry points into the critical neural pathways and use those to work toward mechanistic accounts that are properly built on biologically plausible foundations. In what follows, the promise and challenges of the approach are illustrated by focusing on *FOXP2*, a gene that is at the heart of this new paradigm.

2.2 THE DISCOVERY OF FOXP2

The starting point for the *FOXP2* story was the identification of an unusual family in which multiple close relatives suffered from similar disruptions of speech and language skills. This family, dubbed the KE family, spanned three generations and included 15 affected members as well as a similar number of unaffected relatives. Because the disorder was present in each successive generation and affected approximately half of the family members, it attracted the attention of geneticists who recognized that the pattern was consistent with dominant monogenic inheritance (Hurst, Baraitser, Auger, Graham, & Norell, 1990). In other words, it raised the remarkable possibility that this family's speech and language problems might be explained by a mutation affecting one copy of a single gene. Before any DNA investigations had even begun, commentators already began to speculate excitedly about the discovery of a "language gene" (see Fisher (2006) for a detailed account). At the same time, the affected members of the KE family became the focus of intensive neuropsychological studies to gain more insights into their profile of impairments.

According to these investigations, the most prominent aspect of the disorder is a problem mastering the coordinated movement sequences that underlie fluent speech (Vargha-Khadem et al., 1998). The affected people make articulation errors that are inconsistent (they can differ from one utterance to the next) and that become worse as the length and complexity of the utterance increases (Watkins, Dronkers, & Vargha-Khadem, 2002). These are characteristic features of a syndrome known as developmental verbal dyspraxia (DVD) or childhood apraxia of speech (CAS). The difficulties can be robustly captured by tests in which the participant is asked to repeat a series of pronounceable nonsense words of differing length and complexity (Liegeois, Morgan, Connelly, & Vargha-Khadem, 2011). CAS is generally thought of as a disorder of speech learning and production underpinned by neural deficits in the motor planning of sequences of orofacial movements. Intriguingly, the impairments in the affected KE family members are not confined to speech; they extend to the written domain, disturbing a wide range of linguistic skills, both expressive and receptive. To give some examples, affected relatives perform significantly worse than their unaffected siblings on lexical decision tasks, spoken and written tests of verbal fluency, nonsense word spelling, and processing of sentence- and word-level syntax (Watkins, Dronkers, et al., 2002). Given that these skills have developed in the context of a severe restriction in expressive skills, it is possible that such impairments are secondary consequences rather than primary deficits. In general, many

members of this family (regardless of CAS diagnosis) have a lower than average nonverbal IQ, which complicates discussions over the selectivity of the phenotype. Nevertheless, because nonverbal cognitive difficulties do not appear to cosegregate with the inherited disorder, it is argued that this is primarily a disturbance of speech and language rather than some form of general intellectual disability (Watkins, Dronkers, et al., 2002). These issues are discussed in more depth elsewhere (Fisher, Lai, & Monaco, 2003).

Screening of different parts of the genome revealed that the KE family disorder was strongly linked to genetic markers on one particular section of chromosome 7 (Fisher, Vargha-Khadem, Watkins, Monaco, & Pembrey, 1998). These markers were passed on from the grandmother to all other affected family members, but not to any unaffected relatives; that is, there was perfect cosegregation with the disorder. The molecular mapping data thus provided experimental confirmation that the speech and language problems of the family had a genetic origin and localized the responsible gene to a particular region of chromosome 7, which was given the name *SPCH1* (Fisher et al., 1998). After intensive analyses of this *SPCH1* interval (Lai et al., 2000), and aided by clues from another case (discussed later), the researchers eventually pinpointed a causative mutation in a novel gene given the name *FOXP2* (Lai, Fisher, Hurst, Vargha-Khadem, & Monaco, 2001).

FOXP2 encodes a transcription factor—a regulatory protein that is able to modulate the activities of other genes (Vernes et al., 2006). The protein does so by directly binding to the DNA of these target genes and affecting how efficiently they are transcribed into messenger RNA molecules (the templates that are used for building proteins). *FOXP2* belongs to one particular group of transcription factors defined by the presence of a special type of DNA-binding motif referred to as a forkhead-box (or FOX) domain (Benayoun, Caburet, & Veitia, 2011). All the affected people in the KE family carry the same single nucleotide change in *FOXP2*, a G-to-A transition in a crucial part of the gene (Lai et al., 2001). This missense mutation leads to alteration of the amino acid sequence of the encoded protein. The mutated protein carries a histidine (H) residue, instead of arginine (R), at a key point of the forkhead domain, that prevents it from binding to the usual target sequences and severely disrupts its function as a transcription factor (Vernes et al., 2006). (Because this amino acid substitution is at the 553rd residue from the start of the protein, it is denoted by the symbol R553H.) The mutation is in a heterozygous state in the affected KE family members, meaning that one gene copy is intact and functioning normally but the other is dysfunctional.

Thus, it was hypothesized that two functioning copies of *FOXP2* are necessary for development of proficient speech and language skills (Lai et al., 2001).

2.3 FOXP2 MUTATIONS IN SPEECH AND LANGUAGE DISORDERS

Clearly, studies of the KE pedigree were pivotal in enabling the first identification of a gene contributing to speech and language functions. This family represents the most well-characterized example in the literature with respect to both the neuropsychological profile of the associated disorder and the functional impacts of the etiological mutation (Fisher, 2007). However, contrary to the usual story popularized in media reports and many scientific commentaries, the KE family is not the sole documented case of *FOXP2* mutation. Over the years, distinct etiological disruptions of this gene have been reported in several different families and cases, ranging from point mutations (change of a single nucleotide of DNA) to gross rearrangements of chromosome 7 that disturb the entire *FOXP2* locus (Newbury & Monaco, 2010). In fact, the original *FOXP2* paper included not only the KE family mutation but also an independent case of similar speech/language problems with a chromosome 7 rearrangement disturbing the locus (case CS, which is described later) (Lai et al., 2001), something that is often overlooked by commentators.

The predominant isoform of the *FOXP2* protein is 715 amino acids long and encoded by 2,145 nucleotides of DNA (split between several different coding exons); a disruptive mutation could potentially occur anywhere within this coding sequence. For rare dominant causal variants with large effect size, such as the R553H mutation found in the KE family, it is likely that the sequence change will be “private,” meaning that it is exclusive to just one family or case. Thus, when screening *FOXP2* in new cohorts of people with speech and language problems, it is necessary to thoroughly search for any variants across the entire known coding sequence rather than simply testing for presence/absence of a previously reported mutation. When such screening efforts have been performed in cohorts of people diagnosed with speech disorders, a number of novel *FOXP2* point mutations have been uncovered. For example, Laffin and colleagues (2012) sequenced *FOXP2* in 24 probands with a strict diagnosis of CAS and found that one case carried a heterozygous missense mutation yielding an amino acid substitution (asparagine-to-histidine at position 597, i.e., N597H) just beyond the end of the FOX domain. In a previous screening study of 49 children with clinical reports of CAS, MacDermot and colleagues (2005)

identified another type of causal variant, a nonsense mutation that inserts a stop codon halfway through the gene (arginine-to-stop at position 328, i.e., R328X) that is predicted to yield a severely truncated *FOXP2* protein. This variant was in the heterozygous state, like the other etiological *FOXP2* mutations. It was found in three family members, the proband, his sister who also had a CAS diagnosis, and his mother who had a history of speech problems. A small number of other potential mutations of interest were identified by the MacDermot study, including a Q17L substitution (glutamine-to-leucine at position 17, near the start of the protein), but in those cases the causal significance was unclear because they did not cosegregate with the disorder in affected siblings (MacDermot et al., 2005; Vernes et al., 2006). Most recently, an individual with CAS was identified carrying an intragenic deletion of two nucleotides in the *FOXP2* locus predicted to yield an abnormal truncated protein (Turner et al., 2013). Specifically, the loss of the two nucleotides yields a shift in the reading frame of the coding sequence at position 415 of the protein; after this point, five novel amino acids are incorporated immediately followed by a premature stop codon. Just as for the R328X mutation, the resulting mutant protein completely lacks the FOX domain.

So far, two types of gross chromosomal rearrangements have been reported to affect *FOXP2*: translocations (Feuk et al., 2006; Kosho et al., 2008; Lai et al., 2001; Shriberg et al., 2006) and deletions (Feuk et al., 2006; Lennon et al., 2007; Palka et al., 2012; Rice et al., 2012; Zeesman et al., 2006; Zilina et al., 2012). In the translocation cases, part of chromosome 7 is exchanged with part of another chromosome; because the chromosome 7 breakpoint in these cases lies directly within (or close to) the *FOXP2* locus, this is expected to interfere with the activity of the disrupted copy (Feuk et al., 2006; Kosho et al., 2008; Lai et al., 2001; Shriberg et al., 2006). The first example of a *FOXP2* translocation was found in a child known as CS, as reported in the same paper that uncovered the KE family mutation (Lai et al., 2001). Most reported *FOXP2* translocations are *de novo*—the rearrangement is present in the case but not found in parents or siblings. However, Shriberg and colleagues identified a family (TB) in which a mother and daughter both carried the same translocation directly disrupting *FOXP2* and reported that the associated speech problems (Shriberg et al., 2006), language impairments, and cognitive profiles (Tomblin et al., 2009) were notably consistent with those previously observed for people carrying the missense mutation in the KE family (Watkins, Dronkers, et al., 2002).

In the reported large-scale deletion cases, one copy of *FOXP2* is completely lost from the genome, often together with other flanking genes (Feuk et al., 2006;

Lennon et al., 2007; Palka et al., 2012; Rice et al., 2012; Zeesman et al., 2006; Zilina et al., 2012). Investigations of the phenotypes observed in these cases again support the idea that damage to one copy of *FOXP2* is sufficient to derail speech and language development, although the larger deletions that encompass multiple other genes are often noted to include additional problems. As with the translocations, although most cases are *de novo*, there is at least one report of an inherited rearrangement: a mother and a son carrying the same deletion of *FOXP2* (as well as neighboring genes *MDFIC* and *PPP1R3A*) and both diagnosed with CAS (Rice et al., 2012). Interestingly, there are no reports of any human with disruption of both copies of *FOXP2*, presumably because a total absence of the gene would be lethal (Fisher & Scharff, 2009).

2.4 FUNCTIONS OF FOXP2: THE VIEW FROM THE BENCH

The identification of a particular gene underlying a trait is often portrayed as the endpoint of a scientific study. In reality, this kind of discovery is more akin to a new beginning because it opens up entirely novel avenues for investigating the basis of the trait from the perspective of the gene in question. Thus, the identification of *FOXP2* may have been something of a paradigm shift for the language sciences because it facilitated a series of innovative molecular investigations into the neurobiological pathways and evolutionary history of spoken language using this gene as a unique entry point (Fisher & Scharff, 2009). Such work has called on a diverse array of experimental strategies and model systems, ranging from neuronal cells investigated at a laboratory bench, to genetic manipulations in animals, to studies of humans (Graham & Fisher, 2013).

Laboratory experiments using genetically modified human cells are important for establishing whether putative etiological mutations impact gene function (Deriziotis & Fisher, 2013). As noted, several different point mutations of *FOXP2* have been found in people with CAS; some cosegregate with disorders in a family, like the R553H substitution and the R328X truncation, whereas others are found in just a single proband, such as the Q17L (MacDermot et al., 2005) and N597H substitutions (Laffin et al., 2012). Vernes and colleagues (2006) studied the functional significance of R553H, R328X, and Q17L variants by expressing the mutated proteins in cultured human cell lines, assessing properties such as protein stability, intracellular localization (normal *FOXP2* protein is located in the nucleus of the cell), DNA-binding capacity, and ability to repress target genes. R553H and R328X showed obvious disruptions in most or all of

these assays, strongly supporting their causal roles, whereas Q17L did not show any functional differences from the normal protein in this system, so its etiological relevance remains uncertain (Vernes et al., 2006). At the time of writing this book, no functional analyses of the N597H substitution had yet been reported.

Crucially, even though they involve rather basic model systems (as compared with neural circuits or living brains), cell-based analyses can go well beyond simply validating disruptive effects of mutations. By applying state-of-the-art genomic and proteomic techniques, researchers can use cellular models to gain new insights into neurogenetic mechanisms, which can have direct relevance to human biology (Deriziotis & Fisher, 2013). The *FOXP2* literature provides particularly apt illustrations of this principle in action. Because *FOXP2* encodes a transcription factor working to regulate the expression of other genes, it can be thought of as a hub in a network of molecules, a number of which might also be related to speech and language development. Thus, over the years, several studies have used cellular models to screen parts, or all, of the genome, searching for target genes regulated by *FOXP2* (Konopka et al., 2009; Vernes et al., 2007, 2008).

In 2008, a study of human neuron-like cells grown in the laboratory found that the *FOXP2* protein binds directly to a regulatory sequence within a gene called *contactin-associated protein-like-2*, or *CNTNAP2* (Vernes et al., 2008). The researchers went on to show that when they artificially increased expression of *FOXP2* in cultured cells, this caused a significant reduction in *CNTNAP2* mRNA levels, a finding that was further supported by analyses of developing cortical tissue from human fetuses, in which there was an inverse correlation between expression levels of the two genes. To test for connections between *CNTNAP2* and language development, the team assessed sets of common DNA variations (single-nucleotide polymorphisms [SNPs]) from different parts of the gene in a cohort of 184 families with typical forms of specific language impairment (SLI) previously collected by the UK SLI consortium. They identified a cluster of SNPs in one section of the gene (around exons 13–15) that showed association with measures of performance on language tasks, most notably the nonsense word repetition test; children who carried a particular set of risk variants scored significantly lower than others (Vernes et al., 2008). Intriguingly, in a prior study screening *CNTNAP2* in children with autism, the same risk variants had been associated with delayed language, as indexed by “age at first word” (Alarcon et al., 2008). Because the Vernes et al. (2008) study explicitly excluded any children diagnosed with autism, the convergent findings suggest that the *CNTNAP2* risk variants might be implicated in language-related problems across distinct clinical boundaries of neurodevelopmental disorders.

In a later study, the same variants were shown to be consistently associated with assessments of early language acquisition (at 2 years of age) in 1,149 children from the general population, suggesting that the effects extend beyond disorder into normal variation (Whitehouse, Bishop, Ang, Pennell, & Fisher, 2011).

CNTNAP2 is a member of the neurexin superfamily that encodes a transmembrane protein that has been implicated in multiple fundamental processes in the developing and mature nervous system (Rodenas-Cuadrado, Ho, & Vernes, 2013). It helps to cluster potassium channels at nodes of Ranvier in myelinated axons, and it has also been linked to mechanisms of neuronal migration, dendritic arborization, and spine formation during development (Anderson et al., 2012). Diverse *CNTNAP2* variants (rare mutations and common polymorphisms) have been associated with a range of neurodevelopmental disorders, including not only SLI and autism but also epilepsy, schizophrenia, Tourette syndrome, and intellectual disability (Rodenas-Cuadrado et al., 2013).

After the identification of the *CNTNAP2* connection, additional functional reports have further demonstrated the value of tracing *FOXP2* networks for understanding language-related disorders. *FOXP2* has been shown to regulate *uPAR* and *SRPX2*, genes potentially implicated in a form of rolandic epilepsy that also involves speech apraxia (Roll et al., 2010). (However, see Lesca et al. (2013) for evidence that casts doubt on the role of *uPAR*/*SRPX2* in this disorder, instead implicating a different gene, *GRIN2A*). Intriguingly, *SRPX2* regulation by *FOXP2* is thought to be an important mediator of synaptogenesis (Sia, Clem, & Huganir, 2013). Other *FOXP2* targets of particular clinical relevance include the receptor tyrosine kinase *MET*, proposed as a candidate for autism (Mukamel et al., 2011), and *DISC1*, a gene that was originally implicated in schizophrenia (Walker et al., 2012).

It is not only the downstream targets of *FOXP2* that may be informative for making links to human phenotypes. Transcription factors never act alone; they work together with other interacting proteins to regulate their targets. *FOXP1* is the most similar gene in the genome to *FOXP2*. In some cells in the central nervous system, these two genes are coexpressed (Teramitsu, Kudo, London, Geschwind, & White, 2004), and the resulting proteins have the capacity to directly interact with each other, acting together to regulate targets in a coordinated manner (Li, Weidenfeld, & Morrisey, 2004). Rare causative mutations of *FOXP1* have been implicated in a small number of cases of autism and/or intellectual disability, accompanied by notably severe speech and language problems (Bacon & Rappold, 2012). Moreover, it has been shown that *FOXP1* actively represses the *CNTNAP2* gene, and an autism screening study that sequenced all human protein-coding genes identified an affected child who carried disruptive mutations in both *FOXP1* and

CNTNAP2, “hits” in two different parts of the same functional pathway (O’Roak et al., 2011). Efforts are underway to identify and characterize all the other key protein interactors in this pathway (Deriziotis & Fisher, 2013).

2.5 INSIGHTS FROM ANIMAL MODELS

The human capacity for acquiring complex spoken language appears to be unique in the natural world (Fisher & Marcus, 2006). At first glance this may seem to preclude any chance of biologically meaningful genetic studies in animal models. However, the majority of human genes did not appear spontaneously in our species (Varki & Altheide, 2005). So, after human studies have identified a gene implicated in speech and language, an obvious next step is to examine the broader evolutionary history of the gene and assess whether its function(s) in nonspeaking species can be informative for understanding its contributions to human brain development (Fisher & Marcus, 2006).

FOXP2 has a particularly deep evolutionary history, with versions of the gene described in many different vertebrate species, including monkeys (Takahashi et al., 2008), ferrets (Iwai et al., 2013), mice (Ferland, Cherry, Preware, Morrisey, & Walsh, 2003; Lai, Gerrelli, Monaco, Fisher, & Copp, 2003), rats (Takahashi, Liu, Hirokawa, & Takahashi, 2003), bats (Li, Wang, Rossiter, Jones, & Zhang, 2007), birds (Haesler et al., 2004; Teramitsu et al., 2004), reptiles (Haesler et al., 2004), and fish (Bonkowsky et al., 2008). Researchers have investigated neural expression patterns for most of these species, determining where and when the gene is transcribed and/or translated in developing and mature brain tissue. These studies found striking similarities in distantly related vertebrates, with concordant expression in neuronal subpopulations of cortex, thalamus, basal ganglia, and cerebellum. Thus, it seems likely that activities of *FOXP2* in the human brain are built on evolutionarily ancient functions in the vertebrate central nervous system (Fisher & Marcus, 2006).

As is apparent from the previous paragraph, there have been a large number of studies characterizing the corresponding versions of this gene found in different species. A proper discussion of the many findings from this research area is beyond the scope of this chapter. The interested reader is referred to recent reviews (French & Fisher, 2014; Wohlgemuth, Adam, & Scharff, 2014). Here, a sample of the work is provided, focusing on two of the most extensively studied model systems: mice and (briefly) birds (Fisher & Scharff, 2009). Much progress has already been made in uncovering relevant neural mechanisms via work with these two complementary models, and there is promise of more insights as the field develops.

The laboratory mouse is widely used in the field of neurogenetics, in large part due to the availability of a comprehensive toolkit for genetic manipulations (French & Fisher, 2014). Mice carry their own version of the *FOXP2* gene, which has the symbol *Foxp2*. The most recent common ancestor of humans and mice lived more than 75 million years ago but, despite this lengthy time since divergence, the sequence of the human *FOXP2* protein differs very little from that of its mouse counterpart (Enard et al., 2002). In a sequence of more than 700 amino acid residues, there is one small change in the length of a stretch of glutamines and three sites where one amino acid is substituted for another. In contrast to the substitutions that cause disorder, these evolutionary substitutions occur outside known domains of the protein and are predicted to have only subtle effects on function (see “*FOXP2* in Human Evolution” section for further commentary). In addition to very high conservation of protein sequence, the neural expression patterns are remarkably consistent; for example, in both humans and mice the gene is particularly highly expressed in deep layers in the cortex, medium spiny neurons in the striatum, and Purkinje cells in the cerebellum (Ferland et al., 2003; Lai et al., 2003).

Researchers have generated several different mouse models for studying *Foxp2* functions, including animals in which the gene is completely knocked out (Shu et al., 2005) and others that carry known etiological mutations that cause speech problems in humans (Groszer et al., 2008). If both copies of *Foxp2* are damaged (e.g., when mutations are in the homozygous state), then the mice cannot survive; they live for only 3 or 4 weeks after birth, during which time they develop at a substantially slower rate than normal siblings, show significant delays in maturation of the cerebellum, and have severe general problems with their motor system (Groszer et al., 2008; Shu et al., 2005). Thus, a total absence of functional *Foxp2* protein is lethal, which is consistent with the lack of any reports of humans carrying homozygous mutations in the gene. The cause of death in homozygous animals is unknown but may relate to one of the various non-neural sites in the body where *Foxp2* is expressed; for example, it is switched on in subtypes of cells in the lungs and cardiovascular system (Li et al., 2004). As a brief aside, transcription factors and other regulatory molecules are typically expressed in a range of tissues and cell types in different organs of the body. They exert distinct effects at different sites, depending on the sets of cofactors that they interact with, which is another example where biology takes advantage of the power of combinatorial systems and is a reminder of why specific “language genes” are unlikely to exist (Fisher, 2006).

Despite the associated lethality, investigations of mice that completely lack functional *Foxp2* have revealed some fundamental roles of the gene in early development

and patterning of the central nervous system (French & Fisher, 2014). The results from such studies are helping to inform hypotheses about the contributions of the human gene to development and patterning of neural circuits in our species. For example, one report used *Foxp2* mouse models to uncover networks of direct and indirect target genes during embryonic brain development (Vernes et al., 2011). The researchers found that there was an overrepresentation of genes implicated in biological processes like neurite outgrowth and axon guidance, consistent with prior findings from human cells (Spiteri et al., 2007; Vernes et al., 2007). They went on to validate this putative functional role in striatal precursor cells taken from the mouse embryos, finding that an absence of functional *Foxp2* led to reduced branching and shorter neurites in these cells (Vernes et al., 2011). Other studies of embryonic mouse cortex using different techniques (genetic manipulations in utero) have confirmed roles for *Foxp2* in neurite outgrowth (Clovis, Enard, Marinaro, Huttner, & De Pietri Tonelli, 2012) and also suggest potential functional impacts on other developmental processes such as neurogenesis (Tsui, Vessey, Tomita, Kaplan, & Miller, 2013) and neuronal migration (Clovis et al., 2012).

In stark contrast to the severe consequences of damage to both copies of *Foxp2*, mice that carry disruptions in the heterozygous state (i.e., only one copy is mutated or knocked out) live long healthy lives, usually without any obvious adverse outcome (Groszer et al., 2008). Such findings are concordant with descriptions of humans with heterozygous *FOXP2* mutations, who typically do not have associated medical problems or gross general developmental impairments (Laffin et al., 2012; Lai et al., 2001; Lennon et al., 2007; MacDermot et al., 2005; Rice et al., 2012; Shriberg et al., 2006; Turner et al., 2013).

Several studies of cognition, behavior, and electrophysiology in the heterozygous mouse models have built on prior observations that corticobasal ganglia and corticocerebellar circuits are key conserved sites of expression. Groszer et al. (2008) investigated heterozygous mice carrying the same mutation as the KE family and reported delays in learning to run on accelerating rotarods and voluntary running wheel systems against a background of normal motor behaviors. In slices taken from the brains of these mice, they also observed altered synaptic plasticity in corticostriatal and corticocerebellar circuits, most notably a lack of long-term depression for glutamatergic synapses on medium spiny neurons of the striatum (Groszer et al., 2008). A follow-up study used *in vivo* electrophysiology to record directly from medium spiny neurons in live behaving mice while the animals learned to run on accelerating rotarods (French et al., 2012). In mice that were heterozygous for the KE family mutation, compared with normal littermates, these neurons had significantly elevated basal firing

rates as well as striking abnormalities in both their modulation and their temporal coordination during motor skill learning. The discovery of disturbed striatal plasticity during learning of a complex motor task in mice is intriguing because neuroimaging studies of humans with the same mutation have independently suggested striatal dysfunction as a potential core feature of their disorder (Liegeois et al., 2003, 2011; Vargha-Khadem et al., 1998; Watkins, Dronkers, et al., 2002). Another behavioral study of this mouse model demonstrated reduced performance on a learning task in which the animals had to associate auditory signals with motor outputs (Kurt, Fisher, & Ehret, 2012). This last investigation also compared the learning dynamics with those of another mouse line that carried a different etiological mutation of *Foxp2*, reporting that the degree of impairment seemed to be affected by the type of mutation (Kurt et al., 2012).

It is interesting to note that these mouse studies uncovered effects on auditory-motor associations and motor skill learning that are not confined to the orofacial system. It remains unresolved whether such effects might be detectable in humans with *FOXP2* dysfunction (Peter et al., 2011), or if this instead points to a refinement of gene function in the human lineage. Studies of impacts of rodent *Foxp2* on vocal behaviors have yielded somewhat conflicting data (Fisher & Scharff, 2009; French & Fisher, 2014). What has been consistently established is that mouse pups that totally lack functional *Foxp2* have greatly reduced vocal output (Gaub, Groszer, Fisher, & Ehret, 2010; Groszer et al., 2008; Shu et al., 2005). Normally, when a young mouse pup is isolated from its mother and/or the nest, it produces ultrasonic calls that elicit its retrieval. When *Foxp2* is completely missing, pups produce few (if any) isolation calls; however, they do emit ultrasonic calls with complex properties when put in situations of greater stress. Although some researchers interpret these findings as evidence of specific roles of *Foxp2* in pup vocalization (Shu et al., 2005), others have pointed out that pups that lack this gene have very severe general motor problems and global developmental delay, making it impossible to draw conclusions about selective effects (Gaub et al., 2010; Groszer et al., 2008). For heterozygous mouse pups, which carry one damaged and one normal copy of *Foxp2*, there is debate regarding whether there are differences in amounts of vocalization (Groszer et al., 2008; Shu et al., 2005), and in-depth studies of properties of the vocalizations that are produced failed to find significant differences in normal littermates (Gaub et al., 2010). A study of rats reported that amounts of *Foxp2* protein are higher in brains of male pups, and that this correlates with production of a higher number of isolation calls as compared with female pups (Bowers, Perez-Pouchoulen, Edwards, & McCarthy, 2013). The researchers went on

to assess sex differences of *FOXP2* protein levels in Brodmann Area 44 of the human brain by using post-mortem tissue from a small number of 3- to 5-year-old children (five boys and five girls). One caveat is that although the male versus female samples were age-matched, they differed greatly in ethnic background, introducing a major confound. Bowers and colleagues (2013) observed higher amounts of *FOXP2* protein in the human females and interpreted this as evidence that elevated protein levels “are associated with the more communicative sex.” Given the very small number of data points (particularly from humans) and the fact that there are never going to be simplistic mappings from genes and proteins to communication skills (Fisher, 2006), this wide-reaching conclusion may be premature (French & Fisher, 2014).

At the time of writing this chapter, reports of impacts of rodent *Foxp2* on vocalization skills have focused exclusively on pup calls without describing, for example, effects on the ultrasonic “songs” of adolescent males (Fisher & Scharff, 2009). Nevertheless, although rodent vocalizations can provide a useful readout for studying the bases of social behaviors, it is thought that mice have very restricted abilities for using auditory experience to shape their vocal output (Hammerschmidt et al., 2012). Auditory-guided vocal learning is an important skill that underlies our abilities for acquiring speech, and mice are unlikely to provide an appropriate animal model for investigating this particular trait. Luckily, by looking further afield in the animal kingdom, it has been possible to find alternative model systems. Perhaps the most informative of these has been the zebra finch, a songbird that has provided entry points into both the neurobiology and neurogenetics of vocal learning.

A young male zebra finch learns its song during a critical developmental period by matching it to a template that it hears from an adult tutor (Bolhuis, Okanoya, & Scharff, 2010). Zebra finches have their own version of *FOXP2*, known as *FoxP2*. Intriguingly, expression levels of *FoxP2* in a key site of the songbird brain are correlated with changes in vocal plasticity (Haesler et al., 2004; Teramitsu, Poopatanapong, Torrisi, & White, 2010; Thompson et al., 2013). This key site is Area X, a striatal nucleus that is an essential part of a neural circuit known to mediate vocal learning. The zebra finch studies have gone beyond simply observing correlations by adopting cutting-edge molecular genetic tools to selectively reduce (“knock down”) levels of *FoxP2* expression in the living songbird brain. In a landmark paper, Haesler and colleagues (2007) reported that such *FoxP2* knockdown in Area X (but not surrounding areas) during the developmental period of song acquisition led to incomplete and inaccurate imitation of tutor song. Further studies of knockdown birds indicate that *FoxP2* loss yields reduced density for dendritic spines of spiny

neurons (Schulz, Haesler, Scharff, & Rochefort, 2010) and interferes with dopamine modulation of activity propagation in a corticostriatal pathway involved in song variability (Murugan, Harward, Scharff, & Mooney, 2013). As with the mouse models, neural plasticity in striatal circuitry emerges as a common theme associated with this gene (Murugan et al., 2013; Schulz et al., 2010). There is insufficient space available in this chapter to give a full account of all the relevant songbird studies; for further information on this burgeoning area of work, the interested reader is referred to reviews by Bolhuis et al. (2010), Scharff and Petri (2011), and Wohlgenuth et al. (2014).

2.6 *FOXP2* IN HUMAN EVOLUTION

As shown, *FOXP2* has a deep evolutionary history with conserved functions in neural plasticity of a subset of vertebrate brain circuits. However, given its known links to human speech and language, it is reasonable to ask whether the gene has changed in any interesting ways during the evolution of our species (Fisher & Marcus, 2006). Of the three amino acid substitutions that distinguish the human and mouse version of the protein, two occurred on the human lineage after splitting from the chimpanzee at some point within the past 5 or 6 million years (Enard et al., 2002). These evolutionary changes occur outside the known domains of the *FOXP2* protein and are predicted to have only subtle (if any) effects on function. Moreover, they are entirely distinct from the known mutations that have been implicated in human speech and language disorder. Nevertheless, several investigations support the idea that the differences between the human and chimpanzee proteins have some functional significance. For example, one investigation compared human neuron-like cells expressing each version of the protein and reported quantitative differences in the regulation of some of the downstream targets of this transcription factor (Konopka et al., 2009). To study their effects on a living brain, Enard and colleagues (2009) inserted the human-specific amino acids into the mouse *Foxp2* locus. Remarkably, they observed effects on neurite outgrowth and plasticity that were in the opposite direction to those seen for loss-of-function mutations of this gene (Enard et al., 2009; Groszer et al., 2008; Vernes et al., 2011), and that seemed to be specific for corticobasal ganglia circuitry (Reimers-Kipping, Hevers, Paabo, & Enard, 2011).

The timing of these amino acid substitutions has been a matter of some debate. Initial studies estimated that they had arisen within the past 200,000 years, concordant with evidence that the *FOXP2* locus had been subject to Darwinian selection during the origin of modern humans (Enard et al., 2002). However, subsequent work has

indicated that the supposedly human-specific substitutions are also found in Neanderthal samples, indicating an earlier origin and predating the human–Neanderthal split several hundred thousand years ago (Krause et al., 2007). Further investigations revealed noncoding changes (i.e., those that do not affect amino acid sequences) that occurred on the human lineage after the split from Neanderthals, and that might have affected the way that the expression of *FOXP2* is regulated. It is possible that these later changes may impact on functions of the gene and could explain the evidence of relatively recent Darwinian selection at the locus (Ptak et al., 2009). Thus, human *FOXP2* may have been subject to multiple selective events during human evolution, which might have involved modifications of its functions in neural circuitry. Obviously, we cannot go back in time to formally test whether such modifications were really relevant for the emergence of language. Regardless, based on its deeper evolutionary history, it is unlikely that *FOXP2* was a sole trigger for appearance of this complex suite of skills, but instead it represents one piece of a complex puzzle involving other factors (Fisher & Ridley, 2013).

2.7 CONCLUSIONS

FOXP2 is not the only gene to have been implicated in speech and language, although it provides perhaps the clearest links to the underlying biology. For example, studies of common forms of SLI have suggested several other candidates, like *CNTNAP2* (introduced above), *ATP2C2*, and *CMIP* (Newbury & Monaco, 2010; Newbury et al., 2009). As genomic technologies continue to advance at an astonishing rate, we can expect more and more of the critical molecules to be uncovered (Deriziotis & Fisher, 2013). This chapter has sought to provide an illustration of the new vistas that open up after the identification of a language-related gene, emphasizing that such a discovery is just a starting point for functional investigations. One emerging approach in the language sciences that has not yet achieved its full potential is that of neuroimaging genetics, that is, testing for associations between genetic variants and variability in structure and/or function of language-related circuits of the human brain. Investigations of structural and functional consequences of rare mutations associated with disorder have been informative (Liegeois et al., 2003, 2011; Vargha-Khadem et al., 1998; Watkins, Vargha-Khadem et al., 2002). However, the effects of common variations in genes of interest have been more difficult to decipher (Hoogman et al., 2014), and reports have generally been underpowered for detecting biologically meaningful effects (Bishop, 2013; Graham & Fisher, 2013). It is likely

that large-scale sophisticated studies involving genetic information, structural and function neuroimaging data, and performance on cognitive measures will yield exciting new insights. Overall, these developments in bridging genes, neurons, circuits, brains, and cognition are bringing us closer to understanding the basis of our most mysterious human capacities.

The Ventrolateral Frontal Region

Michael Petrides

Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada

The lateral frontal cortex is a heterogeneous region comprising several distinct areas that differ both in terms of their cellular architecture (cytoarchitecture) and their connections with other cortical and subcortical areas (Figure 3.1). The posterior part of the frontal lobe includes several motor and premotor areas that lie mostly on the precentral gyrus (region in white in Figure 3.1). The compact layer of small neurons (layer IV) clearly separating the pyramids of layer III from those of layer V in primary sensory cortex and other isocortical areas is difficult to discern in the motor/premotor areas because these small neurons are intermixed with larger pyramidal neurons, leading to the tradition of referring to these areas as “agranular.” However, these so-called agranular isocortical motor areas do have small interneurons and must not be confused with the truly agranular phylogenetically older areas of the limbic region of the brain (García-Cabezas & Barbas, 2014). Anterior to these motor areas are several cytoarchitectonic areas that exhibit a compact and distinct layer IV, and this region is often referred to as the “granular” frontal cortex or the “prefrontal” cortex. These prefrontal cortical areas have been shown to participate in several higher-order control processes that regulate attention to the environment, working memory, various aspects of controlled memory retrieval, and behavioral adjustment to changes in the environment (see reviews in Stuss & Knight, 2013). The part of the lateral frontal cortex that extends anterior to the precentral gyrus is traditionally divided into three gyri: the superior, middle, and inferior frontal gyri. The caudal part of the prefrontal cortex on the superior and middle frontal gyri is occupied by subdivisions of area 8, a cortical region regulating attentional processes, which is succeeded anteriorly by the mid-dorsolateral prefrontal region (area 46 and the related areas 9/46) that plays a major role in certain aspects of working memory, such as the tracking of self-generated and externally

generated events in working memory (Petrides, 1996, 2013). Although we might expect the specific roles of these areas in attentional control and working memory to be reflected in language processing, the dorsolateral prefrontal areas are not core language areas in the sense that neither fundamental language comprehension nor production is impaired.

The part of the frontal lobe that is most relevant to language processing is the inferior frontal gyrus and the adjacent ventral part of the precentral gyrus, namely the ventrolateral frontal region (Figure 3.2). The motor representation of the orofacial part of the body is found on the ventral part of the precentral gyrus (Penfield & Boldrey, 1937; Penfield & Rasmussen, 1950). The ventral part of the primary motor cortex (Brodmann area 4) that represents the orofacial musculature is largely hidden in the anterior bank of the central sulcus and, therefore, most of the cortex on the crown of the ventral precentral gyrus is occupied by premotor cortex (i.e., area 6) (Brodmann, 1909). More recent studies have identified two premotor cortical areas on the ventral precentral gyrus, a caudal one, area 6VC (ventrocaudal part of area 6; also known as area F4), and a rostral area, area 6VR (ventrorostral part of area 6; also known as area F5) (see Petrides, 2014, for details). The terms “area F1” (corresponding to area 4), “area F4” (corresponding to area 6VC), and “area F5” (corresponding to area 6VR) were proposed for comparable areas in the macaque monkey by Matelli, Luppino, and Rizzolatti (1985). Immediately anterior to the orofacial part of the precentral gyrus lies the posterior part of the inferior frontal gyrus, namely the pars opercularis, which is occupied by cortical area 44 and is succeeded anteriorly by the pars triangularis (area 45) (Figures 3.1 and 3.2).

The posterior part of the inferior frontal gyrus in the language-dominant hemisphere is traditionally considered to be the classical Broca’s region, namely the

Human

Monkey

FIGURE 3.1 Cytoarchitectonic map of the lateral surface of the human and the macaque monkey frontal lobe by Petrides and Pandya (1994). The white region on the precentral gyrus is the primary motor cortex (area 4) and the various subdivisions of the premotor region (area 6). The inset shows the location of area 44 in the macaque monkey in the fundus of the inferior limb (ramus) of the arcuate sulcus.

frontal cortical region that plays a critical role in certain aspects of language production (Friederici, 2011; Geschwind, 1970; Grodzinsky, 2000). Several attempts have been made to specify more precisely the critical zone for language within the inferior frontal gyrus on the basis of clinical–anatomical correlation studies, but these efforts had only limited success because lesions in human subjects are rarely restricted to specific

FIGURE 3.2 The sulcal and gyral morphology of the ventrolateral frontal region in the human brain. The shaded region represents the orbitofrontal cortex that is continuous with the pars orbitalis of the inferior frontal gyrus. Abbreviations: aalf, anterior ascending ramus of the lateral fissure (ascending sulcus, vertical sulcus); ascsc, anterior subcentral sulcus; cs, central sulcus; ds, diagonal sulcus; half, horizontal anterior ramus of the lateral fissure (horizontal sulcus); IFG, inferior frontal gyrus; ifs, inferior frontal sulcus; iprs, inferior precentral sulcus; los-p, posterior ramus of the lateral orbital sulcus; MFG, middle frontal gyrus; Op, pars opercularis of the inferior frontal gyrus; Or, pars orbitalis of the inferior frontal gyrus; PrG, precentral gyrus; prts, pretriangular sulcus; ScG, subcentral gyrus; STG, superior temporal gyrus; sts, superior temporal sulcus; Tr, pars triangularis of the inferior frontal gyrus; ts, triangular sulcus (incisura capitis).

subdivisions of the inferior frontal region (Mohr, 1976; Mohr et al., 1978). The syndrome of Broca’s aphasia, which is characterized by severe impairment in language production (including impaired syntactic processing), is the result of massive damage to the territory of the upper division of the middle cerebral artery and involves not only the cortical structures in the posterior part of the inferior frontal gyrus (i.e., areas 44 and 45) but also the adjacent frontoparietal opercular region and the anterior parts of the insula (Ackermann & Riecker, 2004; Baldo, Wilkins, Ogar, Willock, & Dronkers, 2011; Dronkers, 1996; Mohr, 1976). The best evidence thus far linking specific parts of the inferior frontal gyrus to language production has been obtained from electrical stimulation of the cerebral cortex under local anesthesia during brain surgery. In this approach that is motivated by the need to spare cortex critical for language during brain surgery, the critical region for speech is considered to be the part of the cortex from which dysphasic speech arrest can be evoked by the application of electrical

stimulation (Duffau, Moritz-Gasser, & Mandonnet, 2014; Ojemann, 1992; Ojemann, Ojemann, Lettich, & Berger, 1989; Penfield & Roberts, 1959; Rasmussen & Milner, 1975). Dysphasic speech arrest occurs most reliably from stimulation of the pars opercularis (area 44) (Rasmussen & Milner, 1975), although speech arrest can also be evoked from stimulation of the posterior part of area 45. Stimulation of the ventral precentral region, where the orofacial musculature is represented, also interferes with speech, primarily in the form of dysarthria and evoked vocalization responses caused by disruption of normal activity in the motor circuits necessary for speech articulation (Penfield & Roberts, 1959; Rasmussen & Milner, 1975).

The studies of Penfield and colleagues established another important region for speech on the posterior part of the dorsomedial surface of the frontal lobe, the supplementary motor area. Vocalization, as well as interference with speech, can result from stimulation of the supplementary motor area (Penfield & Welch, 1951). Several studies have shown that lesions of the dorsomedial frontal region, which include the supplementary motor area but are not restricted to it, lead to significant reduction in speech (Chapados & Petrides, 2013; Goldberg, 1985; Krainik et al., 2003; Nachev, Kennard, & Husain, 2008; Rostomily, Berger, Ojemann, & Lettich, 1991). Furthermore, three somatotopically organized motor areas just ventral and anterior to the supplementary motor region, originally shown in the monkey brain (Dum & Strick, 1993), have also been recently demonstrated in the human brain (Amiez & Petrides, 2014), and there is some evidence that the cingulate motor region may also play a role in speech (Paus, Petrides, Evans, & Meyer, 1993).

3.1 CYTOARCHITECTONIC AREAS OF THE VENTROLATERAL PREFRONTAL CORTEX

Anterior to the ventral premotor region lies a cortical area in which irregular patches of small neurons appear between the pyramidal neurons of layers III and V (Figure 3.3). This area that occupies the most caudal subdivision of the inferior frontal gyrus, the pars opercularis, is Brodmann area 44 (area FCBm of *Economo & Koskinas*, 1925) (Figure 3.1). Area 44 is succeeded anteriorly by prefrontal area 45, which lies on the pars triangularis of the inferior frontal gyrus. In area 45, the small neurons of layer IV create a compact layer and, therefore, the pyramidal neurons of layers III and V are clearly separated (compare Figures 3.3 and 3.4) (Amunts et al., 1999; Petrides & Pandya, 1994, 2002). Area 45 is further characterized by clusters of unusually large and deeply stained pyramidal neurons

FIGURE 3.3 Photomicrograph of area 44 in the human brain. Note the interrupted layer IV, highlighted with yellow. The Roman numerals I–VI mark the six layers of the cortex. Calibration bar equals 1 mm. From *Petrides* (2014) with permission from the publisher.

in the deep part of layer III, a characteristic that unambiguously differentiates area 45 from the surrounding prefrontal areas. This unusual characteristic of area 45 led *Economo and Koskinas* (1925) to refer to it as area FDI; the Greek letter Γ refers to the clusters of giant-like neurons in layer III (Figure 3.4). In conclusion, starting from the ventral part of the central sulcus where the orofacial part of the primary motor cortical area 4 is represented, and proceeding in an anterior direction, there are two premotor areas, 6VC and 6VR, that are succeeded by the transitional area 44 and, further anterior, by the prefrontal cortical area 45 (Figure 3.1).

Anterior and ventral to area 45 lies area 47/12, which occupies the pars orbitalis of the inferior frontal gyrus (Figure 3.1). Although area 47/12 has not been traditionally considered as a core language area, recent functional neuroimaging studies have suggested that it may play a major role in the controlled access to stored conceptual representations (*Badre & Wagner*, 2007) and semantic unification (*Zhu et al.*, 2012). Thus, we provide a brief discussion of its identification and cytoarchitecture here because the architectonic description of

FIGURE 3.4 Photomicrograph of area 45 of the human brain. Note the continuous compact layer IV, highlighted with yellow, which clearly separates layer III pyramidal neurons from those of layer V. Calibration bar equals 1 mm. From *Petrides (2014)* with permission from the publisher.

this cortical region has generated considerable confusion. Brodmann (1909) used the term “area 47” to refer to a region ventral to area 45 that extends through most of the caudal orbital frontal region. Brodmann (1909) commented on the heterogeneity of this region and pointed out that he did not delineate its various parts. The region included in area 47 by Brodmann ranges from a ventrolateral granular part that lies just below area 45 and exhibits a distinct layer IV which separates clearly the pyramidal neurons of layer III from those of layer V, followed by a dysgranular part in which the separation between layers III and V is interrupted and, finally, an agranular part close to the medial end of the posterior orbitofrontal region. The ventrolateral part of Brodmann area 47 corresponds to the caudal part of the area that Petrides and Pandya (1994, 2002) labeled as area 47/12 (Figure 3.1). Area 47/12 corresponds to a ventrolateral prefrontal area in the macaque monkey brain that had previously been referred to as area 12 by Walker (1940). The dysgranular part of area 47 of Brodmann, which lies on the orbital frontal cortex, was

named area 13 by Petrides and Pandya (1994, 2002) to be consistent with the label of the homologous region in the macaque monkey and should not be confused with area 47/12. Area 47/12 is a prefrontal area with a compact layer IV. It differs from area 45 in that its layer III lacks the clusters of unusually large neurons found in area 45. Thus, the distinction between area 47/12 and area 45 can be made easily, permitting a reliable placing of the border between these two areas. Nonetheless, both are related granular frontal areas and constitute the mid-ventrolateral prefrontal system for active controlled memory retrieval (Petrides, 1996, 2002).

3.2 PARIETAL AND TEMPORAL CORTICO-CORTICAL CONNECTION PATTERNS OF THE LANGUAGE PRODUCTION AREAS IN THE VENTROLATERAL FRONTAL REGION

We know from classical gross dissection studies of the white matter in human cadaver brains that various bundles (fasciculi) of cortico-cortical axons connect the inferior parietal lobule, the lateral temporal cortex, and the occipito-temporal junction region with the ventrolateral frontal cortical areas (Klingler, 1935; Ludwig & Klingler, 1956). However, neither the classical gross dissection of these fasciculi in cadaver brains nor their modern reconstructions with diffusion MRI methods in vivo can demonstrate the precise origin of these axons within specific cytoarchitectonic cortical areas or their precise termination within particular cortical areas (Campbell & Pike, 2014; Petrides, 2014; Thomas et al., 2014). The relatively recent demonstration of the homologues of the ventrolateral frontal areas 44 and 45 in the macaque monkey (Petrides, Cadoret, & Mackey, 2005; Petrides & Pandya, 1994, 2002) has permitted exploration of their precise cortico-cortical connections using invasive anterograde and retrograde tract tracing methods that are the gold standard for establishing precise connections in the brain (Frey, Mackey, & Petrides, 2014; Petrides & Pandya, 2002, 2009). More recent studies with resting state functional MRI have permitted the testing of hypotheses, based on the macaque monkey studies, regarding the connectivity patterns of the various ventrolateral frontal cortical areas in the human brain. Such studies have provided evidence that the cortico-cortical connectivity patterns of the ventrolateral frontal areas in the human brain are comparable with those established in the macaque monkey (Kelly et al., 2010; Margulies & Petrides, 2013).

As a rule, all adjacent cortical areas are interconnected. Thus, it is the distant connections of the

FIGURE 3.5 Lateral view of the left cerebral hemisphere of the human brain to illustrate the local peri-central association pathway (in red) linking the primary motor cortical area 4 and the caudal area 6 (i.e., 6VC) with somatosensory cortex on the postcentral gyrus. The cortex of the supramarginal gyrus (areas PF and PFG) and the adjacent anterior intraparietal sulcus (AIP) connect with the rostral premotor cortex (area 6VR) and area 44 via the third branch of the superior longitudinal fasciculus (SLF III) shown in green. Area 44 is also connected with the posterior part of the superior temporal region via the arcuate fasciculus (AF) shown in yellow. Note that adjacent cortical areas are connected with each other and areas 4 and 6VC also have local connections with adjacent frontoparietal opercular areas and insula, but these local connections are not shown in order not to crowd the diagram. From *Petrides (2014)* with permission from the publisher.

FIGURE 3.6 Lateral view of the left cerebral hemisphere of the human brain to illustrate parietal and temporal connections of prefrontal area 45. The cortex of the angular gyrus (area PG) connects with the cortex of the pars triangularis (area 45) via the second branch of the superior longitudinal fasciculus (SLF II). Area 45 is also connected with the posterior part of the superior temporal region via the arcuate fasciculus (AF) shown in yellow and the lateral part of the temporal lobe via the extreme capsule fasciculus (ECF). From *Petrides (2014)* with permission from the publisher.

various ventrolateral frontal areas with specific parietal, temporal, and occipital areas that require clarification. Primary motor cortical area 4 and the adjacent area 6VC are strongly connected with somatosensory cortical areas on the postcentral gyrus (Figure 3.5), therefore forming a local peri-central association system for orofacial sensorimotor control (Pons & Kaas, 1986; Vogt & Pandya, 1978). By contrast, area 6VR and area 44 are connected with the most anterior part of the inferior parietal lobule via the third branch of the superior longitudinal fasciculus (SLF III) (Figure 3.5). This is a distinct part of the parieto-frontal association fiber system, first identified in the macaque monkey (Petrides & Pandya, 1984) and later confirmed with diffusion MRI in the human brain (Frey, Campbell, Pike, & Petrides, 2008; Makris et al., 2005). In the human brain, the rostral part of the inferior parietal lobule forms the morphological entity known as the supramarginal gyrus that is occupied by area PF, anteriorly, and area PFG, posteriorly (Petrides, 2014). The rostral part of the ventral premotor cortex (area 6VR; also known as F5) has been shown to be most strongly linked with area PF while area 44 with area PFG in the monkey brain (Frey et al., 2014; Petrides & Pandya, 2009) and in the human brain (Margulies &

Petrides, 2013; Petrides, 2014) (Figure 3.5). Areas 6VR and 44 are also linked with the cortex in the anterior part of the intraparietal sulcus (area AIP).

Prefrontal area 45 has a strikingly different cortico-cortical connection profile. Area 45 is linked with the cortex in the caudal part of the inferior parietal lobule, area PG, and the nearby cortex in the intraparietal sulcus (area LIP) via the second division of the superior longitudinal fasciculus (SLF II) in the monkey brain (Frey et al., 2014; Petrides & Pandya, 2009) and in the human brain (Margulies & Petrides, 2013; Petrides, 2014) (Figure 3.6). Importantly, area 45 is additionally linked with auditory association cortical areas in the mid-section of the superior temporal gyrus and adjacent multisensory cortex in the superior temporal sulcus and adjacent middle temporal gyrus via the extreme capsule fasciculus, a bundle of axons first discovered in the macaque monkey (Petrides & Pandya, 1988, 2009) and later confirmed to exist also in the human brain (Frey et al., 2008). Area 44 receives relatively minor connections from the mid-temporal auditory and multimodal temporal cortex via the extreme capsule fasciculus (Figure 3.6).

The accumulating recent evidence regarding the precise cortico-cortical connectivity of areas 44 and 45, which in the language-dominant hemisphere of the human brain are known as Broca's region, has revealed a much richer connectivity profile than what had traditionally been presented in standard textbooks

of the neural basis of language. Under the influence of Geschwind (1970), the arcuate fasciculus, a bundle of axons arching around the end of the lateral fissure, was considered to be the main language pathway linking the temporal language comprehension region with the ventrolateral frontal region critical for speech production (Catani & Mesulam, 2008; Petrides, 2014). Diffusion MRI can easily reconstruct an arching set of fibers around the end of the lateral fissure, but it is not possible to establish the precise origin and termination of these fibers. Examination of the arcuate fasciculus in the macaque monkey brain has revealed a number of interesting details. First, the fibers originating from the crown of the most posterior part of the superior temporal gyrus do not terminate in area 44, but rather in the dorsal premotor region and adjacent dorsal prefrontal area 8Ad (Petrides & Pandya, 1988). Later, we learned that the neurons whose axons project to the ventrolateral frontal area 44 lie in the adjacent superior temporal sulcus (Frey et al., 2014; Petrides, 2014).

3.3 FUNCTIONAL IMPLICATIONS

What clues can the anatomical studies provide about the functional organization of the ventrolateral frontal region? First, it is clear that there is a distinct peri-central sensorimotor circuit formed by local association fibers that link primary motor area 4 and the adjacent caudal premotor area 6VC with the somatosensory cortex in the postcentral gyrus (Figure 3.5) and somatomotor areas in the nearby frontoparietal operculum; there are also longer connections from the motor region to the insula and the supplementary motor cortex. It is reasonable to assume that this local sensorimotor circuit underlies the most detailed aspects of orofacial articulation. Thus, lesions relatively limited to the peri-central sensorimotor cortex (including the frontoparietal operculum and adjacent insula) might be expected to result in articulatory deficits, and there is considerable evidence for such impairments in the literature (Ackermann & Riecker, 2004; Baldo et al., 2011; Dronkers, 1996; Graff-Radford et al., 2014).

The local peri-central sensorimotor circuit is succeeded anteriorly by the longer association fiber system of the third branch of the superior longitudinal fasciculus (SLF III) that links the anterior premotor cortical area 6VR and the transitional area 44 with the supramarginal cortex and the cortex in the anterior part of the intraparietal sulcus (Figure 3.5). The anterior part of the inferior parietal lobule (i.e., the supramarginal gyrus) is a multimodal cortical region with a focus on an integrated representation of the body. In the monkey, neurons in the anterior inferior parietal lobule exhibit complex body-centered responses

(Hyvarinen & Shelepin, 1979; Leinonen, Hyvarinen, Nyman, & Linnankoski, 1979; Robinson & Burton, 1980; Taira, Mine, Georgopoulos, Murata, & Tanaka, 1990). It should be noted that, in this older macaque monkey literature, areas PF and PFG were referred to as area 7b. In the left hemisphere of the human brain, this parieto-frontal circuit formed by the third branch of the superior longitudinal fasciculus (SLF III) and perhaps the arcuate fasciculus has been shown to be involved in phonological processing (Saur et al., 2008). For instance, a recent functional neuroimaging study has provided strong evidence that the supramarginal gyrus in the left hemisphere is involved in phonological processing, but there was no evidence of such processing in the posterior inferior parietal lobule, such as in area PG in the left angular gyrus (Church, Balota, Petersen, & Schlaggar, 2011). Thus, we can assume that a phylogenetically old primate parieto-ventrolateral premotor circuit controlling orofacial action has been adapted in the language-dominant hemisphere of the human brain for phonological processing.

The parietal connectivity of prefrontal area 45 is different from that of area 44 (compare Figures 3.5 and 3.6). Area 45 is linked via the second branch of the superior longitudinal fasciculus (SLF II) with the caudal part of the inferior parietal region, which in the human brain constitutes the angular gyrus (area PG) and the adjacent intraparietal sulcal cortex (Petrides & Pandya, 1984, 2009). In the human brain, there is evidence for involvement of the left angular gyrus in semantic processing (Binder, Desai, Graves, & Conant, 2009) and reading (Segal & Petrides, 2013). Furthermore, area 45 has massive connections with the auditory association region of the superior temporal gyrus and the adjacent multisensory cortex in the superior temporal sulcus and adjacent middle temporal gyrus via the extreme capsule fasciculus (Frey et al., 2008; Petrides, 2014; Petrides & Pandya, 2009). The extreme capsule fasciculus, first discovered in the macaque monkey (Petrides & Pandya, 1988) and later shown to exist also in the human brain (Frey et al., 2008), has become the focus of intense interest in recent years as possibly the ventral language system underlying semantic processing (Saur et al., 2008). Area 45 is a rather special prefrontal area. In addition to its strong connections with auditory and multisensory lateral temporal cortex related to the semantic system and its connections with the angular gyrus, it has widespread and strong connections with virtually all the other prefrontal areas. This unique prefrontal cortical area has direct access to the mid-dorsolateral prefrontal monitoring system (areas 46 and 9/46), the posterior dorsolateral attentional systems (areas 8Av, 8Ad, and 8B), and orbitofrontal emotional and motivational control systems, while at the same time having

access to auditory and semantic temporal and parietal information processing systems. Thus, it is in a critical position to mediate between widespread prefrontal control systems and the processing of language information at the highest levels. This unique connective profile led us to refer to this area as the great prefrontal integrator (Petrides, 2014).

What might be the special role of ventrolateral prefrontal area 45 and the related nearby area 47/12? There is now considerable evidence that this ventrolateral prefrontal region is critical for the active controlled retrieval of information that lies in posterior parietal cortex and the lateral temporal cortex (Petrides, 1996, 2002). The role of area 45 in the left hemisphere of the human brain can be viewed as the adapting of its general role in the active controlled retrieval of information to the retrieval of verbal information in the language-dominant hemisphere. If this argument were to be true, one might expect the left ventrolateral prefrontal region (area 45) to be critical for the retrieval of verbal information acquired in specific contexts (Petrides, Alivisatos, & Evans, 1995), the retrieval of words that belong to particular categories (Amunts et al., 2004; Poldrack et al., 1999), the retrieval of synonyms within the same language or corresponding words across languages (Klein, Milner, Zatorre, Meyer, & Evans, 1995), and, more generally, processing in the semantic system (Saur et al., 2008).

In conclusion, in the ventrolateral frontal region of the primate brain there are three distinct distributed neural circuits. First, a circuit focused on the prefrontal granular cortical area 45 (and the adjacent prefrontal area 47/12) that, via its links with the angular gyrus of the inferior parietal lobule and the lateral temporal region (auditory, multisensory, and high-level visual processing), underlies the active controlled retrieval of semantic information (Badre & Wagner, 2007; Petrides, 1996, 2002). Second, a high-level premotor circuit focused on the transitional area 44 and the adjacent rostral premotor area 6VR, via links to the supramarginal gyrus and the caudal superior temporal gyrus, appears to underlie phonological processing in the language-dominant hemisphere of the human brain. Finally, the caudal premotor area 6VC and the primary motor cortex (area 4) together with their local somatic sensory connections underlie fine aspects of orofacial articulation. How can we link these findings to language production? We argue that, regardless of whether a verbal propositional utterance is self-generated or driven by an external question, it must be initiated by the selective controlled retrieval of information that is relevant to the question that the subject must address. This type of controlled retrieval depends on ventrolateral prefrontal cortical areas 45 and 47/12. These areas are linked, in turn, with

transitional area 44, which by virtue of both its location and connections, may act as the intermediary between pure cognitive retrieval and motor articulation, such as the go-between truly prefrontal ventrolateral cortex (areas 45 and 47/12) and purely motor/premotor cortex (areas 6VC and 4). This transitional area, through its linkage with the multisensory but somatomotor focused supramarginal gyrus and the posterior superior temporal region, appears to form a critical phonological circuit. Finally, the sensorimotor peri-central circuit controls the details of articulation in speech. Thus, we can construe three levels of hierarchical processing leading from cognitive selection of what must be articulated (prefrontal areas 45 and 47/12) to high-level planning of motor/syntactical aspects of linguistic action (area 44 and rostral area 6VR) to the details of movement articulation (areas 4 and 6VC and their somatomotor connections).

3.4 NON-VENTROLATERAL PREFRONTAL AREAS AND THEIR POSSIBLE ROLE IN LANGUAGE

What might be the role of dorsolateral prefrontal areas lying on the middle and superior frontal gyrus in language? Damage to these areas yields severe impairments in certain aspects of working memory and in attention control, but there are no obvious impairments in language production or comprehension. However, one might expect the specific contribution of these areas to cognitive processing to be reflected in verbal information processing, particularly in the left hemisphere, because it is obvious that language processing involves virtually all aspects of higher cortical processing. For instance, it has been established that the mid-dorsolateral prefrontal cortical region (areas 46 and 9/46) is critical for the monitoring of information in working memory (Petrides, 2013). Damage to the mid-dorsolateral prefrontal cortex in the language-dominant left hemisphere yields an impairment in the monitoring of verbal information in working memory and neuroimaging studies show increased activity in the mid-dorsolateral prefrontal region during verbal working memory tasks when the monitoring requirements are taxed (Petrides, Alivisatos, Meyer, & Evans, 1993). Of special interest is a particular component of the mid-dorsolateral prefrontal region, area 9/46v, which is strongly connected with areas 44 and 45 and also with the supramarginal gyrus (Figure 3.5). This area is an essential component of the mid-dorsolateral prefrontal region for the monitoring of verbal information.

On the Neuroanatomy and Functional Role of the Inferior Parietal Lobule and Intraparietal Sulcus

Ferdinand Christoph Binkofski^{1,2}, Juliane Klann¹ and Svenja Caspers²

¹Section Clinical Cognition Sciences, Department of Neurology, University Hospital, RWTH Aachen University, Aachen, Germany; ²Institute of Neuroscience and Medicine (INM-1), Research Centre Jülich, Jülich, Germany

4.1 GROSS ANATOMY OF THE IPL AND IPS

The inferior parietal lobule (IPL) covers the ventral aspect of the posterior parietal cortex (Figure 4.1, top right). The rostral and dorsal borders are well-defined, being the postcentral sulcus and the intraparietal sulcus (IPS), respectively. The ventral rim is provided by the Sylvian fissure in its rostral aspect, but there is no such clear definition for the caudal aspect, where the IPL directly merges into the posterior parts of the superior and middle temporal gyri. The caudal border of the IPL is equally loosely defined because there is no prominent demarcation from the occipital lobe. The IPL is composed of two gyri, the supramarginal gyrus rostrally and the angular gyrus caudally. These are separated by the primary intermediate sulcus of Janssen, which is highly variable across brains because it is only present in 24% of the right hemisphere and 80% of the left hemisphere (Ono, Kubik, & Abernathy, 1990). The supramarginal gyrus is situated dorsal to the caudal aspect of the Sylvian fissure. The angular gyrus typically bends around the angular sulcus, which is a continuation of the dorsal-posterior segment of the superior temporal sulcus.

The IPS is the most prominent sulcus within the posterior parietal cortex. It separates the superior from the IPL, and thus runs mainly in the rostrocaudal direction. In most cases, the IPS is directly connected to the postcentral sulcus (64% of the right hemisphere and 72% of the left hemisphere; Ono et al., 1990) or starts immediately adjacent to it (36% of the right

hemisphere and 28% of the left hemisphere; Ono et al., 1990). It usually ends in or close to the transverse occipital sulcus and the lateral aspect of the parieto-occipital sulcus. The IPS typically exists as one continuous sulcus (28% of the right hemisphere and 72% of the left hemisphere; Ono et al., 1990) or as a sulcus with two segments (68% of the right hemisphere and 28% of the left hemisphere; Ono et al., 1990).

4.2 MODERN PARCELLATION OF THE IPL AND IPS

4.2.1 Human

Microstructural parcellations of the IPL can already be found in most of the classical brain maps of the early 20th century. They are based on cytoarchitectonic as well as myeloarchitectonic criteria. Campbell (1905) described one common type of parietal architecture that encompassed the IPL as well as the IPS and the superior parietal lobule (SPL). The first distinction within the IPL was mentioned by Smith (1907), who found not only a division into rostral and caudal IPL (areas pariB and pariA) according to the two main gyri but also a further subdivision within rostral IPL, covering the lateral aspect of the parietal operculum (area pariC). Two years later, Brodmann (1909) provided the most famous parcellation of the IPL, identifying the well-known bipartition into a rostral and a caudal part (BA 40 and BA 39). Using myeloarchitectonic criteria, Vogt (1911) and

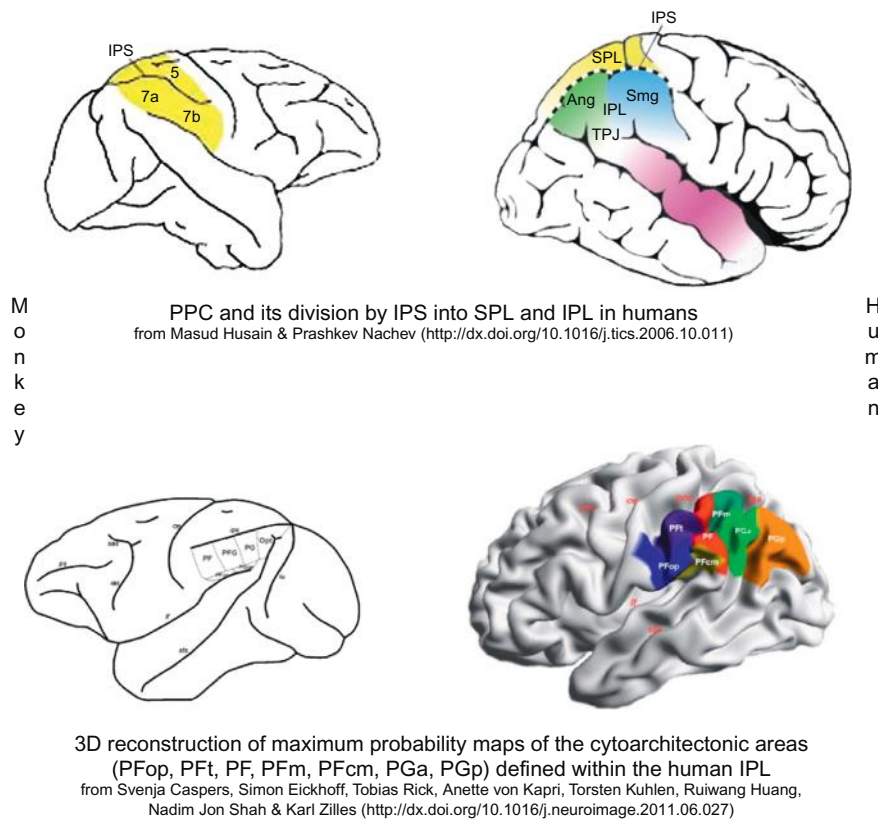

FIGURE 4.1 Gross anatomy (top) and parcellation (bottom) of IPL and IPS in humans (right) and monkeys (left). From Caspers et al. (2006, 2008, 2011) and Husain & Nachev (2006) with permission from the publisher.

Vogt and Vogt (1919) found four major areas within the IPL (areas 74, 88, 89, and 90) with several subareas with modulations of the overall myeloarchitectonic pattern. In 1920, Flechsig proposed a rostrocaudal tripartition of the IPL (areas 26, 37, and 42). von Economo and Koskinas (1925) again adopted the idea of Brodmann of having two major cytoarchitectonic patterns within the IPL (rostral area parietal F (PF) and caudal area parietal G (PG)). Additionally, they identified four local variations of the PF pattern, that is, an opercular area PFop, caudal to area PFcm (columnata magnocellularis), a rostral area PFT (tenuicorticalis), and a caudal variation at the border to PG, area PFm (magnocellularis).

Later, these pioneering maps were largely replicated. Gerhardt (1940) and Batsch (1956) mainly adopted the parcellation scheme of Vogt and Vogt (1919), amending it by additional subdivisions of the areas. Similar results were obtained by Hopf and Vitzthum (1957) and Hopf (1969) who suggested a similar complex myeloarchitectonic organization within the IPL. Sarkissov, Filimonoff, and Preobrashenskaya (1949) again built on Brodmann's bipartition and described additional subfields within these areas (40op, 40p, 40i, and 39p).

In 1984, Eidelberg and Galaburda described a rostrocaudal sequence of areas within the IPL (areas PF, parietal F-G (PFG), PG, and occipito-parietal G (OPG)) that largely resembled that found in macaques at approximately the same time (Pandya & Seltzer, 1982). Additionally, they described an asymmetry in the caudal part of the IPL: the volume of area PG was larger in the left hemisphere than in the right hemisphere, but only in those brains in which the planum temporale was also larger in the left as compared with the right hemisphere. They assumed this asymmetry to be relevant for the left-lateralized language network because it resembled known asymmetries toward the left in language-relevant areas.

Recently, a novel parcellation scheme of the IPL into seven cytoarchitectonically distinct areas was proposed (Caspers et al., 2006, 2008) using an observer-independent, quantitative, statistically testable mapping approach in a sample of 10 postmortem brains (Figure 4.1, bottom right). There are five areas in a rostrocaudal sequence (areas PFT, PF, PFm, PGa, and PGp) and two ventral areas in the caudal aspect of the parietal operculum (areas PFop and PFcm). All five areas on the lateral surface of the IPL abut on areas of the IPS, whereas the ventral areas directly border the areas of

the secondary somatosensory cortex (i.e., areas OP1 and OP4; Eickhoff, Amunts, Mohlberg, & Zilles, 2006; Eickhoff, Schleicher, Zilles, & Amunts, 2006). The most rostro-dorsal area PFT additionally borders area 2 of the primary somatosensory cortex. It is characterized by well-separated layers: a cell-dense layer II, mid to large pyramidal cells in lower layer III, and layer V is separated into an upper part and lower part. Area PFop is located immediately ventral to it. The layers are less well-separated, layer IV is sparsely developed, and layer V cannot be subdivided further. Caudal to these areas, areas PF and PFcm abut in the dorsal and ventral aspects, respectively. Area PF is overall very cell-dense; neurons of neighboring layers, particularly those of layers III/IV, IV/V, and V/VI, are heavily intermingled with each other, and there is a pronounced superficial-to-deep increase in pyramidal cell size in layer III. Area PFcm is characterized by a pronounced columnar arrangement of the cells across layers III to VI and large pyramidal cells in lower layer III. Area PFm is located at the transition between the supramarginal and angular gyrus, which is also reflected at the cytoarchitectonic level, having characteristics of both. Layer IV is better developed, there are large pyramidal cells in lower layer III, and layer V is again separable into an upper and lower part. The angular gyrus is covered by two areas: PGa and PGp. Area PGa is characterized by a shift of layer IV to a more superficial position, causing the supragranular layers to be smaller, a thin layer II, a sudden change in pyramidal cell size from upper to lower layer III, and a well-developed layer IV. Area PGp appears more homogeneous, with an overall decrease in cell size, layers II and III are barely separable from each other, and layer IV stands out very clearly against lower layer III and upper layer V.

These seven IPL areas differ not only in cytoarchitectonic characteristics but also in their receptor distribution patterns, reflecting their molecular architecture (Caspers et al., 2013). The concentrations of the glutamatergic α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), the GABAergic GABA_A, and the cholinergic nicotinic receptors increase from rostral to caudal areas, whereas the concentrations of the serotonergic 5-HT_{1A} and 5-HT₂ receptors decrease. Investigating the similarities in receptor distributions between the IPL areas revealed a tripartition into a rostral (areas PFT, PFop, and PFcm), middle (areas PF and PFm), and caudal part (areas PGa and PGp; for more details, see Figure 8 in Caspers et al., 2013). All parts show a receptor distribution pattern similar to that of Broca's region, whereas middle IPL showed additional similarity with the caudolateral aspect of the SPL, and caudal IPL was also similar to extrastriate visual areas.

Considerably less is known about subdivisions within the IPS. Except for a quite detailed parcellation into

15 cytoarchitectonic areas by Gerhardt (1940), no other "classical" brain map provided information about the architecture within the IPS. Recently, the anterior part of the IPS has been subdivided into three cytoarchitectonically distinct areas: areas hIP1 and hIP2 at the bottom and the lateral wall (adjacent to the IPL) of the sulcus, respectively (Choi et al., 2006), and area hIP3 on the medial wall (adjacent to the SPL; Scheperjans, Hermann, et al., 2008; Scheperjans, Eickhoff, et al., 2008). hIP1 is characterized by larger pyramidal cells in lower layer III, which are clearly separated from thin layer IV by a cell-sparse thin stripe, as well as by homogeneous layer V with small pyramidal cells spread over the whole extent of the layer. hIP2 contains smaller pyramidal cells within all layers; layer II appears more cell-dense as compared with hIP1, and layers V and VI form one continuous infragranular band of cells. In hIP3, layers II and III are clearly separable from each other, large pyramidal cells dominate the architecture within lower layer III, and layer V is comparably cell-sparse. Based on functional studies, additional areas similar to those described in monkeys are expected for the posterior IPS (Grefkes & Fink, 2005; Seitz & Binkofski, 2003). At the time of writing, this needs to be elucidated in future cytoarchitectonical studies.

4.2.2 Monkey

Because quite a lot of evidence regarding the functions and the structural–functional relations of the IPL and IPS have been obtained from studies of macaque monkeys, an overview of the respective microstructural parcellations is provided here as a basis for comparison with the human data.

Brodmann (1905) identified one large area within the IPL of the macaque, BA 7. This area has been subdivided into rostral area 7b and caudal area 7a (Vogt & Vogt, 1919; Figure 4.1, top left). Later, a rostrocaudal sequence of areas within the IPL, namely areas PF, PFG, PG, and Opt, and the adjacent caudal part of the parietal operculum, areas PFop and PGop, were described (Gregoriou, Borra, Matelli, & Luppino, 2006; Pandya & Seltzer, 1982; Figure 4.1, bottom left).

Within the IPS, several areas in the lateral and medial wall have been identified. In the anterior part, there are the anterior, ventral, and medial intraparietal areas (AIP, VIP, MIP), whereas the lateral, posterior, and caudal intraparietal areas (LIP, PIP, CIP) are located in the posterior part (Lewis & Van Essen, 2000; Rizzolatti & Luppino, 2001; Ungerleider & Desimone, 1986). Further subdivisions of these areas have been partially suggested using immunohistochemical staining, that is, a medial and lateral aspect of VIP (VIPm and VIPl) or a ventral and dorsal part of LIP (LIPv and LIPd) (Lewis & Van Essen, 2000).

4.3 CONNECTIVITY OF THE IPL AND IPS

4.3.1 Human

The IPL is anatomically connected mainly via association fibers to other cortical areas. Two major fiber bundles dominate the architecture of the white matter underlying the IPL: the arcuate and the superior longitudinal fasciculus (branch III). The arcuate fasciculus was found to be lateralized to the left and to be separable into three major parts: one continuous part, running between Broca's region and posterior temporal cortex, and a parallel path (separated into two parts), that connects Broca's region with rostral and middle IPL and the latter with posterior temporal cortex (Catani, Jones, & Ffytche, 2005; Parker et al., 2005; Powell et al., 2006). Therefore, this pathway was often referred to as the main connection structure within the language system of the brain. The superior longitudinal fasciculus (branch III) in principle provides comparable, but more widespread, connections between the IPL and the frontal cortex (Rushworth, Behrens, & Johansen-Berg, 2006). However, this pathway seems to be lateralized to the right, which is assumed to be the structural connectional architectural framework for the visuospatial network (Thiebaut de Schotten et al., 2011). Regarding this discussion of lateralization, it needs to be stressed that the arcuate fasciculus has repeatedly been reported as being a part of the superior longitudinal fasciculus (Martino et al., 2013).

Via these fiber bundles, the IPL areas entertain distinct connections with other cortical and subcortical areas. Rostral IPL areas are mainly connected to inferior frontal, premotor, primary and secondary somatosensory, rostral superior parietal, and posterior temporal areas. Moving to middle and caudal IPL areas, the connection patterns shift to more lateral and medial prefrontal, caudal SPL, lateral occipital, posterior cingulate, and anterior middle and inferior temporal areas (Caspers et al., 2011). Caudal IPL is also strongly connected to the parahippocampal gyrus via the inferior longitudinal fascicle (Rushworth et al., 2006), the hippocampus, and the basal ganglia (Uddin et al., 2010).

Anatomical connectivity across the whole brain has been used to parcellate the IPL into areas within distinct connection patterns. This revealed a sequence of five areas within the left IPL and the right IPL, which largely corresponded to the cytoarchitectonic areas PFop, PFt, PFm, PGa, and PGp (Mars et al., 2011; Wang et al., 2012). With a similar approach, Ruschel et al. (2013) identified a tripartition of the IPL, which is in line with the subdivision of the IPL based on similarities in receptor distribution patterns. Using whole-brain functional connectivity patterns as a basis for the

parcellation, a subdivision into seven functionally distinct clusters was identified within the IPL, which could be grouped into rostral, middle, and caudal groups of clusters (Zhang & Li, 2014). This corresponds well to the parcellations obtained by the post-mortem cytoarchitectonic and receptorarchitectonic studies (Caspers et al., 2006, 2013).

The functional connectivity patterns of the IPL as obtained in the resting state were found to be similar to the structural ones. Rostral IPL is functionally connected to inferior frontal and adjacent operculum and supplementary motor and posterior temporal cortex, whereas caudal IPL is connected with lateral and medial prefrontal, posterior cingulate, anterior middle, and inferior temporal cortex, and parahippocampal gyrus (Mars et al., 2011; Yeo et al., 2011).

Within the IPS, major differences in connectivity patterns can be found between its anterior and posterior parts. The anterior IPS has predominant fiber tracts to prefrontal regions, whereas the posterior IPS is mainly connected to the posterior superior temporal gyrus and retinotopically defined visual areas of the occipital cortex (Bray, Arnold, Iaria, & MacQueen, 2013; Greenberg et al., 2012). Specifically, areas HIP1 and HIP2 of anterior IPS were found to be mainly connected with the ventral premotor cortex and the middle frontal gyrus, whereas area HIP3 was already more connected with extrastriate areas, thus resembling the major connections of the posterior IPS. HIP1 was additionally connected with the insular cortex (Uddin et al., 2010). All parts of the IPS have comparable connections with the striatum and the thalamus.

4.3.2 Monkey

Using invasive tracer techniques, the connectivity patterns of the IPL and IPS areas in the monkey have been studied extensively. This section provides an overview of the major results to allow for comparisons with the indirect measure of structural connectivity obtained in humans via diffusion imaging.

The rostral part of macaque IPL (area 7b) is reversely connected with the insular and retroinsular cortex. It projects to secondary somatosensory and superior parietal cortex, anterior intraparietal areas AIP and VIP, as well as premotor area F5. The rostral-most area PF is additionally connected to premotor area F4, whereas area PFG is additionally connected with prefrontal area 46v, orbitofrontal cortex, and posterior superior temporal cortex. The caudal part of the IPL, area 7a, is strongly connected to IPS areas VIP, MIP, LIP, and PIP, parieto-occipital areas, superior, middle and medial temporal areas, as well as prefrontal area 46 and the frontal eye field. Subdivision PG is

mainly connected with intraparietal area MIP, insular and retroinsular cortex, and middle temporal cortex, whereas caudal-most area Opt is more strongly connected with intraparietal area LIP, medial superior parietal and parieto-occipital cortex, as well as premotor area F7 (Andersen, Asanuma, Essick, & Siegel, 1990; Cavada & Goldman-Rakic, 1989a, 1989b; Gregoriou et al., 2006; Mesulam, van Hoesen, Pandya, & Geschwind, 1977; Neal, Pearson, & Powell, 1990a, 1990b; Rozzi et al., 2006; Seltzer & Pandya, 1984).

The IPS areas are densely interconnected among each other and with the surrounding areas of the IPL and SPL. Beyond that, the anterior IPS areas AIP, VIP, and PEip are additionally strongly connected with primary and secondary somatosensory cortex, different areas of the premotor and part of the prefrontal cortex, as well as the posterior temporal cortex. The posterior IPS areas MIP, LIP, and PIP are predominantly connected to anterior and medial temporal cortex as well as striate and extrastriate visual areas (Andersen et al., 1990; Barbas, 1988; Borra et al., 2008; Felleman & Van Essen, 1991; Matelli, Camarda, Glickstein, & Rizzolatti, 1988; Tanné-Gariepy, Rouiller, & Boussaoud, 2002; Ungerleider & Desimone, 1986)

4.4 ANATOMICAL DIFFERENCES BETWEEN HUMANS AND MONKEYS

Comparing the microstructural gray matter parcellations between monkeys and humans gives the impression of a largely similar organization of the IPL between these species. Furthermore, there is converging evidence based on structural and functional connectivity of the IPL areas that several networks are largely preserved across species. But some networks might have evolved more from monkeys to humans than others. In particular, the connections between IPL and rostral aspects of prefrontal cortex, which could be found in humans but have not been reported in monkeys, give rise to the idea that this network evolved in accordance with the pronounced development of the frontal lobe. Comparing the anatomical connectivity of human and monkey, IPL points to potential homology between human areas PFt and PF with monkey area PF, human area PFm with monkey area PFG, human area PGa and monkey area Opt, and human area PGp (Caspers et al., 2011). This anatomical connectivity and topological homology only provide hints to answers to the question of interspecies homologies. Studies on the role of monkey areas PF and PFG and human areas PFt and PF in action processing (Bonini et al., 2010; Caspers, Zilles, Laird, & Eickhoff, 2010; Rozzi, Ferrari, Bonini, Rizzolatti, & Fogassi, 2008) and tool use (Orban

& Rizzolatti, 2012; Peeters et al., 2009) provide additional hints with regard to a functional homology.

It needs to be stressed, though, that a direct comparison between the species based on the functional role of these areas remains difficult, because physiological properties of cells are not available, functional experiments are not always comparable, and lesions to the IPL do not necessarily cause the same symptoms in monkeys and humans (Caminiti et al., 2010).

4.5 FUNCTIONS AND FUNCTIONAL CONNECTIVITY OF THE IPL AND IPS

In humans, the parietal cortex is involved in several functions, including sensory-motor control, motor skills, object and tool use, spatial reception, and language, speech, verbal working memory, and number processing. Similar to the comparable anatomical parcellation, there is some overlap with the functional role of homologue regions in the monkey brain.

4.5.1 Language and Speech

Besides classical perisylvian regions, language and speech functions are also related to left supramarginal (rostral IPL—PFop, PFt, and PFcm) and angular gyri (caudal IPL—PGa and PGp), which are, among others, anatomically interconnected with frontal and temporal parts of the perisylvian language network (Caspers et al., 2011; Seghier, 2013). The cytoarchitectonical parcellation of the IPL into seven different areas as demonstrated motivates the idea of parallel functional subdivisions. Individual language studies have documented the parietal cortex to be involved in diverse functions and processes as reaching from the selection of articulatory gestures (Tremblay & Gracco, 2010) to verbal integration within complex comprehensive contexts like sentences (Lerner, Honey, Silbert, & Hasson, 2011).

Convergent with results in visual perception, recent imaging and electrophysiological studies resulted in growing evidence for two major pathways for auditory perception in humans as well as in the monkey; connecting temporal auditory and frontal regions seems to be supported by two major pathways. Data are in favor of a “ventral” pathway, which may be dedicated to the projection from the primary auditory cortex to prefrontal regions along the superior temporal gyrus via the uncinate fasciculus, and a “dorsal” stream connecting the same regions but involving the IPL. The anatomical pendant of this dual route model of auditory language input was displayed for the first time by using diffusion Magnet Resonance Imaging (MRI)

tractography by [Parker et al. \(2005\)](#). More specifically, they found white matter connections along the dorsal stream connecting classical speech areas and the IPL in the left hemisphere, which hints at a crucial role of the IPL in speech processing. Notably, this dorsal stream is anatomically represented by the arcuate fasciculus, which interconnects BA 44 and BA 45 with IPL ([Parker et al., 2005](#); [Saur et al., 2008](#); [Weiller, Bormann, Saur, Musso, & Rijntjes, 2011](#)), and with posterior superior and middle temporal cortex. This is in line with the predictions of the DIVA (Directions Into Velocities of Articulators) model of speech production ([Guenther, 2006](#)), which maintains a feedback process for motor speech planning relying on Broca's area and involving a somatosensory error map that lies within the rostral part of the IPL.

Apart from that, there is robust proof for the angular gyrus (PGa and PGp as caudal parts of the IPL; [Seghier, 2013](#)) being involved in reading, writing, naming, and verbal repetition ([Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004](#); [Henseler, Regenbrecht, & Obrig, 2014](#); [Zukic, Mrkonjic, Sinanovic, Vidovic, & Kojic, 2012](#)). Lesion studies demonstrate converging evidence for dysgraphia/agraphia, dyslexia/agraphia, and anomia resulting from damage to left angular gyrus. Dysgraphia as part of Gerstmann's syndrome is additionally associated with lesions of the supramarginal gyrus (rostral part of the IPL), which furthermore gives rise to relatively isolated repetition problems and conduction aphasia ([Damasio & Damasio, 1980](#); [Fridriksson et al., 2010](#); [Zukic et al., 2012](#)). The cardinal symptom of conduction aphasia is a proportionally heavy deficit in verbal repetition, implying a central functional role of the rostral IPL in verbal working memory. In recent literature, the repetition deficit is especially associated with phonological problems in short-term memory ([Baldo, Klostermann, & Dronkers, 2008](#); [Dell, Martin, & Schwartz, 2007](#)), which is in line with imaging data revealing that the left supramarginal gyrus fosters phonological short-term memory functions ([Ravizza, Delgado, Chein, Becker, & Fiez, 2004](#)). In contrast, lesion data as well as meta-analyses of language studies have demonstrated that the angular gyrus (caudal part of IPL) supports the processing of semantic content ([Binder, Desai, Graves, & Conant, 2009](#); [Borovsky, Saygin, Bates, & Dronkers, 2007](#); [De Leon et al., 2007](#); [Price, 2000](#); [Vigneau et al., 2006](#)). This might be associated with the grounding of language functions in somatosensory experiences. According to the "action-perception theory" ([Pulvermueller, 1999](#)), it is not a coincidence that both linguistic semantics and action perception rely on action related networks, including the angular gyrus (see [Rizzolatti & Rozzi](#) chapter in this book). Confirmative evidence comes from investigations involving lesion data as well as fMRI, uncovering the frontoparietal junction

underlying action knowledge just as well as the comprehension of action words ([Higuchi, Chaminade, Imamizu, & Kawatoa, 2009](#); [Perani et al., 1999](#); [Pulvermueller, Shtyrov, & Illmoniemi, 2005](#)).

Another speech- and language-related function subserved by the IPL is linked to sequential processing. Increased neural activity in the caudal IPL (corresponding to PGa and PGp; BA 39) and in the anterior speech regions were found with increased syllable sequence complexity ([Bohland & Guenther, 2006](#)). Moreover, [Moser, Baker, Sanchez, Rorden, and Fridriksson \(2009\)](#) proposed that the IPL, especially its rostral parts (BA 40), may play a role in processing the temporal order of speech syllables. The rostral parts of the IPL may even be important for processing more complex constructions like sentences. An fMRI study that investigated single sentence production (e.g., "The child throws the ball") displayed activations of the supramarginal gyrus (BA 40) together with frontal regions (left and right inferior frontal gyri, left superior frontal and precentral gyrus, right medial frontal gyrus and right insula) and left SPL in sentence production as compared with word reading ([Haller, Radue, Erb, Grodd, & Kircher, 2005](#)).

Few functional imaging studies were dedicated to the exploration of discourse. Some of these studies investigated relations between expressive and receptive skills in spoken language ([Awad, Warren, Scott, Turkheimer, & Wise, 2007](#)), sign language communication ([Braun, Guillemin, Hosey, & Varga, 2001](#)), and reading ([Brownsett & Wise, 2010](#)). They underpin the important role of the SPL, IPL, and, more specifically, the left angular gyrus (caudal IPL) in the production of language, regardless of the output modality (spoken, signed, written language). Regarding the aspect of expressive versus receptive language skills, this result was generally supported by a recent fMRI study that, using the independent component analysis (ICA) of resting state data, demonstrated the participation of the left IPL in spoken discourse rather than nonspeech-related repetitive tongue movements ([Geranmayeh et al., 2012](#)). This was manifest in the identification of a left-lateralized frontal-temporal-parietal component involving rostral and caudal IPL (angular and supramarginal gyri) in connection with perisylvian classical language regions, including Broca's area ([Geranmayeh et al., 2012](#)). Using voxel-based lesion-symptom mapping (VLSM) on 50 aphasic patients, [Borovsky et al. \(2007\)](#) analyzed lesion correlates of impaired expressive discourse behavior. The authors found damage of frontal and/or temporal regions combined with a strong focus on the left angular gyrus (caudal IPL), especially when language production was impaired in terms of semantic context. As in most lesion studies of aphasia, nearly all lesions

in this study were large and extended to subcortical white matter tracts (Friederici, 2009).

In summary, it can be assumed that the IPL area and especially its rostral and caudal parts are involved in many different speech and language processes on different linguistic levels up to discourse, as well as independently from input-and/or output modality. Therein, the rostral part seems to be more related to temporal ordering of sound and articulation (speech functions), which is in line with the anatomical connection (arcuate fasciculus; dorsal route of auditory dual-stream model) of PFop, PFt, and PFCm to BA 44, an area of the language network functionally more dedicated to modality-specific oral speech and articulation processes (Horwitz et al., 2003). In contrast, the caudal parts seem to be involved in modality-independent conceptual and semantic processes, including the connection between language and action networks that is linked to the idea of language being grounded in action and sensual experiences. This is supported by the anatomical alliance (arcuate fasciculus; dorsal route of auditory dual-stream model) of PGa and PGp with BA 45 (Caspers et al., 2011), a language area associated with modality-independent language processes (Horwitz et al., 2003). Regarding the caudal parts (PGa and PGp), this is very much in line with the results of a recent review in which the angular gyrus was interpreted, because of its specific involvement in many different functional processes including and beyond speech and language, as a “cross-modal hub where converging multisensory information is combined and integrated to comprehend and give sense to events, manipulate mental representations, solve familiar problems, and reorient attention to relevant information” (Seghier, 2013, p. 43).

4.5.2 Motor Functions and Interaction with Objects

Areas PFop, PFt, and PF in the rostral part of the IPL are strongly associated with motor and action-related functions, from simple motor behavior and tactile reception to motor control of spatially/timely complex movements and tool use. The last two functional processes are also related to the middle IPL consisting of PF and PFm.

Although left rostral IPL is dedicated to tactile perception, that is, its damage impairs the tactile recognition of an object (astereognosis), right rostral and middle IPL are more concerned with spatial coding and spatial attention (Mesulam, 1999). This holds even for motor functions and motor learning. These have been shown to generally recruit a frontoparietal network complemented by cerebellar and subcortical

regions (Seitz, 2001). The rostral IPL seems to be specifically associated with learning and execution of complex sequential motor movements, thereby serving the processing of complexity in terms of time and space. Damage to the supramarginal gyrus, for example, may lead to deficits in the control of complex motor movements (Goldenberg, Hermsdörfer, Glindeman, Rorden, & Karnath, 2007; Goldenberg & Karnath, 2006). In line with the lesion data, functional brain imaging studies revealed that the IPL and especially its middle and rostral parts play a specific role in the control of spatial characteristics of complex motor behavior or attention (Halsband & Lange, 2006; Rauch et al., 1995).

Derived from anatomical and functional data in monkeys, Rizzolatti and Matelli (2003) further subdivided the dorsal stream of visual perception, formerly defined by Mishkin and colleagues (Mishkin & Ungerleider, 1982; Mishkin, Ungerleider, & Macko, 1983), into two separate pathways: the dorso-dorsal stream and the ventrodorsal stream. The dorso-dorsal stream seems to involve the IPS and SPL, whereas the ventrodorsal stream mainly targets the IPL. In humans, recent evidence supports a functional segregation that mirrors anatomically identified routes along the ventrodorsal stream (Binkofski & Buxbaum, 2013; Pisella, Binkofski, Lasek, Toni, & Rossetti, 2006). In contrast to the dorso-dorsal stream, the ventrodorsal stream appears to underlie processing of sensorimotor information based on longer-term object use representations. Damage within the ventrodorsal stream leads to impaired pantomimic and/or real object use, functions that require knowledge about the skilled handling of objects and therefore signify more overtly “cognitive” aspects of action representation. Deficits in object-related actions are a hallmark of limb apraxia (LA). Because optic ataxia (OA) is typically related to damage within the dorso-dorsal stream, one can derive that online motor performance should be spared in LA. A number of studies show reaching and grasping actions within normal range in LA as far as vision of the limb and target are spared, but they usually decrease when they have to be executed “off line” (e.g., when subjects are blindfolded prior to movement performance) (Buxbaum, Johnson, & Bartlett-Williams, 2005; Haaland, Harrington, & Knight, 1999; Jax, Buxbaum, & Moll, 2006; Laimgruber, Goldenberg, & Hermsdörfer, 2005). This and other observations (Dawson, Buxbaum, & Duff, 2010) suggest underlying deficits in anticipatory planning that entails overreliance on online movement correction in this cohort.

A specific example of object use in which the ventrodorsal stream and, more precisely, area PFt in the rostral part of the IPL (Peeters et al., 2009) play a major role is tool use. Although behavioral studies on more

naturalistic multistep tasks involving several tools/objects (e.g., preparing coffee, fixing a cassette recorder) make it evident that the right hemisphere is important for such complex functions, there is an unequivocal observation of only patients with left brain damage suffering from problems with single familiar tools or tool/object pairs (Hartmann, Goldenberg, Daumüller, & Hermsdörfer, 2005; Schwartz et al., 1998). Specifically, it has been reported that left lesions only lead to errors in matching objects to pantomime actions (mainly caudal IPL; Buxbaum, Kyle, & Menon, 2005; Kalénine, Buxbaum, & Coslett, 2010; Vaina, Goodglass, & Daltroy, 1995; Varney, 1978; Vignolo, 1990), pantomiming an action stimulated by an object stimulus (mainly rostral IPL; Barbieri & De Renzi, 1988; Goldenberg, Hartmann, & Schlott, 2003; Goodglass & Kaplan, 1963), or matching objects subserving the same purpose (Caspers et al., 2010; De Renzi, Scotti, & Spinnler, 1969; Rumiati, Zanini, Vorano, & Shallice, 2001; Vignolo, 1990). The same holds for the ability to infer possible functions from structure to apply novel tools linked to their complementary objects by transparent mechanical relationships (Goldenberg & Hagmann, 1998; Heilman, Maher, Greenwald, & Rothi, 1997) or to discover alternative uses of familiar tools (e.g., a coin for turning a screw; Heilman et al., 1997; Roy & Square, 1985). In the same line of evidence, Randerath, Goldenberg, Spijkers, Li, and Hermsdörfer (2010) state, by observation, that inappropriate nonfunctional grasping was committed extremely seldom in a huge group consisting of 42 left hemisphere stroke patients. The authors assumed the preserved dorso-dorsal route to underlie this effect. Furthermore, lesion studies revealed that the left rostral IPL is crucial for inferring the function of an object from its structure correctly (Barbieri & De Renzi, 1988). The anterior portion of IPS in the IPL together with the ventral premotor cortex in the left hemisphere appear to be tool-responsive regions in the ventrodorsal pathway (Binkofski, Buccino, Posse, et al., 1999; Binkofski, Buccino, Stephan, et al., 1999; Boronat et al., 2005; Chao & Martin, 2000; Handy, Grafton, Shroff, Ketay, & Gazzaniga, 2003; Johnson-Frey, 2004; Kellenbach, Brett, & Patterson, 2003). Even in the monkey, the homologue of this region, AIP, is a part of a functional circuit with the ventral premotor cortex related to the coordination of fine-grain hand movements (Jeannerod, Arbib, Rizzolatti, & Sakata, 1995).

In summary, research has identified two distinctive action systems hosted in the IPS, SPL, and IPL: a bilateral system associated with the dorso-dorsal stream (IPS and SPL), which is specialized for online actions directed at currently visible stimuli on the basis of their structure (size, shape, and orientation), and a left ventrodorsal stream (mainly IPL), which is dedicated to capabilities

of skilled object-related actions (Buxbaum, 2001; Buxbaum & Kalénine, 2010; Fridman et al., 2006; Glover, Rosenbaum, Graham, & Dixon, 2004; Johnson-Frey, 2004; Pisella et al., 2006; Randerath et al., 2010; Vingerhoets, Acke, Vandemaële, & Achten, 2009). Integrating the structural and functional knowledge of these different action systems remains to be elucidated at the time of writing. It might be assumed that the cytoarchitectonic subdivisions reflect different processing modules, which are highly connected to each other and help to map visual input onto the motor system.

4.5.3 Spatial Functions

In addition to speech, language, motor, and action-related skills, the parietal cortex also subserves spatial functions, including general spatial perception (mainly PGa and PGp—caudal IPL), estimation of directions, processing of extrapersonal and peripersonal space, as well as the localization of objects. In contrast to language functions that are predominantly assigned to the left hemisphere, spatial functions seem to focus the right parietal cortex. Nevertheless, both hemispheres are involved in both functional systems. For example, the visuospatial component that is also evident in reading and in calculation (as long as the spatial imagery of a magnitude is required) is associated with left caudal IPL and IPS (Seghier, 2013; Simon, Mangin, Cohen, Le Bihan, & Dehaene, 2002).

In humans as in monkeys, these parietal regions, and particularly the IPS, play a role in visuomotor and visuospatial coordination and in constructing spatial characteristics during visuospatial perception (e.g., localizing objects and one's own body in a perceived multidimensional surrounding) (Grefkes & Fink, 2005). Parallel to its anatomical parcellation, functions are segregated into processing of extrapersonal space in area 7a and processing of peripersonal space in area 7b. Area 7 is connected to frontal area BA 8, which is known to be central in eye movement control (frontal eye field). This interconnection might be a prerequisite of goal-directed (hand) movements because it guarantees the further administration of visually noticed impulses as being localized in relation to one's own body and in the spatial surrounding.

The most common disorder associated with damage to the right caudal IPL is spatial hemineglect (Bisiach, Luzzatti, & Perani, 1979; Colombo, De Renzi, & Faglioni, 1976; Driver, Baylis, & Rafal, 1992; Gainotti, Messerli, & Tissot, 1972). Patients with hemineglect typically ignore the visual items in their contralesional side of space even though vision itself is spared. This deficit manifests itself in shaving only the right side of the face and sparing a meal on the left side of a plate while

eating just the food placed on the right side. Besides these perceptive deficits, patients also show expressive problems, for instance, drawing the right side of their face when asked to make a self-portrait or positioning all numbers of a watch in the right half of a given circle when asked to draw a clock. In line with these symptoms, the most popular screening test to detect hemineglect consists of a line cancellation task (Albert's Neglect Test [ANT]; Albert, 1973). There are many hypotheses to explain the underlying mechanisms and causes of hemineglect. The most widespread assumption is an underlying attention deficit (Mesulam, 1999, 1981). In contrast, several theories proposed a deficit in the mental representation of sensory stimuli (Bisiach, Capitani, Luzzatti, & Perani, 1981; Rizzolatti & Berti, 1990) or a disorder in terms of transformation of (multimodal) sensory input into an egocentric coordinates (Karnath, 1994, 1997; Vallar, 1997).

The correlation of lesion site (right caudal IPL) and syndrome (hemineglect) was challenged by a lesion study that showed a significant lesion-deficit association between neglect and right temporal lesions (Karnath, Ferber, & Himmelbach, 2001). Because spatial attention is processed by distributed cortical networks, this finding can be interpreted as proof for a temporal node playing a crucial role within the whole right fronto-temporo-parietal attention network (Corbetta & Shulman, 2011, 2002). This assumption is confirmed by connectivity analyses showing interconnections between these parts of the cortex. According to fMRI studies, the IPL herein is associated with non-spatial functions related to control of spatial attention rather than spatial attention itself (e.g., arousal, reorienting, detection of behaviorally important novel input) (Corbetta & Shulman, 2011).

4.6 SUMMARY

Although there is clear evidence for a cytoarchitectonic parcellation of the IPL into seven subareas, the investigation of potentially equally distributed functions is only at its beginning. So far, the IPL is considered a multifunctional area involved in several different processes and functional networks. To this end, it already has been demonstrated that the IPL's cytoarchitectonic parcellation is reflected in terms of functional fragmentation to some degree. The rostral parts of the IPL (areas PFop, PFt, and PFcm; supramarginal gyrus) have been related with processes of speech and articulation, phonological short-term memory, simple motor behavior, tactile reception, and general higher somatosensory functions. The middle part of the IPL as represented by PF and PFm seems to be dedicated to motor attention, motor control, and motor

planning, especially in the left hemisphere. Last but not least, the caudal part comprising PGa and PGp, which together represent the angular gyrus, was reported to be involved in processes related to spatial attention, spatial perception, spatial memory, mathematical cognition, and modality-independent language functions, as well as conceptual and discourse-related processes and visuomotor integration. In line with this high degree of variable functions within the caudal IPL, it also seems to play a more general role as a cross-modal hub that guarantees comprehension, manipulation, and orientation based on processes of multisensory combination and integration. In contrast to the IPL, the functional and cytoarchitectonical distribution as well as interconnectivity of the IPS in humans still are less clear and need further investigation. The IPS seems to constitute the border between the dorso-dorsal and ventro-dorsal stream within a two-stream dorsal action system. Herein, the dorso-dorsal stream along the IPS and SPL seems to be specialized for online actions directed at currently visible stimuli on the basis of their structure (size, shape, and orientation), and the ventrodorsal stream along the IPL seems to enable skilled object-related actions. The dual-stream model of visuomotor coordination has to be distinguished from the dual-stream model of auditory language processing, which connects the two parts of Broca's area (BA 44 and BA 45) with superior temporal gyrus (STG) and/or IPL via a dorsal and ventral stream.

Based on the fact that the three parts of the IPL are somehow present in the monkey, future work will also have to explore evolutionary aspects of the relationship between cytoarchitectonic and functional parcellation. So far, it is already evident that the human IPL cytoarchitectonically parallels that of the nonhuman primate in respect to PF (human: Pft and PF), PFG (human: PFm), PG (human: PGa), and Opt (human: PGp). Furthermore, hints toward a similar functional role in action processing and tool use are apparent for monkey areas PF and PFG and human areas Pft and PF. Another important aspect that needs further investigation concerns the correlation between each part of the IPL and its function within different cortical networks using the evolving knowledge over the past years about the relation between structure and function of the IPL in both species.

5.1 INTRODUCTION

One of the fundamental discoveries of neuroscience is that sensory regions of cortex are formed of many functionally specialized areas that are organized into hierarchical networks (Kaas & Hackett, 2000; Krubitzer, 2007; Schreiner & Winer, 2007; Van Essen, Felleman, DeYoe, Olavarria, & Knierim, 1990). The simplest features are processed in low-level areas that then pass that information up the hierarchy to perform increasingly complex computations. A general feature of these systems is that the topography of the sensing organ represents the most fundamental stimulus information, which is preserved through much or all of the hierarchy (Brewer & Barton, 2012). It has been suggested that this preservation of topographical organization allows for efficient connectivity between neurons that represent nearby portions of sensory space, likely necessary for processes such as lateral inhibition and gain control (Chklovskii & Koulakov, 2004; Mitchison, 1991; Moradi & Heeger, 2009; Shapley, Hawken, & Xing, 2007). From a researcher's perspective, this topographic preservation allows us to use one set of stimuli to localize a number of sensory areas rather than designing specialized stimuli for each sensory area (Brewer & Barton, 2012).

Many details remain to be elucidated in each cortical network, and it is the goal of this chapter to provide an overview of the current understanding of the cortical organization of the low-level sound processing areas of the human auditory system. It is not within the scope of this chapter to discuss the organization of the entire human auditory system; we only touch on the subcortical areas and higher-order processing areas. However, we note that low-level cortical organization has much to teach us about both subcortical and higher-order processing areas.

Researchers have long been aware that low-level auditory processing occurs on and near Heschl's gyrus (HG) of the human temporal lobe in the lateral (Sylvian) fissure, but many questions have remained unanswered. How many distinct auditory areas exist in this region? What is the proper method to functionally localize these areas? Which computations are performed in which areas?

5.2 CORTICAL FIELD MAPS

The accurate delineation of cortical areas is important to review here. Cortical areas have traditionally been identified in visual cortex, the most studied of the sensory cortices, based on a combination of the following measurements: (i) cytoarchitecture; (ii) connectivity patterns; (iii) cortical field topography; and (iv) functional characteristics. This definition has led to many controversies because these measurements have conflicted at times. Thus, in vision and in audition, investigations have primarily been limited to the measurement of cortical field maps (arising from topographical measurements), which is the principal measurement of cortical areas in the *in vivo* human brain currently available.

The presence of a cortical field map is established according to several criteria. First, by definition, each cortical field map contains a single representation for each point in the sensory domain (DeYoe et al., 1996; Press, Brewer, Dougherty, Wade, & Wandell, 2001; Sereno et al., 1995; Wandell, Dumoulin, & Brewer, 2007). For this to be valid, orthogonal gradients of fundamental sensory dimensions must comprise each field map (Brewer & Barton, 2012; Wandell et al., 2007). In addition, each field map should represent a substantial

portion of sensory space, although cortical magnification of specific subsets of sensory space and measurement limitations may reduce the measurable portion. Second, each representation of the sensory domain must be organized as an orderly gradient that is generally contiguous. Third, the general features of the gradient representations comprising the field maps should be consistent across individuals. It is important to note, however, that even well-accepted cortical field maps in visual cortex can vary dramatically in size and anatomical location (Brewer, Liu, Wade, & Wandell, 2005; Dougherty et al., 2003). Even so, the topographical pattern of adjacency among specific cortical field maps should be preserved across individuals.

An important step forward in understanding the organization of human auditory cortex was the recent discovery of 11 auditory field maps (AFMs) on HG (Barton, Venezia, Saberi, Hickok, & Brewer, 2012). These measurements provide an important framework for the organization of individual AFMs in humans as well as the organization of the AFMs with respect to one another. Whereas this information still leaves much to be discovered, it is a fundamental rethinking of the organization of auditory cortex that has implications that resonate throughout the auditory processing hierarchy.

In particular, this rethinking has important implications for speech perception, which occurs at the upper end of the auditory processing hierarchy (Hickok & Poeppel, 2007). To date, research of the neural basis of speech perception overwhelmingly emphasizes the identification of relatively high-level auditory systems that are specialized for coding speech categories (e.g., phonemes). Such work often compares the cortical response to speech with various acoustic controls to factor out low-level acoustic processes. While valuable, this approach ignores the fact that the input to these higher-level systems is derived from an acoustic signal that is already highly processed. Our increased understanding of the inputs to speech perception systems is critical to understanding what kind of categorical information is ultimately extracted from the speech stream and, from a computational perspective, how that information is extracted (Poeppel, Emmorey, Hickok, & Pylkkanen, 2012).

5.3 TONOTOPY: THE FIRST DIMENSION OF AFMs

Beginning in the ear, the auditory system takes a complex sound wave and breaks it down into individual component frequencies, analogous to a Fourier analysis (Spoendlin, 1979). A topographic gradient of low-to-high frequencies, or tones, is referred to as tonotopy (or less commonly, cochleotopy). This basic auditory information and tonotopic organization are

preserved through multiple subcortical areas and in low-level auditory cortex (for review, see Ress & Chandrasekaran, 2013; Saenz & Langers, 2014).

Each small band of frequency channels is thus processed largely independently of the others in its own computational pipeline and can be thought of as a common topographic reference frame between individual areas. Tonotopy is thus one aspect of the fundamental auditory reference frame. Each auditory area performs one or more computations across the entire reference frame, such as sound onset, offset, duration, intensity, localization, and others. The degree to which tonotopy is preserved remains unclear above the lower levels of the hierarchy (Barton et al., 2012; Humphries, Liebenthal, & Binder, 2010; Kaas & Hackett, 1998). However, it would be surprising if this information were only preserved to a certain point of the system and then abolished (Brewer & Barton, 2012). It is much more efficient to put that information to use, even if it is only a part of the information necessary to perform a high-order computation.

Although this understanding of one aspect of the auditory reference frame is important, it is incomplete for the purposes of delineating individual AFMs (Barton et al., 2012; Brewer & Barton, 2012; Wandell, Brewer, & Dougherty, 2005; Wandell et al., 2007). To identify tonotopic gradients using a single set of stimuli that activate most or all of the maps, researchers present an array of pure tones (or tone complexes or narrowband noise; Barton et al., 2012; Da Costa et al., 2011; Formisano et al., 2003; Humphries et al., 2010; Sweet, Dorph-Petersen, & Lewis, 2005; Talavage et al., 2004; Upadhyay et al., 2007; Woods et al., 2010). However, tonotopy is one-dimensional, whereas the cortical surface, on which we would like to draw the boundaries between auditory areas, is two-dimensional. Thus, any tonotopic gradient with a given width can be divided into any number of arbitrary individual areas with a complete low-to-high tonotopic gradient (Figure 5.1). As such, we can be certain that auditory areas exist where tonotopic gradients exist, but their number and characteristics require additional measurement, as described. To accurately define an AFM, measurements of a second dimension of the auditory reference frame that is orthogonal to tonotopy are needed (Barton et al., 2012; Brewer & Barton, 2012). Auditory researchers have lacked confirmation of a second dimension until recently; as such, they have relied heavily on complimentary methods that are invasive and typically performed using animal models.

5.4 CORTICAL ORGANIZATION OF THE MONKEY AUDITORY SYSTEM

In monkeys, a standard model of the cortical auditory system has been developed through a

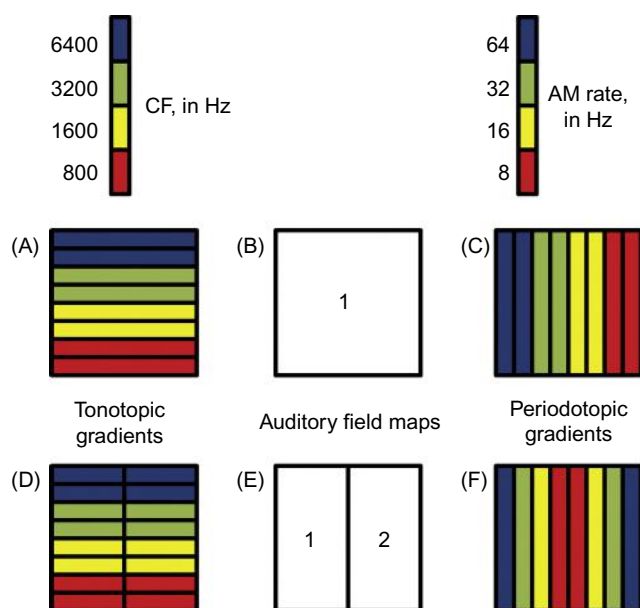

FIGURE 5.1 Orthogonal tonotopic and periodotopic gradients. A cartoon representation of a flattened section of the cortical surface to demonstrate the delineation of AFMs. Inset color legends indicate preferred frequency (tonotopy) or AM rate (periodotopy). The top row is an example showing one AFM existing in the area (B), whereas the bottom row is an example showing two existing in the area (E). (A) and (D) Examples of a tonotopic gradient in the area. Note that without the additional information contained in the periodotopic gradients, it is impossible to know whether there are one, two, or more AFMs in the area. With the information contained in (C), one could conclude that there are orthogonal tonotopic and periodotopic gradients; therefore, one AFM exists in that location (B). Similarly, a combination of the tonotopic gradients in (D) with the periodotopic gradients in (F) would yield two AFMs in the area (E).

convergence of evidence drawn from postmortem cytoarchitectural measurements and tracer studies of anatomical connectivity (de la Mothe, Blumell, Kajikawa, & Hackett, 2006; Fullerton & Pandya, 2007; Hackett, Preuss, & Kaas, 2001; Kaas & Hackett, 1998, 2000), *in vivo* neurophysiological recordings from penetrating electrodes (Kusmirek & Rauschecker, 2009; Merzenich & Brugge, 1973; Morel, Garraghty, & Kaas, 1993; Rauschecker & Tian, 2004; Tian & Rauschecker, 2004), and fMRI measurements (Petkov, Kayser, Augath, & Logothetis, 2006; Petkov, Kayser, Augath, & Logothetis, 2009; Tanji et al., 2010). The model consists of a core comprising three auditory areas (A1, R, and, with less certainty, RT) surrounded by a belt of eight auditory areas (CM, RM, MM, RTM, RTL, RL, AL, and CL). The axis of orientation in the monkey model is indicated by the naming scheme, whereby areas are named by location with respect to A1. The caudal portion of the core is area A1, whereas the more rostral portion contains areas rostral (R) and rostral temporal (RT). The anatomical naming scheme has been adopted for the other maps as well,

with four medial and four lateral maps in the belt encircling the core. Several additional areas have been proposed to comprise the parabelt region abutting the belt region (Kaas & Hackett, 2000; Sweet et al., 2005; Tanji et al., 2010), but these areas are not discussed further here because they are not yet relevant for comparison with the current understanding of human AFMs.

The concept of a “core” can generally be ascribed to studies of cytoarchitectural staining and thalamic inputs, which locate a primary-like region of initial auditory processing along monkey superior temporal gyrus (STG; for review see Kaas & Hackett, 2000). Within the definition of the core, three areas, A1, R, and RT, have further been differentiated on the basis of three tonotopic gradients, with one complete gradient per area. These three gradients are oriented in a “high-to-low-to-high” pattern, with high tones represented in the broadly caudal aspect of A1 and low tones in the broadly rostral aspect that is mirrored in R. RT then mirrors R, which creates two abutting tonotopic gradients that reverse from one gradient to the next at the shared boundary between the areas (Figure 5.3). These gradients were measured using electrode penetrations and recordings from relatively small numbers of neurons and later confirmed by measurements of tonotopy using fMRI in monkey (de la Mothe et al., 2006; Kaas & Hackett, 1998, 2000; Kusmirek & Rauschecker, 2009; Merzenich & Brugge, 1973; Morel et al., 1993; Petkov et al., 2006, 2009; Rauschecker & Tian, 2004; Tian & Rauschecker, 2004). In the belt, some areas have been proposed to contain more coarsely organized tonotopic gradients; however, the tonotopy in other belt areas have primarily been measured using fMRI, and thus assume the boundaries between AFMs in the core and belt without directly measuring them with two orthogonal gradients, leaving open the exact organization of each area (Petkov et al., 2006, 2009; Tanji et al., 2010; Tian & Rauschecker, 2004). Furthermore, it is always possible that there are differences among the species of primate studied (Hackett et al., 2001; Kaas & Hackett, 1998, 2000).

5.5 CORTICAL ORGANIZATION OF THE HUMAN AUDITORY SYSTEM

Naturally, the model of low-level auditory cortical organization in the human is largely a transposition of the monkey model. However, the macaque monkey brains typically studied are much smaller than human brains and diverged from human development during evolution more than 25 million years ago (Kumar & Hedges, 1998). As such, the homology of cortical areas among species is not immediately apparent, nor should we assume that the monkey model is a correct

representation of the human cortical organization. Rather, the monkey model should be viewed as an especially useful but approximate model of human cortex, where differences are expected.

Similar, yet not identical, cytoarchitectural features of core and belt in macaque STG indicate that HG should be the location of the auditory core and belt in humans. Similar cytoarchitectural techniques that identified monkey core reveal in humans a homologous auditory core region on HG, surrounded by regions similar to monkey belt (Dick et al., 2012; Fullerton & Pandya, 2007; Galaburda & Sanides, 1980; Rivier & Clarke, 1997; Sweet et al., 2005). These results suggest that human and monkey STG are not perfectly homologous, with perhaps a portion of monkey STG evolving into human HG. The same data suggest that the human analogue to CM is located on the medial wall of the lateral fissure, near the tip of HG. This is important, because it anchors the expected orientation of the maps from a strictly rostral–caudal axis for A1 to R to RT in monkeys to a medial-lateral axis in humans.

The majority of measurements of low-level auditory cortex are measures of tonotopy using sets of pure tones, tone bursts, tone complexes, and narrowband noise (Da Costa et al., 2011; Formisano et al., 2003; Humphries et al., 2010; Saenz & Langers, 2014; Sweet et al., 2005; Talavage et al., 2004; Upadhyay et al., 2007; Woods et al., 2010). The data across these studies are actually quite similar, but the models put forth based on the interpretation of the data vary widely. In all cases, there is a central low-frequency representation centered on HG with increasing frequencies represented in surrounding bands that form an approximately circular shape. In some cases, portions of the circle are weak, such that the higher-frequency bands resemble a horseshoe shape nearly encircling the low frequencies (Humphries et al., 2010). It is likely that higher-order auditory areas also contain tonotopic gradients, because it is unlikely that the tonotopic information has simply been discarded at this level of processing. Such a persistence of topographic organization into higher-order sensory processing regions has now been measured in the visual system (for reviews, see Brewer & Barton, 2012; Wandell et al., 2007).

Sometimes different naming schemes for these tonotopic measurements of auditory areas have been adopted, but the majority of studies place A1 on the medial or posterior aspect of HG (Da Costa et al., 2011; Formisano et al., 2003; Humphries et al., 2010; Sweet et al., 2005; Talavage et al., 2004; Upadhyay et al., 2007; Woods et al., 2010). Then, R is placed variably on the lateral or anterior aspect of HG, depending on where the strongest “high-to-low-to-high” tonotopic reversal pattern can be identified. Sometimes the “high-to-low-to-high” pattern is a relatively straight path, but in

other cases it is bent. Typically, researchers have guessed at boundaries of cortical areas based on the tonotopic gradient and the potentially homologous monkey model, resulting in either a medial–lateral (consistent with the cytoarchitecture) or anterior–posterior axis of orientation (Da Costa et al., 2011; Formisano et al., 2003; Humphries et al., 2010; Sweet et al., 2005; Talavage et al., 2004; Upadhyay et al., 2007; Woods et al., 2010). In sum, there has been little agreement on how to interpret the similar datasets; there are simply too many ways to interpret sets of one-dimensional gradients when trying to divide them on the two-dimensional cortical surface (for review of similar issues in visual cortex see Brewer & Barton, 2012; Wandell et al., 2007).

5.6 PERIODOTOPY: THE SECOND DIMENSION OF AFMs

Converging evidence suggests that the human homologue of monkey auditory core is located on HG, but the fact that tonotopy is one-dimensional makes it difficult to use tonotopic gradients alone to identify AFMs. An orthogonal gradient is necessary, but for that another fundamental type of information that is a component of the auditory reference frame must be identified. Humans can differentiate sounds based on their pitch, temporal information, loudness, and timber. Of these, timber is very likely a process of recognizing combinations of the other three characteristics when one differentiates a tone played by, for example, a flute or an oboe; thus, it is thought that this is unlikely to be part of the fundamental auditory reference frame, but more likely processed along specific computational processing pathways in auditory cortex (Menon et al., 2002; Rauschecker & Scott, 2009; Zatorre, Belin, & Penhune, 2002). Intensity is a good candidate; it is used in sound localization (Middlebrooks & Green, 1991) (i.e., comparing intensity of the same sound detected by each ear) and sound motion localization (McBeath & Neuhoff, 2002) (e.g., the Doppler effect). However, intensity is very similar to brightness in the visual domain, which is not one of the fundamental gradients used to identify visual field maps (VFMs), and it is encoded in the cochlea and potentially in cortex as increases in firing rates of tonotopically tuned neurons rather than in a gradient organization (Shapley et al., 2007; Spoenclin, 1979; Tanji et al., 2010; Wandell et al., 2007).

Recent human psychophysical studies indicate that there are separable filter banks (neurons with receptive fields or tunings) for not only frequency spectra (as expected given tonotopy) but also temporal information (Dau, Kollmeier, & Kohlrausch, 1997; Ewert & Dau,

2000; Hsieh & Saberi, 2010). Furthermore, gradients based on temporal information have recently been discovered in cat primary auditory cortex and the macaque midbrain (Baumann et al., 2011; Langner, Dinse, & Godde, 2009). In addition, such gradients, known as periodotopic gradients, were measured in both cases to be in the same location as, but orthogonal to, tonotopic gradients. Periodotopy refers to the topographic organization of neurons that respond differentially to sounds of different temporal envelope modulation rates.

Inspired by these studies, Barton et al. (2012) recently presented amplitude-modulated (AM) broadband noise to human subjects to measure the cortical periodotopic responses in humans using fMRI. With these stimuli, temporal duration refers to the length of time from peak-to-peak of the AM noise. This stimulus is designed to activate neurons with tuning to sounds that last for a particular duration; in other words, the stimuli differentiate temporal tuning. These stimuli likely drive neurons that respond to the onset and offset of sounds with different amounts of lag time before they can be reactivated, as well as neurons that respond to sounds that exist for a certain duration. Like the monkey and cat studies, Barton et al. (2012) also presented tonotopic mapping stimuli (narrowband noise with varying AM rates) to the same subjects and investigated the responses in low-level auditory cortex.

Three primary findings resulted from the work of Barton et al. (2012). First, temporal information is the second fundamental type of sound information of the human auditory reference frame, complimenting spectral (frequency) information. Second, tonotopy and periodotopy are represented orthogonally to one another in human cortex, allowing for the localization of individual AFMs. By identifying both tonotopic and periodotopic gradients in the same locations and measuring that these gradients are orthogonal to one another, Barton et al. (2012) were able to localize 11 independent AFMs that largely resemble the 11 AFMs of the monkey model (Figure 5.3). Taking into account many characteristics of their data, as well as the correspondence to the monkey model and the underlying human cytoarchitecture, they named each of the AFMs based on those of the monkey model (hA1, hR, hML, hAL, hMM, hRM, hCM, hCL, hRT, hRTM, and hRTL). Because the monkey areas were named based on orientation and because the human AFMs are oriented medial–lateral rather than caudal–rostral, the human AFMs are only the abbreviated letters, not the full title used for monkeys (e.g., hRM stands for human RM, not human rostral medial), and “h” has been appended to mean “human.” Third, these individual AFMs are organized into at least one “clover leaf” cluster (see Section 5.8) (Figures 5.2 and 5.3).

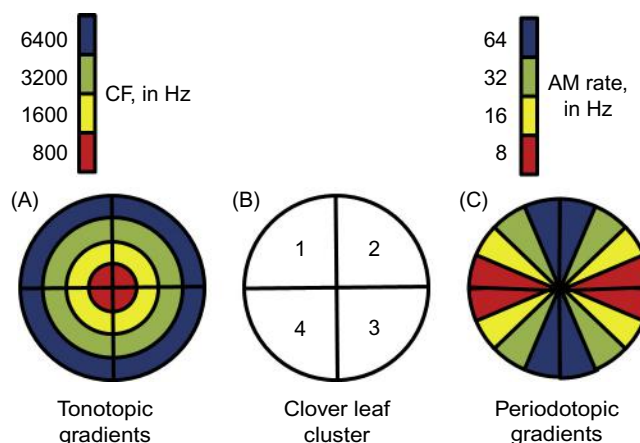

FIGURE 5.2 “Clover leaf” cluster organization. A cartoon example of a “clover leaf” cluster of AFMs on a flattened section of the cortical surface. Inset color legends indicate preferred frequency (tonotopy) or AM rate (periodotopy). This example contains four AFMs, indicated in (B). (A) Each AFM has a complete tonotopic gradient organized such that low-frequency bands are represented in the center of the cluster, with increasing frequencies represented in more peripheral bands of the cluster. (C) Each AFM also has a complete periodotopic gradient organized such that all AM rate bands span from the center to the periphery of the cluster like spokes on a wheel. Each AFM thus has orthogonal tonotopic and periodotopic gradients.

5.7 SIMILARITIES TO AFM ORGANIZATION IN THE HUMAN VISUAL SYSTEM

Visual information is pooled in a series of steps in the retina before being passed through the optic nerve to the thalamus. From there, this information is passed through optic radiations to primary visual cortex into an area known as V1. From there, visual information branches out to visual areas that perform various computations in a generally hierarchical manner from low-level simple visual feature processing to high-level complex feature analysis (for review see Dacey, 2000; Van Essen et al., 1990).

Several characteristics are shared between these areas. At each area, one or more computations are performed for locations of varying size across the entire visual scene (Brewer et al., 2005; Van Essen et al., 1990; Wandell, 1999; Wandell et al., 2005, 2007). These computations are performed by neurons with receptive fields of a portion of visual space, typically in a mutually inhibitory center-surround organization, such that a neuron will receive inputs from other related neurons (Burkhalter & Bernardo, 1989; Carandini & Heeger, 1994; Carandini, Horton, & Sincich, 2007). A very efficient way to accomplish this task is to keep

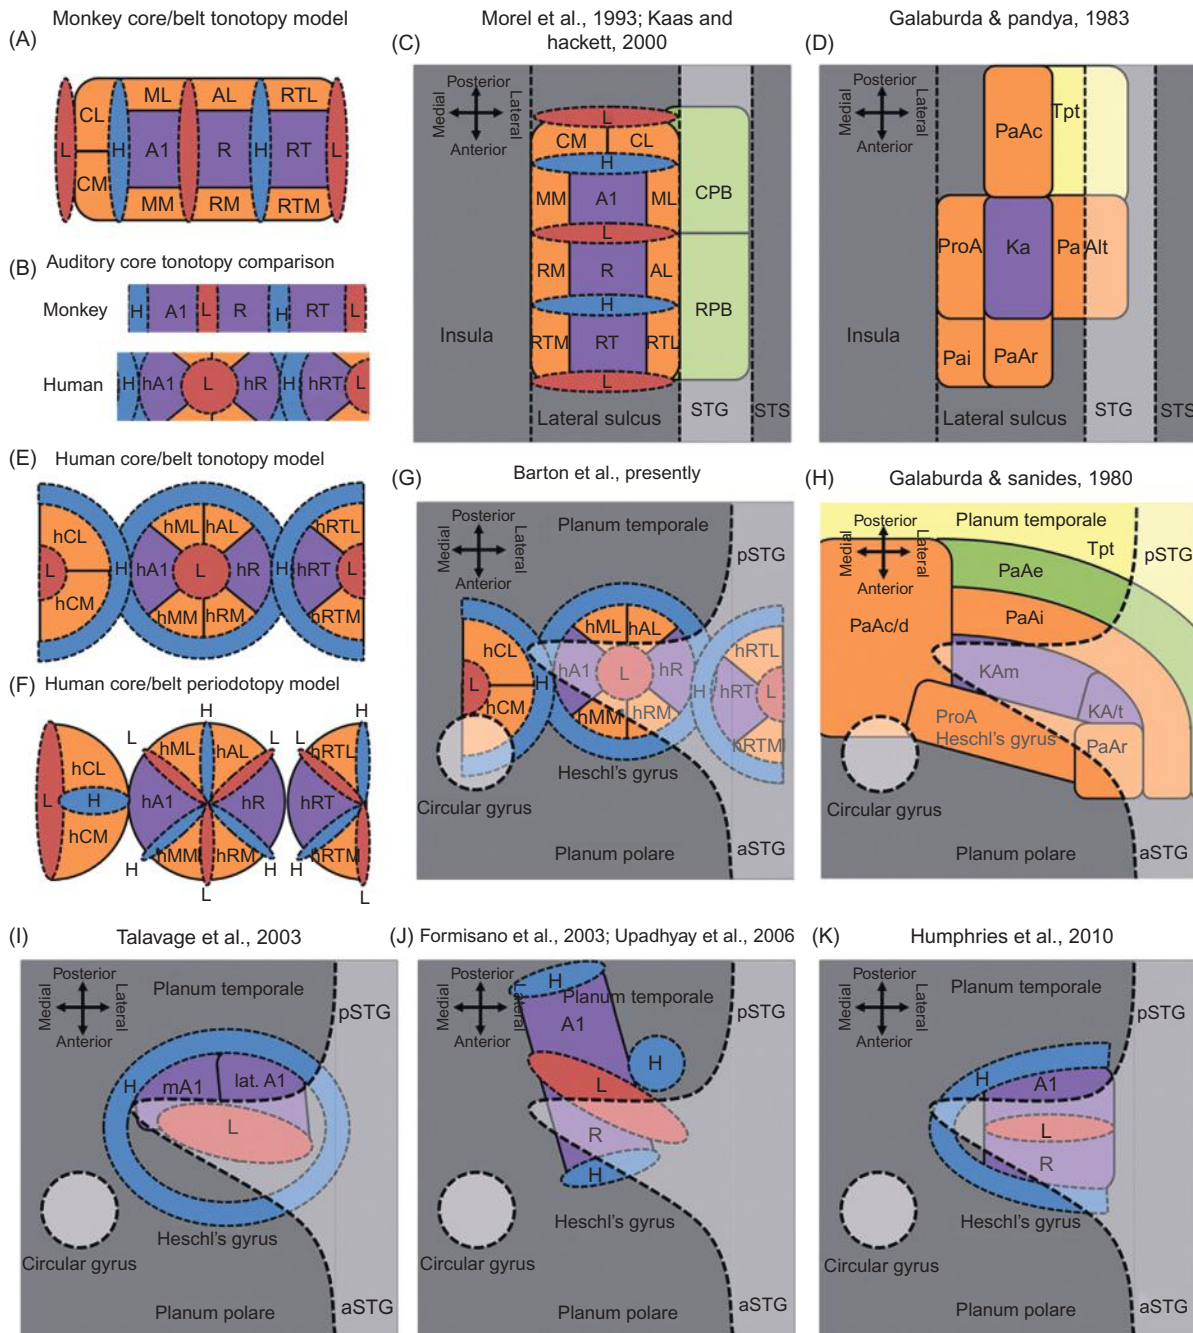

FIGURE 5.3 Comparison of present “clover leaf” cluster organization with human and monkey tonotopic and anatomical data. Cartoon models depict representations of the original models cited above each figure, modified for consistency here. “L” stands for “low” and “H” stands for “high,” referring to low (red regions) or high (blue regions) model tonotopic or periodotopic responses. Dark gray indicates sulci or the plane of the lateral fissure, whereas light gray indicates gyri. Purple regions represent auditory core. Orange regions indicate auditory belt. Green regions indicate auditory parabelt. Yellow regions indicate temporal planum temporal (Tpt). All figures are oriented along the same global axes (see direction legends). (A) Monkey core/belt tonotopy model. (B) Auditory core tonotopy comparison. Top: monkey. Bottom: human. (C) Tonotopic model of monkey auditory core, belt, and parabelt. (D) Cytoarchitectonic model of monkey auditory cortex. (E) Human core/belt tonotopy model. (F) Our human core/belt periodotopy model. (G) Our tonotopic model of human belt and core. (H) Cytoarchitectonic model of human auditory cortex. (I–K) Recent human fMRI tonotopy models.

neurons that analyze nearby locations in space close to one another (Chklovskii & Koulakov, 2004; Mitchison, 1991; Moradi & Heeger, 2009; Shapley et al., 2007). As a result, visual areas are organized retinotopically; that

is, nearby points of visual space are represented by neurons in nearby locations in cortex after the organization in the retina (Brewer et al., 2005; Wandell, 1999; Wandell et al., 2005, 2007). Because visual space is

basically two-dimensional, we can chart two gradients: eccentricity (i.e., distance from a central fixation point) and polar angle (i.e., angular distance around a central fixation point). A VFM can be defined where these two gradients are measured in the same location of cortex, each representing most or all of one hemifield of visual space and positioned orthogonally to one another.

Retinotopy allows for efficient connections within a VFM, but what about between VFMs? One organizational pattern that would maintain efficient connections between nearby points in space across maps would be to have the representations of a visuospatial gradient reverse from one visual area to the next at the visual area boundaries, such that two VFMs abut at a merged representation of, for example, the upper vertical meridian of the visual field, as seen in the adjoining AFMs elsewhere (Barton et al., 2012; Figure 5.2). To be efficient for two gradient dimensions, an efficient pattern is to have approximately circular clusters of maps. Then, reversals of one dimension occur between maps within the cluster (e.g., polar angle) and reversals for the other occur between maps in different clusters (e.g., eccentricity). The result is concentric rings of increasingly eccentric iso-eccentricity representations expanding from the center of a cluster and lines of isopolar angles extending from the center to the periphery of the cluster like spokes on a wheel. Such clusters of VFMs have been discovered in human and monkey visual cortex and have been termed “clover leaf” clusters (Brewer & Barton, 2011; Kolster, Peeters, & Orban, 2010; Wandell et al., 2005, 2007). For a recent detailed discussion of VFM organization and the implications of “clover leaf” clusters, see Brewer and Barton (2012).

5.8 “CLOVER LEAF” CLUSTERS ACROSS SENSES

Revealing a similar macrostructural organization to the visual system, the first “clover leaf” cluster was discovered in the human auditory system on HG (Barton et al., 2012). The same benefit of efficient connectivity is achieved in the same way, by representing nearby portions of auditory acoustic dimensions (i.e., tonotopy and periodotopy) in nearby portions of cortex. Specifically, the first auditory “clover leaf” cluster consists of six AFMs: hA1, hAL, hML, hR, hRM, and hMM. Concentric circles of increasing iso-tone bands expand from the low-frequency representation centered on HG, with iso-period bands extending from the center to the periphery of the cluster like spokes on a wheel. Abutting the cluster where HG meets the STG, there exists a tonotopic reversal into three additional AFMs: hRT, hRTL, and hRTM. Additionally, two more AFMs abut the HG cluster medially: hCM

and hCL. Although hRT, hRTL, hRTM, hCM, and hCL have not been shown to be organized into complete clusters of AFMs yet, we suspect that they are as well; more research is required to determine whether that is the case.

It is important to consider the monkey cortical model now that the first human auditory “clover leaf” cluster has been discovered. Because tonotopy and cytoarchitecture indicate that the early auditory cortical organization is very similar across these primate species, it is very likely that the monkey areas are organized into “clover leaf” clusters as well. Additionally, “clover leaf” clusters in the visual domain have been found to exist in macaque in homologous areas to clusters in humans (Kolster et al., 2009, 2010), suggesting that the same will be true in the auditory domain. It is impossible to know for certain until orthogonal periodotopic gradients are identified in the same monkey cortex as tonotopic gradients (Barton et al., 2012).

One interesting feature of “clover leaf” clusters is that there must be an even number of maps in a cluster, likely to minimize connection length by always having gradient reversals at the adjoining boundaries between maps. With an odd number of maps in a cluster, there would need to be at least one discrete jump between periodotopic gradient representations, which would reduce the connection efficiency. So far, “clover leaf” clusters have only been observed with even numbers of maps in a cluster (Brewer & Barton, 2012; Kolster et al., 2009, 2010; Wandell et al., 2005, 2007). Another interesting feature is that there need not be the same number of maps in each cluster; so far, two, four, and six maps have been observed in “clover leaf” clusters. Finally, the fact that these clusters of sensory field maps have been observed with such similar characteristics across two senses strongly implies that similar organizational schemes are common for sensory systems in the brain in general.

5.9 CONCLUSION

The cortical organization of the human auditory system so far has been incompletely measured. Although we know some of the features and locations of low-level processing in cortex, until recently we did not have the tools to localize individual AFMs. The key insight to the second dimension of AFMs, periodotopy, was recently discovered. Because tonotopic and periodotopic gradients are represented orthogonally to one another along the cortical surface, it is possible to accurately differentiate the locations of individual cortical AFMs rather than to attempt to estimate map boundaries based only on tonotopy. Additionally, a new

organizational scheme of AFMs has been revealed: the “clover leaf” cluster. With these new insights into AFM organization, researchers can now better localize and identify specific regions of auditory cortex across subjects and more accurately investigate which computations each of the AFMs subserves. Human visual and auditory cortex interestingly share a common organizational scheme, with each sensory system compartmentalized into cortical field maps that are themselves arranged on a larger scale into “clover leaf” clusters. Such similarity may be common across many sensory systems, which may aid in the future identification of cortical field maps in the representation of other senses.

Naturally, many important questions remain unanswered. The AFMs identified so far are unlikely to be the last; novel human cortical VFMs continue to be discovered after two decades of research, and we expect that additional AFMs will be measured in human auditory cortex outside of HG. Because complex language is a uniquely human trait, animal models offer little guidance as to which AFMs to expect to perform relevant computations. However, evidence from monkey perception of monkey vocalizations (Petkov et al., 2008) suggests distinct cortical regions as strong candidates for investigation of specific AFMs subserving human speech perception. Armed with greater knowledge of the inputs to and organization of the initial tiers of the auditory processing hierarchy, researchers will finally be in a position to rigorously investigate the nature of higher-order speech perception computations (Hickok & Poeppel, 2007).

Motor Cortex and Mirror System in Monkeys and Humans

Giacomo Rizzolatti^{1,2} and Stefano Rozzi¹

¹Department of Neuroscience, University of Parma, Parma, Italy; ²Brain Center for Motor and Social Cognition, Italian Institute of Technology, Parma, Italy

6.1 INTRODUCTION

There are many ways in which individuals communicate. Undoubtedly, at the core of human communication is speech. However, humans also communicate using gestures, body postures, and facial expressions. Whereas speech is uniquely human, gestural communication is also present in other species of primates. There is still controversy regarding the relation between these two types of communication, yet it is very likely that they have a common evolutionary root.

Starting from these premises, we first review the anatomy and physiology of the motor system in the monkey, with emphasis on those areas that are involved in communicative functions. We then compare the anatomical and functional properties of these areas with those of humans. A particular emphasis is given to the mirror mechanism and its role in communication.

An important point to stress is that communication is not necessarily intentional. Many messages that we receive from conspecifics as well as from individuals of other species are not intentional. Of these two types of communications, the nonintentional one is the most primitive. At the end of this chapter, we argue that intentional communication is an evolutionarily development of nonintentional communication.

6.2 ANATOMY OF THE MONKEY MOTOR CORTEX

6.2.1 The Agranular Frontal Cortex

According to the classical cortical map of Brodmann (1909), the motor cortex is formed by two cytoarchitectonic areas: area 4 and area 6. Although Brodmann

considered area 6 as a single entity, various authors subdivided it into various sub-areas (Vogt & Vogt, 1919; Von Bonin & Bailey, 1947). In recent years, the combination of the cytoarchitectonic techniques with the neurochemical ones has proven to be useful for a more objective assessment of areal borders (see Belmalih et al., 2007; Geyer et al., 2000).

This multi-architectonic approach led to the parcelation of the agranular frontal cortex shown in Figure 6.1 (Belmalih et al., 2009; Matelli, Luppino, & Rizzolatti, 1985, 1991). Over the years, this map has been validated by evidence showing that each of its subdivisions has its own characterizing functional and connectional features, thus fulfilling all the criteria generally accepted for the definition of a cortical area (Van Essen, 1985).

The most caudal agranular frontal area is the primary motor cortex. This area, often referred to as area M1, corresponds to area F1 in the classification of Figure 6.1. The motor areas located rostral to area F1 can be grouped into two major classes: the caudal premotor areas F2, F3, F4, F5_p, and F5_c and the rostral premotor areas F5_a, F6, and F7 (Rizzolatti & Luppino, 2001).

This subdivision, mostly based on their cortical connectivity, fits the organization of the corticospinal and corticobulbar projections of the premotor areas. The caudal premotor areas send direct projection to both the spinal cord and the brain stem (Dum & Strick, 1991; He, Dum, & Strick, 1993, 1995; Keizer & Kuypers, 1989). In contrast, the rostral ones do not project to the spinal cord; their descending fibers terminate in the brain stem (Keizer & Kuypers, 1989). It is interesting to note that while caudal premotor areas display somatotopically organized connections with each other and with the primary motor area F1, rostral

FIGURE 6.1 Lateral and mesial view of the monkey brain showing a modern detailed anatomical and functional parcellation of the agranular frontal cortex and the posterior parietal cortex. Intraparietal, arcuate, and cingulate sulci are shown unfolded. DLPF: dorsolateral prefrontal cortex; AI: inferior arcuate sulcus; AS: superior arcuate sulcus; C: central sulcus; Ca: calcarine fissure; Gg: cingulate sulcus; DLPF: dorsolateral prefrontal cortex; IO: inferior occipital sulcus; IP: intraparietal sulcus; L: lateral fissure; Lu: lunate sulcus; P: principal sulcus; PO: parieto-occipital sulcus; ST: superior temporal sulcus; VLPF: ventrolateral prefrontal cortex. Modified from *Matelli et al. (1991)*.

premotor areas are not connected with F1 and, especially in the case of F6, have widespread connections with other motor areas.

6.2.2 Cortical Connections of the Motor Areas

Cortical afferents to the frontal motor areas originate from three main regions: the parietal cortex, the prefrontal cortex, and the agranular cingulate cortex (*Rizzolatti & Luppino, 2001*).

The strong, reciprocal connections with the parietal cortex are the major source of input to the F1 and the caudal premotor areas. As the agranular frontal cortex, the posterior parietal cortex is formed by a mosaic of areas (*Figure 6.1*), each of which deals with specific aspects of sensory information and with the control of specific effectors. Both the inferior parietal lobule (IPL) and the superior parietal lobule (SPL) receive somatosensory and visual inputs, originating from the “dorsal visual stream” (*Colby, 1998; Rizzolatti & Matelli, 2003*). In general, areas of IPL and the posterior areas of the SPL process either visual only or somatosensory and visual information, whereas the rostral areas of the SPL deal mostly with somatosensory information (*Caminiti, Ferraina, & Johnson, 1996; Rizzolatti, Fogassi, & Gallese, 1997*).

Examining the parieto-frontal organization in more detail, it turns out that each motor area is reciprocally connected to a specific set of parietal areas. Thus, within the general framework of parieto-frontal connections it

is possible to identify a series of largely segregated circuits formed by parietal and motor areas linked by predominant connections. Functional evidence indicates that parietal and frontal areas forming each circuit share common functional properties. Therefore, the functional correlate of this anatomical organization is that each of these circuits is specifically involved in transforming sensory stimuli into motor terms (*Rizzolatti et al., 1997; Rizzolatti, Luppino, & Matelli, 1998*). Thus, these parieto-frontal circuits, and not the frontal motor areas in isolation, should be considered the functional units of the cortical motor system (*Rizzolatti et al., 1998*).

Prefrontal projections to the motor cortex are primarily directed to rostral premotor areas (*Borra, Gerbella, Rozzi, & Luppino, 2011; Gerbella, Belmalih, Borra, Rozzi, & Luppino, 2010; Gerbella, Borra, Tonelli, Rozzi, & Luppino, 2013; Lu, Preston, & Strick, 1994; Luppino, Matelli, Camarda, & Rizzolatti, 1993*). Prefrontal input to area F7 originates only from the dorsal part of the lateral prefrontal cortex (DLPF), that to F6 originates from both the dorsal and the ventral part of the lateral prefrontal cortex (VLPF), and that to F5a originates only from the VLPF. In addition, F6 also receives strong afferents from the rostral cingulate cortex (area 24c). Cingulate connections are considerably weaker for F7 and F5a. However, F5a is densely connected with rostral opercular frontal areas.

Altogether, these data indicate that the caudal and rostral premotor sectors play a different functional role in motor control. Caudal premotor areas are involved

in transformations of sensory information into potential motor acts. Rostral premotor areas appear to play a hierarchically higher role. These areas convey information related to high-order action organization, working memory, and motivation from the prefrontal, cingulate, and opercular frontal cortex to the caudal premotor areas. This information is used by the caudal premotor areas for determining which motor acts will be executed and when, according to external and internal contingencies.

6.2.3 Area F5: Anatomical Subdivisions

The area crucially involved, besides motor control, in communication is area F5. In this and the next sections, we describe its anatomical and functional properties, with particular emphasis on its role in action understanding.

Area F5 forms the rostral part of the ventral premotor cortex. Recent evidence showed that F5 is subdivided into three sectors (Belmalih et al., 2009): F5c, F5p, and F5a. F5c (convexity) extends on the convexity of the postarcuate cortex adjacent to the inferior arcuate sulcus; F5p (posterior) and F5a (anterior) lie within the postarcuate bank, at different antero-posterior levels.

F5p and F5c sectors encode hand and hand and face/mouth motor acts. They host motor and visuomotor neurons, including mirror neurons. F5p is tightly connected with the hand field of the primary motor area and is a source of projections to the brain stem and to the cervical spinal cord (Borra, Belmalih, Gerbella, Rozzi, & Luppino, 2010; Dum & Strick, 1991). These connections enable F5p to generate object-oriented hand motor acts (Prabhu et al., 2009; Shimazu, Maier, Cerri, Kirkwood, & Lemon, 2004).

F5a sector, although basically part of the agranular frontal cortex, displays “transitional” architectonic features between those of PMv and those of the granular frontal cortex (Belmalih et al., 2009). Recent data (Borra et al., 2011; Gerbella et al., 2010; Gerbella, Belmalih, Borra, Rozzi, & Luppino, 2011; Gerbella et al., 2013) showed that F5a is the PMv subdivision most strongly connected to ventral prefrontal areas 12 and ventral 46. Furthermore, its connections with rostral opercular frontal sectors are much stronger than those of the other F5 subdivisions. These data suggest that F5a is a privileged site of integration of sensory motor signals originating from the parietal cortex and higher-order information originating from prefrontal and rostral frontal opercular areas.

Finally, an area located on the fundus of the inferior arcuate sulcus is considered by some authors as the homolog of human area 44 (Petrides & Pandya, 1994). However, the fundal location of this area renders it very difficult to assess its cytoarchitectonic structure

and to study its connectivity. For this reason, naming this fundal region as monkey area 44 could be accepted with some caution.

6.2.4 Motor Properties of Area F5: The Vocabulary of Motor Acts

Single neuron studies revealed that most F5 neurons code specific motor acts, rather than individual movements (Rizzolatti et al., 1988). Using the effective motor act as the classification criterion, F5 neurons were subdivided into various classes. Among them, the most represented are “grasping,” “holding,” and “manipulating” neurons. Neurons discharging for a specific motor act typically do not discharge during the execution of similar movements aimed at a different goal. For example, a neuron that discharges during finger movements for grasping an object does not discharge during similar movements aimed at scratching. In contrast, F5 neurons typically discharge when the same goal is achieved by using different effectors (e.g., the right hand, the left hand, or the mouth), thus requiring completely different movements (Figure 6.2A).

On these bases, it has been proposed that F5 contains a “vocabulary” of motor acts (Rizzolatti et al., 1988). This motor vocabulary comprises “words,” each of which is represented by a population of F5 neurons. Some of them encode the general goal of a motor act, others encode how a specific goal-directed motor act must be executed, and others specify the temporal aspects of the motor act to be executed (Jeannerod, Arbib, Rizzolatti, & Sakata, 1995). A further demonstration that F5 neurons encode motor acts has been recently provided by a study in which the same motor goal (i.e., taking possession of food) was achieved by means of opposite movements (Umiltà et al., 2008). Monkeys grasped objects using “normal pliers” (i.e., pliers that require hand closure to take possession of the object) and “reverse pliers” (i.e., pliers that instead require hand-opening to achieve the same goal) (Figure 6.2B). In both cases the neural discharge correlated with food grasping, regardless of whether it was achieved by closing the hand or by opening it.

6.2.5 Canonical Neurons and the Visuomotor Transformation for Grasping

Beside purely motor neurons, area F5 also contains visuomotor neurons (Rizzolatti et al., 1988). Among them, two main categories were described: canonical and mirror neurons. Canonical neurons are mostly located in area F5p. Their visual discharge is triggered by the presentation of 3D objects (Murata et al., 1997; Raos, Umiltà, Murata, Fogassi, & Gallese, 2006). The majority of canonical neurons respond selectively to objects of a

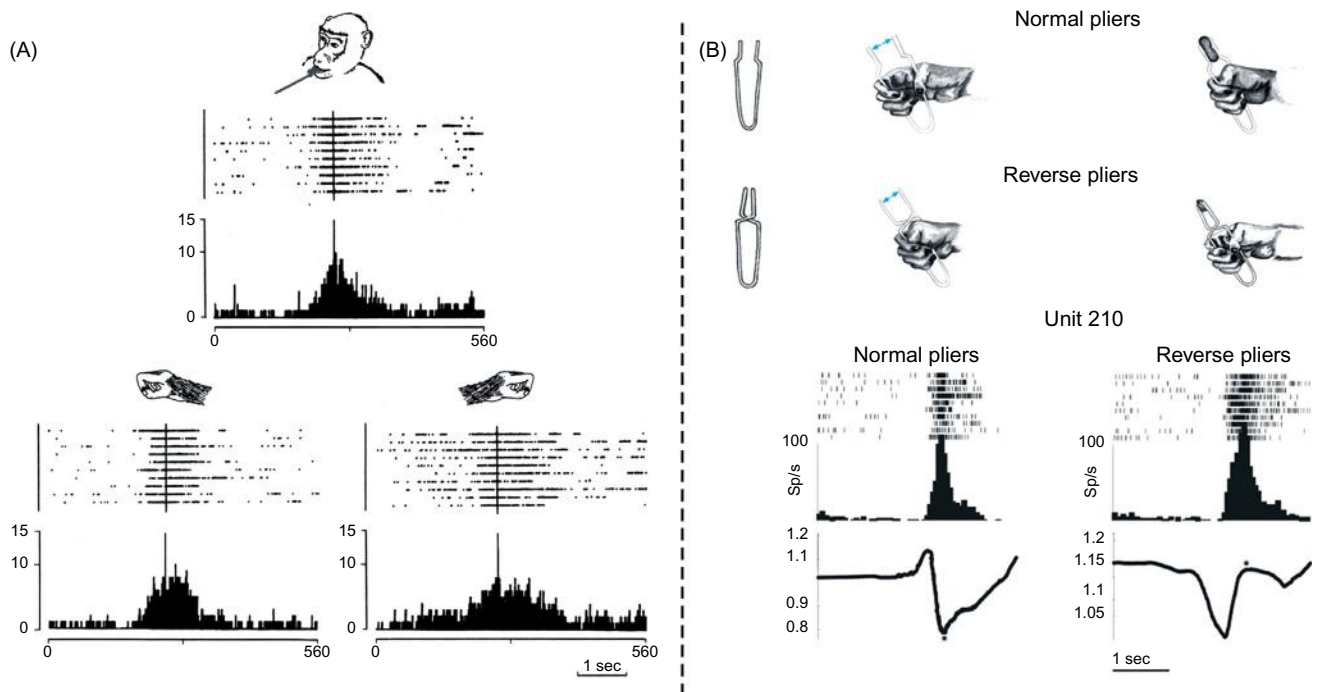

FIGURE 6.2 Goal coding in area F5. (A) Discharge of an F5 neuron active during grasping with the mouth, the right hand, and the left hand. Abscissae: time; ordinates: spikes per bin; bin width: 20 ms. (B) Example of an F5 neuron discharging during grasping with normal and reverse pliers (modified from Rizzolatti *et al.*, 1988). (Upper) Pliers and hand movements necessary for grasping with the two types of pliers. (Lower) Rasters and histograms of the neurons' discharge during grasping with pliers. The alignments are with the end of the grasping closure phase (asterisks). The traces below each histogram indicate the hand position, recorded with a potentiometer, expressed as function of the distance between the pliers handles. When the trace goes down, the hand closes; when it goes up, it opens. The values on the vertical axes indicate the voltage change measured with the potentiometer. Other conventions as in Figure 6.2A. Modified from Umiltà *et al.* (2008).

certain size, shape, and orientation. Typically, the visual specificity is congruent with the motor one (e.g., motor selectivity: precision grip/visual selectivity of small objects; motor selectivity: whole hand prehension/visual selectivity of large objects). The visual responses of canonical neurons cannot simply be explained in terms of motor preparation because they are also present when no response toward the object is required (Murata *et al.*, 1997). The most accepted interpretation of their discharge is that object presentation activates a representation of the observed stimulus in motor terms. In other words, when an object is seen, the discharge of canonical neurons codes a potential motor act congruent with the properties of the presented object, independent of whether the act will be executed. In other words, when an object is seen, the discharge of specific canonical neurons codes a *potential* motor act congruent with the properties of the presented object.

Area F5p is strongly connected with the intraparietal area AIP (Borra *et al.*, 2008; Luppino, Murata, Govoni, & Matelli, 1999), where neurons with similar functional properties have been described (Murata, Gallese, Luppino, Kaseda, & Sakata, 2000; Sakata, Taira, Murata, & Mine, 1995; Taira, Mine, Georgopoulos, Murata, & Sakata, 1990). How do the visuomotor transformations for grasping occur? There

are various models that attempt to explain the role that AIP and F5 play in this process (Fagg & Arbib, 1998; Jeannerod *et al.*, 1995; Rizzolatti & Luppino, 2001; Taira *et al.*, 1990). A common idea underlying these models is that when an object is observed, AIP neurons extract specific aspects of its physical properties and provide F5 with the description of the *possible ways* in which the object could be grasped (*affordances* as defined by Gibson, 1979). On the basis of the intention of the individual and the context, the prefrontal lobe activates AIP visuomotor neurons and neurons in F5 coding the appropriate grip. The information relative to the chosen grip is then sent from F5 to F1, where the different movements necessary to grasp the object are selected and the final command for its execution is generated.

As already mentioned, F5 canonical neurons code potential motor acts that eventually may become actual movements. What is the mechanism that allows the transformation of these potential motor acts into actual movements? Mesial area F6 (pre-SMA) is anatomically connected with F5 (Luppino *et al.*, 1993). In turn, this area receives inputs from prefrontal and cingulate cortex, likely providing it with contextual and motivational information. Thus, area F6 may be a key area to determine, according to the external contingencies, whether the potential motor act will be actually executed.

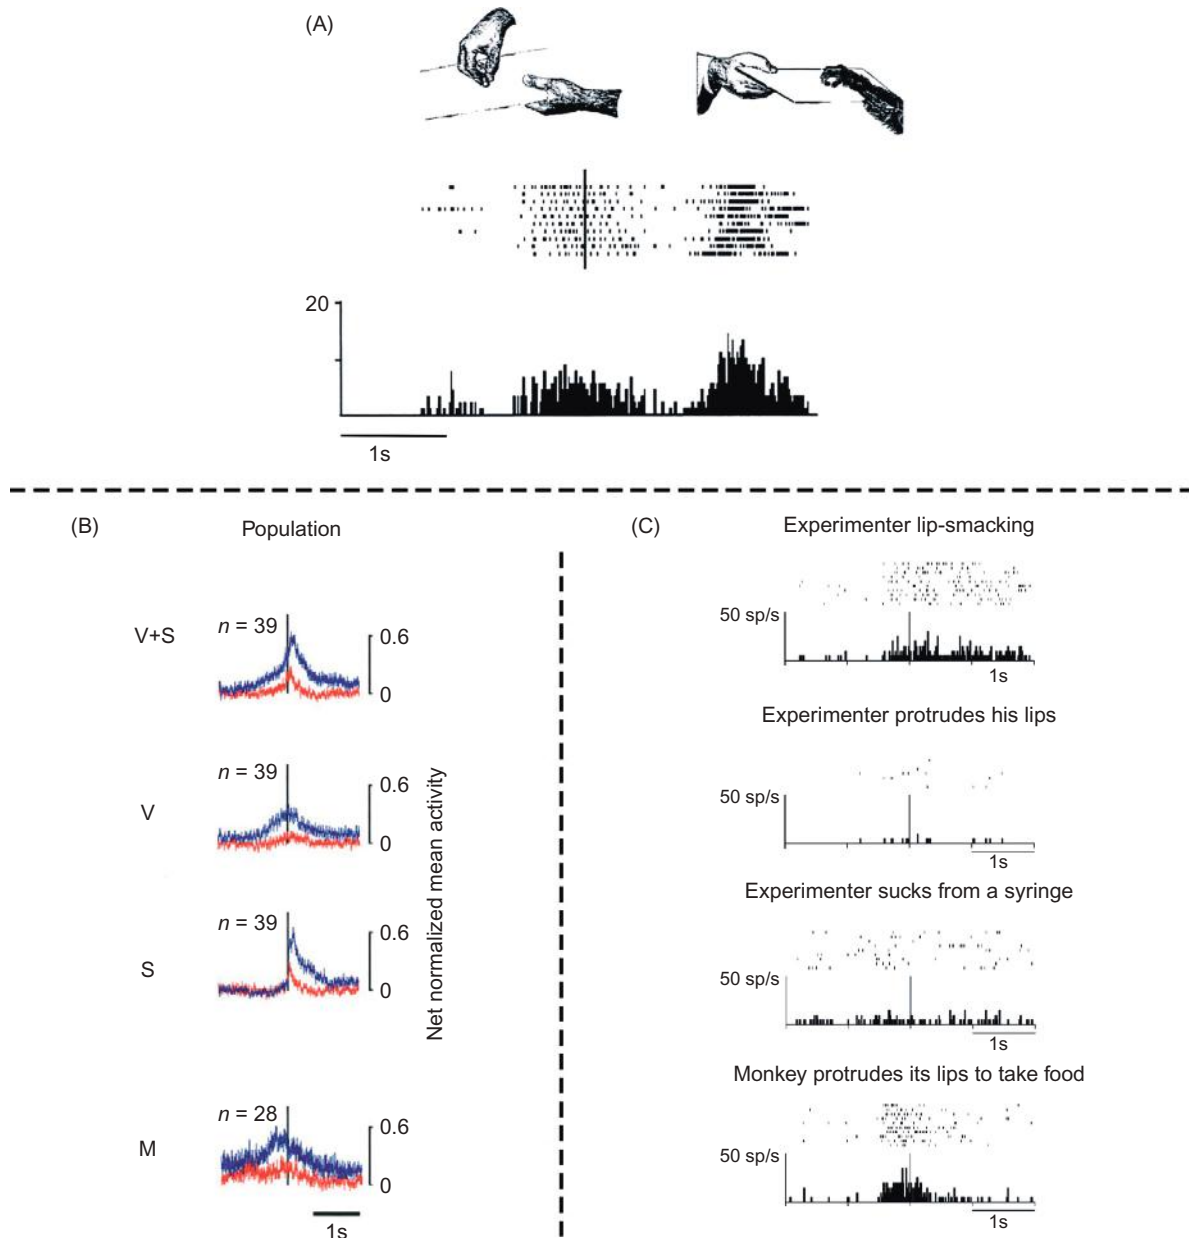

FIGURE 6.3 Examples of F5 mirror neurons. (A) Mirror neuron responding during observation and execution of a hand-grasping motor act. Conventions as in Figure 6.2 (modified from di Pellegrino *et al.*, 1992). (B) Responses of the population of tested neurons selectively activated by the vision-and-sound, vision-only, sound-only, and motor conditions. Responses to the most effective stimuli are shown in blue, and responses to the poorly effective stimuli are in red. Vertical lines indicate the auditory response onset in the population. Y axes are in normalized units for the population (modified from Kohler *et al.*, 2002). (C) Mirror neuron responding during the observation of an intransitive mouth action (lip-smacking). During observation of intransitive actions, the rasters and histograms alignment is at the moment in which the action is fully expressed; other conventions as in Figure 6.2 (modified from Ferrari *et al.*, 2003).

6.2.6 Mirror Neurons and Action Understanding

A second class of visuomotor neurons present in area F5 is that of mirror neurons. Mirror neurons are more frequently located in F5c. They discharge both when the monkey *performs* a goal-directed motor act and when it observes the same, or a similar, motor act performed by another individual (Figure 6.3A; Di Pellegrino,

Fadiga, Fogassi, Gallese, & Rizzolatti, 1992; Gallese, Fadiga, Fogassi, & Rizzolatti, 1996; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). Unlike canonical neurons, they do not respond to object presentation. Furthermore, they do not discharge or discharge less during the observation of biological movements devoid of a goal, including mimicked actions.

The observed hand motor acts more effective in eliciting mirror neurons discharge are grasping,

manipulating, and holding. The visual response of many mirror neurons is invariant with respect to visual aspects of the observed action. However, other mirror neurons show specificity for the direction of the hand movement or the space sector (left or right; close or far) in which the observed motor act is presented or the hand (left or right) used by the observed agent (Caggiano, Fogassi, Rizzolatti, & Thier, 2009; Gallese et al., 1996). As far as the location in depth is concerned, it was found that half of mirror neurons sensitive to this parameter discharged more strongly when the motor act was performed within the monkey peripersonal space, whereas the other half responded better when the same motor act was performed in the extrapersonal space. Interestingly, when the peripersonal space (defined as the space within which grasping is possible) of the monkey was reduced by introducing a transparent barrier, a set of extrapersonal neurons started to discharge within the old peripersonal space transformed into a space no longer reachable (Caggiano et al., 2009). These data indicate that this specific set of mirror neurons code the actions of others in relation to interaction possibilities.

It has been proposed that the property shown by mirror neurons of encoding the visual description of a goal-directed act in motor terms allows the observer to understand *what* another individual is doing, because the observation of a motor act performed by others determines an automatic retrieval of a potential motor act from the “vocabulary” of the observer.

The hypothesis that mirror neurons have an important role in understanding the motor acts of others has been supported by various studies. In one of them it was shown that grasping mirror neurons discharge not only when the monkey observes a grasping motor act (effective visual stimulus) but also when it sees the agent’s hand moving toward the target hidden by an opaque screen (Umiltà et al., 2001). The discharge was absent when the monkey knew that there was no object behind the screen. This finding suggests that mirror neurons use prior information to retrieve the motor representation of the observed motor act.

In another study, sensory information concerning the motor act was presented to the monkey in an acoustic and/or a visual format (Kohler et al., 2002). It was found that a subset of mirror neurons, called “audio-visual mirror neurons,” discharged not only during execution and observation of a motor act (e.g., breaking a peanut) but also by listening to the typical sound produced by that act. This indicates that a motor act is understood regardless of how the information reaches the mirror neurons (Figure 6.3B).

Besides mirror neurons encoding hand motor acts, mouth mirror neurons have also been described. These neurons are mostly found in the lateral part of area F5.

The majority of them respond to the observation and execution of ingestive motor acts such as biting, sucking, and licking (Ferrari, Gallese, Rizzolatti, & Fogassi, 2003). They do not respond to object presentation or to mouth-mimed motor acts. A smaller but significant population of mouth mirror neurons responds specifically to the observation of mouth communicative gestures, such as smacking of the lips or tongue protrusion (Figure 6.3C). Mouth mirror neurons of this sub-category do not respond, or respond very weakly, to the observation of ingestive motor acts. These mirror neurons are of particular interest because they could constitute an evolutionary ancient communicative system evolving from neurons coding ingestive motor acts (Fogassi & Ferrari, 2012; Rizzolatti & Arbib, 1998).

In the experiment just described, it was very difficult to elicit mouth communicative gestures and even more difficult to elicit communicative calls. In a subsequent experiment, however, the monkey turned out to be able, after long periods of training, to emit voluntarily “coo-calls” (Coudé et al., 2011). Single neuron recording demonstrated that in the ventral part of area F5, there are neurons whose discharge correlates with the voluntary call emission (Coudé et al., 2011). This finding is of great interest because it suggests that this F5 sector might be the precursor of the region that controls the voluntary emission of voice in humans.

6.2.7 Mirror Neurons in the Parietal and the Primary Motor Cortex

6.2.7.1 Primary Motor Cortex

The issue of whether the output of premotor and motor cortex contains neurons endowed with mirror properties has been recently addressed. Kraskov, Dancause, Quallo, Shepherd, and Lemon (2009) investigated the activity of corticospinal neurons (PTNs) located in area F5 and in area F1. They found that approximately half of F5 corticospinal neurons responded to action observation. Interestingly, approximately 25% of these PTNs showed a suppression of their discharge when the monkey observed the experimenter grasping an object. The authors suggested that the suppression of the PTNs during grasping observation may play a role in inhibiting the movement of the observer triggered by the observed action.

The same paradigm was applied to F1 PTNs (Kraskov et al., 2009). As in F5, approximately half of these neurons were modulated during action observation. The majority increased their discharge during action observation (“facilitation-type” mirror neurons), whereas some reduced or stopped their firing (“suppression-type” mirror neurons). A comparison

of the properties of PTNs F1 and F5 PTNs mirror neurons showed that the visual response in F1 was much weaker than in F5. Taken together, these data indicate that the understanding of motor goals is not only a function of F5 mirror neurons but also a function of the activation of a complex motor pattern that involves corticospinal tract neurons, including those originating in F1.

6.2.7.2 Parietal Cortex

Mirror neurons were also recorded from IPL and, in particular, from area PFG (Fogassi et al., 2005; Gallese, Fadiga, Fogassi, & Rizzolatti, 2002; Rozzi, Ferrari, Bonini, Rizzolatti, & Fogassi, 2008). There is evidence, however, that mirror neurons are also present in AIP (personal data). PFG grasping neurons have been specifically studied to elucidate whether their discharge was modulated by the overarching action intention (Fogassi et al., 2005). For this purpose their activity was recorded while the monkey executed a motor task in which the same motor act (grasping) was embedded into two different actions (grasping to eat and grasping to place). The neurons were then tested with the monkey observing the same task, performed by an experimenter.

The results showed that a high percentage of parietal neurons discharge with different intensity during grasping execution, depending on overarching goal of the actions. On the basis of these findings, it was proposed (Fogassi et al., 2005) that parietal neurons form prewired chains in which a neuron coding a given motor act is facilitated by the neuron coding that previously executed. Any time an agent has the intention (overarching goal) to perform an action, a specific neuronal chain is activated. This model accounts for the fluidity with which the different motor acts of an action are executed one after another (Jeannerod, Paulignan, & Weiss, 1998; Rosenbaum, Cohen, Jax, Weiss, & van der Wel, 2007).

In the visual task, as in the motor task, it was found that most mirror neurons discharged differently during grasping, depending on overarching goal of the actions. Because in this case grasping was performed by the observed agent, it was suggested that the neuronal selectivity for the action goal during grasping observation activated the chain of motor neurons corresponding to a specific intention. Similar results were also obtained in area F5, where the same paradigm was applied (Bonini et al., 2010).

6.3 THE HUMAN MOTOR CORTEX

The organization of human agranular frontal cortex presents strong similarities with that of the monkey (Von Bonin & Bailey, 1947). First, as in the monkey, the

human motor cortex is formed by a mosaic of areas. Area M1, the primary motor cortex, is located caudally. It is mostly buried inside the central sulcus. Second, as in the monkey, there are two areas located on the mesial cortical surface: the supplementary motor area (SMA/F3) and the presupplementary motor area (pre-SMA/F6; see Zilles et al., 1996). Third, the motor cortex of the lateral convexity consists of two main regions: the dorsal and the ventral “premotor” region. They are frequently referred as PMd and PMv. Unlike in the monkey, where the approximate border between these two regions is easy to recognize because it is marked by the spur of the arcuate sulcus (Figure 6.1), their border is difficult to identify in humans. On the basis of embryological considerations, Rizzolatti and Arbib (1998) suggested that the human superior frontal sulcus plus the superior precentral sulcus should correspond to the monkey’s superior limb of the arcuate sulcus plus the arcuate spur. Thus, according to them, the border between PMd and PMv should lie approximately at the Z level 50 of Talairach coordinates. Recent diffusion tractography data confirmed this location (Mars et al., 2011; Schubotz, Anwander, Knösche, von Cramon, & Tittgemeyer, 2010; Tomassini et al., 2007).

Functionally, human M1 is somatotopically organized with the leg field located medially, the mouth field laterally, and the forelimb field in between. This map does not extend rostrally into area 6, as was found in macroelectrode surface stimulation studies (Penfield & Welch, 1951). The various areas forming area 6 are independent functional entities involved, as in the monkey, in different aspects of sensory motor transformation and in movement control.

Broca’s area (area 44 and area 45) is located rostral to PMv. On the basis of receptor-architectonic data (Amunts et al., 2010; Amunts & Zilles, 2012), these two areas are clustered together with opercular and ventral premotor areas. Most interestingly, recent data obtained using meta-analytic connectivity-based parcellation (Clos, Amunts, Laird, Fox, & Eickhoff, 2013) revealed five separate functional “clusters” in area 44. The two posterior clusters are primarily related to action processes, including phonology and speech, whereas the three anterior clusters are primarily associated with language and cognition. Cluster 4, located in the posterior ventral part of area 44, is associated with the observation of hand action and action imagery.

As stated, although a clear anatomical and functional homology is recognizable between the agranular frontal areas of monkeys and humans, such a homology is difficult to draw for Broca’s area. A homology between this area and the tiny cytoarchitectonic area 44 of monkeys is possible, but not very likely. More interesting for the homology issue is that the data indicating that this region codes not only speech but also

communicative actions (Clos et al., 2013). From this perspective, it is plausible that some functions located in area F5 in monkeys “moved” to the evolutionary new Broca’s region. This point is elaborated in the following sections after presentation of studies of the mirror mechanism in humans.

6.3.1 The Mirror Mechanism in Humans

The existence of the mirror mechanism in humans has been demonstrated by a large number of neurophysiological (EEG, MEG, and TMS) and neuroimaging (PET and fMRI) studies (Rizzolatti & Craighero, 2004). These studies have shown that the mirror network for hand actions includes two main regions: the dorsal part of the IPL comprising the cortex located inside the intraparietal sulcus and the ventral premotor cortex plus the caudal part of the inferior frontal gyrus (area 44). Additional areas, such as the dorsal premotor cortex and the SPL, were also found to be active during action observation (Di Dio et al., 2013; Filimon, Nelson, Hagler, & Sereno, 2007). These last areas are activated by the observation of reaching movements.

Do the mirror neurons of human premotor and parietal cortex encode motor acts, such as movement with a specific goal, as in the monkey? There is clear evidence from fMRI studies that this is the case. Gazzola, Rizzolatti, Wicker, and Keysers (2007) presented volunteers with video-clips depicting either a human or a robot arm grasping objects. The results showed that the parieto-frontal mirror circuit was activated by both these types of stimuli. This observation was extended by Peeters et al. (2009). They investigated the cortical activations in response to the observation of motor acts performed by a human hand, a robot hand, and a variety of tools in both humans and monkeys. Regardless of the type of effector used, the hand grasping circuit was activated in humans as well as in monkeys. In humans, the observation of tool motor acts also activated a rostral sector of the left anterior supramarginal gyrus. Such activation was absent in monkeys even when they observed actions made with the tools they learned to use.

A series of experiments addressed the issue of the somatotopic organization of the areas endowed with the mirror mechanism (Buccino, Binkofski, & Fink, 2001; Sakreida, Schubotz, Wolfensteller, & von Cramon, 2005; Saygin, Wilson, Hagler, Bates, & Sereno, 2004; Shmuelof & Zohary, 2005; Ulloa & Pineda, 2007; Wheaton, Thompson, Syngeniotis, Abbott, & Puce, 2004). These studies showed that the observed motor acts are encoded in the precentral gyrus according to an approximate somatotopic organization similar to that of the classical motor physiology.

A somatotopic organization was also found to be present in the IPL along and within the intraparietal sulcus. The mouth is located rostrally, the hand is in an intermediate position, and the leg is located caudally (Buccino et al., 2001). A recent study by Jastorff, Begliomini, Fabbri-destro, Rizzolatti, and Orban (2010) tried to better define the general principles underlying the somatotopic organization in the parietal and frontal cortex. Four motor acts (grasping, dragging, dropping, and pushing) performed with the mouth, hand, and foot were presented to volunteers. The results confirmed the data from previous authors concerning the premotor cortex. As for the parietal lobe, they showed that different sectors of IPL were activated by the observation of motor acts with the same behavioral valence, independent of the observed effector. More specifically, there was a subdivision between the localization of self-directed (grasping and dragging) and outward-directed motor acts (dropping and pushing). Therefore, it appears that while in the premotor cortex, motor acts executed with the same effector tend to cluster together, but in the parietal cortex the encoding is biased by the action valence.

A few studies showed that in humans the mirror network is involved in intention understanding (Iacoboni et al., 2005; Ortigue, Sinigaglia, Rizzolatti, & Grafton, 2010). In an fMRI experiment, Iacoboni et al. (2005) tested volunteers during three conditions: (i) “context;” (ii) “action;” and (iii) “intention.” During the context condition, individuals were presented with a scene showing either a “ready breakfast” or a “finished breakfast;” in the action condition, they saw pictures of a hand grasping a mug, without context; and in the intention condition, the individuals saw the same hand grasping the mug within one of the two contexts. The context represented the clue that allowed the participants to understand the agent’s intention. The comparison between conditions showed that intention understanding determined the strongest increase in the activity of the mirror system and, in particular, of its frontal node.

6.3.2 Imitation

It is important to stress at the outset of this section that the human mirror system encodes not only the observed motor acts but also the individual movements that form it. Evidence in favor of the encoding of the observed movements came from transcranial magnetic stimulation (TMS) experiments. Fadiga, Fogassi, Pavesi, and Rizzolatti (1995) asked volunteers to observe grasping acts or meaningless arm gestures. The results showed that the observation of meaningless gestures, and not just of motor acts, produced an increase in the motor-evoked potentials (MEPs). This increase was present in the same muscles that

are used to produce the observed movements. These findings were subsequently confirmed and extended by other TMS experiments (Alaerts, Heremans, Swinnen, & Wenderoth, 2009; Cattaneo, Caruana, Jezzini, & Rizzolatti, 2009; Gangitano, Mottaghy, & Pascual-Leone, 2001; Strafella & Paus, 2000).

The existence of the mirror mechanism for simple movements is a fundamental prerequisite of human capacity to imitate others. The term “imitation” includes various phenomena. Two are of interest here. The first is the capacity to *replicate* immediately the observed movements (Prinz, 1990). The second is the capacity to learn a new motor behavior by observing and then by repeating the *same* movements that the teacher executed (Byrne, 2003). In both cases, imitation requires the capacity to translate an observed movement into a motor copy of it.

Evidence that the mirror neuron mechanism is involved in imitation was provided by Iacoboni et al. (1999). Subjects were tested in two main conditions: “observation” and “observation/execution.” In the first, subjects saw a moving finger or a cross depicted on a stationary finger or a cross presented on an empty background. The subjects had to observe the stimuli. In the “observation/execution” condition, the same stimuli were presented, but with the instruction to lift the right finger as quickly as possible when they occurred. The crucial contrast was between the trials of the observation/execution condition in which the subjects made the movement in response to the observed movement (“imitation”) and the trials in which the response was triggered by the cross (“nonimitative behavior”). The main result was that the activation of the caudal part of the inferior frontal gyrus was significantly stronger during “imitation” than during the “nonimitative behavior.”

The mechanism involved in imitation learning is much more complex. Two fMRI studies addressed this issue. In the first, naive participants had to imitate guitar chords made by a teacher (Buccino, Vogt, Ritzl, Fink, & Zilles, 2004). Cortical activations were studied in three epochs: chord observation, chord execution, and the pause between the two. The results showed that during new motor pattern formation (pause epoch) there was, besides activation of the mirror circuit, an activation of area 46 and of the anterior mesial cortex. The importance of area 46 in imitation learning was subsequently confirmed in a study performed with expert players (Vogt et al., 2007).

Following Byrne (2003), a two-step model of imitation learning was proposed: (i) segmentation of the observed action into its individual movements and their transformation, thanks to the mirror mechanism, into corresponding potential movements; and (ii) the organization of these potential movements into specific

temporal and spatial patterns replicating that shown by the teacher. Parsing and sensory motor transformation are performed by the mirror mechanism, whereas the recombination of these elements into a new pattern could be a function of the prefrontal lobe and, in particular, of area 46 (Buccino et al., 2004; Vogt et al., 2007).

6.4 MOTOR SYSTEM AND COMMUNICATION

Some years ago Rizzolatti and Arbib (1998) proposed that the mirror mechanism could represent the mechanism through which language evolved. This proposal was based on the consideration that mirror neurons create a direct link between the sender of a message and its receiver. Thus, thanks to the mirror mechanism, observing and doing become manifestations of a single communicative faculty.

The proposal that speech evolved from gestural communication was by no means new (Armstrong, Stokoe, & Wilcox, 1995; Corballis, 2002, 2003). Its novelty existed in the fact that it identified a neurophysiological mechanism that could create a nonarbitrary link between the communicating individuals. In contrast to theories claiming a gestural origin of communication, other theories maintain that human speech derived from animal calls. Although intuitively appealing, these theories are, however, difficult to accept for various reasons. First, the anatomical basis for speech and animal calls are markedly different. Animal calls are mediated by the cingulate cortex and by diencephalic and brain stem structures (Jürgens, 2002). In contrast, the core circuit underlying human speech is formed by perisylvian areas. Second, human speech, unlike animal calls, is not necessarily related to emotional behavior. Third, speech is mostly a person-to-person communication, whereas animal calls are, typically, directed to all possible listeners. Finally, speech is endowed with combinatorial properties that are absent in animal communication.

Let us examine the assets and the weaknesses of the mirror neuron-based hypothesis of language evolution. The main asset is that mirror neurons solve two fundamental communication problems: parity and direct comprehension of the action. Parity requires the following: what counts for the sender of the message also counts for the receiver. Direct comprehension means that there is no need for an agreement between individuals to understand each other. The comprehension is inherent to neural organization of the individual.

The major weakness of the mirror mechanism-based theory, at least in its original formulation, was that the properties of the mirror neurons known when it was formulated indicate a close system limited to

object-directed actions. As discussed, there is now evidence that humans also possess mirror neurons encoding observed intransitive movements and not just observed motor acts. Thus, the human mirror system is an open system endowed with communicative properties.

How did it occur that the monkey closed mirror system became an open system able to describe actions and objects without directly referring to them? How did this evolutionary leap occur? A possible way to make a hypothesis regarding this point is by examining child development. A splendid example comes from studies by Vygotsky (1934). He described that when objects are located close to a child, the child grasps them; when they are located far from the child, the child extends his/her arm and hand toward them. Thus, an object-related action becomes, progressively, an intransitive communicative gesture. An evolutionary ancient goal-directed motor act becomes “pointing,” a fundamental gesture for communicating.

Another fundamental step in the evolution of speech should be the appearance of a link between gestures and sounds. Is there evidence that such a link exists? A series of recent studies provided evidence in this sense. By using TMS, it was shown that the excitability of the motor field of the right hand increases during reading and during spontaneous speech (Meister et al., 2003; Seyal, Mull, Bhullar, Ahmad, & Gage, 1999; Tokimura, Tokimura, Oliviero, Asakura, & Rothwell, 1996). Control experiments showed that this increase in excitability is not related to word articulation.

The presence of a link between speech and hand gesture was also demonstrated by Gentilucci, Benuzzi, Gangitano, and Grimaldi (2001) using a different approach. In an initial series of experiments, they asked participants to grasp two objects of different size with their mouth and, simultaneously, to open their right hand. The results showed that the maximal finger aperture and time to maximal finger aperture increased when the mouth grasped the large object. A subsequent experiment was crucial. In this experiment they asked the participants to pronounce a syllable, such as GU or GA, during observation and subsequent hand grasping of objects of different size. The syllables were written on the objects. The results showed that both sound production and mouth opening were affected by the size of the grasped object (Gentilucci et al., 2001).

Taken together, these results show that buccal and oro-laryngeal synergies necessary for syllable emission are linked to manual gestures. These findings obviously do not solve the problem of how meaning becomes associated with gestures. The discussion on how this occurred is centered on the possible relations between the sound of a word and its meaning. On the one side, some authors postulate a *natural* origin of the words,

that is, that there are intrinsic links between sounds and what they represent; however, other authors regard the faculty of speech as the result of *cultural* factors that led to an agreement on the word meaning among speakers of the same group. There is, at the moment, no convincing evidence to disentangle this dichotomy, although the hypothesis of a natural origin of language seems to be more satisfactory intellectually.

6.5 CONCLUSION

Traditionally, the caudal, motor part of the frontal lobe was considered as a region not involved in cognitive functions. The discovery of the mirror mechanism radically changed this view. There is now rich evidence that a series of cognitive functions such as space perception and action recognition not only require the activity of the motor system but also are deeply embedded in motor organization. In particular, action understanding relies on potential motor acts that originally evolved for motor behavior and subsequently became the substrate for understanding others (Figure 6.4).

Similar considerations are valid for language. There is clear evidence that the motor system is involved in perception of phonemes. By using TMS, it was shown that during speech listening there is an increase of MEPs recorded from the listeners' tongue muscles when the presented words strongly involve, when pronounced, tongue movements (Figure 6.5; Fadiga, Craighero, Buccino, & Rizzolatti, 2002). Although these data do not provide crucial evidence for the motor theory of speech perception (Liberman & Mattingly, 1985), they certainly indicate that the motor system is involved in phoneme perception.

As far as other aspects of language are concerned, it has been proposed that the semantic representations are grounded in those brain circuits that are also responsible for action organization and perception (Pulvermüller, 1999). This account is referred to as “action perception theory.” It purports that, besides the core perisylvian language circuits, there are sensory motor circuits that become active during linguistic communication. This activation would lead to the understanding of the semantics of actions. In favor of this hypothesis are neuroimaging data that found specific activations of parieto-frontal circuits when subjects listen to action words (Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni, 2006; Hauk, Johnsrude, & Pulvermüller, 2004; Tettamanti et al., 2005). Moreover, TMS data and lesion studies show contributions of motor circuits to the comprehension of phonemes and word semantics (Pulvermüller & Fadiga, 2010). Altogether, these data show that language comprehension relies, at least in part, on parieto-frontal motor systems and

FIGURE 6.4 Cortical areas active during action observation in humans. Three main regions are active: a portion of the superior temporal sulcus; the IPL, including the intraparietal sulcus; and a small part of SPL, the premotor cortex, mainly in its ventral part, and the posterior part of the inferior frontal gyrus. The activated regions depicted on the left and right hemispheres result from a meta-analysis performed in 87 studies. Modified from Caspers, Zilles, Laird, & Eickhoff (2010).

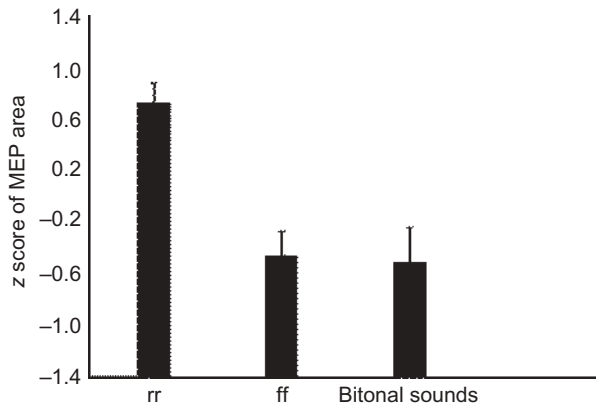

FIGURE 6.5 Activation of tongue muscles during word listening. Average value (\pm SEM) of intersubject normalized MEP total areas recorded from tongue muscles of subjects listening to words containing a double lingua-palatal fricative consonant (rr), a double labiodental fricative consonant (ff), or bitonal sounds. Modified from Fadiga et al. (2002).

indicate that action and language-perception circuits are interdependent. Finally, at present there is no neurophysiological evidence that allows one to identify the neural bases of syntactic aspects of language.

Cerebellar Contributions to Speech and Language

Hermann Ackermann and Bettina Brendel

Department of General Neurology/Center for Neurology, Hertie Institute for Clinical Brain Research,
University of Tübingen, Tübingen, Germany

7.1 INTRODUCTION

Tracing back to clinical observations in the late 19th and early 20th century, cerebellar disorders have been assumed to yield a range of distinct motor abnormalities, including a syndrome of speech motor deficits called ataxic dysarthria, but to spare perceptual and cognitive aspects of verbal communication. During the past two decades, however, a variety of higher-order abnormalities of spoken language (e.g., more or less exclusive agrammatism, amnesic, or transcortical motor aphasia) have been noted—although rather sporadically—in patients with cerebellar vascular lesions and, more frequently, during the course of recovery from a syndrome of transient mutism after resection of posterior fossa tumors in children. In addition, the identification of distinct speech sound categories appears to critically depend on the integrity of cerebellar structures. Besides motor execution, recent functional imaging data point to a contribution of the cerebellum, in concert with dorsolateral and medial frontal areas, to prearticulatory processes of verbal communication such as the sequencing or parsing of an “inner speech” code. Apart from their well-established contribution to vocal tract innervation, these cerebello-frontal interactions might support a variety of other perceptual, linguistic, and executive tasks under specific conditions (Desmond & Fiez, 1998; Ivry, 1996; Thach, 1998; for a recent review see Marien et al., 2014).

7.2 MACROSCOPIC AND MICROSCOPIC ANATOMY OF THE HUMAN CEREBELLUM

Transverse “trenches” of a varying depth subdivide the cerebellum (“small or lesser brain”) into lobes,

lobules, and folia (Nieuwenhuys, Voogd, & van Huijzen, 2008). As the most salient sulci, the posterolateral fissure separates the “small brain” into the corpus cerebelli and the flocculonodulus, and the primary fissure splits the former component into the anterior and posterior lobe (Figure 7.1A). Furthermore, two longitudinal sulci demarcate a medial vermis from the two lateral hemispheres. Unfolded on a two-dimensional surface, these subsections would translate into three rather narrow bands of tissue extending over a length of more than 100 cm each. In their actual convoluted state, the rostral and caudal ends of these strips meet each other near the dorsal surface of the fourth ventricle. An outer mantle of cortex overlies white matter encompassing two pairs of interconnected nuclei at either side: the medio-caudal group comprises the fastigial and globose, and the latero-rostral pair consists of the emboliform and dentate nucleus. In subhuman species, the globose and emboliform gray matter masses are often combined into the interpositus nucleus. Altogether, three “cables” connect the cerebellum with the spinal cord, the brain stem, and the thalamus:

1. The inferior peduncle encompasses several afferent bundles (altogether approximately 0.5 million fibers), especially the spinocerebellar and olivocerebellar tracts (restiform body), as well as direct efferent connections between flocculonodulus and vestibular nuclei (juxtarestiform body).
2. The approximately 20 million fibers of the medial peduncle (brachium pontis) arise from the pontine nuclei of the brain stem.
3. The superior peduncle (brachium conjunctivum) represents the major efferent pathway of the cerebellum, originating in the deep nuclei of the white matter and targeting predominantly the

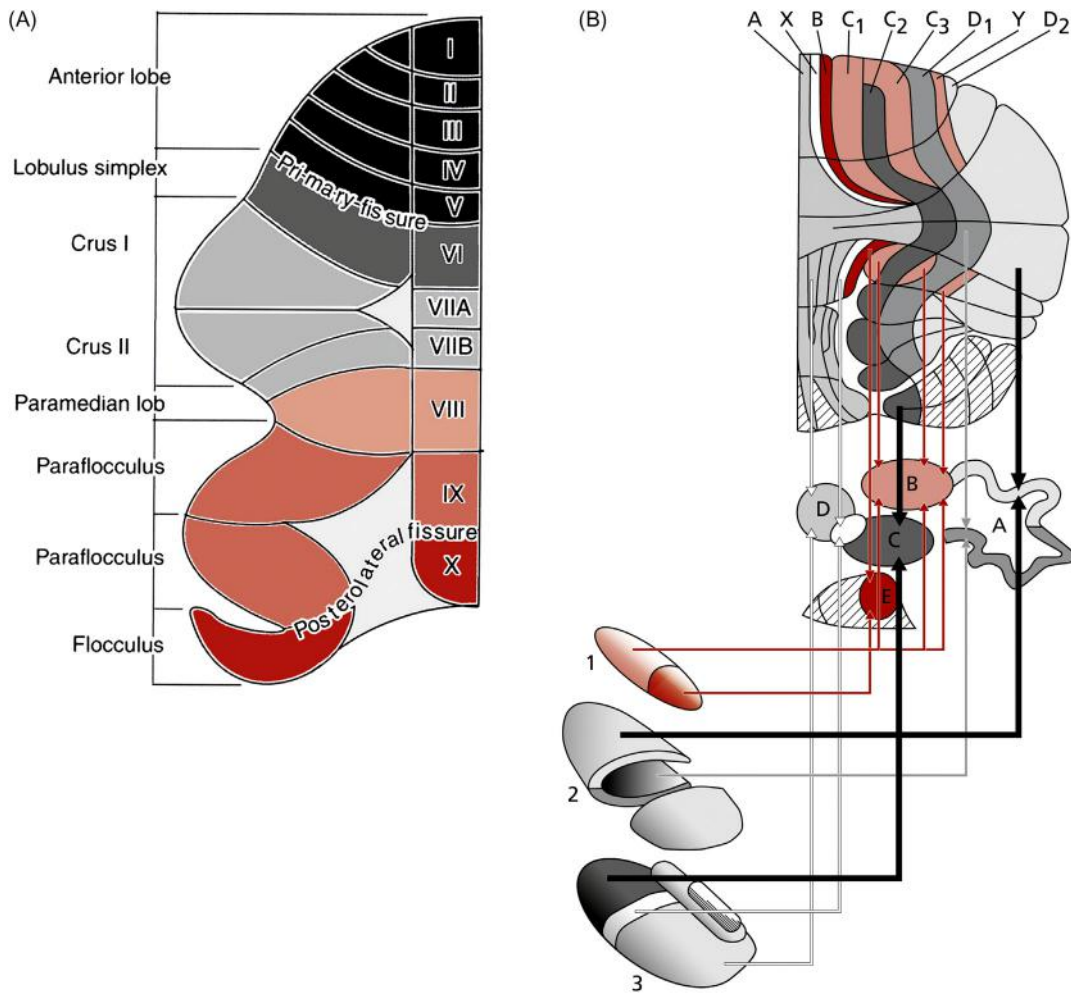

FIGURE 7.1 (A) The major macroscopic subdivisions of the cerebellum (flattened surface of the left hemisphere) concomitant with the widely used nomenclature introduced by Larsell: lobules are labeled consecutively by roman numerals (projected on the left vermis). The ansiform lobule is divided into Crus I and Crus II, separated by the intercruial fissure. (B) The cerebellar cortex is arranged into a multitude of longitudinal zones (A–D2): the Purkinje cells of a given zone project exclusively to the same component of the target nuclei (A = dentate, B = emboliform, C = globose, D = fastigial cerebellar nucleus, E = vestibular nuclei); furthermore, the Purkinje cells of each zone and their respective targets receive climbing fiber input from a particular subcomponent of the inferior olive (1 = dorsal accessory olive, 2 = principal olive, 3 = medial accessory olive); for example, the longitudinal zones C2 and D2 exclusively project to (a subcomponent of) the dentate nucleus or the globose nucleus, respectively, which in turn are targeted by distinct subcomponents of the olivary complex (heavy black lines). Redrawn from *Nieuwenhuys et al. (2008)* with permission from the publisher.

nucleus ruber (red nucleus) as well as various thalamic nuclei.

Afferent and efferent tracts are related to each other by a ratio of approximately 40:1 fibers, forming a massive convergence of information processing within the “small brain.”

Pontine nuclei and several subcomponents of the thalamus represent the relay stations of a cascading cerebrocerebellar circuitry: the afferent (feedforward) limb encompasses sequential corticopontine and pontocerebellar (mossy fibers) projections, and the efferent (feedback) loop encompasses cerebellothalamic and

thalamocortical pathways (*Schmahmann & Pandya, 1997*). The traditional model of cerebrocerebellar interactions assumed a broad range of frontal and parietal regions to project via pontine nuclei to the contralateral cerebellar cortex, whereas the respective efferent connections arising in the deep nuclei predominantly focus—via thalamic structures—on contralateral primary motor and premotor areas (*Rothwell, 1994*). However, more recent transneuronal tract-tracing studies in nonhuman primates found that distinct subcomponents of the deep white matter nuclei project to different areas of the cerebral cortex, including primary motor, premotor, and prefrontal areas, which, in

turn, represent a major source of input to the respective sites of origin, giving rise to a series of parallel closed loops (Strick, Dum, & Fiez, 2009). More advanced magnetic resonance imaging (MRI) technologies are now beginning to provide the opportunity to visualize the structure of cerebellar circuits in the intact human brain, for example, the connections between the cerebellar cortex and the thalamus (Granziera et al., 2009).

The cortex of the cerebellum segregates into three stacked layers: a superficial cell-poor molecular sheet, an adjacent thin tier composed of the perikarya of the large Purkinje cells, and a deep zone of densely packed small granule cells (Figure 7.2). The axons of the Purkinje cells represent the sole “output channel” of the cerebellar cortex, exerting a strong inhibitory impact on their target structures (i.e., the deep nuclei of the cerebellar white matter and the vestibular nuclei of the brain stem). Within some limits, the arrangement of these neural elements and their connections reiterate the longitudino-transversal organization of the cerebellar surface. The flattened dendritic trees of the Purkinje cells are confined to a plane perpendicular to the axons of the granule cells (parallel fibers) “running” in the direction of the transverse fissures. Each Purkinje cell may bear tens of thousands of synaptic connections with the parallel fibers traversing its dendritic tree. However, most of these contacts appear to be “closed” at any given moment due to long-term depression effects (Nieuwenhuys et al., 2008). These

processes may “sculpt the cerebellar cortical network, according to previous experience” and, thus, provide a basis for cerebellum-dependent optimization of movement sequences. Two major afferent systems access the cerebellar cortex: (i) restiform body and middle peduncle conduct mossy fibers, arising from the spinal cord as well as the brain stem and targeting the granule cells; (ii) in addition, the restiform body contains climbing fibers originating in the inferior olive and terminating in the contralateral middle layer (Figure 7.2). Both fiber types, which also give off collateral branches to the deep cerebellar nuclei, have an excitatory effect on Purkinje cells. In anesthetized animal preparations, the cerebellar cortex displays “two complete somatotopic representations of the body,” one in the anterior lobe and one in the posterior lobe (Rothwell, 1994). Perioperative electrical surface stimulation revealed in our species a motor map bound to the posterior cerebellar cortex (other areas were not investigated; Mottolese et al., 2013). Beyond these findings, functional imaging studies suggest that the “small brain” houses up to four distinct somatomotor homunculi (Buckner, Krienen, Castellanos, Diaz, & Yeo, 2011).

The rather uniform architectural design of the “small brain” does not allow for a cytoarchitectonic parcellation similar to the cerebral cortex. Nevertheless, specific input/output arrangements as well as the distribution of marker molecules give rise to a functional compartmentalization of the cerebellum in terms of parallel

FIGURE 7.2 Microscopic organization of the three-layer cerebellar cortex (A = molecular layer, B = Purkinje cell layer, C = granular layer). The flat dendritic trees of the Purkinje cells (large black bodies) are spread out in a parasagittal plane perpendicular to the parallel fibers, running along the transverse plane. Modified from Nieuwenhuys et al. (2008) with permission from the publisher.

longitudinal stripes that intersect the transverse fissures at a right angle (Figure 7.1B). More recent formulations assume that each half of the vermis contains two or three and that each hemisphere contains five or more such elongated but rather narrow cortical zones (Nieuwenhuys et al., 2008). In addition, gene expression patterns provide the basis for a further compartmentalization of the cerebellum in at least four transverse bands, more or less, independent of lobulation (Oberdick & Sillitoe, 2011). In contrast, the traditional separation into vestibulocerebellar, spinocerebellar, and neocerebellar components does not correspond to strict boundaries of the projections of the respective afferent sources (Coffman, Dum, & Strick, 2011). Given a rather uniform internal circuitry, the cerebellar cortex has been assumed to support rather uniform computational processes throughout its entire extent (Ramnani, 2006). Against this background, compartmentalization of the “small brain” could depend upon the functional architecture of the interconnected extracerebellar areas.

7.3 COMPARATIVE ANATOMIC PERSPECTIVES ON SIZE AND COMPOSITION OF THE CEREBELLUM

The overall volume of the cerebellum varies considerably across vertebrate classes—even after scaling to body or hindbrain size (Butler & Hodos, 2005). First, mammals and birds are endowed with a (relatively) larger cerebellum than reptiles and amphibians. Second, electroreceptive fishes such as mormyrids show an exceptionally huge “small brain,” by far exceeding its dimensions in nonelectric relatives and in all four-limbed vertebrates. Furthermore, the various macroscopic components of the cerebellum may show a differential enlargement across species within the same taxon—allegedly related to specific behavioral traits such as beak control in woodpeckers (Sultan & Glickstein, 2007) or acoustic communication in marine mammals (Oelschläger, Ridgway, & Knauth, 2010). Given these rather complicated comparative anatomic relationships, the differentiation between an archicerebellum, paleocerebellum, and neocerebellum, based on the suggestion that the major macroscopic constituents of the “small brain” can be assigned to successive stages of evolution, must be considered with some precautions. As a side note, the neural networks supporting vocal behavior in birds, including song learning, do not seem to encroach on the cerebellum (Ackermann, 2008), whereas motor coordination and skill acquisition in our species, including the domain of speech production, clearly depend on the integrity of the “small brain.”

Brain volume underwent a significant increase during the course of human evolution—allegedly concomitant with a disproportionate expansion of the prefrontal cortex relative to motor areas (see Teffer & Semendeferi, 2012 for a critical review). Furthermore, structural MRI points at a conjoint relative enlargement of the cerebellar lobules connected with prefrontal areas in our species (Balsters et al., 2010). Such morphological correlations have been assumed to indicate a contribution of the cerebellum to cognitive functions such as language. In light of these findings, one model claims that “the cerebellum couples the motor function of articulating speech to the mental function that selects the language to be spoken, thus helping to produce fluent human speech” (Leiner, 2010).

7.4 CEREBELLAR SUPPORT OF MOTOR CONTROL IN HUMANS: UPPER LIMB MOVEMENTS

The systematic experimental analysis of cerebellar functions traces back to Luigi Rolando, who conducted ablation studies in a variety of species around the turn of the 18th to 19th century (Schmahmann, 2010). He found that damage to the “small brain” compromised motor activities of the homolateral body side but spared the (in more recent parlance) sensory, autonomic, and cognitive domains. Holmes (1917, 1939) provided the classic description of cerebellar movement abnormalities in humans. Besides reduced muscle tone (hypotonia) and strength (asthenia)—observed at least in the acute stage after cerebellar damage with significant improvement during further follow-up—“the most prominent disturbances of function that result from destructive lesions of the cerebellum are distinct disorders of voluntary movement,” usually referred to as “ataxia” or “incoordination.” More specifically, Holmes noted a “delay in starting motion,” slowed and irregular execution of a movement, an excessive range or premature arrest of goal-directed motor activities (hypermetria/hypometria), and increased oscillations (tremor), especially during the final approach of an object. Furthermore, cerebellar injuries may give rise to vertigo, “spontaneous deviations of the limbs,” unsteady postural equilibrium and gait ataxia, compromised ocular movements (especially, nystagmus), reflex abnormalities, a loss of associated movements (e.g., of the ipsilateral arm during walking), and “disturbances of speech.” For the most part, these early analyses of the motor deficits of cerebellar disorders have stood the test of time and found their way into generations of subsequent textbooks of clinical neurology (Adams & Victor, 1989; Adams, Victor, & Ropper, 1997).

More recent kinematic and electromyographic (EMG) studies provide evidence for at least two pathomechanisms of cerebellar ataxia in case of single-joint rapid arm movements: deficient timing of agonist/antagonist EMG bursts and compromised implementation of phasic muscle forces (Berardelli et al., 1996). In line with the latter suggestion, functional imaging studies revealed separate subregions of the cerebellum to scale with distinct force-related parameters each (amplitude versus rate of change) during isometric pinch-grip tasks (Spraker et al., 2012). Rather than a failure to generate sufficient force levels *per se*, anticipatory adjustment of and compensation for the arising torques during movement execution appears to be disrupted (see Nowak, 2012 for a brief recent review). An alternative model considers the distorted triphasic innervation patterns of ballistic gestures, giving rise to hypermetria of movements (Rothwell, 1994), as well as the disruption of multijoint sequences in cerebellar ataxia (Ito, 2012, p. 156) to reflect motor timing deficits. Indeed, considerable evidence indicates that the “small brain” engages in the “precise representation of temporal information” (Ivry & Fiez, 2000, p. 1005; see Ivry, 2012 for a recent review).

A variety of clinical and functional imaging data suggest that motor skill acquisition in our species critically depends on the “small brain.” Early computational models of the 1960s considered the neuronal circuitry of the cerebellum a potential substrate of its motor learning capacities (see Ito, 2012 for references). More recent formulations associate these capabilities with internal forward or inverse representations of body–environment interactions (Passot, Luque, & Arleo, 2013). However, the cerebellar subcomponents specifically engaged in motor skill acquisition appear to vary with the experimental paradigm considered (sensorimotor adaptation versus motor sequencing) and the stage of the training process (e.g., early versus late; Hardwick, Rottschy, Miall, & Eickhoff, 2013; see Orban et al., 2011). At the molecular level, durable experience-dependent changes in synaptic transmission efficacy of Purkinje cells through convergent activation of parallel and climbing fibers have been demonstrated (Ito, 2012). Thus, evidence based on different methodological approaches corroborates the notion of a cerebellar contribution to motor learning mechanisms.

7.5 CONTRIBUTIONS OF THE CEREBELLUM TO SPEECH MOTOR CONTROL

7.5.1 The Profile of Ataxic Dysarthria: Auditory-Perceptual and Instrumental Studies

Holmes (1917) provided the first more detailed account of the motor speech deficits after cerebellar

damage, more specifically, unilateral and bilateral gunshot injuries. His early observations are in line with the still authoritative auditory-perceptual investigation of the Mayo Clinic based on patients with different etiological variants of a syndrome of ataxia (Darley, Aronson, & Brown, 1975). Imprecise consonants and distorted vowels, irregular articulatory breakdown, “excess and equal stress” (i.e., scanning speech rhythm), reduced speaking rate, as well as harsh voice quality emerged as the most salient features. Assuming the same underlying pathomechanisms as in other motor subsystems, the label “ataxic dysarthria” was assigned to the profile of speech abnormalities (see Ackermann, Mathiak, & Riecker, 2007; Duffy, 2005 for recent reviews). However, the extent to which extracerebellar pathology contributed to the observed deficits—given the rather limited diagnostic opportunities available at that time—remains unsettled. More recent studies interested in the specific contribution of the “small brain” to speech motor control tried to recruit patients with a disease process restricted to the cerebellum—as documented by neuroradiological techniques—or subjects with a molecular-genetic diagnosis of a distinct hereditary degenerative disease entity such as Friedreich’s ataxia (FRDA; Brendel et al., 2013) or the various subtypes of a spinocerebellar ataxia (SCA; Sidtis, Ahn, Gomez, & Sidtis, 2011; Schalling & Hartelius, 2013). Comparison of various syndromes of a hereditary ataxia (matched for disease severity and disease duration) revealed both commonalities and differences in the respective profiles of speech motor deficits (Brendel et al., 2015). Voice quality and stability, articulatory preciseness, and respiratory support turned out to be the most affected auditory-perceptual dimensions of speech production in patients with FRDA, SCA3, or SCA6. Such comparative analyses may provide the opportunity to further delineate the differential contribution of the various cerebellar subcomponents to speech motor control. At least in initial disease stages, FRDA predominantly affects the afferent fiber tracts that project to the cerebellum, whereas SCA6 pathology appears mostly restricted to the cortical layer of the “small brain” and SCA3 seems, by contrast, to encroach upon the deep cerebellar nuclei (Schalling & Hartelius, 2013). As compared with the other two ataxia variants, SCA6 patients showed a more pronounced reduction in speaking rate and more salient abnormalities of the prosodic modulation of verbal utterances (Brendel et al., 2015). Most noteworthy, several investigations reported the dysarthric signs of degenerative cerebellar diseases (FRDA, SCA subtypes) to be limited to rather mild deficits (e.g., in terms of intelligibility) even after an extended disease duration

of more than two decades (Brendel et al., 2013; Folker et al., 2010; Sidtis et al., 2011). Although patient selection bias cannot be ruled out in these cases, cerebellar disorders appear to have a less devastating impact on motor aspects of spoken language than does damage to left-hemisphere ventrolateral frontal cortex (apraxia of speech) or to the corticobulbar tracts (spastic dysarthria), which in its extreme gives rise to a complete breakdown of articulation and/or phonation (anarthria/aphonia; Ackermann & Ziegler, 2010). A similar dissociation between upper motor neuron disorders and cerebellar dysfunctions at the behavioral level has been observed during tasks involving highly overlearned finger force control (Brandauer et al., 2012).

Acoustic analyses of verbal utterances of patients with ataxic dysarthria concentrated mainly on measurements of durational parameters, such as voice onset time (VOT), syllable length, and vowel duration (see Ackermann et al., 2007 for a review). In line with auditory-perceptual data, an increased duration of syllables, vowels, and smaller segments—giving rise to a reduced speaking or articulation rate—has been repeatedly observed in ataxic patients as compared with healthy control speakers (Brendel et al., 2013; Schalling & Hartelius, 2013). Most noteworthy, the decline of speech rate during syllable repetition tasks appears to approach a plateau at approximately 2.5 to 3 Hz (Ackermann, 2008). In some instances of a cerebellar disorder, acoustic analyses were able to document voice tremor of a similar frequency or enhanced pitch fluctuations during sustained vowel productions (Ackermann et al., 2007; Boutsen, Duffy, Dimassi, & Christman, 2011). “Stabilization at a fixed posture or state” represents one of the fundamental control functions of the cerebellum (Massaquoi, 2012). In light of this notion, the respective cerebellar vocal dysfunctions may result from compromised maintenance of laryngeal sound production.

Because of an inherent nonlinear relationship between vocal tract configuration and the emitted speech signal, acoustic data often do not allow for unambiguous characterization of the underlying vocal tract movements. Among other things, kinematic analyses of lip and jaw excursions found a reduced mass-normalized stiffness (i.e., a decreased ratio of maximum velocity and displacement) in cerebellar patients as compared with control speakers (Ackermann et al., 2007). These findings have been assumed to indicate an impaired ability to generate adequate muscular forces under time-critical conditions, similar to upper limb movements. As an alternative, increased movement durations in cerebellar patients could point to larger articulatory distances during speech production rather than reduced peak velocity (Folker et al., 2011).

7.5.2 The Syndrome of Cerebellar Mutism: Impaired Initiation of Speech Production?

Speechlessness (mutism) after resection of a posterior fossa tumor or a stereotactic lesion of the dentate nucleus predominantly emerges in children at an incidence of up to 30%, but it may sporadically occur in adults as well (Küper & Timmann, 2013). Rarely, cerebellar mutism has also been observed in patients with traumatic injury to or viral inflammation of the “small brain.” As a rule, disrupted speech production develops several hours or days after surgery and frequently is associated with a variety of further behavioral and/or cognitive-mental abnormalities (posterior fossa syndrome). The initial—and always transient—mutism may evolve into speech motor deficits (“syndrome of cerebellar mutism and subsequent dysarthria”), into a syndrome of agrammatism concomitant with impaired executive functions, and/or into emotional/motivational abnormalities (Ackermann et al., 2007). In contrast, auditory speech comprehension as well as repetition capabilities are well-preserved. A recent review points to “crossed cerebello-cerebral diaschisis” as a potential pathomechanism of the initial mutism of the posterior fossa syndrome (i.e., “functional depression” of cerebral areas reciprocally interconnected with the damaged cerebellar region), translating into reduced blood flow (hypoperfusion), decreased oxygen consumption, and hypometabolism of the affected supratentorial structures (Küper & Timmann, 2013, see Botez, Léveillé, Lambert, & Botez, 1991 for further details on this concept). Bilateral lesions of anterior aspects of the medial wall of the frontal lobe may give rise to speechlessness (akinetic mutism), and damage to the left-hemisphere supplementary motor area has been found to compromise speech initiation mechanisms (Ackermann & Ziegler, 2010). Thus, transient cerebellar mutism conceivably reflects bilateral functional depression of mesio-frontal structures, whereas involvement of dorsolateral and/or orbital parts of the frontal lobe may give rise to the associated additional cognitive and/or behavioral abnormalities. In contrast, a persisting ataxic dysarthria that occurs subsequent to cerebellar mutism could reflect local cerebellar injury due to surgical intervention, because mesiofrontal lesions do not give rise to articulatory/phonatory deficits. Therefore, the so-called cerebellar mutism does not necessarily arise from cerebellar dysfunctions proper. Such an interpretation would also be more consistent with the suggestion that damage to the “small brain” yields rather mild speech motor deficits.

7.5.3 Functional Imaging Data Related to Speech Production

A meta-analysis of the “localization” of speech motor deficits in infarctions of the “small brain” found

this constellation to be associated with damage to superior aspects of the cerebellar cortex—more specifically, the area of blood supply of the superior cerebellar artery (Urban, 2013). In line with these clinical findings, functional imaging studies focusing on motor aspects of spoken language in healthy subjects reported that speech production tasks elicit robust bilateral hemodynamic responses centered around lobule VI (Figure 7.3). Three pieces of evidence support the notion of a crucial role of lobule VI in speech production:

1. A bilateral somatomotor map of the face has been documented at this level.
2. The execution of nonspeech movements of the tongue and lips yields bilateral signal changes within the same area.
3. Resting-state functional connectivity MRI was able to demonstrate tight functional coupling between the topographic motor representations of the frontal cortex and cerebellar lobule VI (Buckner et al., 2011; Grodd,

Hülsmann, & Ackermann, 2005; O'Reilly, Beckmann, Tomassini, Ramnani, & Johansen-Berg, 2010).

Taken together, these findings suggest that the superior corpus cerebelli must be considered an essential component of the brain network of (motor) speech production engaged, presumably, in the online control of articulatory movement sequences, regardless of stimulus type.

Signal changes in lobule VI lateralized toward the right side have been documented even during inner (covert, subvocal) speech tasks (see Ackermann & Riecker, 2010 for references). Psycholinguistic models (e.g., Levelt, 1989) often equate covert utterances with overt speech production—minus motor execution. As a consequence, inner speech must be expected to rely on a prearticulatory but otherwise fully specified verbal code. From this perspective, speech motor control separates into at least two stages: (i) the generation of a prearticulatory code (i.e., preparatory/planning processes) and (ii) its subsequent execution.

FIGURE 7.3 Spatial distribution of the signal maxima (Montreal Neurological Institute [MNI] space) of a series of published functional imaging studies addressing various aspects of speech and nonspeech motor control (Brendel et al., in preparation): pseudowords (red), repetitive syllables (green), single vowels (blue), lexical items (yellow), as well as nonspeech oral movements of tongue, lips, and jaw (white). Signal peaks represent main effects (experimental condition compared with a baseline, i.e., rest condition; coordinates are superimposed on the Collins brain template) and extend in the anterior–posterior direction (y -dimension) from -53 to -67 (divided into three segments). The majority of the peaks fall in this range, although a few signal maxima have either a more anterior or posterior location, respectively; the anatomical landmarks (right column) are based on Schmahmann, Doyon, Toga, Petrides, and Evans (2000).

In light of these findings, hemodynamic activation bound to inner speech may be related to a prearticulatory level of spoken language—although the computational processes involved are still a topic of debate (e.g., Geva et al., 2011). Some preliminary evidence for cerebellar involvement in these higher-level processes derives from the observation of functional coupling between superior aspects of the right cerebellar hemisphere and left premotor cortex, insula, and Broca's area (Buckner et al., 2011; Riecker et al., 2005). Importantly, these latter supratentorial areas of the language-dominant hemisphere are assumed to be crucially engaged in speech motor planning (Ackermann & Ziegler, 2010).

In contrast to the clinical data on the cerebellar topography of speech motor control, functional imaging yielded a more complicated picture because additional activation of caudal-inferior parts (lobule VIIIA) emerged across speech and nonspeech vocal tract tasks—although in a more inconsistent and variable way. Whereas this area also incorporates a somatomotor map of the vocal tract and displays strong resting-state functional connectivity with supratentorial sensorimotor cortex, the functional role of lobule VIIIA within the framework of speech production is still a matter of speculation. Given that inner speech is assumed to represent an important rehearsal strategy to temporarily maintain information in the phonological buffer of the verbal working memory circuit, a particularly puzzling aspect of these functional neuroimaging findings is that signal changes in lobule VIIIA have been repeatedly observed during verbal working memory tasks (Chen & Desmond, 2005; Durisko & Fiez, 2010), but not during subvocal speech. Hypotheses about the contributions of the inferior cerebellum to speech production range from a strictly “basic” motor/sensorimotor function (Stoodley & Schmahmann, 2009) to an involvement in “higher-level” linguistic processes, such as those supporting “fast-loading” mechanisms of phonological representations (Bohland, Bullock, & Guenther, 2010).

7.6 ENGAGEMENT OF THE CEREBELLUM IN NONMOTOR FUNCTIONS

7.6.1 The Cerebellar Cognitive Affective Syndrome

A classical tenet of clinical neurology tracing back to the early 19th century and passed down via generations of textbooks until approximately two decades ago generally restricted cerebellar symptomatology to the motor domain (compare Adams & Victor, 1989 with Adams et al., 1997, p. 92). However, the lateral

hemispheres of the “small brain” showed an overproportional increase of size during the course of human evolution, and a large portion of corticopontine projections arises within the prefrontal cortex. Considering, among other things, such (comparative) neuroanatomic data, the notion of an engagement of the “small brain” in mental skills attracted more and more attention from the 1970s and 1980s onward (Leiner, 2010; Schmahmann, 2010). Whereas the morphological findings referred to could just reflect enhanced capabilities for visuomotor control of manual tasks, systematic neuropsychological studies of larger groups of patients with pathology restricted to the “small brain” revealed—beyond the preceding (rather anecdotal) clinical observations—altered nonmotor functions such as compromised executive operations (verbal working memory, set-shifting, etc.), impaired visual-spatial capacities, disrupted memory as well as language deficits (Schmahmann & Sherman, 1998). Besides mental-cognitive disorders, personality changes in terms of blunted affect and inappropriate behavior could be observed as well. This “cerebellar cognitive affective syndrome” has been reported to include deviations of speech prosody (i.e., a high-pitched voice of a “whining, childish, and hypophonic quality”) emerging, especially in bilateral or generalized disease processes (Schmahmann & Sherman, 1998, p. 564). Rather than a cognitive-linguistic deficit, these abnormalities might reflect disruption of laryngeal motor control mechanisms. In accordance with these clinical data, the available imaging studies point to a functional compartmentalization of the cerebellar cortex in that motor, cognitive, and “limbic” tasks elicit activation patterns of a distinct topographical distribution each (Stoodley & Schmahmann, 2009). As an interesting side note, nonmotor abnormalities appear to be more prominent in acute rather than chronic pathologies.

7.6.2 Lexical-Semantic and Syntactic Disorders of Spoken Language

In addition to executive/visual-spatial dysfunctions and behavioral abnormalities, lexical-semantic deficits in terms of compromised picture naming, verb-for-noun generation, word stem completion, and verbal fluency have been documented in a variety of cerebellar disorders such as ischemic infarctions, cerebellitis, or degenerative diseases (Fiez, Petersen, Cheney, & Raichle, 1992; Schmahmann & Sherman, 1998; Stoodley & Schmahmann, 2009). Furthermore, functional imaging studies and transcranial magnetic stimulation techniques (implementation of a virtual transient lesion) point to a predominant engagement of posterolateral aspects

of the right cerebellar hemisphere in these tasks (De Smet, Paquier, Verhoeven, & Marien, 2013; Stoodley & Schmahmann, 2009). Rather than compromised access to the mental vocabulary, the observed lexical-semantic disorders have been assumed to reflect impaired cognitive search strategies and error monitoring (Stoodley & Schmahmann, 2009)—operations that are conceivably related to interactions of the cerebellar hemispheres with those parts of the prefrontal cortex supporting executive functions.

Silveri et al. (1994) reported for the first time signs of agrammatic speech concomitant with slightly reduced verbal fluency in a patient who had a right-hemisphere cerebellar ischemic lesion. Verbal utterances were characterized by the omission of free-standing grammatic morphemes and the use of infinitives in place of inflected verb forms. Otherwise, language examination was entirely unremarkable (see Zettin et al., 1997 for a further example). Whereas structural neuroimaging failed to detect any supratentorial lesions in the two aforementioned case studies, measurements of hemodynamic functions revealed marked hypoperfusion of the entire dominant hemisphere (crossed cerebello-cerebral diaschisis). During further follow-up, an increase of left-hemisphere cerebral blood flow paralleled the improvement of language deficits. A subsequent group study noted—mostly mild—agrammatism in 6 out of a total of 20 patients with a cerebellar disorder (Schmahmann & Sherman, 1998). Apart from a single exception (midline tumor removal), all of them had a diagnosis of bilateral or right-hemisphere infarction, whereas subjects with cerebellitis or cortical atrophy did not display any abnormalities of the syntax of spoken language at bedside testing. Beyond exclusive agrammatism, right-hemispheric cerebellar infarctions may give rise to a broader profile of speech-language abnormalities resembling transcortical motor or amnesic aphasia (for a recent review, see De Smet et al., 2013). Similar to cerebellar agrammatism, these more extensive constellations of disrupted verbal communication may also be associated with crossed cerebello-cerebral diaschisis effects. For example, left-frontoparietal perfusion was again found to increase in parallel with the improvement of speech-language pathology during follow-up.

Variants of an acquired dyslexia/dysgraphia have—although rarely—been observed in cerebellar stroke patients as well (De Smet et al., 2013). Most presumably, these constellations are also related to the pathomechanism of crossed cerebello-cerebral diaschisis, “the most plausible explanation posited to date” (Murdoch & Barwood, 2014) for higher-level language deficits, at least in cerebellar lesions of a vascular origin. As a further disorder of written language capabilities, developmental dyslexia is often associated with

signs of a cerebellar dysfunction (up to approximately 80% of cases; Nicolson, Fawcett, & Dean, 2001). Therefore, this syndrome has been assumed to reflect a more general impairment of cerebellum-dependent automatic performance of learned skills including, but not restricted to, the acquisition of written language capabilities (“cerebellar deficit hypothesis” of developmental dyslexia; Nicolson et al., 2001; for a recent brief review see Nicolson & Fawcett, 2014).

7.6.3 Contributions of the Cerebellum to Nonmotor Functions: Speech and Nonspeech Auditory Perception

Although Holmes (1917) did not find unambiguous evidence for perceptual deficits in patients with acute gunshot injuries of the cerebellum, more recent investigations reported that disorders of the “small brain” may compromise, for example, visual motion discrimination (Bastian, 2011) or the assessment of spatio-temporal relationships. In line with preceding observations of a disrupted evaluation of the length of time intervals bound by tones (see Ivry & Fiez, 2000 for a review), a series of studies was able to further document impairments in perceptual encoding of temporal aspects of speech sounds in cerebellar patients (Mathiak, Hertrich, Grodd, & Ackermann, 2002). Both the English and the German language comprise pairs of syllables or lexical items exclusively differing in a single durational parameter of the acoustic signal. For example, the English word “rapid” is characterized by a short period of silence (closure or occlusion time [CLT]) signaling the intraword stop consonant /p/. Variation of CLT from 10 to 110 ms gives rise to a phoneme-boundary effect: long intraword pauses yield the percept “rapid,” whereas short variants lead to the recognition of “rabbit,” with a rather abrupt transition from one response type to the other in-between. Under these conditions, word recognition solely depends on the processing of a durational acoustic cue. Using a German analogue of the “rabbit/rapid” paradigm (“Boden” [bodn] = short CLT, Engl. “floor” versus “Boten” [botn] = long occlusion time, “messengers”), patients with diffuse cerebellar atrophy did not show any significant phoneme-boundary effect (Ackermann, Gräber, Hertrich, & Daum, 1997). Apart from CLT, the difference in sound structure between the lexical items “Boten” and “Boden” can be signaled by VOT of the wordmedial stop consonants /t/ and /d/ ([bo:then] versus [bo:den], with the /t/-sound of the first item being characterized by a short aspiration noise). An fMRI study asked subjects to discriminate the same lexical items (i.e., “Boten” versus “Boden”) either by analysis of a durational parameter such as CLT

(experimental condition) or a noise segment such as VOT (control condition). Subtraction of the hemodynamic responses to the “noise stimuli” from the activation pattern obtained during application of the CLT items yielded a circumscribed activation focus within the right cerebellar hemisphere. Most noteworthy, a subsequent fMRI study found the discrimination of nonspeech time intervals bound by tones to elicit hemodynamic activation at the level of the right cerebellar hemisphere concomitant with a left-sided prefrontal cluster (Mathiak, Hertrich, Grodd, & Ackermann, 2004). Thus, a right-cerebellar/left-prefrontal loop appears to be engaged in the decoding of durational parameters of speech and nonspeech acoustic signals.

7.7 CONCLUSION

(i) It is well established that the cerebellum engages in movement preparation/execution as well as motor skill acquisition, although the underlying mechanisms remain to be further elucidated. These capacities also extend, at least partially, to the control of up to approximately 100 vocal tract muscles engaged in speech production. Disorders of the “small brain” may give rise to the syndrome of ataxic dysarthria, characterized by (among other things) compromised stability of sound production, slowed execution of single articulatory gestures, especially under enhanced temporal constraints, and disrupted coordination/sequencing of orofacial and laryngeal activities. These abnormalities accord quite well with the pathophysiological deficits observed in upper limb ataxia. Most noteworthy, reduced maximum speaking rate appears to approach a plateau at approximately 2.5–3 Hz in cerebellar patients. Therefore, the processing capabilities of the cerebellum seem to provide a necessary prerequisite to push the verbal sequencing capacities beyond this level and, furthermore, to modulate the rhythmic structure of verbal utterances (see Ackermann, 2008 for more details). (ii) From a phylogenetic perspective, inner speech mechanisms—based on a prearticulatory verbal code—may have “emerged from overt speech and motor systems as an evolutionary adaptive way to boost cognitive processes that rely on working memory, such as language acquisition” (Marvel & Desmond, 2010, p. 8). Conceivably, the computational power of the cerebellum also subserves the sequential organization of internal verbal codes. Therefore, cerebellar disorders may compromise cognitive capacities associated with “inner speech” such as the subvocal rehearsal component of verbal working memory or may impede the linguistic scaffolding of executive functions. Conceivably, a prearticulatory verbal code

might also support—under specific conditions—the perceptual resolution of temporal aspects of speech sounds. (iii) As a further pathomechanism of nonmotor higher-order language disorders, the tight reciprocal interactions between prefrontal cortex and lateral cerebellar hemispheres during a variety of mental tasks may elicit cerebello-cerebral diaschisis effects, especially in acute vascular disorders, giving rise to aphasia-like or mutism-like syndromes.

The Anatomy of the Basal Ganglia

Kate E. Watkins¹ and Ned Jenkinson^{2,3}

¹Department of Experimental Psychology, University of Oxford, Oxford, UK; ²Nuffield Department of Clinical Neuroscience, University of Oxford, John Radcliffe Hospital, Oxford, UK; ³School of Sport, Exercise and Rehabilitation Sciences, The University of Birmingham, Birmingham, UK

8.1 INTRODUCTION

The basal ganglia are a collection of highly interconnected subcortical nuclei in the brain. Classically, the basal ganglia comprise the striatum (caudate nucleus and putamen), the globus pallidus, subthalamic nucleus (STN), and substantia nigra. The principal input to the basal ganglia arises in the cerebral cortex and its principal output targets are frontal areas of the cortex. As such, the basal ganglia appear to form a series of parallel functionally segregated loops originating in partially discrete cortical areas with which they form a circuit. Historically, the basal ganglia have been associated with the control of movement, and it is the motor function of the basal ganglia that has been most extensively studied. The closed cortico-striatal-thalamo-cortical loops serve a role in selecting between competing possible actions such that appropriate behaviors are chosen and less appropriate ones are suppressed. By considering the broader implications of this principal function of the basal ganglia, we can see that these nuclei, and pathways through them, can contribute to a number of processes, including planning, decision-making, action selection, learning, sequencing, and the initiation and timing of movement. Because diseases of the basal ganglia impair gross motor control of the limbs and manifest in symptoms such as involuntary movement, akinesia, rigidity, and tremor, the likely role of the basal ganglia in speech motor control has been largely overlooked. Given that basal ganglia circuits encompass expansive cortical territories, including those known to contribute to linguistic processes such as lexical selection, cognitive control over competing languages in multilingual speakers, and learning of grammar rules, it seems likely that the basal ganglia themselves contribute to these processes.

8.2 HISTORICAL BACKGROUND

The basal ganglia play an undisputed role in the control of movement. This is largely known because of the obvious motor symptoms of two major diseases of the basal ganglia, Parkinson's disease (PD) and Huntington's disease (HD). These diseases and their symptoms were first described in the nineteenth century, well before the advent of modern neurology. Although, at the time, the involvement of the basal ganglia could not have been known, subsequent study of these diseases has defined our investigations of the functions of the basal ganglia. As such, the basal ganglia have been exclusively associated with motor control for most of the history of neuroscience. In the past few decades, however, it has become increasingly clear that the structures of the basal ganglia are crucial to cognitive functions such as learning and memory. Regardless, comparatively little is known about the contribution of the basal ganglia to behaviors such as speech and language. This is somewhat surprising given that neurologists contemporary with Paul Broca, such as Pierre Marie, observed language impairment in association with lesions in these nuclei (Marie, 1906). Even Broca himself observed that the lesion in his famous patient M. Leborgne extended to the striatum, which MRI scans of the preserved specimen recently confirmed (Dronkers, Plaisant, Iba-Zizen, & Cabanis, 2007).

Here, we review the anatomy of the basal ganglia and current models of their function. We then consider these functions in the context of the human brain's unique abilities to communicate using speech and language. Critical questions concern whether the human basal ganglia has speech-specific and language-specific circuitry, or if the speech and language impairments associated with basal ganglia dysfunction reflect more general processes.

8.3 OVERVIEW OF BASAL GANGLIA ANATOMY

Classically, the basal ganglia is considered to be a group of subcortical nuclei located in each hemisphere, including the caudate nucleus, putamen, globus pallidus, substantia nigra, and STN.

The caudate nucleus and putamen are two spatially distinct gray matter masses that comprise the dorsal striatum. In the human brain, the caudate nucleus is a C-shaped structure that lies lateral to the lateral ventricle and medial to the putamen (Figure 8.1). It has a large head at the rostral end, which extends caudally to a narrower body and slender tail that curves around into the anterior temporal lobe. The putamen is located lateral and posterior to the head of the caudate nucleus and medial to the insula cortex from which it is separated by the external capsule, claustrum, and extreme capsule. The two portions of the dorsal striatum become separated during development when fibers to and from the cortex become numerous enough to form a contiguous internal capsule that divides the caudate nucleus from the putamen. However, the structures always remain connected dorsally by small bridges of tissue interdigitated by white matter projections traveling in the internal capsule. The stripy appearance created by this arrangement of the bundles of projection neurons gives the structure its Latin name the *corpus striatum* (striated body). In lower mammals, such as the rat, the caudate nucleus and putamen are not divided but

instead form a single complex with fibers passing through in the form of numerous fascicles. Regardless of the anatomical relationship of these two cell masses, their cellular anatomy is identical; together, they comprise the largest subcortical cell mass in the mammalian brain. The majority of cells in the striatum—approximately 75% of the total—are medium-sized neurons with extensive dendritic branches. The branches are packed with dendritic spines, giving the cells a characteristic appearance and their name, medium spiny neurons (MSNs). All MSNs are GABAergic; therefore, they inhibit the targets to which they project. In addition to these projection neurons, there are several groups of intrinsic interneurons, all of which have smooth aspiny cell bodies. Of these groups, most are inhibitory and there is one excitatory group with noticeable large cell bodies that express acetylcholine.

The globus pallidus (pale globe) is a triangular nucleus immediately medial to the putamen and separated from it by a thin white-matter sheet (Figure 8.1). The globus pallidus contains many large, sparsely distributed fusiform (spindle-shaped) cells. Because of the low cellular density and the large number of myelinated axons that course through the nucleus, the globus pallidus is pale in appearance in fresh specimens compared with the putamen or caudate nucleus, hence its name. The globus pallidus is split by the medial medullary lamina into the internal and external segments, also known as the medial and lateral segments, respectively. Both segments of the globus pallidus

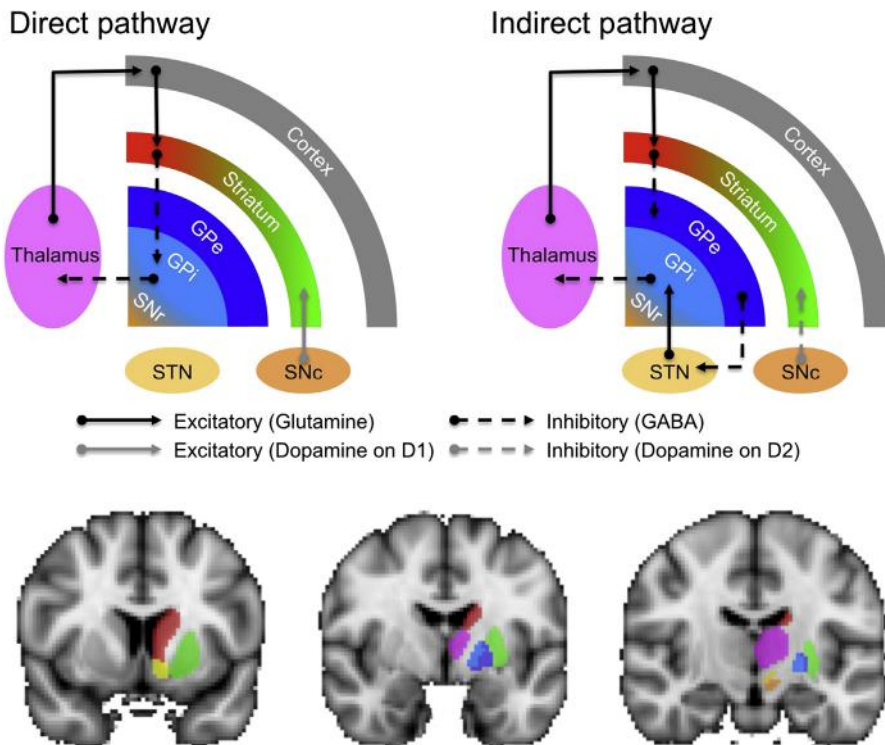

FIGURE 8.1 Basal ganglia nuclei and connections. Top row: schematic representations of the direct and indirect pathways through the basal ganglia. Bottom row: Coronal sections through the T1-weighted MNI152 average brain are shown from left to right at 8 mm in front of the vertical plane through the anterior commissure and at 4 and 14 mm behind it. Colored areas on the right side of the images correspond to the structures labeled in the schematics above. Red, caudate nucleus; green, putamen; yellow, nucleus accumbens; pink, thalamus; dark blue, globus pallidus, external segment (GPe); light blue, globus pallidus, internal segment (GPi); dark orange, substantia nigra (pars reticulata, SNr; pars compacta, SNc); light orange, subthalamic nucleus (STN). Black arrows indicate projections within the cortico-striatal-thalamo-cortical loops. Gray arrows indicate the dopamine innervation of the striatum from the SNc.

receive afferent input from MSNs of the striatum. Efferent projections from both segments of the globus pallidus are GABAergic (inhibitory), but the internal segment (GPi) projects to the thalamus, whereas the external segment (GPe) projects to the STN.

The STN is a small nucleus located in the midbrain ventral to the zona incerta and dorsal to the internal capsule/cerebral peduncle junction (Figure 8.1). The STN consists of large triangular and polygonal cells with dendritic trees that form ellipsoid domains within the structure. The STN receives a large inhibitory GABAergic input from the GPe and an excitatory glutaminergic input from the cortex. Neurons within the STN are glutaminergic and send excitatory projections to the GPi and pars reticularis of the substantia nigra.

The substantia nigra is the largest cell mass in the mesencephalon and located ventral to the STN (Figure 8.1). The nucleus was initially split cytoarchitectonically (on the basis of cell density and appearance) into two subdivisions: the cell-rich, dorsal pars compacta (SNc) and the less cell-dense, ventral pars reticularis (SNr). More modern cytochemical methods have confirmed these divisions, demonstrating that the pars compacta comprises large darkly pigmented cells that synthesize dopamine (and also give the structure its name due to its dark appearance in fresh specimens). The pars reticularis, however, consists of smaller GABAergic cells. The cyto-architecture and chemo-architecture of the SNr are strikingly similar to that of the GPi, and both receive excitatory glutaminergic inputs from the STN.

Here, we have defined the structures of the basal ganglia. Next, we outline the major connections between these structures.

8.3.1 Inputs to the Basal Ganglia

The majority of extrinsic input to the basal ganglia originates from excitatory glutaminergic neurons in layer 5 of the cortex. There are two points of input to the basal ganglia from the cortex. The first, and largest, is the corticostriatal input. The whole of the neocortex sends projections that terminate topographically throughout the whole striatum (caudate nucleus and putamen). The organization of these projections is such that restricted areas of cerebral cortex project to longitudinal territories that run the length of the striatum but are limited in their medio-lateral aspect so that the cortical input to the striatum is arranged in a number of strips or bands orientated along the rostrocaudal axis (Selemon & Goldman-Rakic, 1985). The excitatory glutaminergic input from the cortex terminates directly onto the output neurons of the striatum (i.e., the MSN).

The second cortical input to the basal ganglia is an input from the cortex to the STN. These cortical afferents arise mainly (though not exclusively) in the primary, premotor, and supplementary motor cortices (Nambu, Tokuno, & Takada, 2002). It should be noted that the STN was not considered a classical input nucleus of the basal ganglia. Instead, this input has been viewed as a “shortcut” through the basal ganglia.

8.3.2 Outputs from the Basal Ganglia

The two major output nuclei of the basal ganglia are the GPi and the SNr. As previously stated, these two nuclei share a similar cellular anatomy and provide the major output of the basal ganglia in the form of GABAergic projections that terminate in the thalamus (Haber & McFarland, 2001). Pallido-thalamic projections initially arise in two separate fiber bundles, the lenticular fascicularis and the ansa fascicularis. These fascicles merge to form the thalamic fasciculus whose fibers cross the internal capsule and terminate principally in the ventral anterior (VA) nucleus and oral subdivision of the ventral lateral (VL) nucleus of the thalamus, which in turn project back to the cortex (Nauta & Mehler, 1966). As well as projection to these principal thalamic nuclei, collateral fibers are given off to the centromedian nucleus. The centromedian nucleus is part of the intralaminar thalamic nuclei, which completes an internal loop by sending projections back into the striatum. Nigrothalamic fibers also terminate in VA as well as the paralaminar portion of the mediodorsal thalamus (Carpenter, Nakano, & Kim, 1976). VA and VL project to the primary, premotor, and supplementary motor cortices, whereas the mediodorsal nucleus projects to the prefrontal cortex, as well as the frontal eye fields. These thalamocortical projections are excitatory.

Therefore, although the entire cortex sends input topographically to the striatum, the frontal cortex uniquely receives the output from the basal ganglia via the thalamus. In the next section, we see that although the inputs and outputs of the basal ganglia appear the same, there are actually two segregated pathways through the basal ganglia that have opposing effects on behavior.

8.3.3 Pathways Through the Basal Ganglia

The segregated pathways through the basal ganglia start at a cellular level in the striatum, where MSN can be grouped according to the type of dopamine receptors and peptides that they express: D1-type and substance P or D2-type and enkephalin (Gerfen et al., 1990). The two groups of cells project to different

targets: the SNr and the GPi in the case of D1 MSN and GPe in the case of D2 MSN. The specificity of this segregation is very high (~95%; [Bertran-Gonzalez, Herve, Girault, & Valjent, 2010](#)) and is the start of two distinct pathways that are known as the direct and indirect pathway ([Figure 8.1](#)). The direct pathway is called such because this pathway runs directly through the basal ganglia from the input (striatum) directly to the output nuclei (GPi/SNr). The indirect pathway connects the input to the output via the GPe and the STN. In terms of basal ganglia output, these two pathways have opposite effects. In the direct pathway, input from the cortex increases firing in the D1 MSN in the striatum that project directly to the output nuclei GPi/SNr. Because both sets of projection neurons in these nuclei are GABAergic, the net effect is decreased inhibition (i.e., disinhibition) of the thalamus, releasing it to excite the cortex. Therefore, activity in the direct pathway increases activity in the cortical targets and, as such, acts as a “go” signal and can provide positive feedback. In the case of the indirect pathway, input from the cortex increases firing in the D2 MSN projection from the striatum to GPe, which is inhibitory and therefore reduces the inhibition of GPe neurons on the STN. This increases the excitatory influence of the STN on the inhibitory output nuclei (GPi/SNr), thereby increasing the inhibition of the thalamic relay to the cortex. Therefore, the net effect of activity in the indirect pathway is to decrease activity in the cortex, producing the opposite action to that of the direct pathway (i.e., it acts as a “stop” or “no-go” signal) and can provide negative feedback.

The final pathway through the basal ganglia starts at the input from the cortex to the STN. Due to the shortness of the path and the fact that this pathway avoids the classical input to the basal ganglia, it is called the hyperdirect pathway. As the excitatory input from the cortex increases STN firing, which in turn excites the inhibitory output of the GPi/SNr, the hyperdirect pathway is thought to provide rapid inhibition of basal ganglia output ([Nambu et al., 2002](#)).

It is thought that normal function of the basal ganglia is produced by a balanced combination of these pathways, and as such it has been suggested that diseases of the basal ganglia are the result of imbalance between these pathways ([Mink, 1996](#)). For example, the paucity of movement in PD is associated with an overactivation of the indirect pathway and underactivity in the direct pathway, whereas in Huntington’s chorea it is associated with the opposite pattern of abnormal activation in these pathways ([Wichmann & DeLong, 1996](#)). Experimental findings have challenged this view of basal ganglia function, however. It is proposed that the activity in these two pathways is more coordinated than first thought ([Cui et al., 2013](#)), and that

there is considerable interaction both structurally and functionally between them (see [Calabresi, Picconi, Tozzi, Ghiglieri, & Di Filippo, 2014](#) for further discussion).

The anatomy up to this point has described the basal ganglia in the classical context. However, the last three decades have seen an expansion of the concept of the basal ganglia to include a ventral striatal complex. The ventral striatum—as opposed to dorsal striatum—is centered on the nucleus accumbens. The cellular and histochemical make-up of the nucleus accumbens is similar to that of the caudate nucleus, with the substantia innominate, or ventral pallidum, analogous to the GP. These nodes of the ventral striatum form a loop with the cortex in a similar manner as those described in the classical description of the basal ganglia, or dorsal striatum. The ventral striatum primarily receives input from mesocortex and allocortex (inputs that are shared with the dorsal striatum). Specifically, parts of the “limbic” system, including the hippocampal formation, amygdala, and orbitofrontal and temporal cortex, send inputs to the ventral striatum, which is thought to play a crucial role in gating behavior due to emotional or motivational stimuli or both ([Haber, Lynd, Klein, & Groenewegen, 1990](#)). Another crucial similarity of the two striatal systems (dorsal and ventral) that comprise the basal ganglia is the powerful modulatory role of dopamine on both.

8.3.4 Dopamine in the Basal Ganglia

The basal ganglia receive dopaminergic input from two dopaminergic nuclei in the mesencephalon. The pars compacta subdivision of the substantia nigra provides a massive dopaminergic input to the entire striatum. The ventral tegmental area, with a lesser input from the substantia nigra. Dopamine has been ascribed many functions in the brain since it was first described as an independent neurotransmitter in 1957 ([Carlsson, Lindqvist, & Magnusson, 1957](#)), and the substrate of most of those functions is the basal ganglia. A loss of cells in the SNc that leads to a decrease in the ambient levels of dopamine—or dopaminergic tone—in the brain is known to cause PD. A huge body of work has described the importance of dopamine for normal motor function. However, a growing understanding of the role of temporal phasic release of dopamine in the dorsal and ventral striatum and beyond are beginning to unravel the role of dopamine in other behaviors, such as associative learning, response association, decision-making, and working memory. In addition, the finding that the input to the direct and indirect pathway is segregated by dopamine receptor type suggests a key role for dopamine in the delicate balancing of input to these pathways.

The normal action of dopamine is to selectively promote activity in the direct pathway. Activation of D1 and D2 receptors produces opposite effects; D1 neurons are excited by dopamine, whereas D2 neurons are inhibited (Gerfen, Keefe, & Gauda, 1995). The D1 and D2 receptors are predominantly expressed on the neurons comprising the direct and indirect pathways, respectively. Therefore, dopamine release selects for activity in the direct (D1) pathway and inhibits the competing indirect (D2) pathway (Bamford et al., 2004).

8.3.5 Functional Circuits Through the Basal Ganglia

As noted, the cortical input to the striatum arises from the cortical mantle, and the output from the thalamus projects back to the cortex. Several segregated loops are proposed to run in parallel through the basal ganglia (Alexander, DeLong, & Strick, 1986). Their purported function is based on the cortical areas from which the basal ganglia input arises and also the part of the striatum receiving this input. For example, a motor loop via the putamen to the supplementary motor area receives input from premotor, primary motor, and somatosensory cortex. Another loop is formed by input from the dorsolateral prefrontal cortex to the head of the caudate nucleus and output back to this area from the basal ganglia via the thalamus. The function of this loop is thought to be “associative” or “executive,” contributing to frontal-lobe cognitive processes such as decision-making, working memory, and attention, for example. The ventral striatum receives its main input from medial and orbitofrontal cortex and amygdala and, in turn, projects back to these areas via the medial dorsal nucleus of the thalamus. The function of this latter circuit is often described as “limbic,” indicating a role in emotional processing, motivational states, and reward-based learning. Studies in nonhuman primates describe further functional loops through the basal ganglia, for example, one involved in oculomotor control. It is probable that the human brain contains specialist loops through the basal ganglia for auditory-motor control and vocal learning, homologous to those described in songbirds (Bolhuis, Okanoya, & Scharff, 2010; Nottebohm, 2005).

Although the functional loops through the basal ganglia are described as parallel, they are not strictly segregated; information flowing through these loops is convergent, allowing integration of information across areas. For example, the MSNs in the putamen receive convergent input from primary motor and primary somatosensory representations of the same body part (Flaherty & Graybiel, 1993). One cortical area may

innervate multiple targets in the striatum, however, and these divergent projections reconverge on pallidal structures downstream (Flaherty & Graybiel, 1994). Furthermore, there may be cross-talk between the parallel loops mediated by recurrent striato-nigral-striatal circuits through the three major divisions of the striatum (Haber, 2003).

8.3.6 Disorders of the Basal Ganglia

Much of our understanding of the motor function of the basal ganglia has been gleaned from studies of two neurodegenerative diseases, namely PD and HD. In PD, the dopamine-containing neurons in the SNc degenerate, leading to the loss of dopamine innervation to the striatum. This loss typically starts posteriorly, affecting the putamen and resulting in motor characteristics that are symptomatic of the disease. As more anterior regions of the striatum become affected during the disease progression, the effects on cognitive and emotional processes are observed. Motor symptoms in PD are characterized by impairment in initiating movement (akinesia), slower and smaller movements (bradykinesia), resting tremor, muscle rigidity, and postural instability. The lack of facial movements results in a loss of expression and characteristic “mask.” In HD, movements are uncontrollable and described as choreiform (“dancing”); there are also emotional and cognitive disturbances that are attributed to degeneration of cortical areas. The disease is caused by an expanded CAG triplet repeat in the Huntington gene. The MSNs in the indirect pathway degenerate in HD. At the simplest level, excessive inhibition of movement in PD appears to result from overactivity in the indirect pathway; the dopamine depletion results in reduced activity of the direct pathway and a corollary reduction in the inhibition of the indirect pathway, with the net result being increased inhibition of the thalamus. Conversely, the choreiform movements associated with HD would result from overactivity in the direct pathway due to the selective loss of the MSN in the indirect pathway that normally inhibit the GPi/SNr output via GABAergic projection to the STN. As noted, this direct/indirect pathway model of basal ganglia function has been challenged, in particular, with respect to its explanation of pathological conditions such as PD and HD. Even so, recent optogenetic studies support the notion that this model can help explain the pathophysiological basis for the cardinal signs of PD. For example, using optogenetics, selective excitation of the MSNs in the indirect pathway produced Parkinsonian symptoms in a rodent model that were reduced by activation of direct pathway MSNs (Kravitz et al., 2010).

In addition to causing disorders of movement control, such as PD and HD, pathology within the basal ganglia has been linked to a range of other disorders, including neuropsychiatric ones such as obsessive–compulsive disorder, Tourette’s syndrome, and addiction. Common to these disorders is impairment in the control of behavior in general, not just in the control of movement. One explanation for this is found in the role of dopamine in linking rewards to actions, thereby providing motivation or “will.” Dopamine modulation is critical to signaling reward, lack of expected reward, and predicting rewards during learning (Schultz, 1997). A loss of dopamine might lead to reduced motivation or apathy. Similarly, too much dopamine might lead to excessive or risky behaviors, such as pathological checking or gambling.

8.3.7 Learning and Memory and the Basal Ganglia

The role of the basal ganglia in learning and memory is largely thought to be nondeclarative (procedural or implicit), leading to refinement of motor skills through practice and the acquisition of behavioral routines or habits (Graybiel, 2008; Wickens, Horvitz, Costa, & Killcross, 2007). Behaviors can be learned and habits can be acquired over long time periods (days or years) and, once established, they are performed almost automatically, without awareness. Such habits are typically sequences of motor or cognitive behaviors evoked in response to a specific stimulus or context (Yin & Knowlton, 2006). In pathological states, these habits or routines become motor stereotypes or repetitive behaviors and thoughts that can feature in diseases such as HD, schizophrenia, obsessive–compulsive disorder, and others. The basal ganglia also contribute to another form of nondeclarative memory, namely, the development of stimulus–response associations underlying conditioning or reinforcement learning (Schultz, Dayan, & Montague, 1997).

8.3.8 Summary

The basal ganglia contribute to the control of movement and selection of actions through the balance of activity in the direct and indirect pathways that serve to release the thalamic output to the cortex or further inhibit it. In this way, the basal ganglia gains control over the smooth execution of movements. Therefore, diseases affecting the structure or function of the basal ganglia result primarily in impairment in movement control. The role of the basal ganglia in promotion of desired motor behaviors and suppression of undesired ones can be generalized to the cognitive domain.

Similarly, their role in learning is not restricted to the motor domain. For the remainder of this chapter, we briefly outline how these basal ganglia functions might contribute to the control of speech and language.

8.4 THE ROLE OF THE BASAL GANGLIA IN SPEECH MOTOR CONTROL

As noted, the most commonly studied function of the basal ganglia is their role in the control of movement. Speech production requires precise control of movement of a large number of muscles, from the diaphragm and intercostal muscles involved in breath control to those involved in very rapid, tiny movements of the tongue to alter the shape of the vocal tract and passage of air through it. This complex process requires coordination of activity in multiple brain regions to plan, sequence, time, execute, and monitor these movements. The coordination of sequences of articulatory movements that comprise the elements of speech—phonemes and syllables—is normally achieved smoothly and with little effort. It seems likely that this control, like limb-movement control, is achieved by basal ganglia regulation of thalamocortical outputs to prefrontal cortical areas. These cortical areas include ventrolateral prefrontal cortex, ventral and dorsal premotor cortex, presupplementary and supplementary motor areas, as well as primary sensorimotor cortex.

Patients with damage to basal ganglia nuclei are commonly reported to have disturbances affecting speech production, such as apraxia of speech and dysarthria (Pickett, Kuniholm, Protopapas, Friedman, & Lieberman, 1998). Hypophonia, reduced speech output and initiation, and poor articulatory and phonatory control, in general, appear consequential to lesions of the striatum (particularly the putamen) and pallidum. In accord with these lesion data, speech production in PD appears to be similar to the hypokinesia described for limb movements in these patients; pitch variation and loudness are reduced so that speech is monotonous and low (Ho, Ianssek, Marigliani, Bradshaw, & Gates, 1999). In contrast, patients with HD can produce erratic speech with increased variation and loss of control of pitch and loudness (Hartelius, Carlstedt, Ytterberg, Lillvik, & Laakso, 2003).

Sequencing the individual elements of speech utterances relies on timing cues. These internal cues are thought to signal the end of one submovement and trigger the initiation of the next submovement in a sequence via phasic changes in basal ganglia output to the supplementary motor area (SMA) (Brotchie, Ianssek, & Horne, 1991). When the relative timing of speech elements is altered in speech production, the listener often perceives a change in accent. The

meaning of an individual word or its emphasis can also be altered by timing changes and the timing of words within an utterance affects prosody, which, in turn, changes meaning. One example of this is seen in foreign accent syndrome, which can occur after lesions to the basal ganglia, particularly to the left putamen (Gurd, Bessell, Bladon, & Bamford, 1988). In this disorder, previously fluent speakers appear to produce their native language with a foreign accent mostly likely caused by disturbed timing, prosody, and articulation that, combined, give the impression of nonnative speech production (Blumstein, Alexander, Ryalls, Katz, & Dworetzky, 1987).

Strikingly, cortico-striatal-thalamo-cortical circuit abnormalities are a key feature of a genetic disorder of speech and language demonstrated by affected members of a large multigenerational family who have a mutation in the gene *FOXP2* (see Chapter 2). Family members carrying the mutation have developmental verbal dyspraxia. They are impaired at repeating sequences of syllables that are either familiar (words) or unfamiliar (nonwords), and they are impaired at imitating sequences of nonverbal orofacial movements, but not of limb movements (Watkins, Dronkers, & Vargha-Khadem, 2002). Brain imaging revealed structural and functional abnormalities of the dorsal striatum in individuals carrying the mutation (Watkins, Vargha-Khadem, et al., 2002).

FOXP2 is expressed in MSN in the striatum (among many other cortical and subcortical areas). Mice with one copy of *Foxp2* knocked out show abnormal synaptic plasticity at the level of the MSNs and are impaired at learning to run on an accelerating rotating rod (Groszer et al., 2008). Songbirds express *FoxP2* in striatal spiny neurons. One portion of the avian striatum, Area X, is specialized for vocal learning and shows increased *FoxP2* expression during vocal learning. When levels of *FoxP2* are reduced in Area X, juvenile zebra finches show impaired learning of their tutor's song (Haesler et al., 2007).

Basal ganglia dysfunction is suspected to cause another developmental speech disorder, namely stuttering (Alm, 2004); neurogenic stuttering acquired after brain injury is also frequently associated with basal ganglia lesions. The main difficulty in stuttering is with the initiation of speech segments and producing smooth transitions between them. Dopamine blockers, such as haloperidol, can improve speech fluency, and early imaging studies showed abnormal levels of dopamine metabolism in people who stutter. More recent imaging studies confirm functional abnormalities in the basal ganglia and their cortical targets (see Chapter 79). People who stutter often experience periods of fluency and can achieve fluency through practice or via external cues and altered feedback.

Interestingly, patients with PD also benefit from external cues to initiate and perform sequences of limb movements fluently (Glickstein & Stein, 1991).

The motor circuitry involving the striatum is critical for the control of movement sequences more generally and not specifically for speech, yet neither the affected members of the KE family nor people who stutter exhibit impairments in the control of other movements. It could be that speech-specific corticostriatal circuits are affected in these disorders, or that fluent speech production requires relatively more rapid and complex coordination of movements than the control of other effectors. It could also be the case that speech is special because it requires integration with auditory feedback, and that this is critical for accurate timing of movement. The inputs to the basal ganglia allow convergence of related motor and sensory representations as described.

8.5 THE ROLE OF THE BASAL GANGLIA IN LANGUAGE

The role of the basal ganglia in language is less clearly established relative to their role in speech motor control. Language disturbance is commonly reported in association with damage to nuclei in the left hemisphere (Fabbro, Clarici, & Bava, 1996). Aside from the speech fluency deficits associated with lesions to the putamen and pallidum described, problems with lexico-semantics are typically associated with damage to the head of the caudate nucleus. However, lesions that cause language impairment tend to be extensive, with damage often extending to the white matter tracts adjacent to the striatum, including the internal, external, and extreme capsules. Such damage would interrupt communication to and from the thalamus or between temporal and frontal language areas, which could explain the subsequent language impairment rather than the deficits being the result of specific lesions to the basal ganglia (Nadeau & Crosson, 1997). Furthermore, the language impairments described in patients with PD, such as comprehension of syntactically complex sentences, could be explained by more general processing deficits in attention, working memory, or general slowing (Grossman et al., 2003). In sum, a consensus opinion has emerged that selective pathology of the basal ganglia nuclei does not cause aphasic symptoms like those seen after damage to cortical language areas. Rather, it may result in more subtle disturbances that contribute to complex language functions.

One example of a complex language function to which the basal ganglia likely contribute is in the implicit learning and application of morphosyntactic

rules. Language learning is clearly analogous to other forms of learned behaviors that become habits. Language acquisition typically occurs over many years. The rules that govern the construction of sequences of morphemes and words are learned implicitly. These rule-governed sequences are produced accurately, effortlessly, and without awareness, even when operating on novel combinations of language elements. According to one model, the basal ganglia contribute to the use of rules such as the one for producing the regular past tense in English (add -ed) (see Chapter 76). Patients with PD have difficulty applying this rule to novel verbs (e.g., “Everyday, he *plags* his lawn. Yesterday, he...?” [*plagged*]), whereas patients with HD overregularize (e.g., “Everyday, he *prunes* his roses. Yesterday, he...?” [*pruned*]) (Ullman et al., 1997). Both groups of patients are unimpaired at production of irregular past tense word forms because these are learned as individual lexical items and do not require rules to produce them. However, another study found that similar groups of patients with PD and HD or with basal ganglia vascular lesions were unimpaired on priming tasks that tested these past-tense relationships (Longworth, Keenan, Barker, Marslen-Wilson, & Tyler, 2005). In that study, some patients had problems inhibiting semantically appropriate alternatives to novel word forms, which is consistent with a role for the basal ganglia in inhibiting competing alternatives during selection.

8.6 SEGREGATED FUNCTIONAL LOOPS FOR SPEECH AND LANGUAGE

Previously, we described two loops through the basal ganglia labeled as “motor” and “executive.” The putamen was the primary recipient of inputs from premotor, primary motor, and somatosensory cortex in the “motor” loop, whereas the caudate nucleus received inputs from prefrontal cortex as part of the “executive” loop. Findings from functional imaging studies of bilinguals and lesion and brain stimulation studies of patients support a similar division for motor and cognitive control of speech and language. For example, the caudate nucleus is robustly activated when bilinguals switch between languages and need to exert control over language production (Crinion et al., 2006). Language switching requires selection of the desired output (the correct language) and suppression of the undesired one (the competing alternative), which could be achieved by activation of the direct and indirect pathways through the basal ganglia, respectively. In contrast, the left putamen contributes to articulatory processes when speaking a second language, but only if the speaker is not highly proficient in the second language (Abutalebi et al., 2013). Further

evidence for a differential role of the caudate nucleus and putamen in language functions comes from a functional mapping study of the dominant striatum in patients undergoing tumor removal. Electrical stimulation of the head of the caudate nucleus elicited perseveration of previously named pictures, consistent with a role for this nucleus in selection of linguistic items. However, stimulation of the putamen produced anarthria with no accompanying interruption of hand movements or facial muscular contraction. This is consistent with the role of the putamen in motor coordination for speech articulation (Gil Robles, Gatignol, Capelle, Mitchell, & Duffau, 2005).

8.7 SUMMARY

The role of the basal ganglia in motor function in general is evident in the contribution they make to speech motor control. Even so, the impairments noted in speech due to pathology of the basal ganglia are not as severe as those seen for limb-movement control in the same patients. More severe speech and language disruptions are seen in developmental disorders with known or suspected basal ganglia pathology, which points to a more critical role played by these circuits in language acquisition. The significance of the basal ganglia in language acquisition is also supported by the literature on second language learning. However, a definite role for the basal ganglia in more cognitive aspects of language processing has not yet been established, because specific linguistic impairments could be explained by more general cognitive control mechanisms that are known to be impaired by basal ganglia pathology. In this brief review of basal ganglia contributions to speech and language processing, we focused primarily on the production side. Nonetheless, speech perception and language comprehension (in particular the comprehension of syntax) rely on accurate perception of timing and the ability to predict cues in auditory sequences of speech and language (Kotz, Schwartze, & Schmidt-Kassow, 2009). The basal ganglia circuitry is a strong candidate substrate not only for the production of speech but also for the processes involved in abstracting statistical information from perceptual sequences, a function that might be critical for learning rules and producing apparently rule-governed behavior, such as syntax.

The Thalamus and Language

Daniel A. Llano

Department of Molecular and Integrative Physiology, University of Illinois at Urbana-Champaign, Champaign, IL, USA

Is there a role for the thalamus in language? This question has vexed investigators for decades. As early as 1959, Penfield and Roberts postulated that certain areas of the thalamus may integrate information across distant cortical areas (Figure 9.1). This was based on their awareness of clinical findings that patients with left thalamic lesions may have aphasia, and because of their own findings that anterior and posterior language areas appeared to be highly functionally integrated, even when intervening areas of peri-Sylvian cortex were lesioned, suggesting a subcortical integration site (Penfield & Roberts, 1959). Over the ensuing decades, a great deal has been learned about the functional organization of the thalamus as well as the clinical impact of small lesions within the thalamus. Based on this body of work, there have been recent attempts to integrate the clinical literature (reviewed in De Witte et al., 2011) as well as the imaging literature (reviewed in Llano, 2013) with modern theories about thalamic function into a coherent view of the potential role for the thalamus in language function (Crosson, 2013; Hebb & Ojemann, 2013; Klostermann, Krugel, & Ehlen, 2013). This chapter summarizes these contributions and offers suggestions for future approaches to link human and animal studies to better understand the role of the thalamus in language.

9.1 OVERVIEW OF THALAMIC ORGANIZATION

The thalamus comprises at least a dozen subnuclei that project in an approximately topographic fashion to all areas of the cerebral cortex (Table 9.1). Therefore, a reasonable starting point in the study of the potential role for the thalamus in language is to ask which thalamic nuclei project to the frontal, temporal, and parietal cortical regions that are typically reported as playing a

role in language. However, this question is complicated by the fact that connectivity data are mostly available for nonhuman primates and are relatively scarce in humans. Thus, we are left to examine thalamic inputs to cortical regions that bear some structural and functional similarities to human language areas, such as the macaque ventral premotor cortex and the superior temporal gyrus, including the supratemporal plane (Gil-da-Costa et al., 2006). A restricted retrograde tracer injection placed into the caudal portion of the macaque ventral premotor cortex, a putative homologue of Broca's area, produces substantial retrograde labeling in no fewer than 10 thalamic nuclei: ventrolateral nucleus, ventral anterior nucleus, ventral medial nucleus, centrolateral nucleus, centromedian nucleus, medial dorsal nucleus, area X, lateral posterior nucleus, medial pulvinar, and ventral posterior nucleus (Morel, Liu, Wannier, Jeanmonod, & Rouiller, 2005), thus revealing the difficulty in assigning thalamic nuclei to cortical regions in a one-to-one fashion. More recently, a study by Bruce Crosson's group using high-resolution diffusion-weighted imaging tractography in humans identified the ventral anterior thalamus and pulvinar as sites of connectivity with Broca's area in humans (Ford et al., 2012, 2013). Injections of retrograde tracers into the macaque caudal superior temporal gyrus, a putative homologue of Wernicke's area, retrogradely labeled neurons in multiple thalamic nuclei: the medial pulvinar, lateral posterior nucleus, suprageniculolimitans nucleus, and the medial division of the medial geniculate body (Hackett, Stepniewska, & Kaas, 1998). In each of the tracer studies, a convergence of projections of neurons from both principal and intralaminar or paralaminar nuclei to a single cortical area is observed. This type of convergent organization is not restricted to language cortex homologues, because other cortical areas in the macaque receive inputs from multiple thalamic nuclei (Schmahmann & Pandya, 1990). These findings

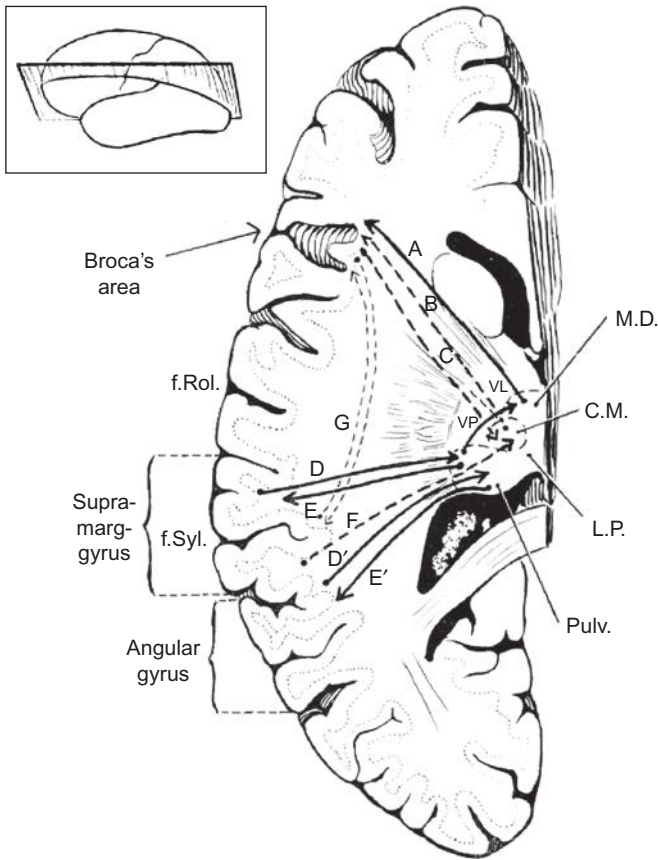

FIGURE 9.1 Penfield and Roberts' model of thalamic involvement in language. Penfield postulated that there were multiple thalamic regions that were reciprocal relationships with language-related cortical structures. Solid lines represent connections that (at the time) were established via monkey tract-tracing and electrophysiological recordings. Dotted lines represent connections only established via electrophysiological recordings. From *Penfield & Roberts (1959)* with permission from Princeton University Press.

suggest that any viable model of the thalamic contribution to cognitive function should account for the multiplicity of thalamic inputs to individual cortical regions.

9.2 DEFINING THE ROLE OF THE THALAMUS IN LANGUAGE

There are substantial numbers of case reports and case series documenting an impairment of language function after thalamic damage. However, the anatomical precision of the lesions and the quality of behavioral assessments (both language and other cognitive functions) performed in these studies are extremely variable. To restrict this review of the literature to studies in which reasonable structure–function relationships can be established, this chapter focuses on patients with ischemic stroke or who have had stereotactic neurosurgery and does not include literature in the meta-analysis from patients with intracranial hemorrhage and with thalamic tumors, given the potential for remote CNS damage and the development of compensatory mechanisms in these clinical scenarios, respectively. In addition, the studies that have performed more than a cursory language and cognitive assessment will be included in this analysis and, as a benchmark, only studies that permit classification into the Wernicke–Geschwind model (i.e., studies that have assessed naming, speech production, speech comprehension, and repetition) have been included.

Given these restrictions, the author has compiled a list of 36 case reports and series from the English-language literature and these are displayed in [Table 9.2](#). Several generalizations can be made from these data. First, although nearly all lesions causing language dysfunction

TABLE 9.1 Major Groups of Thalamic Nuclei, Their Putative Domain of Function and Major Projection Targets

Thalamic nucleus	Putative domain of function	Major projection target
Anterior nuclear group	Memory	Cingulate cortex
Mediodorsal nucleus	Executive function	Prefrontal cortex
Intralaminar + midline nuclei (including centré-median and parafascicular group)	Attention, arousal	Frontal and parietal cortices
Pulvinar + lateral posterior	Higher order sensation	Frontal and parietal cortices
Ventral anterior and ventrolateral nuclei	Motor	Primary and supplementary motor cortex
Lateral geniculate nucleus	Vision	Visual cortex
Ventral posterior nucleus	Somatosensation	Somatosensory cortex
Medial geniculate body	Audition	Auditory cortex

The nomenclature proposed by [Hirai and Jones \(1989\)](#) will be used here rather than the nomenclature commonly seen in the older literature ([Hassler, 1959](#)).

TABLE 9.2 Case Reports of Thalamic Aphasia

Reference	Location	Naming	Repetition	Production	Comprehension	Other findings
<i>ISCHEMIC INFARCTS</i>						
Cohen, Gelfer, and Sweet (1980)	Left anterior thalamus	Impaired	Preserved	?	Impaired	Decreased spontaneous speech
Archer, Ilinsky, Goldfader, and Smith (1981)	Left ventrolateral or ventral anterior nucleus	Impaired	Impaired	Preserved	Impaired	Perseveration Fluctuating performance Improvement to mild anomia at 2 months
Case 1 McFarling, Rothi, and Heilman (1982)	Left lateral thalamus	Impaired	Preserved	Impaired	Impaired	Perseveration Poor spontaneous speech Fluctuating performance Grammar preserved No paraphasic errors No followup data
Case 2 McFarling et al. (1982)	Left lateral thalamus	Preserved	Preserved	Impaired	Preserved	Poor verbal fluency on FAS test Grammar preserved No paraphasic errors Etiology not known, but no hemorrhage Authors note remarkable improvement while in hospital
Lhermitte (1984)	Infarct of whole left thalamus	Preserved	Impaired	Impaired	Preserved	Semantic paraphasic errors Poor short-term verbal memory
Case 1 Graff-Radford, Eslinger, Damasio, and Yamada, (1984)	Left anterior thalamus	Impaired	Preserved	Preserved	Impaired	Perseveration Paraphasic errors On SSEP: Delay in first three negative waves after P14
Case 2 Graff-Radford et al. (1984)	Left thalamus	Impaired	Preserved	Preserved	Impaired	Perseveration Semantic paraphasic errors Significant improvement after 2 months, but continued word-finding-difficulty and difficulties with comprehension after 4 years
Case 1 Bogousslavsky, Regli et al. (1986)	Left anterior thalamus—tuberohalamic artery distribution	Impaired	Preserved	Preserved	Impaired	Naming deficit worse than comprehension deficit Decrease in spontaneous speech Semantic paraphasic errors Grammar preserved Dyscalculia
Case 2 Bogousslavsky, Regli et al. (1986)	Left anterior thalamus—tuberohalamic artery distribution	Impaired	Preserved	Impaired	Impaired	Many semantic and phonological paraphasic errors Perseveration

Margolin et al. (2008)	Left anterior and paramedian thalamus	Impaired	Preserved	Impaired	Impaired	Hypophonia Skew deviation Phonemic paraphasic errors General improvement over first 8 days, but naming still poor (BNT = 8/60) No language deficits at 1 year
De Witte et al. (2011)	Right midline—lateral thalamus (patient right-handed)	Impaired	Preserved	Preserved	Impaired	Semantic paraphasic errors Neologisms Persistent dysnomia at 18 months Perfusion SPECT at 1 year showed severe hypoperfusion in right temporo-parietal, anterior frontal cortex and right thalamus
Hoffmann (2012)	Left lateral posterior thalamus	Preserved	Preserved	Impaired	Preserved	Semantic paraphasias Impaired oral word and sentence reading Impaired picture word matching and writing
SURGICAL LESIONS						
Bell (1968)	10 cases of VL thalamotomy	Impaired	Preserved	Impaired	Preserved	Perseveration seen 5 patients better within 3 weeks 4 patients had gradual improvement with some persistent deficit 1 with persistent deficit after 4 years
Samra et al. (1969)	8 patients with ventrolateral thalamotomy (7 on left, 1 on right)	?	Impaired in 2/8	Impaired in 8/8	Impaired in 4/8	All cases pathologically confirmed to be within ventrolateral nucleus
Darley, Brown, and Swenson (1975)	Left ventrolateral thalamotomy	Preserved	?	Impaired	Impaired	
Vilkkii and Laitinen (1976)	Left pulvinar or ventrolateral thalamotomy	Impaired	?	?	Impaired	Recovery at 3 months

are in the dominant thalamus, the specific thalamic nucleus involved varies considerably (see Figure 9.2 for a summary of lesion locations). This anatomic heterogeneity is further addressed later. Clinically, there is an almost universal deficit in naming, often severe, and, importantly, most naming errors in these studies take the form of semantic substitutions, rather than omissions. Second, across most studies, there is a relative preservation of repetition, often including the repetition of complex utterances. Beyond these features, the findings are more variable. Not all studies describe a clear deficit of language production or comprehension, but of those that do, most describe relatively mild deficits,

more commonly in comprehension than in production, with general congruence of verbal and orthographic deficits. Therefore, applying a Wernicke–Geschwind scheme to these data (with all appropriate provisos regarding the Wernicke–Geschwind taxonomy), one would describe most of these patients as having a transcortical sensory aphasia, a transcortical motor aphasia, or, most commonly, an anomic aphasia.

Another notable feature in this population is the high degree of individual performance variability, often moment to moment, which seems to track with the level of arousal of the patient (Archer et al., 1981; Ebert et al., 1999; McFarling et al., 1982), seen in both ischemic and

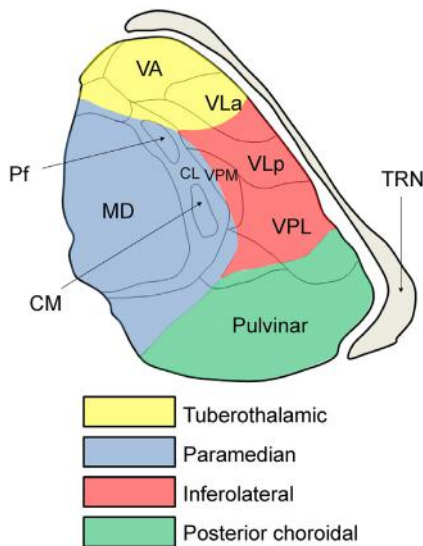

FIGURE 9.2 Thalamic blood supply. CL = centrolateral division, CM = center median, MD = medial dorsal, Pf = parafascicular, TRN = thalamic reticular nucleus, VA = ventral anterior, VLa = ventrolateral anterior region, VLP = ventrolateral posterior region, VPL = ventral posterior lateral, VPM = ventral posterior medial. *Redrawn and modified from Carrera & Bogousslavsky (2006).*

hemorrhagic stroke, and detailed in an early study of a thalamic hemorrhage patient (Mohr, Watters, & Duncan, 1975). In addition, many authors have noted a high frequency of semantic paraphasic errors (Demeurisse et al., 1979; Ebert et al., 1999; Karussis et al., 2000; Radanovic & Scaff, 2003; Raymer, Moberg, Crosson, Nadeau, & Rothi, 1997) and perseverations (Bell, 1968; Bogousslavsky, Regli, & Assal, 1986; Bruyn, 1989; Demeurisse et al., 1979; Graff-Radford et al., 1984; Levin et al., 2005; McFarling et al., 1982; Puel et al., 1992). Finally, a commonly reported feature of these patients is a relatively rapid recovery of language deficits. When recovery has been described, most patients recover to a significant degree within 6 months of the ictus (Archer et al., 1981; Graff-Radford et al., 1984; McFarling et al., 1982; Raymer et al., 1997; Vilkki & Laitinen, 1976), although several patients with persistent aphasic deficits after focal thalamic lesions have been described as well (Bell, 1968; Demeurisse et al., 1979; Graff-Radford et al., 1984; Karussis et al., 2000; Puel et al., 1992; Radanovic & Scaff, 2003). Although not included in Table 9.2 for the reasons described previously, it is worth mentioning here that a large number of patients with thalamic hemorrhage have been described (etiologically more common than isolated thalamic infarction) with a virtually identical symptom complex (Karussis et al., 2000; Mohr et al., 1975; Radanovic & Scaff, 2003; Wallesch, 1997).

Although the Wernicke–Geschwind formulation provides a bird’s eye view of thalamic aphasia as primarily a disorder of naming and mild comprehension deficits with spared repetition, it does not provide sufficient detail about language and cognitive behavior to assist in

the generation of neural models to explain the role of the thalamus in language. Several authors have provided more detailed accounts of the language deficits in patients with thalamic lesions, and these data are briefly reviewed here. Note that several patients with thalamic hemorrhage have been included in this analysis because hemorrhage sizes were small and the quality of the language data is high. Raymer et al. (1997) and Crosson (1999) described the language deficits of two thalamic stroke patients, one with a stroke damaging the ventrolateral, ventral anterior, centré-median, and thalamic reticular nuclei and another with damage to the ventral anterior, ventrolateral, mediodorsal, centré-median, parafascicular, and thalamic reticular nuclei. Both subjects had significant difficulty with naming across modalities but had no difficulty with writing to dictation or reading aloud. Furthermore, the majority of the naming errors (84% and 63% in the two subjects) were semantic. These suggested to Crosson that the core deficit was neither purely lexical nor purely semantic. Instead, the deficit was one of *retrieval of lexical items from semantic input* (Crosson, 1999).

Another study of a patient with Parkinson’s disease undergoing left thalamotomy of the ventrolateral nucleus and studied before and 3 months after thalamotomy showed no change in performance on the Boston Naming Test but demonstrated decreases in category fluency and deficits in higher-level tests of language function, such as combining lexical units into sentences, as well as significant difficulty remembering word pairs. If a semantic strategy were used to attempt to remember word pairs, then both the word pair deficit and the deficit in sentence creation could potentially be explained by a deficit in the mapping of semantic to lexical information (Whelan, Murdoch, Theodoros, Silburn, & Hall, 2002). Further breakdown in lexical-semantic processing was noted by Segal, Williams, Kraut, and Hart (2003) in a case of left tuberothalamic artery stroke. Their patient had poor naming, halting speech, impaired comprehension, and impaired performance in category fluency, with preserved reading and repetition of words and sentences. Other deficits were also present, including mild impairments on property judgment, category judgment, and semantic association, and severe disruption of semantic recall (i.e., the patient was given two words or a word plus picture and asked to generate the concept of an item that is associated with both). The patient reported that he could only generate a semantic item 64% of the time, but more importantly he was not able to provide the name of the semantic item for any of the pairs. These data point to a deficit in the mapping of semantic information to lexical units and may also suggest a deficit in the generation of new conceptual representations.

In addition to these lexical-semantic difficulties, patients with thalamic lesions have marked variability in language performance and often have significant perseveration. Two particularly dramatic cases were

described by [Mohr et al. \(1975\)](#) in the setting of left thalamic hemorrhage. In the acute stage, both patients ranged in performance from essentially normal language to marked logorrheic jargonaphasia with perseverative components. An excerpt from the logorrheic state:

Examiner	Patient
How are things going?	<i>I thinks, a, going fine, and . . . I can say, s'quit alright, si sings say, rou, rup . . .</i>
What happened?	<i>Well, . . . See up chup a lupdup. Cheche den, etc., and, a, she is quite please at that.</i>
What did you say?	<i>She said, that was fudal wedel wedl And she also, when she comes in, eetosaïd You have it every time it nevel a dedal wedel.</i>

Seven days later, the patient had generally improved but continued to have periods of jargonaphasia with more overt perseveration:

Examiner	Patient
How are you today?	<i>Just fine.</i>
Anything wrong?	<i>Yes, I feeling fine.</i>
How old are you?	<i>Ahh, 59.</i>
Where are you?	<i>59.</i>
No, where are you?	<i>Where, 59.</i>

Mohr commented that increases in the level of arousal were associated with improved language performance. Another example was provided by [Luria \(1977\)](#), who described a patient with a lesion secondary to aneurysmal hemorrhage into the left thalamus. This patient was fluent, with normal grammar and prosody, but had severe loss of spontaneous speech, repetition, and naming, and could understand only fragments of speech. Many of his errors were perseverative in nature and his performance fluctuated significantly. Luria noted that the patient's speech was marked by "extraneous associations, influences of the immediate situation, and fragments from former traces" which Luria termed "pathological inertia." The patient appeared to do better when structure was imposed on the range of semantic information that needed to be culled for a task (i.e., his performance during picture description was better than during spontaneous speech). A similar improvement was noted during discussion of a restricted range of familiar versus unfamiliar topics in a patient with hemorrhage into the lateral nucleus of the thalamus and the anterior superior pulvinar ([Crosson et al., 1986](#)). Although it is possible that the fluctuations described may be related to secondary effects of the hemorrhage such as edema or nonconvulsive seizures, similar findings have been described (although without similar

vivid descriptions) in both ischemic thalamic stroke and thalamotomy patients.

Given the heterogeneity of lesion location in these patients, the marked performance variability, the lack of a uniform aphasic syndrome, the absence of language deficits in many patients with injury to the dominant thalamus, and the generally rapid recovery of language function after thalamic damage, several authors have questioned the role of the thalamus in language at all ([Luria, 1977](#); [Van Buren, 1975](#)). For example, [Cappa et al.](#) reported five consecutive patients with dominant thalamic lesions who did not have aphasia ([Cappa, 1986](#)), and [Wallesch et al.](#) found few differences in language performance between patients with small left-side versus right-side thalamic strokes ([Wallesch et al., 1983](#)). Given these conflicting clinical data, it seems likely that subjects with focal thalamic damage without language deficits must fall into one of three categories: (i) patients without damage to structures and/or connections that play a role in language performance; (ii) patients who recovered rapidly and thus escaped detection of any deficits because they were not present at the time of testing; or (iii) patients with actual deficits that were not detected for other reasons, such as inadequate examination.

The relative consistency in naming deficits despite heterogeneity in thalamic lesion locus is not dissimilar to what has been described for the cerebral cortex. For example, [Ojemann \(1991\)](#) and [Penfield & Roberts \(1959\)](#) described dysnomia in response to cortical stimulation across virtually the whole peri-Sylvian cortex, without clear location specificity to the patterns of errors observed. These data point to two features of naming. First, it requires many different component processes to achieve, from early vision to visual object recognition to modality-dependent (and/or modality-independent) conceptual access to lexical access to phonological assembly to phonemic mapping and motor output, functions that are subserved by networks extending throughout the whole peri-Sylvian region. Second, many regions throughout the peri-Sylvian cortex and associated thalamic nuclei probably participate in a distributed network that encodes word meanings and conceptual information, such that a lesion in any part of the network causes a breakdown in lexical-semantic processing. This similarity in the clinical presentation of focal thalamic and cortical lesions extends to recovery in language function after focal thalamic lesions. Rather than being evidence for the absence of a role for the thalamus in language, we note that both thalamic and focal cortical lesions demonstrate recovery ([Mohr et al., 1978](#); [Penfield & Roberts, 1959](#)) and point to a high level of redundancy and plasticity in thalamocortical networks that are important for language.

Another criticism of “thalamic aphasia” is one that has been articulated by Luria and others, stating that thalamic language deficits are not bona fide *language* deficits at all in that there is no deficit in the formulation or understanding of grammatical structure, but rather they reflect instability of cortical language traces. As described, it may be that the absence of grammatical formulation errors in patients with dominant thalamic injury serves as an important constraint on any model of thalamic function for language. Given the well-known role of the thalamus in arousal function, it may be that a key role for the thalamus is to sustain cortical representations of language during production or comprehension of language, which is explored in [Section 9.4.1](#).

9.3 A THALAMIC “LOCUS” FOR LANGUAGE?

At a first approximation, one might think it could be possible to resolve some of the heterogeneity in clinical presentation from careful analysis of lesion location or vascular distributions of thalamic infarcts. Unfortunately, this approach has proven to be quite challenging. For example, there is not a single thalamic blood vessel that has been exclusively associated with thalamic aphasia. The thalamus receives its blood supply from the tuberothalamic, paramedian, inferolateral, and posterior choroidal arteries, which are derived from the posterior circulation and all have been implicated in thalamic aphasia ([Bogousslavsky, Miklossy, Deruaz, Regli, & Assal, 1986](#); [Bogousslavsky, Regli, et al., 1986](#); [Karussis et al., 2000](#); [Levin et al., 2005](#); [McFarling et al., 1982](#); [Neau & Bogousslavsky, 1996](#); [Perren, Clarke, & Bogousslavsky, 2005](#); [Radanovic et al., 2003](#); [Raymer et al., 1997](#)). Analysis of the distributions of these infarcts is further complicated by the fact that certain regions of the thalamus, such as the pulvinar, receive a dual vascular supply ([Morandi et al., 1996](#); [Takahashi et al., 1994](#)), and because patients with pulvinar lesions tend to also have associated (often devastating) midbrain or brainstem lesions, making any analysis of language difficult. This may create the impression that the pulvinar is not involved in language. However, given the widespread projections of the pulvinar to regions of the cortex that are involved with language ([Romanski, Giguere, Bates, & Goldman-Rakic, 1997](#)) and findings using other clinical sources (hemorrhage, deep brain stimulation, tracing degenerating axons), all point to a potential role for the pulvinar in language ([Crosson et al., 1986](#); [Ojemann, Fedio, & van Buren, 1968](#); [Van Buren & Borke, 1969](#)).

Another approach is to examine lesion location and perform a traditional lesion-deficit analysis. One starting hypothesis may be that anterior thalamic infarctions

would be more likely to cause deficits in language motor production, and posterior thalamic infarctions would be more likely to cause deficits in language comprehension. Such an analysis has been performed, and the anterior/posterior distinction has not solved the problem. For example, several investigators have described infarction of the tuberothalamic artery, which serves the anterior thalamic nuclei, ventral pole of the dorsal medial nucleus, ventral anterior nucleus, and intralaminar and rostral ventral lateral nucleus ([Figure 9.2](#)). In these patients, the clinical syndromes span the full range of language behaviors, without a clear predominance of “sensory” or “motor” manifestations. Of the patients described in [Table 9.2](#), seven can be described as having primarily a “sensory” aphasia, and one might predict that the lesions in these cases predominantly affect portions of the thalamus known to project to superior temporal, inferior parietal, or adjacent areas of the cortex (i.e., “Wernicke’s area”). However, five out of seven of these patients had lesions in the territory of the tuberothalamic artery, which supplies anterior thalamic structures (ventral anterior nucleus, ventral lateral nucleus, mediodorsal nucleus, anterior thalamic nuclei, and the anterior intralaminar nuclei), which are generally not known to project to areas within or near Wernicke’s area.

The author has examined the locations and extents of lesions in the case reports and series (when figures were available from the original publications) and has superimposed this information onto generic maps of the thalamus (taken from [Morel, 2007](#)); these maps are shown in [Figure 9.3](#). As shown, the distribution of lesion sites demonstrates a propensity for sites to be located in the anterior nuclei (possibly for the reasons stated), but importantly demonstrates that lesions producing aphasia can be found in nearly all regions of the thalamus.

It may be possible to avoid some of the biases introduced by analysis of the vascular distributions of thalamic ischemic infarctions and the nonspecific effects of hemorrhage by analyzing data from patients undergoing therapeutic thalamotomy or deep brain stimulation. Here, for therapeutic reasons, most of the lesion/stimulation sites have been in the ventral lateral nucleus, intralaminar nuclei, and pulvinar. Much of the classic work in this field was performed by Ojemann and his colleagues. They found that stimulation in adjacent areas of the left ventral lateral nucleus and pulvinar caused dysnomia, and that the dysnomia was not related to motor speech difficulties. Most of the errors were substitution errors, which stands in contrast to errors made in a similar paradigm using stimulation of subcortical white matter beneath parietal cortex, which mostly causes omission errors ([Ojemann et al., 1968](#); [Ojemann & Ward, 1971](#)).

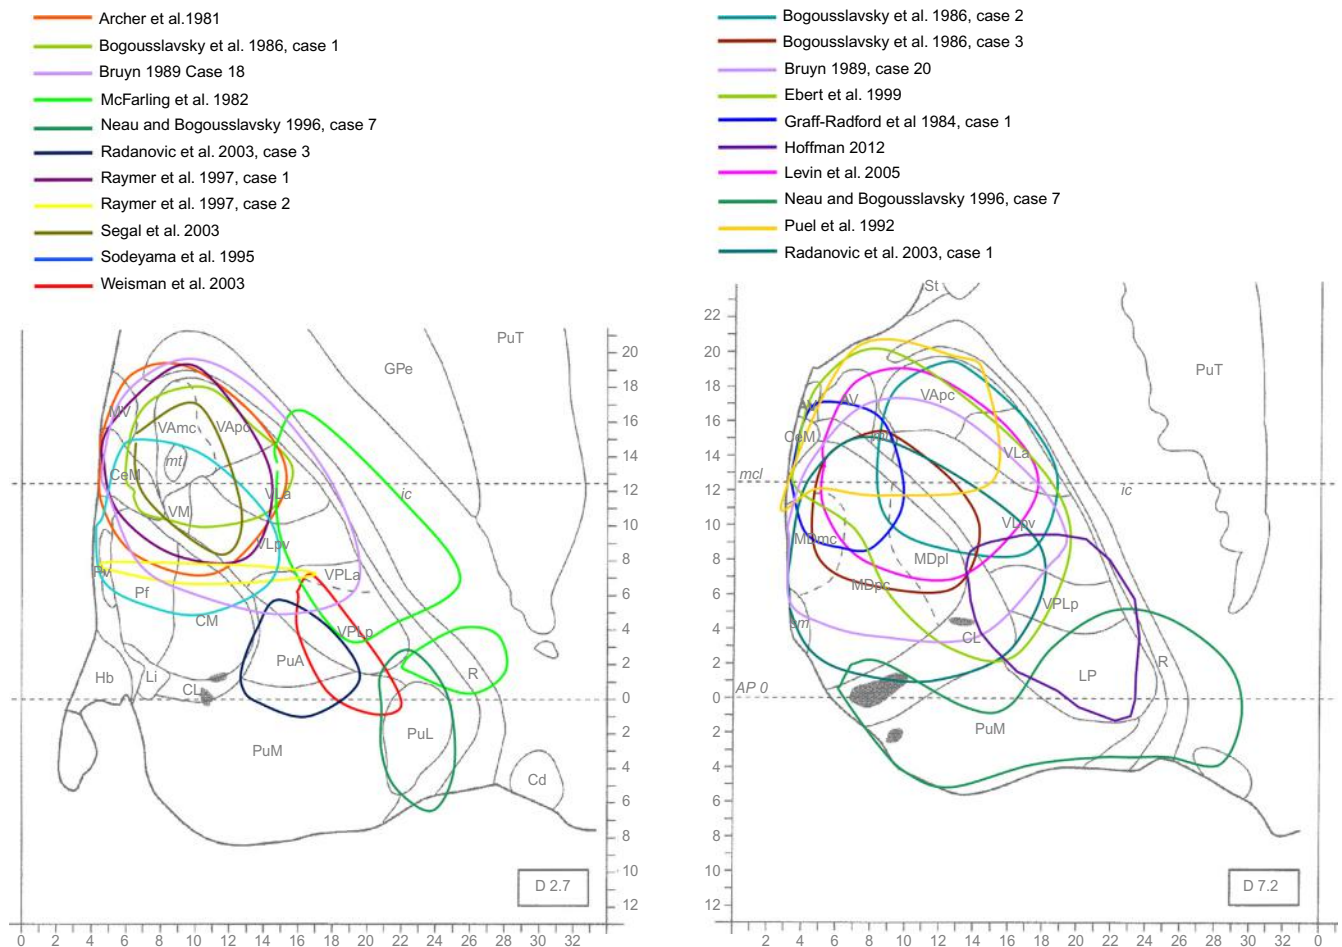

FIGURE 9.3 Perimeters of lesions taken from original publications referenced in Table 9.2 (when good-quality images were available), overlaid on a generic axial map of the thalamus, taken from (Morel, 2007). Two different superior-inferior levels are shown (left 2.3 mm, right 7.2 mm dorsal to posterior commissure). Background images of the thalamus obtained with permission from Taylor and Francis Group LLC Books.

The notion that the pulvinar plays a role in language, which was not obvious from the lesion data (Figure 9.3), was supported by work by Fedio and Van Buren, who also performed a direct brain stimulation study of picture naming. They predominantly found substitution errors during stimulation of the left pulvinar, but no errors during stimulation of areas anterior or inferior to the left pulvinar (or the right pulvinar). These findings contrast with those of Vilkki and Laitinen (1976), who compared language performance of patients undergoing thalamotomy of the ventral lateral nucleus with those undergoing pulvinotomy. They found decreases in word fluency and token test performance in those undergoing left ventrolateral thalamotomy, but only nonsignificant trends toward worsening token test performance and naming for patients undergoing pulvinotomy. Finally, more recent work involving patients undergoing deep brain stimulation of the centré-median nucleus of the intralaminar group of nuclei has induced enhancement across a number of cognitive domains (language, memory, and

reasoning). Many language tasks showed improvement, including object naming, recall, antonym recall, word fluency, sentence comprehension (Token test), and verbal expression (Bhatnagar, 2005). These studies, coupled with the previously described neurosurgical literature, interpreted conservatively, implicate the ventrolateral nucleus, the pulvinar, and possibly the centré-median nucleus in engaging in language.

A third approach to determining the anatomical site within the thalamus for language performance is to attempt to trace specific areas of the cortex known to play a role in language (e.g., inferior frontal gyrus, posterior superior temporal gyrus) to specific thalamic nuclei. There are very few data using this approach in humans, but the data generally point to the same nuclei that emerged from the thalamic lesion literature. For example, limited human autopsy studies examining patterns of degeneration after cortical aphasic stroke involving posterior regions important for language (e.g., superior temporal gyrus, supramarginal gyrus, angular gyrus)

produced degeneration in the central lateral nucleus (an intralaminar nucleus), lateral posterior (part of the pulvinar complex), and pulvinar proper. For example, a patient with stroke suffering from a “motor aphasia with perseverations” involving cortical damage to the post-central gyrus, superior insula, and parietal operculum, yielded thalamic degeneration in ventral posterior medial nucleus, medial geniculate body, ventral anterior nucleus, and the centrolateral nucleus (Van Buren & Borke, 1969). Most recently, as mentioned, Ford and colleagues identified the ventral anterior nucleus as demonstrating strong connectivity with Broca’s area (Ford et al., 2013), suggesting that this region is involved in the motor and/or grammatical aspects of speech. Overall, these data again implicate the pulvinar, intralaminar nuclei, the ventrolateral nucleus, and the ventral anterior in language function, with some regional anatomical specificity such that ventral anterior nucleus may have direct projections to Broca’s area and more posterior language areas having connectivity with pulvinar and possibly the intralaminar nuclei. These analyses are very preliminary and, as tractography techniques advance, we are likely to learn much more about thalamic correlates to physiologically identified cortical regions involved with language.

Given what appears to be a general conservation of the topology of the cortical structures involved in language superimposed on the thalamus, it is peculiar that the functional distinctions between the anterior and posterior language systems, evident in the cortex, are not evident in the thalamus. In other words, although naming tends to be distributed widely throughout brain language centers, other more specific types of language deficits appear to have a more segregated anatomical distribution in the cortex but do not appear to do so in the thalamus. Some light on this issue has been shed by work examining cortical perfusion in the setting of acute thalamic stroke. Puel et al. (1992) demonstrated cortical hypoperfusion via SPECT imaging in the peri-Sylvian, posterior temporal, and temporo-occipital regions of the left hemisphere, regions not innervated by the anterior group of nuclei and occupying a larger area than would be predicted by a lesion of one or more of these nuclei. These results were confirmed and extended by Shim et al. (2008), who demonstrated decreased regional cerebral blood flow in several peri-Sylvian cortical regions, including the left inferior frontal gyrus, supramarginal gyrus, and superior temporal gyrus after infarction of left anterior thalamic structures manifested by dysnomia and poor semantic and phonemic fluency (Figure 9.4). Similar decreases across broad regions of cortex were also seen by Lanna et al. (2012). These data point to an apparent lack of a 1:1 structural–functional

relationship of the thalamic nuclei and their cortical targets with respect to language. This difficulty was noted by Crosson (1999), who suggested that the common deficits produced by disparate lesions point to the possibility of damage to different portions of a common neural system, rather than separable neural systems with separate roles each. This distinction will become important as different models of thalamic involvement in language are discussed.

9.4 IMAGING OF THE THALAMUS IN LANGUAGE TASKS

A complementary approach to the lesion-deficit analysis presented is to measure thalamic activation during language tasks using functional imaging. The author has systematically reviewed the relevant fMRI and PET literature previously (Llano, 2013) and summarizes the findings here. Despite a large number of functional imaging studies having been performed over the past 20–30 years measuring brain activity during language tasks, very few have described the patterns of activation seen in the thalamus (or any other subcortical structures). There are several reasons for this. First, thalamic nuclei are relatively small (a few millimeters in diameter, typically) relative to the smoothing windows for most studies, which range from 5 to 20 mm, full width at half maximum. Second, movement artifact due to respiration and heart rate is more prominent in subcortical rather than cortical structures (Guimaraes et al., 1998). Third, it is likely that neurometabolic coupling is different in cortical regions versus thalamus (Llano, Theyel, Mallik, Sherman, & Issa, 2009), such that canonical hemodynamic response functions, optimized for cortex, may not be optimal for thalamus. There may also be fundamental differences in redundancies and integrative properties between thalamus and cortex, yielding different metabolic requirements during the activations of these structures. Finally, and possibly most importantly, most investigators do not place regions of interest in the thalamus and/or do not optimize their spatial resolution on subcortical structures, leading to a lack of detection of activation in thalamus during a language task.

Despite these limitations, the author previously identified 50 studies that demonstrated thalamic activation while normal subjects performed a language task (Llano, 2013). Two of the most common tasks leading to thalamic activation were word or sentence generation tasks and naming. Less commonly, activation was seen during lexical decision, reading, and working memory tasks. Activation was generally seen throughout the thalamus, but with a predominance of activation sites in the left thalamus, and was associated with activations in frontal and temporal cortical regions typically associated

FIGURE 9.4 (Top) T2-weighted images of four patients with isolated infarcts to the left tuberothalamic artery. with language tasks (Figure 9.5). These analyses indicate that the thalamus may be involved in processes that involve manipulations of lexical information, particularly when based on semantic cues.

9.4.1 Models of the Role of the Thalamus in Language

The data presented suggest that the thalamus plays an important role in language, although its specific role or roles are not yet known. Several models of thalamic function in language are considered here. Any model of thalamic function in language should be able to reproduce the key findings described in the clinical literature on thalamic aphasia and should be constrained by the known anatomical and physiological features of thalamic circuitry. As such, it is proposed

that a reasonable model should be able to reproduce the following elements:

1. The primary cognitive deficits in thalamic aphasia involve the following three features:
 - a. The deficit is one of lexical selection based on semantic information
 - b. The deficits fluctuate with level of arousal
 - c. The deficits do not involve repetition
2. These deficits can be produced via lesions in multiple different loci in the dominant thalamus, with the primary nuclei involved being the ventrolateral, centré-median, and pulvinar.
3. The model should be constrained by the known anatomical and physiological properties of the thalamus.

Several investigators have developed descriptive models of thalamic mechanisms that underlie language

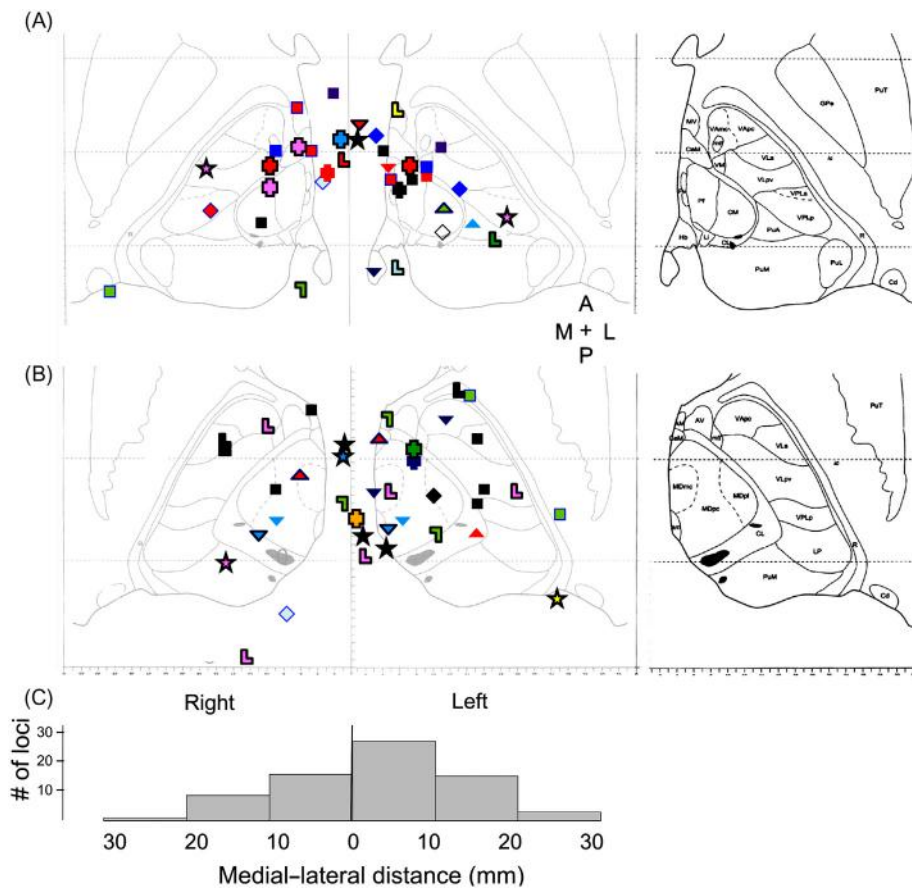

FIGURE 9.5 Compilation of the center of activation foci taken from Talairach and Tournoux coordinates (either given in original publications or transformed from MNI coordinates). Two axial sections are shown. (A) Taken from 2.7 mm superior–inferior (base image reproduced from Morel, 2007). (B) Taken from 8.1 mm superior–inferior. Each study is represented by a different symbol. (C) Histogram of the number of activation loci within each 10 mm of midline in the medio-lateral dimension. Different symbols represent activations from different studies. A = anterior, P = posterior, M = medial, L = lateral, AM = anteromedial nucleus, AV = anteroventral nucleus, Cd = caudate nucleus, CeM = central medial nucleus, GPe = globus pallidus externa, Hb = habenular nucleus, ic = internal capsule, Li = limitans nucleus, LP = lateral posterior nucleus, MDmc = mediodorsal nucleus, magnocellular division, MDpc = mediodorsal nucleus, parvocellular division, MDpl = mediodorsal nucleus, paralamellar division, mtt = mammillothalamic tract, Pf = parafascicular nucleus, PuA = anterior pulvinar, PuL = lateral pulvinar, PuM = medial pulvinar, PuT = putamen, Pv = paraventricular, R = thalamic reticular nucleus, sm = stria medullaris, VAmc = ventral anterior nucleus magnocellular, VApc = ventral anterior nucleus parvocellular, VLa = ventrolateral anterior, VLpd = ventrolateral posterior nucleus dorsal division, VLpv = ventrolateral posterior nucleus ventral division, VM = ventromedial, VPLa = ventral posterior nucleus anterior division, VPLp = ventral posterior nucleus posterior division. processing. Most of these models have ascribed an attentional role to the thalamus (Crosson, 1999; Johnson & Ojemann, 2000; McFarling et al., 1982; Riklan & Cooper, 1975). Two of the more well-developed and most referenced are described here after a brief description of relevant thalamic anatomy and physiology.

9.5 THALAMIC CIRCUITRY AND PHYSIOLOGY

One challenge in understanding the role of the thalamus in language is the heterogeneity of organization within this structure. There have been many attempts to

bring order to the thalamus by classifying thalamic nuclei and thalamocortical neurons. The main points of distinction between thalamic neurons and thalamic nuclei have been the types of inputs received by a thalamic neuron, and therefore the direction of information flow through the thalamus, and the layer of termination in the cortex of thalamocortical neurons and, therefore, the types of effects that a thalamic neuron can have on the cortex. For example, it is possible to distinguish between principal thalamic nuclei, such as the lateral geniculate nucleus for vision, which sends specific sensory information to middle layers of the occipital cortex, compared with the intralaminar nuclei, whose cortical projections show a more widespread distribution and

tend to terminate in upper layers and have been implicated in the control of arousal (Purpura & Schiff, 1997; Van der Werf, Witter, & Groenewegen, 2002) (Figure 9.6A). Although this distinction has heuristic value, it is muddled by the presence of layer 1-projecting neurons in principal nuclei (Abramson & Chalupa, 1985; Rockland, Andresen, Cowie, & Robinson, 1999). An additional parcellation scheme is based on the types of inputs received by thalamic neurons. Thalamic neurons receive inputs from many sources: primary sensory afferents (e.g., the retina for the lateral geniculate nucleus), brainstem monoaminergic and cholinergic nuclei, the thalamic reticular nucleus, and the cerebral cortex. It has been proposed that these inputs can be divided into “drivers,” which are inputs with morphological and physiological specializations characterized by very high synaptic efficacy, and “modulators,” which are physiologically better suited to regulate the tuning functions of thalamic neurons (Sherman & Guillery, 1998). Based on these distinctions, Sherman and Guillery divided the thalamus into “first-order” nuclei, such as the lateral geniculate nucleus, which receive their drivers primarily from the sensory periphery and “higher-order” nuclei, such as the pulvinar, which receive their drivers from the cerebral cortex (Figure 9.6B). The relevance here for language is that higher-order nuclei may serve as an alternative route for the transmission of long-range cortical communication via a cortico-thalamo-cortical route (Theyel, Llano, & Sherman, 2010).

The other important and relevant features of the thalamus concern the physiological properties of thalamic neurons and the main readout of thalamocortical neurons: the thalamocortical synapse. Most thalamocortical neurons contain T-type calcium channels, which de-inactivate with protracted (100 s of milliseconds) hyperpolarization and, then, with a low threshold,

produce a large depolarization leading a burst of spikes (Figure 9.6C). Therefore, thalamocortical neurons may exist in one of two response modes: *tonic* or *burst* (Jones, 2007; Sherman, 2001). In addition, thalamocortical synapses can show profound *short-term depression* (Boudreau & Ferster, 2005; Castro-Alamancos & Oldford, 2002; Chung, Li, & Nelson, 2002; Gil, Connors, & Amitai, 1999), which limits the types of patterns of thalamic discharges that are likely to elicit cortical responses. Therefore, high-frequency tonic patterns of spiking activity, often assumed to be the “relay” mode of thalamic neurons, may be nearly completely suppressed at the level of the cortex, and other patterns of thalamic activity, such as bursts and pauses, may, in fact, be more suited to drive postsynaptic cortical activation.

The presence of bursting in thalamocortical neurons and synaptic depression in thalamocortical synapses opens the door to coding schemes beyond the simple gated relay model often referenced in the literature. Of particular interest is the micro-organization of circuits that engage GABAergic neurons in the thalamic reticular nucleus, which is closely associated with the thalamus and implicated in thalamic models of language (Crosson, 2013). The thalamic reticular nucleus receives input from thalamus and cortex, as well as the basal forebrain and amygdala (Asanuma & Porter, 1990; Zikopoulos & Barbas, 2012), and sends GABAergic projections to thalamocortical neurons. By hyperpolarizing thalamocortical cells, the thalamic reticular nucleus may modify cortical activation by: (i) diminishing spiking in thalamocortical neurons; (ii) introducing a pause in the thalamic spike train, resulting in relief of tonic depression at thalamocortical synapses; (iii) synchronizing populations of thalamic cells; and/or (iv) inducing low-threshold bursting behavior, which has been shown to be a highly effective mechanism to drive postsynaptic activation

FIGURE 9.6 Models of thalamic organization. (A) Principal nuclei primarily project to middle cortical layers while intralaminar nuclei project to layer 1. (B) First-order nuclei receive their driving input from the sensory periphery, whereas higher-order thalamic nuclei receive their input from layer 5 of cortex, and relay that input to other areas of cortex. (C) An example of a neuron in tonic mode (top) and burst mode (bottom). Data from Llano laboratory.

(Denning & Reinagel, 2005; Lisman, 1997; Mukherjee & Kaplan, 1995; Person & Perkel, 2005; Reinagel, Godwin, Sherman, & Koch, 1999; Smith, Cox, Sherman, & Rinzel, 2000; Swadlow & Gusev, 2001). Therefore, the influence of the thalamic reticular nucleus may be an increase or decrease of cortical activation, depending on the ongoing activity in thalamic cells and the relative timing of inputs from the thalamic reticular nucleus and other structures. These data indicate that simple linear models of thalamic function are unlikely to capture the range of influences that the thalamus may have on cortical function.

9.6 MODELS OF THALAMUS AND LANGUAGE

Two influential models of thalamic function and language are considered here in more detail: that of Ojemann (Johnson & Ojemann, 2000, updated in Hebb & Ojemann, 2013) and Crosson (1999) (updated in Crosson, 2013). George Ojemann and colleagues have attributed a “specific alerting response” to the thalamus, generated by ventrolateral thalamus and pulvinar, which gates the entry of language information to the peri-Sylvian regions. The specific alerting response is also required for the retrieval of specific lexical information, which is embedded into peri-Sylvian circuits. This descriptive model is based on four types of evidence driven by Ojemann’s body of work using deep brain electrical stimulation in human subjects. First, as described, naming deficits occur during electrical stimulation of ventrolateral thalamus and pulvinar (Ojemann et al., 1968; Ojemann & Ward, 1971). These errors are typically misnaming errors rather than omissions or speech arrest. Second, stimulation of the ventrolateral nucleus during the presentation of verbal material enhanced the ability to recall this material, but stimulation during recall of previously learned material impaired this process (Ojemann, Blick, & Ward, 1971). Third, stimulation of the left ventrolateral nucleus during the presentation of nonverbal information impaired the retention of this information. This suggests that the enhancement effects seen with left ventrolateral nucleus stimulation are restricted to verbal information. Fourth, silent naming induced desynchronization in the electrocorticogram across peri-Sylvian structures known to be important for naming (Ojemann, Fried, & Lettich, 1989). In this context, it is worth noting that Slotnick et al. noted a decrease in low-frequency power during a semantic recall task across multiple cortical sites that was correlated with a decrease in low-frequency power in the thalamus, bilaterally (Slotnick, Moo, Kraut, Lesser, & Hart, 2002). The four points described led Ojemann to speculate that specific left thalamic areas (most likely ventrolateral nucleus and pulvinar) selectively engage language cortex

to support the retrieval of lexical information (Johnson & Ojemann, 2000). The most recent update of the model (Hebb & Ojemann, 2013) offers speculation about regional specialization and circuit-based mechanisms such that the ventral tier nuclei (such as the ventrolateral nucleus) and intralaminar nuclei modulate the specific alerting response either by recruiting striatal networks or via intralaminar thalamocortical or thalamoreticular projections. They also speculate that the pulvinar may synchronize oscillations of related cortical regions representing different features of an object to be named, a hypothesis for which there is recent support from the literature involving monkeys (Saalman, Pinski, Wang, Li, & Kastner, 2012).

Bruce Crosson and colleagues have proposed several potential models of the role of the thalamus in language (Crosson, 2013), and these have been derived primarily by the detailed study of patients with thalamic damage and aphasia. In the most recent instantiation, Crosson and colleagues hypothesized that the language deficits observed in their patients were caused by a failure to activate cortical circuits needed to retrieve lexical information from semantic representations. Further, they proposed that the failure was due to a lesion in the fronto-inferior thalamic peduncle-nucleus reticularis-centré-median thalamus system. This is based on the idea that the frontal cortex can gate the transmission of information through the thalamus to other areas of cortex (Brunia, 1993; Yingling & Skinner, 1975). This model focuses on the intralaminar nuclei (centré-median nucleus) rather than the ventrolateral nucleus and pulvinar, based on several arguments. They claim that there is a lack of anatomical specificity in electrical stimulation studies of ventrolateral nucleus and pulvinar due to spread of current to adjacent nuclei or fibers of passage, and that infarctions may have encroached on neighboring structures (such as the inferior thalamic peduncle, centré-median, or their connections). In addition, they note that their patients with strokes in apparently disparate areas within the thalamus have in common the disruption of the inferior thalamic peduncle-nucleus reticularis-centré-median thalamus system. They further argue that the intralaminar system, by virtue of its unique anatomical and physiological properties, is more suited to serve an attentional language function (Nadeau & Crosson, 1997).

This attentional model is derived from the cardinal findings that their patients with thalamic aphasia had particular difficulties with retrieval of lexical information from semantic information. They have argued that this process is more dependent on attention than is pure lexical processing or pure semantic processing. This postulate is supported by data from Crosson’s group, which showed that incorporation of a lexical-semantic task (semantic associate generation) was far more distracting

than a lexical-lexical task (word reading) in a modified Posner paradigm (Crosson, 1999). A more specific form of attention, such as selective engagement, may also be utilized during these tasks. Specifically, they have proposed that the role of this type of selective engagement of cortex is to enhance differences in the activation level of semantically related lexical items. Failure of selective engagement increases the likelihood that inappropriate lexical items will be selected.

Most recently, Crosson has updated this model by attempting to unify the multiple different processing streams that exist in thalamocortical and thalamocortical networks. He proposed four different circuits responsible for different aspects of language function and used the process of naming a hammer to illustrate these mechanisms. First, for example, to generate the name "hammer," Broca's area exerts control over disparate areas of cortex responsible for the semantic representation of a hammer (e.g., fusiform gyrus for the visual form of the hammer and inferior parietal lobule for motor sequences). This control occurs via layer 6 corticothalamic projections to the thalamic reticular nucleus, which, in turn, controls activation of pulvino-cortical circuits, potentially by inducing gamma oscillations (Figure 9.7A). This is a modification of the specific alerting response mentioned, and the suggestion that pulvina may conjoin disparate areas of cortex using oscillatory assemblies is supported by some recent experimental data (Saalmann et al., 2012). It should also be mentioned that this type of frontal cortex-thalamic organization has long been speculated to be part of a mechanism of frontal cortical control over widespread cortical networks (Brunia, 1993; Skinner & Yingling, 1977) and is consistent with recent observations of the existence of prefrontal cortical circuits that target portions of the thalamic reticular nucleus that influence parts of the thalamus that do not necessarily send a return projection to the prefrontal cortex (Zikopoulos & Barbas, 2006).

Once appropriate areas of the cortex are activated via the alerting response described, a cortico-thalamocortical route may transfer semantic feature information from these areas to the posterior parietal cortex (Figure 9.7B). There is some support for the existence of cortico-thalamocortical transmission in animal models (Llano & Sherman, 2008; Theyel et al., 2010), although all of the current work to date has focused on sensory processing within a single modality. A third mechanism involves the activation of modulator-type corticothalamic projections, which have been shown to augment and potentially sharpen thalamic activations within sensory systems (Alitto & Usrey, 2003; Sillito, Cudeiro, & Jones, 2006), and may facilitate word retrieval by activating particular regions of the thalamus (Figure 9.7C). Finally, word selection, analogous to movement selection, may

occur via pathways that involve presupplementary motor areas that project to basal ganglia circuits that project to the ventral anterior nucleus (Figure 9.7D). This may diminish the chance of errors in lexical selection. For further discussion of the potential role of the basal ganglia in language, please see Chapter 8 in this volume on the basal ganglia.

This multi-level model of thalamic function may help to explain: (i) the number of thalamic nuclei implicated in thalamic aphasia; (ii) the widespread cortical metabolic impact of restricted thalamic lesions (Figure 9.4); and (iii) the convergence of multiple thalamic nuclei to individual cortical areas (Hackett et al., 1998; Morel et al., 2005), such that different thalamic subnuclei may play distinct roles in cortical processing.

9.7 SUMMARY AND CONCLUSIONS

The clinical literature demonstrates that lesions of the dominant thalamus can cause dysnomia that is frequently coupled with perseverations and fluctuations in performance related to arousal. The dysnomia is likely driven by a deficit in lexical selection based on semantic information. Anatomically, the clinical and the imaging literature have not consistently pointed to a particular responsible thalamic nucleus, although certain nuclei, such as the ventrolateral nucleus, the centré-median nucleus, and medial pulvina are frequently implicated. Review of previous models of large-scale thalamocortical organization suggests that multiple mechanisms may underlie thalamic involvement in language. Specifically, the thalamus may play a key role in arousal of specific cortical networks necessary for language function and may use the ubiquitous layer 6 corticothalamic projections to refine these representations. Further, cortico-thalamocortical communication may be required to route information represented in different regions of the cortex to the posterior parietal cortex. Finally, lexical selection may take place via pallidothalamic circuits. This type of multi-function model of the thalamus helps to reconcile some of the disparate clinical and imaging data, which point to lesions or activations in virtually all thalamic nuclei in aphasic patients and imaging studies, respectively.

Many questions remain, however, and many of these have to do with fundamental questions regarding the physiologic organization of thalamic functions. For example, core features of thalamic physiology, such as the role of transitions between tonic and burst modes, which will have substantially different effects on their postsynaptic targets, are not specified in these models. Further, the role of convergent thalamic inputs, particularly those to layer 1 and layer 4, speculated to play a key role in the ability of the thalamus to activate cortex (Linás, Leznik, & Urbano, 2002; Purpura & Schiff, 1997)

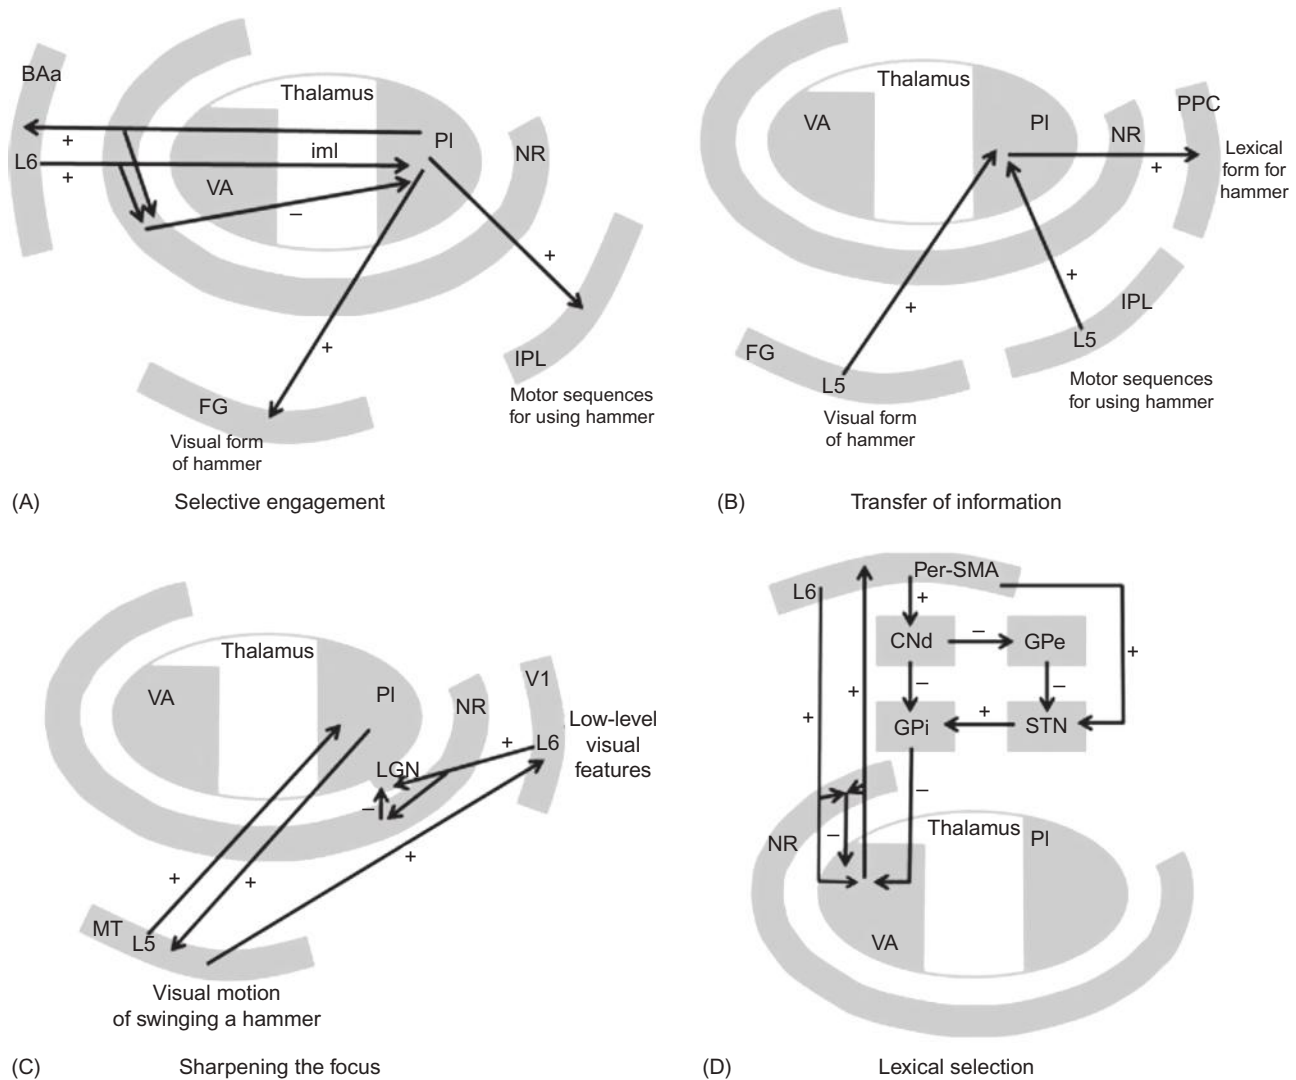

FIGURE 9.7 Four mechanisms proposed by Crosson (2013) to explain thalamic involvement in language. (A) A selective engagement model whereby corticothalamic projections from Broca’s area to the thalamic reticular nucleus and/or pulvinar initiate more widespread activation of cortical areas involved in the representation of a particular object to be named. (B) A transfer of information model whereby information from cortical areas representing features of the object to be named is routed to the inferior parietal lobe via cortico-thalamocortical routes. (C) Layer 6 corticothalamic neurons sharpen the focus of activation in the thalamus in its primary sensory representation (in this case, the visual cortex). (D) Lexical selection is performed using basal ganglia circuits involving the direct, indirect, and hyper-direct loops from pre-supplementary motor cortical areas via the basal ganglia and the ventral anterior nucleus. Sharpening may also be possible here via layer 6 projections to the thalamic reticular nucleus. From Crosson (2013) with permission from the publishers. BAa = anterior Broca’s area, GPi = internal globus pallidus, GPe = external globus pallidus, CNd = dorsal caudate nucleus, FG = fusiform gyrus, iml = internal medullary lamina, IPL = inferior parietal lobule, L6 = cortical layer 6, LGN = lateral geniculate nucleus, NR = nucleus reticularis, PI = pulvinar, PPC = posterior perisylvian cortex, STN = subthalamic nucleus, V1 = primary visual cortex, VA = ventral anterior nucleus.

have not explicitly been tied to language function, although such convergence models could support the “specific alerting system,” as conceived of by Ojemann and colleagues (Hebb & Ojemann, 2013; Johnson & Ojemann, 2000). Finally, the thalamic reticular nucleus, whose function remains quite mysterious, given its relative inaccessibility to experimentation, has been speculated to be involved in language (Crosson, 2013; Nadeau & Crosson, 1997), but basic questions about this structure remain unanswered. For example,

previous models postulate that the thalamic reticular nucleus can impact the flow of information between thalamic nuclei. Although this possibility is intriguing and some data do support this (Crabtree & Isaac, 2002; Kimura, Imbe, Donishi, & Tamai, 2007; Pinault & Deschênes, 1998), to date there is a very poor understanding of how such “open-loop” networks are organized, or even if they cause inhibition or paradoxical excitation (via low-threshold bursting) in their thalamic targets.

Therefore, to make progress in this area, it will be necessary to develop a better basic understanding of the role of the thalamus in long-range cortical processing and, specifically, how the individual circuit elements found in the thalamus alter patterns of activation found in the cortex. In addition, more work will be needed using human subjects to better delineate the thalamic nuclei involved in task-based activations and in structural imaging studies to more precisely define the connectivity of thalamic nuclei with functionally defined regions of cortex. Finally, longitudinal functional and structural imaging studies of patients recovering from thalamic lesions will help us to understand the degree to which alternate or redundant pathways may contribute to cortical language processing. Therefore, the basic and the clinical literatures have served complementary roles in further developing our understanding of the thalamus and language to this point, and both will continue to shape our understanding of this critical yet poorly understood structure.

Acknowledgments

The author thanks Joe Beatty, Bruce Crosson, Anthony Dick, Uri Hasson, Iraklis Petrof, and Steve Small for their contributions to this and earlier versions of this manuscript.

The Insular Cortex

Jessica D. Richardson and Julius Fridriksson

Department of Communication Sciences and Disorders, The University of South Carolina, Columbia, SC, USA

10.1 GROSS ANATOMY

Rudimentary sketches of the insular cortex appeared as early as the 1500s (Shelley & Trimble, 2004). The first notable description of the insula was published in 1796 by Johann-Christian Reil (Binder, Schaller, & Clusmann, 2007), who later named it “die Insel” in 1809 (Shelley & Trimble, 2004). Illustrations appeared in the first edition of *Gray’s Anatomy* (1858), with the earliest detailed descriptions published by Korbinian Brodmann (1909), Binder et al. (2007), and Kurth et al. (2010). The insular cortex, also referred to as the “island (or isle) of Reil,” “Reil’s island,” “insula Reili,” and the “central lobe,” is a discrete lobe in the cerebral cortex covered by considerable vasculature and the frontal, temporal, and parietal opercula (Afif & Mertens, 2010; Stephani, Vaca, Maciunas, Koubeissi, & Luders, 2011; Ture, Yasargil, Al-Mefty, & Yasargil, 1999). Popular illustrations of this hidden cortical island reveal it by locating the Sylvian fissure and pulling away the opercula to view the structure underneath (Figures 10.1 and 10.2).

The insula is divided into anterior and posterior portions by a central insular sulcus (CIS). The CIS is generally continuous with the central cerebral sulcus (Rolandic fissure), sharing an axis of development and orientation with the overlying cortex (Afif & Mertens, 2010; Varnavas & Grand, 1999). The insula is generally described as triangular in shape, with three peri-insular sulci (anterior/inferior/superior). Recently, a morphometric study performed using fresh human cadaver brain specimens revealed that, in all hemispheres dissected (10 left, 10 right), there were four peri-insular sulci (anterior/inferior/posterior/superior) separating a *trapezoidal* insula from surrounding structures (Afif & Mertens, 2010). There are eight sulci

facing the underside of the operculum. Anterior to the CIS (moving outward from center) are the pre-CIS, anterior IS (AIS), and the anterior peri-IS (ApIS). Posterior to the CIS are the post-CIS and the posterior peri-IS (PpIS). The remaining two sulci are the inferior and superior boundaries to the insula (inferior and superior peri-IS [IpIS, SpIS]). There are six insular gyri, four in the anterior insula and two in the posterior insula. Located anterior to the CIS are the short posterior insular gyrus (sPIG), short middle IG (sMIG), and short anterior IG (sAIG). There is a smaller transverse insular gyrus (TIG) below the apex of the insula, readily viewed in a majority of brain specimens (Ture et al., 1999). In approximately half of the brain specimens, there is an accessory gyrus on the ventral anterior insular cortex (it is underdeveloped or absent in the other half; Ture et al., 1999). Located posterior to the CIS are the long anterior insular gyrus (lAIG) and the long posterior IG (lPIG) (Figure 10.3).

10.2 CYTOARCHITECTURE

Brodmann (1909) first identified two distinct areas within the insula—an anterior agranular area and a posterior granular area (Kurth et al., 2010). Since then, cytoarchitectural parcellations ranging from 3 to 30+ subdivisions have been proposed (for review, see Kurth et al., 2010; Nieuwenhuys, 2012). Presently, the most popular scheme for humans involves three divisions following a posterosuperior to anteroinferior gradient of decreasing granularity—posterior insula-granular (Ig), intermediate insula-dysgranular (Idg), and anterior insula-agranular (Iag) (Figure 10.3). Several additional subdivisions have been independently proposed with some convincing and/or

FIGURE 10.1 The hidden insula is revealed by locating the Sylvian fissure and separating the overlying opercula. Artist: C. Vincent Collier.

FIGURE 10.2 High-resolution T1 MRI with left hemisphere insula featured in coronal (upper left), axial (lower left), and sagittal (right) planes.

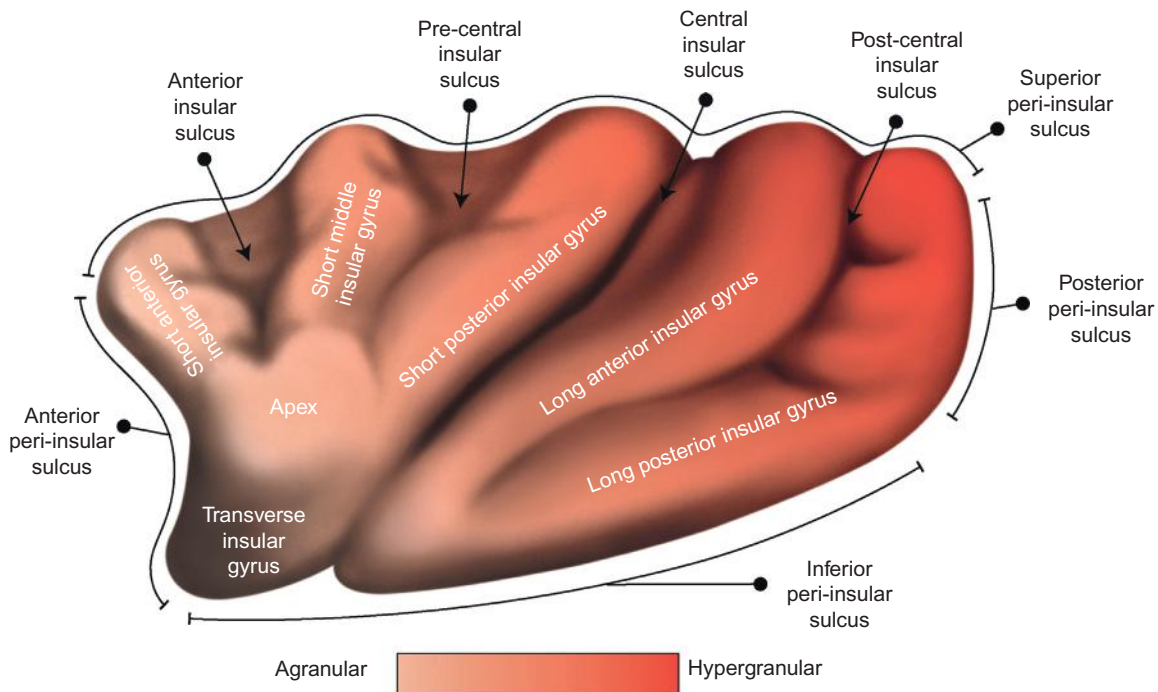

FIGURE 10.3 The left hemisphere insula is shown with sulci and gyri labeled. The color gradient represents the posterosuperior to antero-inferior gradient of decreasing granularity. Artist: C. Vincent Collier.

convergent results (despite differences in boundaries and terminology):

- Two Ig areas (posterior), with the most extreme posterosuperior section described as “hypergranular”
 - G and Ig (Morel, Gallay, Baechler, Wyss, & Gallay, 2013)
 - Alternatively, Ig1 and Ig2 (Kurth et al., 2010)
- Three Idg areas (intermediate), with progressively decreasing granule cell layer representation
 - Id3, Id2, and Id1, from greatest to least layer II/IV representation (Kurth et al., 2010; Morel et al., 2013)
- Two Iag areas (anterior), with no granule cell layer representation and the presence of von Economo neurons (VENs; Box 10.1)
 - Ia2 and Ia1 (Morel et al., 2013)
 - Or, agranular anterior zone (AA) and insular limbic cortex (ILC) (Nieuwenhuys, 2012)
 - Or, “frontoinsular cortex” (referring to the section of anterior insula heavily populated with VENs) and agranular insular cortex (Allman et al., 2011; Bauernfeind et al., 2013; Butti, Santos, Uppal, & Hof, 2013; Cauda et al., 2013).

10.3 VASCULATURE

The insula receives its blood supply from the middle cerebral artery (MCA), which is generally divided into

four segments (Gibo, Carver, Rhoton, Lenkey, & Mitchell, 1981; Tanrovier, Rhoton, Kawashima, Ulm, & Yasuda, 2004; Tatu, Moulin, Bogousslavsky, & Duvernoy, 1998; Ture, Yasargil, Al-Mefty, & Yasargil, 2000):

- M1: sphenoidal (the main trunk, before bi- or trifurcation; Kahilogullari, Ugur, Comert, Tekdemir, & Kanpolat, 2012; Ture et al., 2000)
- M2: insular
- M3: opercular
- M4: cortical (which may be further divided into separate “parasylvian” and “terminal” segments; Ture et al., 2000).

The insula is perfused primarily by M2, with some additional contribution from M1 and M3 (Tanrovier et al., 2004; Ture et al., 2000). The accessory MCA, which originates from the anterior cerebral artery, has also been observed to serve the insula (Tanrovier et al., 2004). The insula is drained by deep (deep middle cerebral vein) and superficial (superficial Sylvian vein) venous drainage systems (Tanrovier et al., 2004). Although deep venous drainage predominates for the insula as a whole, there are cortical areas within the insula primarily drained by superficial drainage systems (e.g., sAIG, sMIG, insula apex) and many areas draining into both deep and superficial systems.

Isolated insular infarction is rare. Most often, the insula is just one of many regions damaged when MCA is compromised. However, if infarction extends

BOX 10.1

VON ECONOMO NEURONS (VENs)

In the early 1900s, Ramon y Cajal first described large spindle cells in the human cortex that seemed to only appear in the cingulate and insular cortices (Butti et al., 2013; Seeley et al., 2012). Soon thereafter, Constantin von Economo (and George Koskinas) provided the first detailed illustration and description of these neurons in 1925 (Butti et al., 2013; Sak & Grzybowski, 2013; Seeley et al., 2012), referring to them as rod cells (Stabzellen) and corkscrew cells (Korkzieherzellen) (Seeley et al., 2012). In humans, VENs appear in the cingulate and insular cortices and are also present in the frontal cortex and hippocampal formation (Butti et al., 2013; Fajardo et al., 2008; Nimchinsky et al., 1999). VENs have been reported in non-human primates, whales, elephants, hippopotamus, manatees, zebras, walrus, and dolphins (Bauernfeind et al., 2013; Butti & Hof, 2010; Butti et al., 2013; Sak & Grzybowski, 2013) and are thought to be related to social

cognition (Allman et al., 2011; Bauernfeind et al., 2013) and vocalizations (Butti & Hof, 2010). Interestingly, although they are present in other species, they only appear in cluster formations in humans and great apes (Bauernfeind et al., 2013). VENs are thought to be specialized for rapid and long-distance signal transmission (Butti et al., 2013; Fajardo et al., 2008; Menon & Uddin, 2010; Sridharan, Levitin, & Menon, 2008) and are present in agranular and dysgranular areas, specifically layers V and III (Butti & Hof, 2010; Butti et al., 2013; Morel et al., 2013).

Another large cell appears alongside VENs in the anterior insula. These cells are similarly large and long, but they have two large dendrites pointing away from the cell soma and have thus been described as fork cells (Gabelzellen) (Seeley et al., 2012). These cells are less studied but are of interest because they only appear in the anterior insula.

to the insula after MCA damage, then it is thought to be a special risk factor for increased tissue damage (Ay, Arsava, Koroshetz, & Sorensen, 2008; Kamalian et al., 2013). Ay et al. (2008) revealed that when MCA infarcts lead to insular damage, they resulted in significantly greater volume of infarct progression (ischemic-to-infarcted tissue conversion) than MCA infarcts without insular damage, even when controlling for volume of ischemic tissue and site of occlusion. Further, when more than 25% of the insular cortex is infarcted at admission, it is a stronger predictor of infarct progression than stroke scale score (NIHSS), infarct volume at admission as judged by diffusion weighted imaging, or other imaging-based scores (Kamalian et al., 2013). The reason for insular damage as a risk factor is unclear—whether it is due to its numerous connections, whether it initiates other harmful events (Ay et al., 2008), or whether greater insula damage leads to further stroke complications (e.g., vasoconstriction, immunodepression, and sympathetic hyperactivation; Kamalian et al., 2013; Walter et al., 2013) requires further scrutiny.

10.4 CONNECTIVITY

The anterior insula is considered to be a paralimbic region (Eslinger, 2011; Mesulam, 2003; Nieuwenhuys,

2012; Stephani et al., 2011). Briefly, there are four stages of cortical differentiation (Mesulam, 2003):

1. Corticoid—Basic differentiation into “cortex-like structures;” inconsistent organization/patterning
2. Allocortex—Moderate differentiation of bands of neurons; includes paleocortex and archicortex
 - *Corticoid plus Allocortex form the limbic region
3. Paralimbic (or periallocortex)—Greater differentiation; transition zone from limbic regions to neocortex; divided into olfactocentric and hippocampocentric groupings, with the insula as part of the olfactocentric group (Eslinger, 2011)
4. Neocortex—Most complex differentiation

As a paralimbic structure, the anterior insula has extensive interconnections with other paralimbic structures along a cortical differentiation continuum (i.e., the more allocortical-like insula is connected to more allocortical-like portions of other paralimbic structures, and the more neocortical-like insula is connected to the more neocortical-like portions of other paralimbic structures) (Eslinger, 2011). Additionally, the insula is well connected with primitive limbic regions and more advanced neocortex (Augustine, 1996; Eslinger, 2011; Nieuwenhuys, 2012).

Since Augustine’s (1985, 1996) seminal reviews on primate (human and nonhuman) insular circuitry, the topic has been extensively studied with varied approaches. Because of the different techniques,

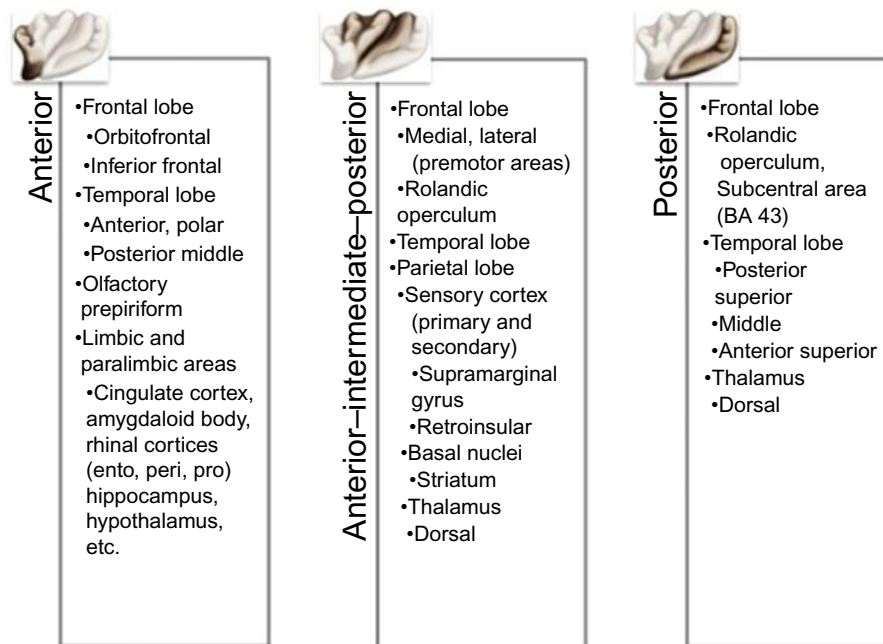

FIGURE 10.4 Basic illustration of insular structural circuitry based on reviews and investigations of primate (human and nonhuman) insula (Augustine, 1985, 1996; Catani et al., 2012; Cloutman et al., 2012; Mesulam & Mufson, 1982, 1985; Nieuwenhuys, 2012). The shaded areas represent approximate estimates of the insular territory associated with the specified connections: anterior insula (left), anterior–intermediate–posterior (center), and posterior (right). Artist: C. Vincent Collier.

regions of interest, methodologies, and terminology utilized, it is difficult to generate a coherent picture of insular circuitry. For example, translating the circuitry information from the mixed human and nonhuman primate literature should be performed with caution, given that recent tractography work has revealed some inconsistencies between the two populations, specifically regarding connections between the insula and the anterior cingulate cortex (Cerliani et al., 2012; Cloutman, Binney, Drakesmith, Parker, & Lambon Ralph, 2012). Additionally, nomenclature may be similar, but definitions often differ; not all anterior, intermediate, or posterior insular divisions are the same. Divisions may be determined by granularity, sulcal boundaries, functional connectivity, or other structural or functional features. Even if authors use a similar technique but different thresholds for determining boundaries, location and size of divisions will vary. The expanse of these divisions is also known to differ between humans and nonhuman primates, with positive allometric relationships (i.e., hyperallometric) between insula volume and total brain volume observed when comparing across primate brain volumes. This means that as total brain volume increases in primates, insula volume increases to a slightly greater degree (Bauernfeind et al., 2013). Interestingly, the lag exhibits greater hyperallometry than Idg and Ig (Bauernfeind et al., 2013).

In Figure 10.4, we merge connectivity findings in an attempt to provide a basic illustration of structural circuitry. No information about direction of information flow is provided here, because previous reports often differ and/or may stem from nonhuman primate or mixed human/nonhuman primate reports. Further, the boundaries and number of divisions (e.g., anterior/posterior versus anterior/intermediate/posterior) vary. We have included:

- Aforementioned (reciprocal) connections with paralimbic and limbic structures (to and from anterior insula)
- Neocortical structures
 - Frontal, temporal, parietal lobes
- Basal nuclei
 - Striatum
- Olfactory prepiriform cortex
- Dorsal thalamus

Cloutman et al. (2012) recently utilized *in vivo* probabilistic tractography in humans to investigate insular circuitry. Relying on gross anatomical gyral landmarks for seed positioning, they hypothesized that the pathways carrying information between neocortical and insula structures identified in their research might include the following fasciculi: arcuate, inferior fronto-occipital, middle longitudinal, and uncinata. They also hypothesized that the extreme capsule (EC) was a path

of information flow, but some consider the EC not as a separate tract but rather as a thoroughfare for more distinct tracts.

In addition to these connections, animal and human research has revealed abundant and reciprocal intra-insular connections (not included in Figure 10.4). In nonhuman primates, the informational flow has been described as traveling from anterior to posterior (i.e., abundant anterior to posterior, little posterior to anterior; Flynn, 1999; Mesulam & Mufson, 1982). In humans, Cloutman et al. (2012) revealed strong interconnectivity within anterior and posterior divisions, and an intermediate division with heavy connections to both anterior and posterior divisions. In addition, there were significant connections between the anterior apex and the posterior pole. Almashaikhi et al. (2014) performed an electrophysiological study complementary to Cloutman et al. (2012) due to their use of gyral landmarks for electrode placement (placed electrodes in all gyri used as seed regions in Cloutman et al., excluding only apical and polar regions). Interpreting their electrophysiological findings within the anterior–intermediate–posterior framework used by Cloutman et al., they demonstrated predominantly unidirectional flow of information from sAIG to more posterior regions (with only stimulation of sMIG resulting in sAIG response) and reciprocal connections between intermediate and posterior regions. The agreement between these tractography and electrophysiology results bolsters confidence in the findings. Commissural fibers, via anterior commissure and corpus callosum, have received little attention (Flynn, 1999), and the recent study by Almashaikhi et al. produced surprising results because no electrodes stimulated resulted in evoked potentials in the contralateral hemisphere. (Almashaikhi et al. urge caution when interpreting the predominantly unilateral information flow from sAIG as well as the contralateral findings because of small sample sizes specifically for these regions.)

Knowledge of these unique structural connections is helpful in the quest for determining insular function. The insula seems uniquely situated and connected to serve important integrative functions. Indeed, “paralimbic and related limbic system structures may be particularly important for developmentally establishing and mediating links between cognition, visceral states, and emotion” (Eslinger, 2011; see also Mesulam, 2000; Mesulam & Mufson, 1985).

10.5 INSULAR CORTEX AND BEHAVIOR

Research of the function of the insula using a variety of techniques has revealed functional divisions that

are generally consistent with structural connectivity data. Although the number of divisions identified differs, there is some agreement between different research groups and methods that point toward three functional divisions—posterior, dorsal anterior, and ventral anterior (Chang, Yarkoni, Khaw, & Sanfey, 2013; Deen, Pitskel, & Pelphrey, 2011; Kelly et al., 2012; Kurth et al., 2010). *Resting state fMRI* and *metanalytic* research conducted by Chang et al. (2013) revealed the following functional relationships: posterior insula is coactivated with *supplementary motor area (frontal)*, *somatosensory cortex (parietal)*, *posterior temporal lobes*, *hippocampus*, and *rostral ACC*; dorsal anterior insula is coactivated with *dorsal ACC*, *dorsolateral prefrontal cortex (DLPFC)*, *dorsal striatum*, and *temporoparietal junction (TPJ)*; and ventral anterior insula is coactivated with *amygdala*, *ventral tegmental area (VTA)*, *superior temporal sulcus (STS)*, *temporal poles*, *posterolateral orbitofrontal cortex (pLOFC)*, *medial prefrontal cortex (MPFC)*, and *ventral striatum*. Posterior (and central) insula has been implicated in sensory, motor, interoceptive, and language behaviors (Chang et al., 2013; Kelly et al., 2012; Kurth et al., 2010). Dorsal anterior insula has been associated with goal-directed cognitive tasks, including speech and language, and memory (Chang et al., 2013; Kelly et al., 2012; Kurth et al., 2010). Finally, ventral anterior insula is implicated in social/emotional, autonomic, and chemosensory behaviors (Chang et al., 2013; Kelly et al., 2012; Kurth et al., 2010).

Discussion of every suggested role of the insula is beyond the scope of this chapter and textbook because the insula has been tied to nearly every human behavior as well as numerous disorders (Box 10.2). It has been proposed that because of the insula’s unique positioning at the junction of structures that mediate lower level and higher level functions, the insula performs an important integrative role, specifically regarding the salience of stimuli and events (Craig, 2009, 2010, 2011; Menon & Uddin, 2010; Seeley, et al., 2007). Craig (2009, 2010) has proposed that: (i) the feelings we experience (e.g., anger, trust, surprise, and joy) are a result of the neural encoding of “the unified representation of all salient conditions;” (ii) these feelings are updated continually, with each sampling of feelings at a point in time constituting a “global emotional moment;” (iii) these “global emotional moments” beget a sense of awareness, or sentience, which is used to evaluate and predict energy utilization; (iv) *all* feelings are correlated with anterior insula activation; and (v) therefore, the processing that takes place within the anterior insula is the foundation for sentience.

Relatedly, recent cortical network research has identified two prominent networks in brains during tasks and at rest—the central executive network (CEN) and the default mode network (DMN) (Greicius, Krasnow,

BOX 10.2

INSULAR FUNCTION

The insular cortex in humans is unique in that it includes allocortical, paralimbic, and isocortical sections. Because of its unique architecture and positioning within the central nervous system, and because of the numerous connections with limbic, paralimbic, and isocortical association cortices, it is no surprise that the insula has been credited with many and varied functions and disorders.

Visceral

- Sensory (esophageal/gastric/abdominal)
- Motor (cardiovascular function, respiration, vomiting)

Sensory

- Audition, vestibular sense
- Gustation, olfaction
- Somatosensation (tactile, pain, temperature, itch)

Motor

- Articulation (speech)
- Ocular movements
- Swallowing
- Voluntary respiratory control

Integration

- Awareness, bodily awareness, consciousness, emotion processing and recognition, interoception, mood, motivation
- Time awareness
- Music (listening, singing)

- Sensorimotor
- Self-recognition

Higher-Order/Complex/Cognitive

- Attention, decision-making, error awareness, working memory
- Speech and language

Disorders

- Addiction, craving
- Agnosia, neglect
- Alzheimer's disease, frontotemporal dementia, primary progressive aphasia
- Anxiety, depression
- AOS, speech fluency
- Dysphagia
- Eating disorders (anorexia nervosa, bulimia nervosa)
- Schizophrenia
- Seizures

Plasticity/Recovery

Ackermann and Riecker (2010), Augustine (1996), Bates et al. (2003), Couto et al. (2013), Craig (2009, 2010, 2011), Dronkers (1996), Garavan (2010), Ibanez, Gleichgerrcht, and Manes (2010), Kim, Ku, Lee, Lee, and Jung (2012), Klein, Ullsperger, and Danielmeier (2013), Kosillo and Smith (2010), Lee and Reeve (2013), Manoliu et al. (2013), Nagai, Kishi, and Kato (2007), Nieuwenhuys (2012), Palaniyappan and Liddle (2012), Rossi et al. (2013), Sliz and Hayley (2012).

Reiss, & Menon, 2003; Menon & Uddin, 2010). Consistently demonstrated is a pattern of increased CEN activation and decreased DMN activation at onset of tasks requiring cognitive effort, with decreased DMN activation correlated with "accurate behavioral performance" (Kelly et al., 2008; Menon & Uddin, 2010). Menon and Uddin (2010) have expanded this model by identifying with rs-fMRI research a salience network (SN) that includes as a key component the anterior insula, along with dorsal ACC, amygdala, VTA, and thalamus (Menon & Uddin, 2010; Seeley et al., 2007). The anterior insula seems to be crucial for integrating internal state with external state/stimuli, determining the salience of external state/stimuli, and communicating with higher-order structures

that are capable of initiating goal-directed behavior (Menon & Uddin, 2010). In other words, the anterior insula seems to be the structure that switches between CEN and DMN modes. This is supported by fine-grained analysis of the timing of network responses, which shows the anterior insular activation occurring before the increase in either CEN or DMN activation changes. Such a role is consistent with the structural and functional connections we have so far reviewed in this chapter. Further, the existence of the VENs in CEN, DMN, and SN structures would provide the necessary rapid signaling required for this crucial and time-sensitive network communication because VENs are thought to be specialized for quickly transmitting information over long distances (see Box 10.1).

10.6 ASSOCIATION WITH SPEECH–LANGUAGE BEHAVIOR

The insula has been associated with speech–language production since the beginning of the search for the “seat” of this complex behavior. One of the earliest appearances of the insula in association with (or actually in dissociation from) speech–language behavior was in Broca’s (1861) report of the famous case of Leborgne (“Tan-Tan,” Mr. Tan, Patient Tan). When describing changes over time, Broca divided the behavioral deficits into the first clinical period and the second clinical period. The first period involved more restricted deficits (i.e., speech production) and the second clinical period involved the appearance of additional motor and cognitive deficits. Broca hypothesized that the speech–language deficits demonstrated by Leborgne were attributed to damage (softening) of the left inferior frontal gyrus and that the additional deficits occurred only when the softening progressed to other structures (Broca, 1861; Kann, 1950).

Broca’s early descriptions of Leborgne’s speech referred to reduced “faculty to coordinate the movements which belong to the articulate language, or simpler, it is the faculty of articulate language” (Broca, 1861). This description is more consistent with our current understanding of apraxia of speech (AOS), a motor speech impairment, rather than aphasia (Berker, Berker, & Smith, 1986; Lazar & Mohr, 2011; Richardson, Fillmore, Rorden, Lapointe, & Fridriksson, 2012). Another patient of Broca’s, Lelong, demonstrated expressive deficits (could only utter five words, some mispronounced) and similar damage to the left inferior frontal lobe, but with sparing of the insula (Dronkers, Plaisant, Iba-Zizen, & Cabanis, 2007; Pearce, 2009). His early judgment was then that the insula was not necessarily a contributor to speech articulation.

Many and conflicting reports of insular involvement in speech–language disorders ensued. Jules Parrot (1863) reported a case in which the entire insular cortex and inferior frontal cortex of the *right* hemisphere were damaged but speech and cognition were preserved, lending support to language lateralization theories (Bateman, 1890; Klingbeil, 1939). M. Flaubert (1866) reported a case of extensive damage, including “flattening” of the insula in both hemispheres, with no observable motor or speech–language deficits (Bateman, 1890; Klingbeil, 1939), supporting the notion that the insula was not necessary for motor or speech–language functions. However, William Sanders (1866) and D.C. Finkelnburg (1870) theorized, based on separate case observations of insular lesions, that damage to the insula, rather than inferior frontal convolutions (i.e., Broca’s area), was responsible for

speech impairment or “palsy” (Bateman, 1890; Duffy & Liles, 1979; Elder, 1897; Klingbeil, 1939).

In the late 1860s to early 1900s, there was much discussion and debate regarding the relationship between insular damage and conduction aphasia, a type of fluent aphasia in which individuals produce output containing phonemic paraphasias, have little to no auditory comprehension deficits, and demonstrate marked difficulty with speech repetition (Goodglass, 1992). Theodor Meynert, Karl Wernicke, and Ludwig Lichtheim all separately hypothesized that damage to the insular region was related to conduction aphasia (Ackermann & Riecker, 2010; Goldstein, 1948; Henderson, 1992), with Lichtheim (1885) even proposing use of the term “insular aphasia” (Henderson, 1992). However, a close examination of their discourse reveals that they all eventually attributed conduction aphasia to damage to the white matter fibers coursing near or through the insula, particularly the arcuate fasciculus fibers that branch off and travel through the EC (Ackermann & Riecker, 2010; Goldstein, 1948; Henderson, 1992; Palumbo, Alexander, & Naeser, 1992). Between the early and late 1900s, the insula was consistently linked to reports of conduction aphasia, although damage was rarely restricted to the insula (but see Goldstein, 1948). Over time, discussions of conduction aphasia included less of an emphasis on the insula and more of an emphasis on the arcuate fasciculus, EC, inferior parietal lobule, Sylvian–parietal–temporal, and others (Damasio & Damasio, 1980; Geschwind, 1965; Goodglass, 1992; Hickok, 2009; Palumbo et al., 1992; Saur et al., 2008). Schuell et al. (1964) summarized this ever-evolving debate—“Speech functions have been ascribed to [the insula], although conclusive evidence for this is lacking” (p. 69).

Notions about the involvement of the insula in speech processing changed considerably with the publication of a seminal paper by Dronkers (1996). In this study involving stroke patients, a strong relationship was revealed between damage to the anterior portion of the left insula and AOS. Specifically, each of the 25 patients who presented with AOS also had damage to the anterior insula, whereas 19 patients who were not diagnosed with AOS had cortical damage that did not involve the same portion of the anterior insula. Thus, this study presented a strong dissociation between patients with or without AOS whose stroke either did or did not involve the left anterior insula, respectively. Based on these findings, Dronkers concluded that the left anterior insula, and not Broca’s area, was a crucial region for speech articulation, a claim that challenged the long-held view that speech articulation was associated with Broca’s area. Although this study was

particularly remarkable for its unexpected findings, it was also important in that it was one of the first to use a lesion overlay method to compare and contrast patients with different behavioral profiles. It is important to note, however, that several years before, Naeser et al. (1989) had utilized statistical methods to compare lesion locations among patients with different levels of speech fluency and found that damage to the subcallosal fasciculus (deep to Broca's area, with projections to cingulate gyrus, supplementary motor area, and striatum) and periventricular white matter (deep to sensorimotor cortical areas for mouth) was particularly detrimental to speech fluency in stroke patients with left hemisphere damage. Nevertheless, Dronkers' study probably had greater effects on the field based on its implications of the insula, instead of Broca's area, in speech articulation. Had Dronkers relied on the statistical methods outlined by Naeser and colleagues, it is unlikely that their conclusions would have changed based on the reported "double dissociation," where 25 out of 25 patients with AOS had insular damage and 19 out of 19 patients without AOS did not have insular damage.

In a follow-up study that included some of the same patients from the studies of Dronkers (1996), Baldo, Wilkins, Ogar, Willock, and Dronkers (2011) found that complex speech articulation (i.e., speech sound clusters, high articulatory travel, greater number of syllables) is particularly vulnerable in patients who have damage to a subregion of the anterior insula, the superior portion of the short posterior insular gyrus (superior sPIG), referred to as the superior precentral gyrus of the insula (SPGI). Similar to the study by Dronkers (1996), a clear association between Broca's area damage and speech articulation was absent. It is important to note that this study relied on relatively few patients ($N = 33$) and that their lesion overlay map yielded limited statistical power in regions outside the anterior insula. Therefore, it is perhaps not surprising that this study implicated the anterior insula because it had limited potential to highlight other regions that might potentially contribute to speech articulation. Because the insula receives its blood supply from the MCA, maximum lesion overlap in the anterior insula is fairly typical among lesion studies and, as a result, attributing specific behavioral processes to the insula should be performed with caution unless it can be demonstrated that ample statistical power is achieved in other cortical regions.

Although the studies by Dronkers (1996) and Baldo et al. (2011) provided concordant evidence regarding the role of the anterior insula, specifically the SPGI, in speech articulation, others have provided contradictory evidence. In a study that included 80 left MCA stroke patients (40 with insular damage, 40 without insular damage), Hillis et al. (2004) found limited involvement

of the anterior insula in AOS. In contrast, damage to Broca's area was found to be a far stronger predictor of AOS. The Hillis et al. study only included acute patients and damage to Broca's area, and the anterior insula was evaluated by raters who were blinded to clinical examination (i.e., the presence of AOS).

To provide a clearer picture of the role of the left insula in speech articulation, Richardson et al. (2012) attempted to replicate the seminal study by Dronkers (1996). Two notable improvements were included by Richardson et al. First, brain damage among the patients examined by Dronkers was determined based on MRI or CT scans. The spatial resolution of early CT scans was typically limited, making it difficult to ascertain lesion boundaries. Patients ($N = 50$) included in the Richardson et al. study all underwent high-resolution MRI scans collected using a 3T MRI scanner, making lesion detection relatively easier compared with lower resolution modalities. Second, Richardson et al. utilized voxel-wise lesion symptom mapping (VLSM; Bates et al., 2003), the current standard for determining lesion–behavior relationships and a method that was not available to Dronkers in the 1990s. VLSM relies on binary maps of cortical damage that typically is demarcated by a trained expert and compares patients' behavioral scores on voxel-by-voxel basis in standardized brain space. The lesion overlay comparisons among patients with and without AOS in the Richardson et al. study were relatively similar to Dronkers, with one major exception: patients with AOS had the greatest lesion overlap in the SPGI, whereas the greatest overlap in damage was found in the left middle temporal lobe among patients without AOS. (Also, unlike Dronkers' patients without AOS, several of the AOS-negative patients examined by Richardson et al. had cortical damage that involved the anterior insula, including the SPGI.) However, the VLSM analysis used by Richardson et al. yielded very different results compared with those of Dronkers. Instead of implicating the anterior insula, their findings showed a strong relationship between AOS and damage to the posterior portion of Broca's area, the *pars opercularis*, as well as areas of the left precentral gyrus. In addition to relating frank cortical damage to AOS, Richardson and colleagues examined cerebral perfusion in relation to AOS. Both structural damage and hypoperfusion in Broca's area were strongly associated with AOS, a finding that corroborates findings by Hillis et al. (2004) but strongly contradicts Dronkers and the later study by Baldo et al. (2011).

One final lesion study is of particular relevance to the role of the insula in speech production. A unique study by Graff-Radford et al. (2014) included patients who had pure AOS as a result of stroke. Although AOS is fairly common after left frontal stroke, the

majority of AOS patients also have aphasia, making pure AOS a very rare syndrome. Among seven patients, five of whom had pure AOS and two who had AOS plus only very minor language impairment, the greatest lesion overlap was found in the left premotor cortex with relative or complete sparing of the left insula. Although this lesion study included a small patient sample, its finding of nearly complete sparing of the insula among patients with pure AOS further suggests that the insula does not play a specific role in speech articulation.

So far, we have focused mostly on lesion studies that examined speech deficits in stroke patients. Hillis et al. (2004), Richardson et al. (2012), and Graff-Radford et al. (2014) provide strong evidence against a central role of the insula in speech production. Evidence from dementia patients tells a similar story. A recently identified syndrome, primary progressive apraxia of speech (PPAOS), is a form of dementia where the primary behavioral deterioration manifests in impaired speech articulation with relative sparing of language and other cognitive functions (Josephs et al., 2012). Although PPAOS is a very rare syndrome, a few studies have shown that the primary areas of deterioration include gray matter in the premotor and motor cortex with relative sparing of other regions such as the insula. Decreased metabolism is observed in the same cortical regions and in the underlying white matter areas. Along with the aforementioned stroke studies, evidence from dementia patients further suggests that the insula is probably not the cortical seat of speech articulation.

Whereas several lesion studies have yielded compelling evidence against the insula as playing an important role in speech, numerous functional imaging studies have revealed insula activation during speech processing (for a review, see Ackermann & Riecker, 2010). As is typical among functional studies, it is difficult to determine if insula activation is crucial for speech or if such activation represents other processes involved in task completion but not specific to speech. To address this issue, Fedorenko, Fillmore, Smith, and Fridriksson (in press) used fMRI to examine speech-related activity in the anterior insula, including the SPGI. This research differed from previous studies (where insula activation was typically revealed in a whole-brain group analysis) by functionally defining speech-related regions of interest (ROI) within the insula on a subject-by-subject basis and then comparing activation across different functional tasks. In addition to the insula, functional activation was also examined in the left inferior frontal gyrus (LIFG), an area commonly implicated in speech production. Twenty control participants completed several tasks during fMRI scanning: speech production (easy versus

difficult articulation), vowel production (/a/, /i/, /u/), breath patterns (e.g., breathe in slowly, breathe out fast), and nonspeech oral movements (e.g., move tongue to touch the upper and lower lips). In addition, all participants completed a visual–spatial working memory task to verify that functional activation reflected process-specific activation and not effort related to completing the tasks. The study revealed very limited activation in the SPGI or other areas of the insula during speech production, vowel production, breathing, or working memory tasks. As importantly, the SPGI and other insula regions did not respond preferentially to more difficult speech articulation. In contrast, the LIFG showed significant modulation during speech articulation and enhanced activation during the difficult (compared with easy) speech articulation condition. Although the LIFG was active during other tasks, it showed by far the greatest activation during speech articulation. Somewhat surprisingly, the SPGI seemed to be selectively recruited during the nonspeech oral movement task. Fedorenko and colleagues concluded that although the left SPGI or other subregions of the insula are somewhat engaged during speech tasks, it is probably not specific to speech articulation. Further study is needed to better understand insula involvement during oral movements that are not speech-specific.

It seems less likely that the insula is essential for speech articulation and more likely that the insula is important for other behaviors that accompany or facilitate speech articulation. For example, it could be that the insula is primarily involved in the social aspects of speech (or other communication modalities). Alternatively, the insula could be more involved in the emotional tone of speech production, which would require modulation of respiratory, phonatory, and articulatory systems to alter rhythm and prosody appropriately. Given the wealth of knowledge about insula involvement in interoception and salience networks, and given the connections discussed in this chapter (Catani et al., 2012), it seems most likely that the insula is involved in: (i) monitoring internal states (visceral and emotional, Catani et al., 2012) and perhaps articulatory and auditory states (Hickok & Poeppel, 2004; Tourville & Guenther, 2011); (ii) monitoring external state/stimuli; and (iii) communicating with other structures to assist with modulation of speech. Whatever the role in speech, language, or communication, the only thing that can be said with certainty is that there is much more to be learned about the role of the insula in human behavior, and that research in the area of communication, both typical and disordered, will continue to inform this knowledge base. As reviewed in this chapter, there are many qualities of the insula unique to humans, and it is an

exciting time to explore the potential relationships between this structure and behaviors, such as speech and language, that are also unique to humans.

11.1 INTRODUCTION

For many decades, the neural basis underlying cognitive functions was conceived in a localizationist and fixed framework. According to this view, the brain was thought to be organized in highly specialized critical zones (e.g., Broca’s and Wernicke’s areas) for which any injury induces severe and irrevocable functional impairment, and in “noneloquent” regions (that is, areas that are not generating neurological deficits when they are damaged). This dogma of a static functional organization of the brain had numerous implications for neuroscience, notably resulting in the elaboration of simplistic and rigid models of cognition. In this setting, the subcortical connectivity has received less attention, especially in humans. Although many studies on the structural anatomy of white matter pathways have been performed in monkeys because of the possibility of using anterograde and retrograde tracers (Schmahmann & Pandya, 1990), in the 20th century only a few works of anatomic dissection on cadavers were reported in humans (Déjerine, 1895; Klingler, 1935; Ludwig & Klingler, 1956).

Because of the development of connectomics (i.e., the map of neural connections), an alternative hodotopical account was proposed in which brain functions are subserved by the dynamic interactions of large-scale distributed and parallel subnetworks (Catani, 2007; de Benedictis & Duffau, 2011; Duffau, 2013). The recent development of diffusion tensor imaging (DTI), allowing a tractography of white matter tracts *in vivo*, provided new insights into the cerebral connectivity (Catani, Jones, & ffytche, 2005). However, it is noteworthy that every recent review article about DTI has noted its shortcomings and underlined the need for rigorous anatomical validation (Hubbard & Parker, 2009;

Jbabdi & Johansen-Berg, 2011; Le Bihan, Poupon, Amadon, & Lethimonnier, 2006). In this context, Klingler’s work has received renewed interest because it is applicable for correlating the DTI results to actual anatomic evidence provided by postmortem dissection of white matter bundles (Fernandez-Miranda et al., 2008, 2012). However, the classical fiber dissection methodology consists of extensive removal of surrounding brain tissue and hampers analysis of cortical terminations. Recently, a modification of Klingler’s technique was proposed in which removal of brain tissue was kept to a minimum to preserve the cortex and relationships within the brain until the end of the dissection (Martino et al., 2011). Using this cortex-sparing fiber dissection, the trajectory and the orientation of white matter tracts as well as their cortical terminations can now be identified reliably and reproducibly, including in humans (Martino et al., 2013; Sarubbo, De Benedictis, Maldonado, Basso, & Duffau, 2013). A validation of this new technique in a macaque would nonetheless be useful.

Beyond structural considerations, a better understanding of the functional role of subcortical pathways was made possible thanks to advances in intraoperative mapping achieved in patients who underwent awake surgery for brain lesions. Direct electrical stimulation (DES) of the brain offers a unique opportunity to investigate functional anatomy. It has become common clinical practice to awaken patients to assess the functional role of restricted cortical and subcortical regions, and to avoid neurological impairments. Patients perform cognitive tasks while DES temporarily inactivates discrete brain areas: if the patients produce wrong response, then the stimulated site is preserved. DES interacts locally with a small cortical or axonal site, but also nonlocally, as the focal perturbation disrupts the

whole (sub)network sustaining a given function. Therefore, DES induces a transient virtual lesion by inhibiting a subcircuit during a few seconds. By gathering all cortical and axonal sites where the same type of errors were observed when stimulated, one can build-up the subnetwork of the disrupted subfunction. DES identifies with a great accuracy (approximately 5 mm) and reproducibility, *in vivo* in humans, the structures—not only cortex but also white matter tracts—crucial for cognitive functions (Duffau, 2011). Combining transient disturbances elicited by DES with the anatomical data provided by preoperative and postoperative MRI enables performance of real-time anatomo-functional correlations both at cortical and subcortical levels, supporting a network organization of the brain and leading to the reappraisal of cognitive models—notably regarding language (Duffau, Moritz-Gasser, & Mandonnet, 2013).

Here, the goal is to review the recent literature on the structure and function of white matter pathways in humans. In addition, the limiting role of subcortical tracts in cerebral plasticity is discussed.

11.2 PROJECTION PATHWAYS

11.2.1 Motor Corticospinal Tract and Somatosensory Thalamocortical Pathways

Recent anatomical–functional studies have transformed our understanding of cerebral motor control away from a hierarchical structure and toward parallel and interconnected specialized circuits. First, anatomic dissection, DTI, and DES in humans have confirmed that the corticospinal tracts come from the primary motor cortex run with a somatotopical organization within the corona radiata (with, from lateral to medial, the pyramidal tracts of the face, upper limb, and lower limb) and then within the posterior limb of the internal capsule (with, from anterior to posterior, the pyramidal tracts of the face, upper limb, and lower limb) before reaching the brainstem and the spinal cord (Duffau, Capelle, Denvil, Sichez, et al., 2003; Maldonado, Mandonnet, & Duffau, 2012). Furthermore, the existence of an additional “modulatory motor network” was recently evidenced, eliciting movement arrest or acceleration when stimulated in awake patients, with no loss of consciousness. The subcortical stimulation sites were distributed veil-like, anterior to the primary motor fibers, suggesting descending pathways originating from premotor areas known for negative motor response characteristics. Further stimulation sites in the anterior arm of the internal capsule indicate a large-scale motor control circuit (Schucht, Moritz-Gasser, Herbet, Raabe, &

Duffau, 2012). More recently, the first evidence of bilateral negative motor responses elicited by unilateral subcortical DES has been reported. Such findings support the existence of a bilateral cortico-subcortical network connecting the premotor cortices, basal ganglia, and spinal cord involved in the control of bimanual coordination (Rech, Herbet, Moritz-Gasser, & Duffau, 2013).

Posterior thalamocortical somatosensory pathways and their somatotopy have also been investigated by anatomic studies and using DES, which generate dysesthesias or tingling in awake patients (Duffau, Capelle, Denvil, Sichez, et al., 2003). Of note, stimulation of the white matter under the retrocentral gyrus may also induce disturbances in movement control (Almairac, Herbet, Moritz-Gasser, & Duffau, 2014), possibly due to transient inhibition of U fibers within the rolandic region (Catani et al., 2012). Regarding a frontoparietal sensory-motor network connection through thalamic nuclei, few studies in nonhuman primates demonstrate connections between these two structures (Gharbawie, Stepniewska, Burish, & Kaas, 2010). Anatomical tracer studies have shown that the posterior parietal cortex receives input from motor nuclei in the thalamus and shares overlapping thalamocortical connections with the frontal cortex (Gharbawie et al., 2010). In human, on the basis of DES findings, a fronto-thalamo-parietal network cannot be excluded (Almairac et al., 2014; Schucht et al., 2012). Moreover, in patients who experienced interference with movement during subcortical DES, fibers that induced inhibition or acceleration were located immediately posterior to thalamocortical somatosensory pathways. Therefore, a thalamo-parietal connection distinct from somatosensory pathways remains a possibility (Almairac et al., 2014; Schucht et al., 2012).

11.2.2 Optic Radiations

The optic radiations arise from the lateral geniculate body in three bundles. The anterior bundle curves anterolaterally above the temporal horn (Meyer’s loop), usually reaching beyond the anterior limit of the temporal horn, and then loops backward along the inferolateral wall of the atrium. The middle bundle courses laterally around and turns posteriorly along the lateral wall of the atrium and the occipital horn. The posterior bundle courses directly backward, also along the lateral wall of the atrium and occipital horn.

Recently, visual pathways have also been mapped in awake patients. Interestingly, their stimulation generates a “shadow” (negative effect) or phosphenes (positive effect) in the contralateral visual field, possibly associated with metamorphopsia (i.e., visual

illusion) or visual hemianopia. In all cases, these various and complex phenomena lead to a transitory visual deficit in the contralateral hemifield (Gras-Combes, Moritz-Gasser, Herbet, & Duffau, 2012).

11.3 LONG-DISTANCE ASSOCIATION PATHWAYS

Since the seminal work by Underleider and Haxby (1994), the process of visual information has been divided in a dorsal stream dedicated to the analysis of the spatial position (“where”) and in a ventral stream specialized in object identification (“what”). By analogy, a dual-stream model for auditory language processing was suggested, with a dorsal stream involved in mapping sound to articulation and a ventral stream involved in mapping sound to meaning (Hickok & Poeppel, 2004). New insights into the connectivity subserving this model have recently been provided in humans (Dick, Bernal, & Tremblay, 2013).

11.3.1 The Dorsal Superior Longitudinal Fascicle/Arcuate Fascicle Complex

11.3.1.1 Anatomy

Recent fiber dissection and DTI tractography studies in humans have investigated the anatomical connectivity of the superior longitudinal fascicle (SLF)/arcuate fascicle (AF) complex (Catani et al., 2005; Martino et al., 2013). The different components of the perisylvian SLF were isolated and the fibers were followed until their cortical terminations. Three segments of the perisylvian SLF were identified: (i) anterior segment of the lateral SLF, connecting the supramarginal gyrus and superior temporal gyrus (in the region just posterior to the Heschl’s gyrus) with the ventral portion of the precentral gyrus (ventral premotor cortex); (ii) posterior segment of the lateral SLF, connecting the posterior portion of the middle temporal gyrus with the angular gyrus; and (iii) long segment of the AF, deeply located, stemming from the caudal part of the temporal lobe, mainly the inferior and middle temporal gyri, that arches around the insula and advances forward to end within the frontal lobe, essentially within the precentral gyrus and posterior portion of the inferior and middle frontal gyri. Based on these original results, and challenging the traditional view, it was suggested that the fibers from the posterior part of the superior temporal gyrus are part of the anterior portion of the perisylvian SLF and not of the AF (Martino et al., 2013).

11.3.1.2 Structural–Functional Correlations

In awake patients performing a picture-naming task, cortically, phonemic paraphasia can be elicited by DES of the inferior parietal lobule and inferior frontal gyrus in the dominant hemisphere (Maldonado, Moritz-Gasser, & Duffau, 2011). Axonally speaking, phonemic paraphasias were elicited when stimulating the AF (Duffau et al., 2002; Martino et al., 2013). Geschwind (1970) previously postulated that lesions of this tract would produce conduction aphasia, including phonemic paraphasia, and this supports the role of the subpart of the dorsal stream mediated by the AF in phonological processing. Interestingly, the posterior cortical origin of the AF within the posterior part of the inferior temporal gyrus corresponds to the visual object form area (Martino et al., 2013). This region represents a functional hub involved in semantic and phonological processing dedicated to visual material (Vigneau et al., 2006). Thus, phonological processing subserved by the AF is performed in parallel to the semantic processes implemented by the ventral route. In addition to this direct dorsal route, the indirect dorsal stream of the lateral SLF is implied in articulation and phonological working memory, as demonstrated by DES. Cortical areas eliciting articulatory disorders are located in the ventral premotor cortex, supramarginal gyrus, and posterior part of the superior temporal gyrus (Duffau, Capelle, Denvil, Gatignol, et al., 2003). Axonally, stimulation of the white matter under the frontoparietal operculum and supramarginal gyrus, laterally and ventrally to the AF, induces anarthria as well (van Geemen, Herbet, Moritz-Gasser, & Duffau, 2014). This bundle corresponds to part III of the SLF according to Makris et al. (2005). This lateral operculo-opercular component of the SLF constitutes the articulatory loop by connecting the supramarginal gyrus/posterior portion of the superior temporal gyrus (which receives feedback information from somatosensory and auditory areas) with the frontal operculum (which receives afferences bringing the phonological/phonetic information to be translated into articulatory motor programs and efferences toward the primary motor area) (Duffau, Capelle, Denvil, Gatignol, et al., 2003).

Using the same paradigm, DES also demonstrated that syntactic processing was subserved by delocalized cortical regions (left inferior frontal gyrus and posterior middle temporal gyrus) connected by a subpart of the left SLF. Interestingly, this subcircuit is interacting but independent of the subnetwork involved in naming, as demonstrated by a double dissociation between syntactic (especially grammatical gender) and naming processing during DES. These findings support a parallel rather than serial theory, calling into question the principle of “lemma” (Vidorreta, Garcia, Moritz-Gasser, & Duffau, 2011).

The left SLF seems also to underpin word repetition (Moritz-Gasser & Duffau, 2013).

In the same vein, DES showed that spatial cognition was subserved by several cortical areas, including the right supramarginal gyrus, connected together by a subpart of the SLF (Thiebaut de Schotten et al., 2005). In such a “connectionist” view of brain organization, interactions between different systems have also been described. DES evidenced the existence of an executive system (including prefrontal cortex, anterior cingulate, and caudate nucleus) involved in the cognitive control of a more dedicated subcircuit for language switching—itsself constituted by a wide cortico-subcortical network comprising postero-temporal areas, supramarginal and angular gyri, inferior frontal gyrus, and a subpart of the SLF (Moritz-Gasser & Duffau, 2009). In addition, it seems that the frontal aslant tract, which connects the presupplementary motor area and anterior cingulate with the inferior frontal gyrus (Catani et al., 2013; Thiebaut de Schotten, Dell’Acqua, Valabregue, & Catani, 2012; Vergani et al., 2014), might play a role in language control, especially with regard to planning of speech articulation (Kinoshita et al., 2014). In the same vein, a cortico-subcortical loop involving the deep gray nuclei, especially the caudate nucleus was also demonstrated as participating in the control of language (selection/inhibition) because DES of the head of the caudate nucleus in the left hemisphere generated perseverations with a high level of reliability (Gil Robles, Gatignol, Capelle, Mitchell, & Duffau, 2005). This cortico-striatal loop could be anatomically supported by the frontostriatal tract (Kinoshita et al., 2014).

11.3.2 The Ventral Stream

11.3.2.1 Anatomy

The ventral route connects the occipital and posterior temporal areas with the frontal lobe. This ventral stream is referred to by some authors as “extreme capsule fiber system” with reference to connectivity studies in the primate (Makris et al., 2009; Saur et al., 2008). It nonetheless seems more adapted to speak about fascicles rather than the “extreme capsule,” because the latter only considers a discrete anatomical structure and the former considers actual neural pathways with their cortical termination in a hodotopical view. If one takes account of the sole subcortical region without any considerations regarding the cortical epicenters connected by the white matter tracts, then it does not allow the understanding of the whole eloquent network.

Using both anatomic dissection and DTI, it has recently been demonstrated that the ventral stream is supported by direct and indirect pathways. The direct

pathway is represented by the inferior fronto-occipital fascicle (IFOF). This IFOF has never been described in animals, explaining the debate about its role (Schmahmann & Pandya, 2006). In humans, the IFOF is a ventral associative bundle that connects the occipital lobe, parietal lobe, and the postero-temporal cortex with the frontal lobe. Recent anatomic studies (Martino, Brogna, Gil Robles, Vergani, & Duffau, 2010) combined with DTI have investigated the main course of the IFOF (Sarubbo et al., 2013). From the posterior cortex, it runs within the sagittal stratum in the superior and lateral part of the atrium; it reaches the roof of the sphenoidal horn in the temporal lobe; it joins the ventral part of the external/extreme capsule and runs under the insula at the posterior two-thirds of the temporal stem; and then it joins the frontal lobe (Martino et al., 2010). Two layers of the IFOF have been described (Sarubbo et al., 2013). The superficial and dorsal layers connect the posterior portion of the superior and middle occipital gyri, the superior parietal lobule, and the posterior part of the superior temporal gyrus to the inferior frontal gyrus (pars triangularis and opercularis). The deep and ventral subcomponent connects the posterior portion of the inferior occipital gyrus, the posterior temporal-basal area including the Fusa (fusiform area at the occipito-temporal junction), and the posterior part of the middle temporal gyrus to the frontal lobe—orbitofrontal cortex, middle frontal gyrus, and dorsolateral prefrontal cortex.

In parallel, the ventral stream is subserved by an indirect pathway comprising the anterior part of the inferior longitudinal fascicle (ILF) (running below the IFOF) that links the posterior occipitotemporal region (Fusa) and the temporal pole (TP) and is then relayed by the uncinate fasciculus (UF) that connects the TP to the basifrontal areas by running within the anterior third of the temporal stem (in front of the IFOF) (Mandonnet, Nouet, Gatignol, Capelle, & Duffau, 2007). Of note, the posterior part of the ILF links the occipital lobe to the posterior occipitotemporal junction (visual object form area) (Mandonnet, Gatignol, & Duffau, 2009). This means that this indirect route connects the occipital/Fusa to the orbitofrontal cortex, which is partially overlapped with the IFOF. Finally, although previously observed in monkey, another pathway has recently been described in humans: the middle longitudinal fascicle (MdLF) (Makris et al., 2009). It connects the angular gyrus with the superior temporal gyrus up to the TP and courses under the superior temporal sulcus, lateral and superior to the IFOF (Maldonado et al., 2013; Menjot et al., 2013).

11.3.2.2 Structural–Functional Correlations

In the awake patient during picture naming, DES of the IFOF, at least in the left dominant hemisphere, elicited semantic paraphasias either associative

(e.g.,/key/ for /padlock/) or coordinate (e.g., /tiger/ for /lion/) in more than 85% of cases. It did not matter what portion of the IFOF was stimulated (parieto-occipital junction, temporal, subinsular, or frontal part) (Duffau et al., 2005). These language disorders were mainly generated by stimulating the superficial layer of the IFOF. Interestingly, semantic paraphasias were never observed during stimulation of the dorsal route (SLF) (Maldonado et al., 2011). Of note, IFOF stimulation may also generate verbal perseveration (Khan, Herbet, Moritz-Gasser, & Duffau, 2013).

DES of the IFOF also induced nonverbal comprehension disturbances in more than 90% of cases during nonverbal semantic association test (e.g., Pyramid and Palm Trees Test). The patients were no longer able to make a semantic choice during DES, with some of them still able to join a short verbal description of their feelings, like “I don’t know at all,” “what do I have to do?,” and “I don’t understand anything” (Moritz-Gasser, Herbet, & Duffau, 2013). These comprehension disorders were mainly generated by stimulating the deep layer of the IFOF and elicited a double dissociation: semantic paraphasia with normal nonverbal semantic choice during DES of superficial IFOF and *vice versa* during DES of deep IFOF. Thus, it was suggested that there exists a superficial component involved in verbal semantics and a deep component involved in amodal semantic processing.

These data are in agreement with the cortical terminations of the IFOF (prefrontal, temporal-basal, and parietal areas) that correspond with the cortical network involved in semantic control (Whitney, Kirk, O’Sullivan, Lambon-Ralph, & Jefferies, 2011). Consequently, an original anatomo-functional model of semantic processing has recently been proposed in which the crucial pathway is represented by the IFOF. In this model, visual information is processed at the level of the occipital and temporal-basal associative cortices, and auditory information is processed at the level of the temporal and parietal associative cortices. They are transmitted directly on an amodal shape to the prefrontal areas, which exert top-down control over this amodal information to achieve successful semantic processing in a given context. DES of this fascicle generates a disruption of these rapid direct connections. The transient semantic disorganization observed when stimulating the IFOF would therefore be caused by dis-synchronization within this large-scale network, simultaneously interrupting the bottom-up transmission and the top-down control mechanisms (Moritz-Gasser et al., 2013). Thus, IFOF might play a crucial role not only in verbal and nonverbal semantic processing but also in the awareness of amodal semantic knowledge, namely noetic consciousness. From a phylogenetic perspective, because recent studies in the

primate failed to identify this tract, one could suggest that the IFOF is the proper human fascicle. This multifunction fascicle allows humans to produce and understand language, to manipulate concepts, and to comprehend the world (i.e., metalinguistics, conceptualization, and awareness of knowledge), and it contributes to making the human what he/she is, with his/her infinite wealth of mind.

The functional role of the indirect ventral pathway is still debated. This indirect route connects areas involved in semantic processing such as Fusa and lateral frontal cortex (Vigneau et al., 2006). Moreover, the major cortical relay between the ILF and UF is the TP, which is a “hub” (i.e., a functional epicenter allowing a plurimodal integration of the multiple data coming from the unimodal systems [subserved by ILF, UF, and MdLF]), explaining its role in semantics and its implication in semantic dementia when (bilaterally) damaged (Holland & Lambon-Ralph, 2010). However, except for the posterior part of the ILF for which injury generates alexia (Chan-Seng, Moritz-Gasser, & Duffau, 2014; Mandonnet et al., 2009), the indirect pathway can be functionally compensated when (unilaterally) damaged. DES of both the anterior ILF and UF never elicited any naming or nonverbal semantic disorders (Duffau, Gatignol, Moritz-Gasser, & Mandonnet, 2009; Mandonnet et al., 2007). This was also confirmed by functional recovery after anterior temporal lobectomy in tumor and in epilepsy surgery (Duffau, Thiebaut de Schotten, & Mandonnet, 2008). Even if very mild and selective deficit may persist, as with proper name retrieval after resection of the UF (Papagno, Miracapillo, et al., 2011), this is a good illustration of the concept of “subcortical plasticity” in which a subnetwork (IFOF, direct pathway) is able to bypass another subnetwork (indirect pathway) and functionally compensate for it (Duffau, 2009). Similarly, DES of MdLF and resection of its anterior part failed to induce any functional disorders (De Witt Hamer, Moritz-Gasser, Gatignol, & Duffau, 2011), demonstrating that this fascicle converging to the TP can also be compensated.

11.4 IMPLICATION OF A HODOTOPICAL VIEW OF BRAIN ORGANIZATION IN HUMANS: RETHINKING THE CONNECTIVITY OF LANGUAGE AND ITS RELATIONSHIPS WITH COGNITION

These original data based on the better knowledge of functional neuroanatomy of the subcortical white matter pathway result in the elaboration of new models of cognition. For example, the connectivity underpinning picture naming based on multiple direct and indirect cortico-subcortical interacting subnetworks involved in

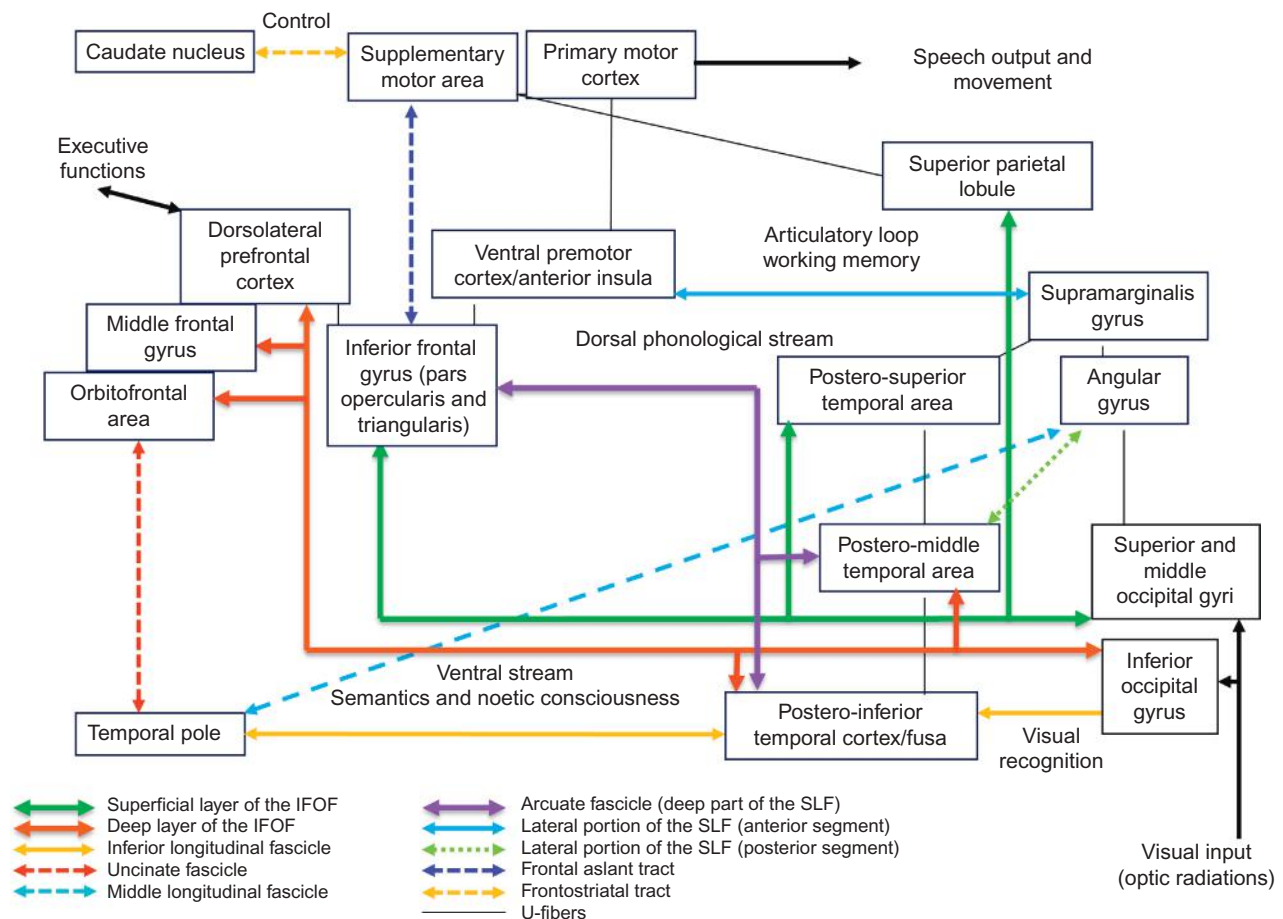

FIGURE 11.1 Proposal of a new model of connectivity underlying language processing and its relationships with executive functions (as judgment, decision-making, or problem-solving), with incorporation of anatomic subcortical constraints and elaborated on the basis of structural–functional correlations provided by dissection, DTI, and intraoperative DES. *Modified from Duffau et al. (2013) with permission from the publisher.*

semantic, phonological, and articulatory processes has recently been reevaluated. This model offers several advantages in comparison with previous ones: it explains double dissociations during axonal DES (e.g., semantic versus phonemic paraphasias); it takes into account the subcortical anatomic constraints; and it explains the possible recovery of aphasia after a lesion within the “classical” language areas (Figure 11.1).

Beyond language, by using subcortical DES and performing anatomic–functional correlations, it has recently been demonstrated that low-level and high-level mentalizing accuracy were correlated with the degree of (dis)connection in the AF and the cingulum, respectively (Herbet, Lafargue, Bonnetblanc, et al., 2014). These findings, which constitute the first experimental data on the structural connectivity of the mentalizing network, suggest the existence of a dual-stream hodotopical model and could lead to a better understanding of disorders that affect social cognition. Finally, intraoperative DES of the posterior cingulate connectivity may also elicit

transient behavioral unresponsiveness with loss of external connectedness, supporting the role of functional integrity of this subcortical network for maintaining consciousness of external environment (Herbet, Lafargue, de Champfleury, et al., 2014).

11.5 THE LIMITING ROLE OF AXONAL CONNECTIVITY IN BRAIN PLASTICITY

Although a huge plastic potential has been demonstrated in humans at the cortical level, subcortical plasticity is low, implying that axonal connectivity should be preserved to allow postlesional compensation (Papagno, Gallucci, et al., 2011). Lessons from stroke studies have taught us that damage of the white matter pathways generates a more severe neurological outcome than lesions of the cortex. Recently, we proposed the elaboration of a probabilistic postsurgical residue atlas computed using a series of patients who

underwent incomplete resection for a glioma on the basis of intraoperative DES (Ius, Angelini, de Schotten, Mandonnet, & Duffau, 2011). We gathered 58 postoperative MRI results of patients who underwent operation for WHO grade II glioma under direct electrical cortico-subcortical stimulation with a tumor resection performed according to functional boundaries. Postoperative images were registered on the Montreal Neurological Institute (MNI) template to construct an atlas of functional resectability for which each voxel represents the probability of observing residual nonresectable glioma, that is, noncompensable area (Ius et al., 2011). The anatomic-functional correlations obtained by combining the intrasurgical functional data with postoperative anatomical MRI findings provided new insights into the potentials and limitations of cerebral plasticity. This probabilistic atlas highlighted the crucial role of the axonal pathways in the reorganization of the brain after a lesion. It provided a general framework to establish anatomic-functional correlations by computing for each brain voxel its probability to be left—due to its functional role—on the postoperative MRI. Its overlap with the cortical MNI template and a DTI atlas offered a unique tool to analyze the potentialities and the limitations of interindividual variability and plasticity for cortical areas and axonal pathways. We observed low probability of residual tumors on the cortical surface, whereas most of the regions with high probability of residual tumor were located in the deep white matter. Thus, projection and association axonal pathways seem to play a critical role in the proper functioning of the brain. In other words, the functions subserved by long-range axonal pathways seem to be less subject to interindividual variability and reorganization than cortical sites (Duffau, 2009; Ius et al., 2011). The reproducibility of these results may suggest the existence of a “minimal common brain” necessary for the basic cognitive functions, even if likely insufficient for more complex functions such as multiprocessing.

11.6 CONCLUSION

Neuroscientists should improve their knowledge of white matter circuitry. Understanding axonal connectivity is crucial to optimize the models of neurocognition (movement, language, behavior, and even consciousness), which should integrate the anatomic constraint represented by the subcortical pathways. In addition, according to the principle of connectomics, cerebral plasticity seems to be possible only on the condition that the white matter fibers are preserved to allow spatial communication and temporal synchronization among large interconnected networks.

Phonology

William J. Idsardi^{1,2} and Philip J. Monahan^{3,4}

¹Department of Linguistics, University of Maryland, College Park, MD, USA; ²Neuroscience and Cognitive Science Program, University of Maryland, College Park, MD, USA; ³Centre for French and Linguistics, University of Toronto Scarborough, Toronto, ON, Canada; ⁴Department of Linguistics, University of Toronto, Toronto, ON, Canada

12.1 INTRODUCTION

Phonology is typically defined as “the study of speech sounds of a language or languages, and the laws governing them,”¹ particularly the laws governing the composition and combination of speech sounds in language. This definition reflects a segmental bias in the historical development of the field and we can offer a more general definition: the study of the knowledge and representations of the sound system of human languages. From a neurobiological or cognitive neuroscience perspective, one can consider phonology as the study of the mental model for human speech. In this brief review, we restrict ourselves to spoken language, although analogous concerns hold for signed language (Brentari, 2011). Moreover, we limit the discussion to what we consider the most important aspects of phonology. These include: (i) the mappings between three systems of representation: action, perception, and long-term memory; (ii) the fundamental components of speech sounds (i.e., distinctive features); (iii) the laws of combinations of speech sounds, both adjacent and long-distance; and (iv) the chunking of speech sounds into larger units, especially syllables.

To begin, consider the word-form “glark.” Given this string of letters, native speakers of English will have an idea of how to pronounce it and what it would sound like if another person said it. They would have little idea, if any, of what it means.² The meaning of a word is arbitrary given its form, and it could mean something else entirely. Consequently, we can

have very specific knowledge about a word’s *form* from a single presentation and can recognize and repeat such word-forms without much effort, all without knowing its meaning. Phonology studies the regularities of form (i.e., “rules without meaning”) (Staal, 1990) and the laws of combination for speech sounds and their sub-parts.

Any account needs to address the fact that speech is produced by one anatomical system (the mouth) and perceived with another (the auditory system). Our ability to repeat new word-forms, such as “glark,” is evidence that people effortlessly map between these two systems. Moreover, new word-forms can be stored in both short-term and long-term memory. As a result, phonology must confront the conversion of representations (i.e., data structures) between three broad neural systems: memory, action, and perception (the MAP loop; Poeppel & Idsardi, 2011). Each system has further sub-systems that we ignore here. The basic proposal is that this is done through the use of phonological primitives (features), which are temporally organized (chunked, grouped, coordinated) on at least two fundamental time scales: the feature or segment and the syllable (Poeppel, 2003).

12.2 SPEECH SOUNDS AND THE MAP LOOP

The alphabet is an incredible human invention, but its ubiquity overly influences our ideas regarding the

¹Longman Dictionary of Contemporary English.

²Urban Dictionary (<http://www.urbandictionary.com/>) states that it means “to slowly grasp the meaning of a word or concept, based on the situation in which it is used” (i.e., almost grokking a concept).

basic units of speech. This continues to this day and is evident in the influence of the International Phonetic Alphabet (IPA; <http://www.langsci.ucl.ac.uk/ipa/>) for transcribing speech. Not all writing systems are alphabetic, however. Some languages choose orthographic units larger than single sounds (moras, syllables) and a few, such as Bell's Visible Speech (Bell, 1867) and the Korean orthographic system Hangul (Kim-Renaud, 1997), decompose sounds into their component articulations, all of which constitute important, interconnected representations for speech.

12.2.1 Action or Articulation of Speech

The musculature of the mouth has historically been somewhat more accessible to investigation than audition or memory, and linguistic phonetics has often displayed a bias toward classifying speech sounds in terms of the actions needed to produce them (i.e., the articulation of the speech sounds by the mouth). For example, the standard IPA charts for consonants and vowels (Figure 12.1) are organized by how speech sounds are articulated. The columns in Figure 12.1A arrange consonants with respect to *where* they are articulated in the mouth (note: right to left corresponds to anterior to posterior position within the oral cavity), and the rows correspond to how they are articulated (i.e., their manner of articulation). The horizontal dimension in Figure 12.1B represents the relative frontness-backness of the tongue, and the vertical dimension represents the aperture of the mouth during production. These are the standard methods for organizing consonant and vowel inventories in languages.

Within the oral cavity, there are several controllable structures used to produce speech sounds. These include the larynx, the velum, the tongue (which is further divided into three relatively independently moveable sections: the tongue blade, the tongue dorsum, and the tongue root), and the lips (see Figure 12.2 reproduced from Bell, 1867; for more detail see Zemlin, 1998).

Each of these structures has some degrees of freedom of movement, which we describe in terms of their deflection from a neutral posture for speaking. The position for the mid-central vowel schwa, [ə], is considered to be the neutral posture of the speech articulators. In most structures, two opposite directions of movement are possible, yielding three stable regions of articulation, that is, the tongue dorsum can be put into a high, mid (neutral), or low position. In the neutral posture the velum is closed, but it can be opened to allow air to flow through the nose, and such speech sounds are classified as nasal (as in English "m" [m]). The lips can deflect from the neutral posture by being rounded (as in English "oo" [u]) or drawn back (as in English "ee" [i]). The tongue tip can be curled concavely or convexly either along its length (yielding retroflex and laminal sounds, respectively) or across its width (yielding grooved and lateral sounds, respectively). The tongue dorsum (as mentioned) can be moved vertically (high or low) and horizontally (front or back), and the tongue root can be moved horizontally (advanced or retracted).

The larynx (Figure 12.3) is particularly complex and can be moved along three different dimensions: modifying its vertical position (raised or lowered), modifying its tilt (rotated forward to slacken the vocal folds or rotated backwards to stiffen them), and changing the degree of separation of the vocal folds (adducted or abducted). Furthermore, the lips and the tongue blade and dorsum can close off the mouth to different degrees (termed the "manner" of production): completely closed (stops), nearly closed with turbulent airflow (fricatives), or substantially open (approximants). Taken together, these articulatory maneuvers describe how to make various speech sounds. For example, an English [s], as in "sea", is an abducted (voiceless, high glottal airflow) grooved fricative. Furthermore, as described in Section 12.3, the antagonistic relationships between articulator movements serve as the basis for the featural distinctions (whether

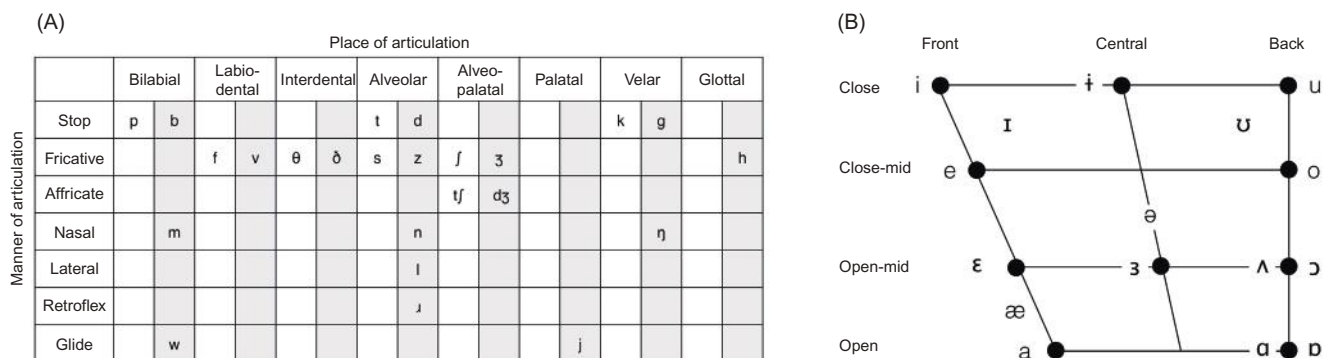

FIGURE 12.1 IPA charts for American English (A) consonants and (B) vowels.

monovalent, equipollent, or binary; see Fant, 1973; Trubetzkoy, 1969) that have proven so powerful in understanding not only the composition of speech sounds but also the phonology of human language.

| 4. The action of the soft palate in closing the nasal passage | 8. The lips |

FIGURE 12.2 Speech articulators. Note that terminology in 1–8 are all still in current usage (Zemlin, 1998:251) and that there are many synonymous terms in common use. In the current chapter, articulator 5 is known as the tongue dorsum, 6 is the tongue blade or corona, and 7 is the tongue tip or apex. From Bell (1867) with permission from the publishers.

12.2.2 Perception or Audition of Speech

A great deal of the literature regarding speech perception deals with how “special” speech is (Liberman, 1996) or is not. Often, this is cast as a debate between the motor theory of speech perception (Liberman & Mattingly, 1985) and speech as an area of expertise within general auditory perception (Carbognell & Lotto, 2014). The motor theory of speech perception posits speech-specific mechanisms that recover the intended articulatory gestures that produced the physical auditory stimulus. General auditory perception models, however, posit that the primary representational modality of speech perception is auditory and the mechanisms used during speech perception are the same as those responsible for nonspeech auditory perception. This dichotomy, in some ways, parallels debates about face perception (Rhodes, Calder, Johnson, & Haxby, 2011). Since the development of the sound spectrograph (Potter, Kopp, & Green, 1947) and the Haskins pattern playback machine (Cooper, Liberman, & Borst, 1951), it has been known that it is technologically feasible to analyze and accurately reproduce speech with time–frequency–amplitude analysis techniques, as in the spectrogram in Figure 12.4, where time is on the horizontal axis, frequency is on the vertical axis, and amplitude is illustrated in the relative darkness of the pixels.

FIGURE 12.3 The external view of the larynx. From Olek Remesz, http://commons.wikimedia.org/wiki/File:Larynx_external_en.svg, with permission from the publisher.

FIGURE 12.4 Sound spectrogram of a male voice saying “tata.”

Linking such technologies with neuroscience, [Aertsen and Johannesma \(1981\)](#) demonstrated that auditory neurons display particular spectro-temporal receptive fields (STRFs) to auditory stimuli, akin to a set of building blocks for spectrograms. So, this sets a strong goal for phonology: find lawful relationships between the available articulator movements and their acoustic/auditory consequences (as in [Stevens, 1998](#)), especially in terms of STRFs. We return to this question in the discussion of features. More recently, [Mesgarani, David, Fritz, and Shamma \(2014\)](#) have shown that STRFs derived from measuring responses in ferret primary auditory cortex can be used to “clean” speech in various kinds of noise, including reverberation, demonstrating that the auditory system enhances the neural representation of speech events against background noise.

12.2.3 Memory or the Long-Term Storage of Speech

It is a remarkable fact that humans can retain detailed knowledge about a great number of words, arbitrarily pairing forms with meanings across tens of thousands of cases. This, again, is reminiscent of our memory abilities for faces. More remarkably, the landscape of the form-meaning relation is not at all smooth, because small physical changes in form between two words (what linguists call “minimal pairs”) can have profound differences in meaning. If the form-meaning relation were smooth, then there would be many more pairs like “ram” and “lamb,” which differ only in their first sound and share a great deal in meaning (“a male sheep” and “a young sheep,” respectively, definitions from Merriam Webster’s Collegiate Dictionary 11th edition). Instead, most cases are like “ramp” and “lamp,” which differ in the same small sound attribute

(“r” versus “l”), but share nothing discernible in meaning (see [Hinton, Nichols, & Ohala, 1994](#) for cases of phonaesthesia).

The fundamental question of long-term memory representations in speech is one of abstraction: attending to and storing critical differences between forms while ignoring irrelevant differences. This is homomorphic to a fundamental problem in vision. A primary problem for visual object recognition is to account for “discrimination among diagnostic object features and generalization across nondiagnostic features” ([Hoffman & Logothetis, 2009](#)). The traditional linguistic solution to this problem has been to posit a single long-term memory representation (called the underlying representation [UR], notated with / /) and a set of transformations that yield the observed pronunciation variants (called surface representations [SRs], notated with []). Determining URs for word-forms and the nature of the transformations responsible for SRs (given a particular UR) has been the core goal of generative phonology for the past 50 years ([Chomsky & Halle, 1968](#)) and survives as the dominant question in modern generative models of phonology, such as Optimality Theory (OT), which posit ranked violable constraints instead of transformations ([Prince & Smolensky, 2004](#); see [Idsardi, 2006](#) for an argument that OT may not be computationally tractable). This is the analog of “view invariant” models of visual object recognition ([Booth & Rolls, 1998](#)). The relation between various URs and SRs can become quite complicated, but it boils down to two kinds of basic cases: derived homophones and derived differences.

Consider the two words “intense” and “intents,” which can both be pronounced so that their pronunciations end in [nts]. This is a case of derived homophones. [Yoo and Blankenship \(2003\)](#) show that in an experimental setting such pairs have substantially overlapping pronunciations, and also that a statistical analysis of a corpus shows that the [t] in “intense” is somewhat shorter on average. However, another related word-form, “intensive,” is much less likely to exhibit an intrusive [t], with the “ns” usually being pronounced [ns]. [Ohala \(1997\)](#) provides a compelling misproduction explanation for this effect due to the difficulty in precisely coordinating the closing of the velum during production in /ns/ with the simultaneous transition from a complete closure in [n] to a narrow incomplete closure in [s]. If these two changes are not completely synchronized, then for a short period there can be a complete closure in the mouth and a closed velum, resulting in the presence of an intrusive [t]. As [Ohala \(1997: 85\)](#) notes: “the emergent stop is purely epiphenomenal and, indeed, such brief unintended stops are often observed in spontaneous

speech.” Now the listener faces the following problem: is that [t] a critical aspect of the word-form or is it an irrelevant detail? Presumably relying on statistics and the pronunciations of related word-forms, such as “intensive” and “intent,” learners generally do arrive at different long-term memory representations, one with a /t/ (“intents”) and one without (“intense”), as the usual English spellings reflect. But, Ohala argues, the listener cannot always reliably reconstruct the speaker’s intent, and this is one cause of historical language change.

The other situation, that of derived differences, is already also illustrated by part of the previous example in that “intensive” is less likely to have an intrusive [t] in its pronunciation than “intense” is, so the pronunciations of the “intense” portion diverge. However, much more dramatic examples can be found in other English words. Consider the word “atom” in Standard American English, for instance. On its own, it can be pronounced as a homophone with “Adam” (the /t/ and /d/ both pronounced as a flap, notated as [ɾ]). When the suffix “-ic” is added to “atom” to create “atomic,” its pronunciation contains a portion homophonous with “Tom,” where the /t/ now has a pronunciation canonically associated with word-initial position, [t^h]. Adding “-ic” to “Adam,” however, gives “Adamic” with a portion pronounced as “damn.” So, ideally we would like to know how to recognize /t/ from the speech signal. That is, what invariant aspects are obtained across [ɾ] and [t^h] (and any other pronunciations of /t/)? Such speech sound sized memorized units are known as phonemes, or as archi-phonemes (Trubetzkoy, 1969) when their pronunciation ranges over an even wider variety of pronunciations, as in the final sound of the negative prefix “in-,” which is pronounced [ɪ] in “illegal,” [ɪ] in “irregular,” [m] in “impossible,” and [ŋ] in “incomplete.”

The goal, then, is to discover representations that abstract away from irrelevant changes in pronunciation but include diagnostic differences and differentiate between word-forms when they do have distinct pronunciations, such as “atomic” and “Adamic.” These two words differ in [t^h] and [d], motivating a /t/ versus /d/ difference in long-term memory. Note that they also differ in their middle vowels, /a/ versus /æ/, a difference also missing in the corresponding portion of “atom” and “Adam.”

Most importantly, memory serves as the mediating representation between audition and articulation (Gow, 2012). That is, the repetition of an auditorily presented word-form must be first mapped from a perceptual representation to a memory representation, and only then mapped to an articulatory representation. There is no short-cut directly from audition to articulation.

12.3 FEATURES OR THE INTERNAL COMPOSITION OF SOUNDS

Let us now return to the “glark” example, but this time consider its cursive written form in English, as in Figure 12.5.

The motions necessary to produce cursive “glark” can be accomplished with a finger (as in finger painting), a handheld stylus or pencil, a computer mouse (as was used to produce Figure 12.5), the tip of the nose, the elbow, or other body parts or instruments. This wide variety of available “articulators” to produce a cursive “glark” is a simple demonstration of the notion of motor equivalence (Wing, 2000). Motor equivalence is one kind of many-to-many mapping between causes and effects, and often is a symptom of an ill-posed inverse problem (of reasoning backward from effects to their causes). In contrast, speech exhibits only limited motor equivalence. It is not generally possible to substitute other coordinated sound-producing gestures (such as finger snapping) even when their acoustic effect might be appropriate (for example, as substitutes for the click sounds found in southern African languages, some of which are described as sounding like “sharply snapped fingers;” see http://en.wikipedia.org/wiki/Click_consonant). One stereotypical (and racist) example of a strong form of motor equivalence is the portrayal of Native American war chants with a “woo woo” sound produced by repetitively covering the mouth with a hand (and infants often explore such activities, e.g., <https://www.youtube.com/watch?v=tcWmMPNUVb4>). In this case, the acoustic effect of closing and opening an acoustic tube at one end can be accomplished either by closing and opening the lips or by placing and removing the palm of the hand from the lips; however, even though infants explore such gestures, no language uses the hand to make the bilabial approximant [w].

However, it is true that some conditions (ventriloquism, speaking with an object held by the teeth) show that some limited, approximate compensation is possible, but other simple “experiments” (such as the children’s taunt of saying “I was born on a pirate ship” while holding your tongue with your fingers) show that some speech features can really only be performed by a single articulator, and no adequate compensation is possible. Speakers robustly compensate during production when their vocal tract is obstructed (Guenther, 2006), and vowels exhibit more

FIGURE 12.5 The word “glark” as drawn with a mouse.

compensation possibilities than consonants generally (see Ladefoged & Maddieson, 1996: 300ff on tongue root position, for example), and English /r/ is notorious for its variety of articulations (Zhou, Espy-Wilson, Tiede, & Boyce, 2007). Although we have no solution to offer for the problem of /r/, we simply note that the range of different articulations for /r/ includes flaps, trills, and uvulars, which have a similarly wide range of acoustic manifestations, so this goes well beyond what is meant by motor equivalence (where there are multiple ways to achieve the same acoustic consequence). Whatever the reason for the extreme variability in /r/ realizations, it cannot be just motor equivalence.

Thus, given the limited amount of motor equivalence, we may have a reasonable inverse problem; therefore, we may also have the possibility of finding lawful relationships between articulatory actions and their acoustic/auditory consequences following the lead of Halle (1983), Jakobson, Fant, and Halle (1952), and especially Stevens (1998). The general neurobiological conceit here is that pre-existing auditory feature detectors for ecologically important events for mammals were paired with actions that the mouth could perform and thereby packaged as discrete units (features) for storage in long-term memory. Returning once again to the traditional articulatory descriptions of speech sounds, we describe them in terms of manner, place of articulation (POA), and laryngeal posture. Importantly, the cues for POA and laryngeal posture are dependent on the manner of articulation, so the cues for manner serve as “landmarks” for the analysis of the speech signal (Juneja & Espy-Wilson, 2008; Stevens, 2002) and constrain the subsequent search for POA and laryngeal attributes. We provide here only a very oversimplified catalog of these relationships.

One result that has persisted throughout theoretical innovation within phonology is the notion that speech sounds are composed of smaller units of representations (i.e., distinctive features; Jakobson et al., 1952). These features have traditionally been binary in nature (i.e., either a positive or negative value) and relate to a speech sound’s articulation. For example, a consonant is either produced with the lips (i.e., [+labial]) or not (i.e., [-labial]), or a vowel is either produced with an advanced tongue root (i.e., [+ATR]) or not (i.e., [-ATR]). These binary distinctions incorporate the apparent antagonistic relationship between articulator positions discussed in Section 12.2.1. The power of distinctive features in generative phonology has been their ability to explain why certain cross-linguistic phonological patterns are observed and why others are not. Consider the case of word-final consonant devoicing, which occurs in German and Dutch among other languages. When the sounds /b, d, v, z, g/ occur in

the final position of word, they are pronounced as their devoiced counterparts [p, t, f, s, k] (e.g., bewei[z]en “to prove” is produced as bewei[s] “proof”). The sounds that undergo this process form a natural class (i.e., voiced obstruents) that can be represented as [+voiced, +obstruent]. The expectation, then, is that all consonants that are [+voiced, +obstruent] that exist in German or Dutch are to participate in this process. Thus, a very straightforward transformation can be formulated to account for this process: /+voiced, +obstruent/ → [-voiced]/__ # (in word final position). What we do not observe in natural language is for phonological rules to target non-natural classes of sounds, such as /i, g, θ, j, a/. These sounds do not form a natural class and, consequently, are not predicted to undergo systematic alternations like what we observed in German word-final obstruent devoicing. Thus, the utility of distinctive features in explaining observed cross-linguistic phonological patterns is obvious. That the features themselves are cast in articulatory terms or binary in nature have been points of substantial debate. We would argue that neither is necessary to maintain their explanatory power. As a point of fact, distinctive features were initially described in auditory/acoustic terms (Jakobson et al., 1952; see Clements and Hume, 1995 for a discussion of different proposals for features valences).

There are four broad classes for manner of articulation: stops (plosives), fricatives, nasals, and approximants. Stops have a complete closure in the mouth and are characterized acoustically by a period of very low energy or silence often followed by a burst, similar to percussive environmental events with discontinuities such as twigs snapping or rocks colliding. Fricatives are made with a narrow channel causing turbulent airflow and are characterized acoustically by sustained aperiodic noise (which may be overlaid on a periodic signal) as with wind noise or rushing water. Nasals are made with a closed oral cavity and an open velum, and they are characterized acoustically by having a single, strong single frequency resonance, a hum such as some insects produce (but see Pruthi & Espy-Wilson 2004 for a comprehensive discussion of other important attributes for nasals). Finally, approximants are made with a relatively open vocal tract and are characterized by having a rich resonance structure of multiple formants; these sounds are characteristic of animal vocal tracts in particular and would have served as a useful kind of animal detector within the mammalian auditory system. Neurobiologically, this four-way division into “major class” features also seems to be well-reflected in a coherent cortical map. Mesgarani, Cheung, Johnson, and Chang (2014) measured the responses in implanted electrical cortical grids (ECOG) placed along the superior temporal

gyrus (STG) in presurgical epilepsy patients and found remarkable correlations between articulatory characteristics (consistent with phonological classes) and single electrode sites. In the supplemental materials for their article, we can see that electrode e1 responds to stops, e2 responds to fricatives, e5 responds to nasals, and e3 and e4 respond to approximants with dorsal and coronal POA, respectively.

POA is primarily characterized by the most active (most displaced) articulator, as described: the lips (labial), tongue blade (coronal), tongue body (dorsal), tongue root (pharyngeal), or the larynx alone (laryngeal). As already noted, the acoustic correlates of POA are heavily dependent on the manner of articulation. In the case of approximants, POA is signaled by the relative frequencies of the first three formants (Monahan & Idsardi, 2010), in fricatives by the dispersion and center of the friction noise (often termed center of gravity), and in stops and fricatives by the formant transitions with neighboring approximants. POA also appears to be topologically organized in cortex. ECOG recordings (Bouchard, Mesgarani, Johnson, & Chang, 2013) find a two-dimensional dorso-ventral by anterior–posterior POA map in STG, and cluster analysis of the electrode responses recapitulates the POA categories labial, coronal, and dorsal. Most importantly, the POA categories cut across the various manner classifications (stop, fricative, nasal, and approximant). Taking the ECOG findings together, this suggests a complex spatially entwined set of multidimensional maps for manner and POA, broadly consistent with other speech sound featural maps found using magnetoencephalography (Scharinger, Idsardi, & Poe, 2012).

Phonetic feature information is encoded in the brain in several different ways. Along with the recent cortical topographic findings, it is also known that the latency of the evoked magnetoencephalographic M100 response tracks vowel height (Roberts, Flagg, & Gage, 2004), manner of articulation of consonants (Gage, Poeppel, Roberts, & Hickok, 1998), and POA of consonants (Gage, Roberts, & Hickok, 2002), and that the electrophysiological mismatch negativity (MMN) response is sensitive to native language phonetic and phonological category representations (Kazanina, Phillips, & Idsardi, 2006; Näätänen et al., 1997; Sharma & Dorman, 2000). So, although maps are often a satisfying answer to the question of neural coding, the brain seems to be using all the methods at its disposal in coding speech.

Now that we have features at our disposal, we can redefine our intuitive notion of segments as “feature bundles” (Chomsky & Halle, 1968: 64), overlapping features that are phonologically coordinated during a period of time.

12.4 LOCAL SOUND COMBINATIONS AND CHUNKING

Speech sounds can be combined together, but not all combinations are possible. Given the set of sounds {a, g, k, l, r}, some combinations are possible English words (e.g., the now-familiar “glark” and others like “gralk”), but other combinations are not licit, “*rlgka.” One important constraint on sound sequences in word-forms is (approximately) that they must form a legal sequence of syllables in the language, and within syllables there are a limited set of pre-vowel and post-vowel consonant sequences. Moreover, these local sequence constraints often depend on the manner features of the segments. For example, a stop-approximant sequence is an acceptable pre-vowel sequence in English (as in “blue”), but approximant-stop is not (“*lbue”). Berent (2013) summarizes a number of investigations into this preference, which is exhibited even when listeners lack language experience to both kinds of consonant sequences (“bl” and “lb”). Building on this work, Berent et al. (2014) show modulation of the fMRI BOLD response across such contrasts, with anterior portions of BA 45 showing less activation to syllables beginning with “lb” and posterior portions showing more activation relative to that for “bl.” Additionally, listeners are sensitive to vowel–consonant sequence restrictions, exhibiting negative deflections in event-related potentials in response to illicit sequences (Steinberg, Truckenbrodt, & Jacobsen, 2011). In short, listeners are clearly sensitive to licit and illicit local sequences within syllables, and these can be detected with various different methods.

But what is the motivation for another layer of organization that groups segments together? Ghitza (2012) and Ghitza, Giraud, and Poeppel (2012) suggest that the dual time-scale organization is related to endogenous brain rhythms in the theta (syllable) and gamma (segment) bands. The idea here is that syllables can be identified from gross, easily tracked properties of the speech signal, namely its envelope. Once syllables have been chunked, the signal can be further analyzed to yield segment and feature information, guided by the syllable parsing. This proposal is similar to the landmarks proposal reviewed in that an initial *coarse* coding of the signal is performed and then elaborated into finer distinctions as necessary. Taken together, these proposals suggest another possible indexation method for the mental lexicon, similar to hash tables. If the signal is coarsely processed into manner classes (Plosive, Fricative, Nasal, Approximant) and syllable chunks are identified, then listeners can retrieve the lexical items matching that coarse form (e.g., both “nest” [nɛst] and “mashed” [mæʃt] would fall into the

<NAFP > group). We could then do further segment and feature discovery guided by the manner class, the syllabic position, local sequence constraints, and the pool of retrieved candidates, which would significantly be a reduction in the search space of a couple orders of magnitude compared with the entire lexicon.

So, then do we need segments at all, or could we do with just organizing features into syllables without segmental organization? This has been proposed at least for perception (Hickok, 2014). The strongest argument for segments comes from resyllabification effects. Russian provides a particularly clear example. Consider the name “Ivan.” Alone, this name is pronounced with two syllables, indicated with parentheses: [(i)(van)]. Russian nouns are inflected for case with suffixes, and so the form for “to Ivan” adds a prefix “k-” meaning “to,” and the appropriate case suffix “-u,” so that we have (abstractly) “k-Ivan-u.” But Russian strongly prefers that every consonant–vowel sequence be grouped together into a syllable and, consequently, the syllabification in the pronounced form is [(ki)(va)(nu)] (the vowel change from [i] to [i] is symptomatic of the resyllabification). Notice that now none of the original syllables survive into the derived form, but the segment sequence [. . .ivan. . .] does (with a slight vowel change). If we store forms as syllables and features without a segment level of representation, then we would have to build large tables of syllable correspondences such as (ki) ⇔ (i), (va) ⇔ (van) to recognize “Ivan” in “k-Ivan-u.” But such syllable correspondences are straightforwardly captured if segments are available to us. Moreover, the extent of resyllabification is usually limited to a single segment, so, for example, Russian [(gart)] “printer type metal nom. sg.” resyllabifies to [(gar)(ta)] in the plural, even though syllables can begin with /rt/, [(rtut’)] “mercury nom. sg.”. In languages with small syllable inventories and restricted syllable types (e.g., Hawaiian, Japanese), eschewing segmental representations might suffice; however, once we consider languages with complex syllable structures (e.g., Russian, Polish), frequent resyllabification (e.g., Korean), and complex morphology (e.g., Navajo), it becomes more difficult to maintain segment-less representations during perception. As such, resyllabification remains the greatest conceptual challenge to understanding the appropriate data structure for the organization of the mental lexicon.

12.5 NONLOCAL SOUND COMBINATIONS

The local sound sequence restrictions discussed are widely known and form the conceptual basis for n-gram models in natural language processing. Less

well-known are the nonlocal, action-at-a-distance phonological effects such as vowel and consonant harmony and disharmony. For example, in languages with vowel harmony, the set of vowels of the language are divided into two classes and an individual word-form will canonically draw all of its vowels from only one of the two sets. To illustrate vowel harmony, consider the following paradigm from Turkish (Clements & Sezer, 1982: 216) providing the nominative (nom) and genitive (gen) forms for the singular (sg) and plural (pl) versions of representative nouns.

	nom.sg	gen.sg	nom.pl	gen.pl
“rope”	ip	ip-in	ip-ler	ip-ler-in
“girl”	kiz	kiz-in	kiz-lar	kiz-lar-in
“face”	yüz	yüz-ün	yüz-ler	yüz-ler-in
“stamp”	pul	pul-un	pul-lar	pul-lar-in
“hand”	el	el-in	el-ler	el-ler-in
“stalk”	sap	sap-in	sap-lar	sap-lar-in
“village”	köy	köy-ün	köy-ler	köy-ler-in
“end”	son	son-un	son-lar	son-lar-in

The suffix in the genitive singular forms alternates between [in]/[in] and [ün]/[un]. The suffix is produced as [in]/[in] when the root vowel is [-round] (/i, i, e, a/) and [un]/[ün] when the root vowel is [+round] (/u, ü, o, ö/). Moreover, the suffix is produced with a front vowel [in]/[ün] when the root vowel is [-back] (/i, ü, e, ö/) and with a back vowel [in]/[un] when the root vowel is [+back] (/i, u, a, o/). In short, two dimensions of the Turkish vowel space (i.e., backness and roundedness) participate in the harmony process (and the suffixes then need only contain vowel height information, a classic case of archi-phonemes). Similar analyses account for the nominative plural and genitive plural paradigms. Vowel harmony illustrates “action-at-a-distance” because these patterns hold despite the presence of intervening consonants. That is, these are nonlocal phonological dependencies, unique from local assimilation patterns we find in many languages (in English, /a/ is pronounced as a nasalized /ã/ before nasal consonants, e.g., [bãn] “ban”). Consonant harmony is similar to vowel harmony, except that the harmony process is between consonants and not vowels. Disharmony refers to processes that cause two sounds (at a distance) to be less similar.

A remnant of a process of consonant disharmony in Latin survives statistically in English in the choice of the adjective forming suffixes “-al” and “-ar,” which tend to alternate with a preceding “l” or “r” in the

FIGURE 12.6 Google n-gram frequencies for “linear” (blue) and “lineal” (red).

word so that “circle” derives “circul-ar” but “flower” derives “flor-al,” and the higher frequency of “line-ar” as compared with “line-al” (see Figure 12.6), even though the “l” in “linear” is three syllables apart from the “r.”

Heinz and Idsardi (2011, 2013) argue that such effects cannot be reduced to iterated local effects of coarticulation across the intervening sounds and constitute a separate type of phonological generalization with distinct computational properties (perhaps also motivating larger grouping structures such as feet and phonological phrases that we are ignoring here). So far, there are few studies examining brain responses to vowel and consonant harmony (see Scharinger, Poe, and Idsardi, 2011 for a preliminary study of Turkish vowel harmony and see Monahan, 2013 for Basque sibilant harmony). Even though such action-at-a-distance effects may seem exotic, and even though the experimental materials are more difficult to construct (because they must eventually test the effects across various distances), it is important to examine the neuropsychological properties of these phonological laws to determine how they differ from the local sequence laws (for instance, whether the discontinuous sequence effects decrease with increasing distance).

12.6 SUMMARY

In this chapter, we have provided neurobiological motivations for what we feel are the core concepts of phonology: features, segments, syllables, abstraction, and laws of combination (both local and long-distance). Although we obviously do not yet understand how speech is mentally represented for action,

perception, and memory, we feel confident that features, segments, syllables, abstraction, and laws of form will be crucial in explicating the mental representations and computations used in listening and speaking. We have deliberately not attempted to provide a comprehensive review of the neuropsychological findings in speech relevant for phonology. For two reviews in that vein, see Idsardi and Poeppel (2012) and Monahan, Lau, and Idsardi (2013).

13.1 INTRODUCTION

Within linguistics, morphology is the subdiscipline devoted to the study of the distribution and form of “morphemes,” taken to be the minimal combinatorial unit languages use to build words and phrases. For example, it is a fact about English morphology that information about whether a sentence is in the past tense occurs at the end of verbs. This fact reduces to a generalization about the distribution of the tense morpheme in English, which is a fact about “morphotactics” (the distribution and ordering of morphemes) in morphology. It is also a fact about English morphology that the (“regular”) past-tense morpheme is pronounced /t/ after a class of voiceless consonants (*walked*, *tipped*, *kissed*) and /d/ after a class of voiced consonants and after vowels (*gagged*, *ribbed*, *fizzed*, *played*). This fact is a fact about “allomorphy” (alternations in the pronunciation of morphemes). Traditionally, then, morphology concerns itself with morphotactics and allomorphy.

Although the division or decomposition of words and phrases into smaller units seems relatively intuitive, linguistic morphologists have repeatedly questioned basic assumptions about morphemes. With one view, instead of dealing with the distribution and pronunciation of small pieces of language, morphology is about the form of words, where, for example, *kick*, *kicks*, *kicking*, and *kicked*, are all forms of the same verb *kick* (Matthews, 1965) but are not composed of a sequence of morphemes. With this view, languages are claimed to make a strict distinction between words and phrases, with only the latter having an internal structure of organized pieces. From this morphemeless perspective, *kicked* is a form of the stem *kick*, not the combination of *kick* + PAST TENSE, where PAST TENSE is realized as /t/. Other morphologists also endorse a

strict division between words and phrases but still analyze words as consisting of morphemes; with this view, the internal arrangement of morphemes within words falls under a different set of principles than the arrangement of words into sentences. However, in the morphological theory most closely associated with generative grammar in this century, distributed morphology, there is no strict word/phrase distinction (Matushansky & Marantz, 2013). The internal arrangement of morphemes both within words and within phrases and sentences is explained by a single *syntactic* theory, and morphology provides an account of the way in which these morphemes are realized phonologically (in sound), whether inside words or independently arranged in phrases.

This chapter explains aspects of the theory of morphology with a view of the way that morphology has been explored in neurolinguistics. An important conclusion of the chapter is that although the types of investigation of morphology currently found in neurolinguistics might seem to rely on motivated linguistic distinctions, such as that between derivational and inflectional morphology, linguistic theory itself does not support such distinctions in the manner required to motivate neurolinguistic experiments. Although research in the neurobiology of language does at least sometimes adopt the vocabulary of linguistic morphology in investigating the neural bases of morphology, the attention given to linguistic analysis is often superficial, with the consequence that experimental results are difficult to interpret with respect to central questions of language processing in the brain. There is hope that recent advances in psycholinguistics and in computational linguistics may help bridge the gap between linguistic theory and the theory of neurolinguistic processing, such that linguistics’ deep understanding of the

nature of language can inform neurolinguistics and, in turn, neurolinguistic findings can help shape linguistic theory.

Although some controversies within linguistics over the correct analysis of morphological phenomena are explained in this chapter, in general I adopt the assumptions and results of distributed morphology. As explained in Marantz (2013b), distributed morphology is relatively conservative from a historical perspective, preserving the insights of mainstream linguistics from the 20th century. In experimental work, one can attempt to explicitly test differing predictions made by competing representational theories of language, and so an experimentalist could choose to pit predictions of distributed morphology against available alternatives. However, experimental work related to morphology must make some theoretical commitments; it is not possible to be agnostic over issues such as whether words decompose into morphemes.

13.2 WHY MORPHOLOGY?

There seems to be an obvious need for a theory of syntax that would explain the constraints on how smaller linguistic units combine into and distribute across words and phrases, or for a theory of phonology that would explain the way that the pronunciation of units is conditioned by their environments in sentences, or for a theory of semantics that would explain the way that meanings of smaller units combine to form meanings of larger units. Syntax, phonology, and semantics together represent the essential structure of grammar: an engine of combination (syntax) and two interpretive “components” that translate the combinations into sound (phonology) and meaning (semantics). However, the role of morphology in language presents more of a puzzle. If we think of morphology as exemplified by the stuff we add to English words—things like the past-tense ending or a prefix like *re-* in *repaint*—the question arises: *why is there morphology* in addition to syntax, phonology, and semantics? For the investigation of the nature of language, we can ask why languages appear to add stuff to words and why that stuff takes the particular shapes we observe cross-linguistically. For linguistics, we can ask whether an account of this stuff requires a special (sub-)theory of “morphology” in addition to syntax, phonology, and semantics—a theory of an independent morphological component of grammar—or whether the theory of morphemes can be reduced to these other theories (with the properties of morphemes distributed across the syntactic, phonological, and semantic components, as in distributed morphology). This chapter explains why contemporary morphologists claim that morphology is not a special component of

grammar and that the interaction of syntax, phonology, and semantics produces the morphological phenomena we observe and allows for the variation in the expression of morphemes that is exhibited cross-linguistically.

The *why morphology?* question can be usefully divided into three issues. The first issue concerns the reason why certain information is sometimes indicated by attaching sounds to a word while the same information could be carried by an independent word. Why should the past tense in English be indicated by a suffix on *walk* in a statement, *He walked*, but by an auxiliary verb *did* in a yes/no question, *Did he walk?* Why should we say *repaint* when the two words *paint again* can be used with the same meaning? Why do languages ever use prefixes or suffixes, given that independent words can serve the same function? If every language chose independent words for these functions, there is a sense in which there would be no morphology.

A second, related question is why such diversity exists in the way that morphemes are realized across the world’s languages. Languages can signal information like past tense by copying part of a verb stem (reduplication), by tucking phonological material inside of a verb stem (infixing), and by other means, as well as by concatenating a stem and a tense prefix or suffix or by using a phonologically independent word. Do these different modes of signaling information correspond to deep grammatical differences between languages?

A third question involves particular types of morphemes such as agreement and case affixes. For a prefix like *re-*, it should be clear why English might want to use the morpheme for the expression of a meaning also expressible by the independent word *again* (*John repainted the house* = *John painted the house again*): the meaning contrast between *repaint* and *paint* hinges on the presence of the prefix on the first verb. However, the necessity of agreement morphology on verbs (*He runs every day*, *They run every day*) and case marking on nouns and pronouns (*He saw him*, where the subject is “nominative” and the object “accusative”) is less obvious, given that many languages lack such markings. Even in languages like English that show some limited agreement and case marking, any help that such morphology might provide in disambiguating word strings is minimal. For example, modal verbs like *may* in English show no agreement (*he may*, *they may*), whereas auxiliary verbs like *be* do (*he is*, *they are*), but the lack of agreement on *may* does not cause comprehension difficulties.

For each of these questions about the necessity of morphology for language, the answer that comes from the theory of morphology is this: do not be misled to generalize a language-particular choice along a spectrum of possibilities to a universal about the nature of

language. That is, from a general perspective of the structure of grammar, the variations in morphologies cross-linguistically can be seen as superficial variations on strong universal themes.

Taking “morpheme” to be defined as the smallest unit combined by the syntax of a language, morphology makes a strong distinction between the roots of the so-called lexical categories—nouns, verbs, and adjectives—and all other morphemes. This distinction between roots and other morphemes underlies an often cited but less technical distinction between content words and function words and morphemes. The root morphemes, like *cat*, describe properties of entities, states, and events. Their meanings are strongly connected to our a-linguistic cultural and conceptual knowledge, and the set of root morphemes varies considerably across languages and people. However, nonroot morphemes are sets of grammatical features that operate in a uniform way across languages and are central to the grammatical system. A past-tense morpheme would consist of features available to the grammar of every language and would likely be shared across speakers of the language. Root morphemes need to combine with the lexical category morphemes that create nouns, verbs, and adjectives to be used in phrases and sentences; each root morpheme + category-determining morpheme complex will, in general, anchor a phonological word, part of the “open class” vocabulary of a language (cases of compounding like *blackbird* and similar phenomena in other languages allow for multiple roots in a single phonological word). Nonroot morphemes, so-called functional morphemes that form the “closed class” of items in a language, find their phonological realization either by joining a root in a phonological word anchored by the root or by forming a phonological word of their own, perhaps with other functional morphemes. In general, then, the answer to the first question about the existence of morphology—why some languages express certain types of information piled up in a single word while other languages might express the same information on separate words—follows from the generalization that language makes a cut between root morphemes and functional morphemes. The general principles about the sound realization of root morphemes demand that they anchor independent phonological words cross-linguistically. The general principles about the sound realization of functional morphemes allow languages plenty of room for variation, giving the appearance that some languages have more morphology—more of the functional morphemes appear as affixes on root-based phonological words—whereas others have less—more of the functional morphemes appear as or as part of root-less phonological words (i.e., as function words). In addition, the phonological realization of a functional

morpheme is not forced by any general, universal principle; such morphemes often are silent. Thus, the inventory of phonologically realized morphemes also differs across languages, in addition to the differences in how pronounced morphemes are phonologically realized.

The distinction between root and functional morphemes and the distinction between morphemes as combinable constituents and the phonological (sound) forms of these morphemes also provide the answer to the second issue regarding the variety of alternatives cross-linguistically for the sound expression of various morphemes. The organization of morphemes within a word or phrase is determined by the syntax and can be displayed in a hierarchical tree structure. Linguists have developed a general account of the way that individual morphemes are realized that covers not only roots like *cat* that have the phonological form of a syllable but also suffixes like past tense /d/ that are a single consonant, and the roots of Semitic languages like Arabic, which might consist of just three consonants without vowels or syllable structure. The same generalized account that assigns each morpheme a bit of phonological substance can describe cases of reduplication, where the added phonological material is in a sense borrowed from the stem, and even truncation, where it looks like the addition of a morpheme results in a shortening of the stem. That is, the general picture has each morpheme determining a bit of phonological content (perhaps phonologically null), with the phonological forms of the morphemes combining according to the phonological principles of the language. The exoticness of infixing and reduplication—or the expression of a morpheme as a tone on the vowel of a stem or via gemination of a stem consonant—is relative to the phonological structure of English; from a cross-linguistic standpoint there is no reason to treat these morphemes’ expression as more unusual than affixation.

Finally, we may address the issue of why certain types of syntactically dependent morphology should exist, particularly agreement and case marking. The overt realization of agreement between subject and verb (or verb and object, etc.) and the overt realization of case marking on constituents of noun phrases (nouns, adjectives, determiners, numerals) are certainly not necessary for the processing of language; many languages do fine with minimal expression of such morphology. But the general characteristic of such morphology is the reflection of grammatical relations among constituents of a sentence that are present and necessary with or without the morphology. Subject–verb agreement, for example, reflects the computation of a relation between (features of) a subject and (a constituent of) a verb that underlies the grammatical analysis of a sentence. The general picture of the syntax of language, then, is one of the

recursive combination of morphemes into hierarchical constituent structures PLUS the computation of certain relations between morphemes—like the subject–verb (tense) relation—that are not completely reducible to constituency (like “sister” relations in a tree) or linear relations (like “next to”). Such grammatical relations (with traditional names like “subject” and “object”) involve the transfer or checking of features on functional morphemes. These features are phonologically realized as case and agreement morphology in some languages, but the syntactic operations and computations that underlie this morphology are present in every language.

13.3 WHAT MAKES MORPHOLOGY, MORPHOLOGY

In answering the question of why language includes morphology, we have sketched a picture of a structure of grammar that denies a distinction between the organization of morphemes within words and the organization of words within sentences; that is, the contemporary linguistic perspective on morphology makes no principled distinction between syntax and morphology. Nevertheless, the sound system of a language organizes the pronunciation of sentences into units of different sizes, with smaller units nested inside larger units, that is, “phonological words” combined into “phonological phrases” (Hall, 1999). These phonological units are the locus of certain phonological processes and generalizations. For example, in many European languages, including German and Russian, voiced consonants like /b/ or /d/ are pronounced voiceless—/p/, /t/—at the end of a phonological word. In English, some of the units we write as separate words do not contain enough phonological material to be pronounced as phonological words; for example, *the* and *a* pronounced as they usually are before a consonant-initial noun must be joined with the noun in a phonological word. In general, the phonological constraints on these phonological constituents require a certain mismatch between the syntactic structure and the phonological structure, as is well-known from such examples as *the queen of England’s hat*, which is pronounced with the possessive morpheme joined with *England*, although the hat belongs to the monarch rather than the country. The grammar of a language must describe how the syntactic arrangement of hierarchically organized morphemes is realized as the phonological organization of phonological words and phrases, and which morphemes will come together into single phonological words, as *’s* and *England* come together in our example. What we call the morphology of a language includes an account of how the grammar of the language packages some morphemes into

phonological words, and how these morphemes are pronounced.

Contemporary generative grammar, as described within the “Minimalist Program” associated with Noam Chomsky (Chomsky, 1995), describes the essence of linguistic structure as involving the recursive “merger” of morphemes. Two morphemes are merged into a constituent, which might undergo further merger with another morpheme or with some previously constructed complex of morphemes. Repeated operation of merger yields familiar hierarchical constituent structures. For morphemes interpreted as semantic functions or operators, the hierarchical structure determines their scope. For example, if morphemes interpreted as *make*, *want*, and *go* are merged into a structure like *[make[want[go]]]*, then the interpretation would involve causing the desire to leave, while a structure that swaps the structural positions of *want* and *make*—*[want[make[go]]]*—would involve the desire to cause leaving. If we imagine that these hierarchical structures built by repeated merge operations hold no implications for the linear order of the two constituents joined by each merge, the usual pronunciation of these syntactic structures must involve a decision, for each merger, regarding the order of each merged pair. Because the decision to order a complex constituent X before a complex constituent Y causes each subconstituent of X to be ordered before each subconstituent of Y, the linearization of a hierarchical syntactic structure will result in morpheme order reflecting the hierarchical structure. Within words, this correspondence between hierarchical structure and linear order of morphemes has come to be called the “Mirror Principle” (Baker, 1985), which is not really a “principle” but an observation about this correspondence.

The interface between the syntax of a language that determines the hierarchical structures of morphemes and the phonology of a language that determines the pronunciation of these structures must decide which morphemes to group together into phonological words and how to pronounce these morphemes. The environment in which a morpheme appears will determine how the morpheme is pronounced to a greater or lesser extent, depending on properties of the language and the particular morpheme itself. Several factors may condition the form of a morpheme. For example, as morphemes are linearized in the phonological interpretation of a hierarchical syntactic structure, a morpheme might show a different form (a different allomorph) depending on the phonological shape or the actual identity of a neighboring morpheme. The indefinite article *a/an* in English is pronounced *a* before a consonant-initial word and *an* before a vowel-initial word—allomorphy conditioned by the phonology of a neighboring morpheme. The plural suffix is pronounced *-en* after *ox* but as silence after *sheep*—allomorphy conditioned by the

identity of the morpheme to which it attaches, not its phonological shape. Similarly, an allomorph of a morpheme might be conditioned by general phonological properties of the language and of the morpheme, or the allomorph might be unconnected to phonological properties of the language. The pronunciation of the past-tense morpheme as /t/ after voiceless consonants in English but as /d/ after voiced consonants follows from general phonological facts about English. However, the choice of *an* before vowel-initial stems in the English indefinite article is not determined by general phonological properties of English; English does not generally insert an /n/ between vowels to avoid a hiatus.

From this short sketch, the reader can already project some of the investigations that occupy morphologists. For example, questions arise regarding whether there are constraints on how close two morphemes must be to influence each other's pronunciation, and whether closeness should be measured in terms of the hierarchical structure of morphemes or in terms of a linear string of their pronunciations. What kinds of information associated with morphemes could serve as triggers for particular phonological alternations on morphemes, and do the constraints on types of contextual information depend on the relative location of the morphemes within a hierarchical tree? Morphologists have discovered that these interactions between morphemes are very local and are very dependent on the hierarchical syntactic structures in which the morphemes appear (Embick, 2010). The locality of so-called contextual allomorphy (the pronunciation of a morpheme triggered by its linguistic context) seems convenient for language processing and would seem to constrain accounts of how language might be acquired.

13.4 TYPES OF MORPHEMES, TYPES OF MORPHOLOGIES, TYPES OF MORPHOLOGICAL THEORIES

Given this general picture of morphology as the exploration of principles governing the organization of morphemes into words and their pronunciation in context, we can turn to certain contrasts between sets of morphemes and between theories of morphemes that hold potential importance for the study of language in the brain. A commonly invoked division between morphemes divides the "inflectional" from the "derivational." On some definitions, inflectional morphology creates different forms of an individual word, while derivation creates new words from words. For example, English tense would be inflectional, because the past-tense form of a verb is arguably a form of the verb, rather than a word with its own distribution and meaning, whereas the suffix *-able* is derivational,

creating an adjective from an input verb, as in *knowable* from *know*. Although there is no doubt that tense morphemes and category-changing morphemes like *-able* differ in many ways, one must ask two general questions about the distinction.

First, does language make a binary distinction between two classes of morphemes such that it is coherent and important that we can identify a given morpheme as either inflectional or derivational, with certain characteristics deducible from the identification (e.g., whether it changes grammatical category or whether it may be realized as reduplication)? Second, given a division into inflection and derivation, do any linguistic generalizations or principles rely on the feature of being inflectional or derivational, or do properties that characterize one or the other class of morphemes follow from specific features of the morphemes themselves, not the inflection versus derivation label? That is, does the theory of linguistics call on the features "inflectional" and/or "derivational"? The emerging answer to both questions from contemporary morphology is "no."

Recall that the syntax of a language places various constraints and requirements on different sets of morphemes. For example, a main clause in English requires a tense morpheme, and a present-tense verb in English must agree with a third-person singular subject, usually with the *-s* suffix (*He walks*). However, a prefix like *re-* in English behaves like an optional modifier—like the independent word *again*. A suffix like *-able* parallels to some degree the adjective *able*: *This game is winnable* parallels *Someone is able to win this game*. The question arises whether morphemes split into large classes such that properties of morphemes follow from their membership in these classes. A recurrent proposal has been to divide morphemes into "inflection" versus "derivation," where inflection would include "grammatical" morphemes like tense and agreement that are relevant to the syntax, and derivational morphemes would include those that derive words of one category (noun, verb, adjective) from words of a different category. However, although linguists have discovered some features of morphemes that determine their behavior, no characterization of the inflection versus derivation split has proved relevant within morphological theory.

For example, within distributed morphology it has been observed that morphemes that attach directly to roots, such as the morphemes that create nouns, verbs, and adjectives from roots, share properties governing the conditioning of allomorphy on roots that are not shared by morphemes that attach to constituents that already contain these category-determining morphemes (Embick & Marantz, 2008; Marantz, 2013a). Subclasses of functional morphemes, then, share properties that a theory of morphology should explain.

However, there is no particular evidence that, for example, tense and number morphemes form a coherent class with case and agreement morphemes (the putative class of inflection) as opposed to category-changing morphemes (the putative class of derivation) that might motivate a broad distinction between inflection and derivation.

The search for contrastive properties for inflection versus derivation was motivated by the observation that some morphemes, such as tense, were required by a syntactic environment and selective regarding their host words (e.g., tense is required in main clauses in English and attaches to verbs), whereas other words, while perhaps selective regarding their hosts (*-able* attaches generally to verbs), were not required by the broader sentential context in any important sense (although one might construct a syntactic environment that requires an adjective, this environment would not require an adjective made with the *-able* suffix). Historically, linguists have explored two main hypotheses about properties that might follow from the inflection versus derivation distinction, characterized in this way by the morphemes' sensitivity to their syntactic environment. First, it has been claimed that inflection is paradigmatic while derivation is not. Second, and relatedly, it has been claimed that inflection and derivation involve different mechanisms for the phonological realization of the information carried by the morphemes.

The notion of a paradigm should be familiar for readers learning a classical language or a highly "inflected" language like Finnish or Russian. For verbs, the various combinations of tense, aspect, and mood features that modify verbs, along with the features of agreement (usually subject agreement) that can be signaled on the verb construct a multidimensional grid of feature values such that each cell of the grid is filled by a form of the verb whose paradigm is being displayed. In English, the paradigm for the present tense of the verb *to be* would have six cells, one for each of the combinations of person and number for the subject of the verb: (*I am*); (*you are*); (*he is*); (*we are*); (*you PLURAL are*); and (*they are*). Two important features of paradigms are that for each verb, noun, or adjective associated with an inflectional paradigm, there is expected to be a form for each cell in the paradigm (although one form may fill multiple cells, as *are* does for *to be* in English) and, in general, only a single form fills each cell. The latter property is behind the notion of "blocking": an irregular form that fills a cell specific to a particular stem or class of stems "blocks" the creation of a regular, predicted form for that stem to fill that paradigm cell. For example, the irregular *is* blocks the creation of regular *be* for the third-person singular cell of the paradigm for the verb *to be*.

Although the possible role of paradigms in a speaker's knowledge of language is still a somewhat controversial subject in linguistics (Bachrach & Nevins, 2008), properties of paradigms do not motivate a distinction between inflection and derivation, for two main reasons. First, to the extent that a derivational relation is made available by the general properties of language, derived forms can be displayed paradigmatically such that a form is predicted for each cell for each noun, verb, or adjective stem and such that there is a blocking relation between an irregular form (specific to a stem or set of stems) and a regular form. For example, the function served by the English *-er* suffix, attaching to verbs to create a noun referring to a person that habitually does what the verb describes, is generally available cross-linguistically, and every verb with the appropriate meaning is predicted to allow an *-er* formation. A definition of inflection that related to the formation of paradigms would include category-changing *-er* as inflection. Blocking effects in canonical category-changing derivational morphology are less easy to illustrate with simple English examples for the reasons described in Embick and Marantz (2008); however, such effects are definitely found. For example, the productive phonological realization of the morpheme creating nouns from adjectives with the meaning "the quality or property of being *adjective*" is the suffix *-ness*. The suffix *-ity* is a phonological realization of the same morpheme, but with a more restricted environment. In particular, when a stem ends in the affix *-able*, *-ity* is the preferred pronunciation, and *-ness* is "blocked": we get *transferable* and *transferability*, but not *transferableness*. The function of the morpheme *-ness/-ity*, then, creates a type of paradigm for adjectives, as well as a blocking relation between forms.

In addition to the fact that canonical derivational morphemes can be paradigmatic and exhibit blocking, a crucial fact that undermines any categorical distinction between inflection and derivation is that apparently inflected forms are often used in languages as category-changing derivation. In English, for example, the present participles of verbs, as *-ing* forms, are often used to create nouns, as in gerunds (*the running of the race*), and passive participles of verbs are often used to create adjectives (*the closed door*, *a typed note*).

In addition to the possible correlation between paradigms and inflectional morphology, linguists have explored the possibility that the phonological expression of morphemes differs fundamentally between derivation and inflection. For example, in Anderson's A-Morphous Morphology theory (Anderson, 1992), inflection involves phonological alterations to a stem, whereas derivation involves the concatenation of the stem with morphemes with independent phonological form (standard affixation, for example). However, a

major outcome of research in the 1970s and 1980s was the demonstration that derivation and inflection cannot be distinguished phonologically. Apparent “processes” altering the forms of stems such as reduplication and truncation are not limited to canonical inflection, and in general it is not possible to predict anything about the phonology of a morpheme based on the inflection versus derivation distinction.

This conclusion about phonological realization is more general: the organization of grammar computes the phonological realization of morphemes and combinations of morphemes without universal constraints based on their syntactic or semantic features. Individual languages may impose constraints on the phonological forms of classes of morphemes; for example, the roots of verbs in Arabic are sequences of two to four consonants, with further constraints observed regarding possible sequences of identical consonants. But the general principles of language do not impose such constraints on roots, nor do they restrict reduplication to any subset of functional morphemes. As already mentioned, these principles do impose locality constraints on what might serve as context for choice of phonological realizations, and other properties of syntactic structures may determine aspects of phonological realization due to the very architecture of the grammar. For example, if phonological realization is restricted to syntactic units of a particular size, as it is in theories in which linguistic computation is “cyclic,” then information carried by morphemes outside these cyclic realizational (“spell-out”) domains cannot influence the pronunciation of morphemes inside these domains. But grammatical principles governing the phonological realization of morphemes do not seem to refer directly to classes of morphemes.

The uniformity of phonological realization across types of morphemes extends to the distinction between morphemes like case and agreement that reflect grammatical relations between elements in a syntactic structure and all other morphemes. The principles of morphology that govern how root or functional morphemes are pronounced do not single out case and agreement morphemes, although features of such morphemes do require special mechanisms in the syntax above and beyond the merger of morphemes into hierarchical structure. The fact that case and agreement cannot be identified solely on the basis of their phonology holds crucial clues regarding the organization of grammar and the nature of language acquisition. Although syntactic structure feeds semantic and phonological interpretation, its operation is autonomous and opaque in the phonological forms that language learners encounter.

In addition to investigating the significance of certain pretheoretical distinctions between classes of

morphemes, like that between inflection and derivation, linguists have asked whether apparent typological differences between classes of languages, organized by their morphological systems, are theoretically meaningful. For example, languages are sometimes divided among the isolating and synthetic languages, with synthetic languages further divided into the fusional and the agglutinative. Isolating languages, to some degree, seem to lack morphology altogether. Within the morphological framework used in this chapter, these languages would be said to realize each root morpheme and each functional morpheme in an independent phonological word, with no affixation. Synthetic languages place multiple morphemes within a single phonological word, including multiple functional morphemes with a root. Latin is often cited as an example of a synthetic language, because, for example, a single verb might include information about tense (e.g., past), aspect (e.g., perfect), voice (e.g., active), person of the subject (e.g., first person), and number of the subject (e.g., plural): *portavimus* (“we carried (PERFECT)”). Among synthetic languages, fusional languages seem to use a single phonological piece, such as a single suffix, to express multiple grammatical features simultaneously (as English *-s* expresses both present-tense and third-person singular subject agreement), whereas agglutinative languages might string together long sequences of functional morphemes, each of which expresses an independent feature. This is exemplified in Turkish *çekoslovakyalılaştıramayacaklarımızdanmıydınız*, discussed in Lieber (2010) from Inkelas and Orgun (1998: 368):

1. çekoslovakya-	lı-	laş-	tır-	ama-		
Czechoslovakia-	from-	become-	CAUSE-	unable-		
yacak-	lar-	ımız-	dan-	mı-	ydı-	nız
FUT-	PL-	1PL-	ABL-	INTERR-	PAST-	2PL

“Were you one of those whom we are not going to be able to turn into Czechoslovakians?”

Even in describing these typological differences we have implied that languages do not fall into pure categories along the dimensions implied by their descriptions (English can illustrate isolation, fusion, and agglutination, for example). That is, languages are more or less isolating, and more or less fusional. Moreover, there do not appear to be any linguistic principles or generalizations that follow from the classification. That is, although being mostly isolating might be statistically correlated with other typological properties at a descriptive level of analysis, there is no direct relationship between the expression of functional morphemes as independent words and any syntactic or morphological properties of a language. The isolating/synthetic continuum, then, is descriptive rather than essential.

A final distinction between possible approaches to morphological theory will serve to illustrate another crucial property of the phonological realization of morphemes, that of the “default” realization. Traditional generative approaches to morphology have been “lexical” in the sense that they proposed that the “lexical” or storage form of morphemes included both the sets of features they displayed to the syntax and the phonological form they carried to the sound realization of sentences. In contrast, this chapter has been describing a “realizational” theory of morphology in which the syntax combines “formless” (phonology-free) morphemes and the phonological form is part of the phonological interpretation of a morpheme, constrained by the syntactic features the morpheme contains but separated from these features. For example, a past-tense morpheme would be identified as “past” and “tense” in the syntax, but its pronunciation would be determined after syntactic combination, during phonological interpretation.

A crucial difference between the lexical and realizational theories is their approach to “syncretism”: a situation in which a single phonological form is used across a variety of sets of features. For example, the form *walk* in English is syncretic as a present-tense verb, being identical across first-person and second-person subjects as well as third-person plural subjects, but contrasting with *walks* for third-person singular subjects. With a realizational approach, a present-tense morpheme is realized as *-s* when it carries third-person singular features but is realized as null elsewhere (as a default). For the null suffix to work as a default, the grammar must setup a competition between *-s* and null for the realization of a present-tense feature with subject agreement features that are already present in the structure being realized. The *-s* realization wins the competition if the agreement features are third-person singular; otherwise, the null realization is used. With a lexical approach, phonologically identified morphemes must carry syntactic features into the syntactic derivation. With this approach, defaults that clearly behave as “elsewhere” cases in opposition to more featurally specified morphemes cannot exist because the notion of “elsewhere” implies the pre-existence of a structure with syntactic features, yet on the lexical approach it is the morphemes themselves that provide the features for the syntax. Lexical approaches would postulate five homophonous *walks* for the various non-third-person singular sets of agreement features and attempt to provide other ways of explaining the apparent redundancy here.

The notion of default in phonological realization extends to “suppletion,” where the same set of features is realized by different phonological forms in different environments (a type of contextual allomorphy, as

described). For example, *-en* is the suppletive allomorph of the plural morpheme in English used in the environment of the stem *ox*; the default plural allomorph is *-s*. The *-en/-s* alternation is not an example of syncretism because the same feature—plural—is realized by both allomorphs. Such suppletion, however, is an example of the general asymmetry between a more specified phonological realization (*-en* for plural in the environment of *ox*) and a default realization (*-s* elsewhere) that covers syncretism in a realizational account. In general, the cross-linguistic properties of asymmetric syncretism (with less specific phonological realizations acting as defaults with respect to more specific realizations) and of (asymmetric) suppletion have supported realizational theories over lexical theories.

13.5 THE VIEW FROM ABOVE

This chapter describes a theory of grammar in which morphemes are the minimal units of syntactic combination. Within such a theory, morphemes are subject to a recursive merge operation that builds hierarchical structures of constituents. In addition, certain syntactic relations between constituents are computed, leading to the features that are realized as case and agreement morphology. Languages differ in their vocabularies of morphemes, particularly with respect to the root morphemes that anchor the major syntactic categories of nouns, verbs, and adjectives. Differences in the vocabularies of functional morphemes across languages directly influence typological differences in syntax, as described by syntacticians concerned with the “parameters” of variation between languages.

The linguistic subfield of morphology concerns itself with a number of topics surrounding morphemes and their realization. For example, what is the substantive inventory of functional morphemes from which individual languages must choose for their vocabularies? How do features of morphemes interact in the syntax, particularly with respect to the computation of case and agreement? The bulk of research specific to morphology concerns the phonological realization of morphemes, both the manner in which sets of morphemes get packaged into phonological words and the computation of allomorphy—the choice of phonological realizations for a morpheme and the ways in which phonological realization might be influenced by context and by competition among phonological forms (as for syncretism, suppletion, and blocking, described previously). The theory of morphology is therefore about the choice of functional morphemes, the way that language-specific choices in morphemes and features interact with the syntax, the syntactic principles

that distribute and constrain features like case and agreement on morphemes, the principles by which morphemes receive their phonological and semantic interpretation, and the way that the phonology of a language packages the phonological material of morphemes into words and phrases.

Morphology presents an account of a speaker's knowledge of language inconsistent with the idea that words could be studied in isolation from larger syntactic constituents. The word itself—to the extent that it corresponds to anything real in a person's grammar—is a phonological unit, not a unit of syntactic combination, and even as a phonological unit its properties are dependent on other phonological words within its phonological phrase. That is, linguistics provides no basis for the notion of a mental lexicon consisting only of stored words with gestalt properties as wholes. The recognition or production of a word—to the extent that the word is being recognized or produced as belonging to a speaker's language—necessarily involves a sequence of grammatical computations, including syntactic merger of morphemes and their phonological realization and packaging.

13.6 WORDS AND RULES: THE MODERN CONSENSUS ON DECOMPOSITION

Psycholinguistic and neurolinguistic work since the 1990s has taken as its starting point the perspective of Pinker's "words and rules" framework (Pinker, 1999). From the viewpoint of linguistics, Pinker's theory was based on a fundamental analytic mistake, because it postulated a grammatical difference between regular and irregular inflectional morphology. For Pinker, it was a syntactic fact that an irregular past-tense form like *taught* was a single computational unit, represented as a nonbranching tree structure, as compared with a regular form like *walked*, which would consist of a separate stem and past-tense morpheme in hierarchical syntactic structure. In fact, from any consideration of syntax and morphotactics, irregular and regular forms behave identically—the difference is entirely within the realm of the realization of morphemes phonologically (allomorphy). This linguistic error of the words and rules framework was paired with an interesting but empirically falsified separation between memory for morphemes and experience with "rules," such as the combination of morphemes. For the retrieval of morphemes, Pinker hypothesized frequency effects, but he proposed that no frequency

effects would be observed from the operation of (regular) rules.¹ Frequency modulates behavior across both retrieval of the memorized forms of morphemes and the composition of these forms. This observation does not undermine the essential distinction between the atoms of linguistic composition—the morphemes—and combinatory operations that produce and modify structures of morphemes, but it does put pressure on any distinction between words and phrases.

From the viewpoint of linguistic morphology, experiments using single word processing aimed at uncovering properties of a mental or neural lexicon are choosing a somewhat arbitrary unit for their stimuli. Phonological words (from open-class categories) consist at least of a root and a morpheme carrying syntactic category information, as well as the various functional morphemes from the root's syntactic environment that are required to join the root in the same word. A verb in English, for example, as a token of the language, would consist of at least three morphemes: the root, a morpheme that carries the syntactic category "verb," and a syntactically required tense morpheme. Single word experiments, then, might be seen as "small syntax" experiments; such experiments are not necessarily misguided, but they should not be presented as somehow in opposition to experiments using sequences of words. Even a simple experimental paradigm like confrontational picture naming requires the participants to produce minimal units of linguistic articulation; these would be phonological words, which are the output of a computation involving the syntactic combination of morphemes and the phonological interpretation of the resulting structure.

As explained in this chapter, morphology is not an independent "component" of grammar for linguistics, which recognizes a generative syntactic component and two "interfaces." One interface is concerned with the realization of syntactic structures in sound (or sign or orthography), and one is concerned with the semantic interpretation of those structures. Morphologists study particular aspects of the syntactic component and the interfaces that center on the minimal units of syntactic composition, but their special interests do not pick out a subsystem of grammar with linguistically significant autonomy. Therefore, neurobiological research aimed at denying the presence of "morphology" in the brain (Devlin, Jamison, Matthews, & Gonnerman, 2004) is not targeting the claim that morphology is neurologically isolatable—because the claim would be incoherent from a linguistic perspective—but rather the claim that the connection between sound

¹For some discussion of the behavioral evidence apparently supporting a binary distinction between irregular and regular inflection, from the point of view of morpheme-based linguistics, see Albright and Hayes (2003), Embick and Marantz (2005), Fruchter, Stockall, and Marantz (2013), and the references cited therein.

and meaning involves an autonomous computation of a syntactic structure.

Computational linguists that seriously consider both the linguistic and the experimental evidence also come to the conclusion that there is no principled distinction between the structure and realization of morphemes within (phonological) words and the structure and realization of combinations of words and phrases. However, such linguists may also deny the existence of morphemes, claiming that the appearance of structured units in the mapping between sound and meaning is an emergent property of systems learning such mappings, not an a priori feature of the learner's language acquisition system, as in Baayen, Milin, Đurđević, Hendrix, and Marelli (2011). That is, for a generative linguist, the language learner's task is to learn the grammar—the morphemes, constraints on their combination, rules for their phonological realization, and semantic interpretation—to account for observations about the correlation of sound and meaning. Regarding the opposing view of Baayen et al. (2011), learners would be acquiring unmediated sound/meaning correspondences, and morphemes would reflect general sound/meaning correspondences that converge, for example, on contiguous sequences of sounds.

There are linguists who might question the analysis of words as hierarchical organizations of morphemes. In this chapter, we have seen some reasons why the consensus within generative grammar strongly supports the decomposition of words into such syntactic structures. Despite these disagreements over morphological decomposition within words and the possibility of an a-morphous morphology, no productive research program in linguistics has pursued the idea that sentences are a-syntactic. All competing accounts of the well-formedness of sentences and the connections between sound and meaning at the sentential level assume a syntactic analysis that involves structures of morphemes—both the elements and the relations between the elements—that are relatively abstract with respect to their interpretations. For example, all major theories of syntax assume a set of syntactic categories—like noun, verb, and adjective—that although associated with distributional categories and connected to meanings can be reduced to neither. The absence of a motivated analytic dividing line between words and phrases pushes the linguists' conclusions into the interior of words: the connections between sound and meaning within and between words involve the computation of syntactic structures of morphemes.

Because the most striking claims of morphology involve the decomposition of words into syntactic structures of morphemes, much of the neurolinguistic research in the era of brain imaging and brain monitoring of

healthy intact human brains has, along with corresponding psycholinguistic work, centered on demonstrating that speakers decompose words into morphemes in visual and auditory word recognition (see Ettinger, Linzen, & Marantz, 2014; Fruchter et al., 2013; Lewis, Solomyak, & Marantz, 2011; Rastle, Davis, & New, 2004; Solomyak & Marantz, 2010; Zweig & Pylkkänen, 2009 and the references cited therein). These studies provide striking, although from a linguist's perspective inevitable, support for “full decomposition” models of recognition in which readers and listeners recognize morphologically complex forms via recognition and combination of their parts.

As Marcus Taft (2004) has pointed out, the apparent incompatibility of full decomposition models with the observation that the surface frequency of a complex word is the primary predictor of reaction time to the word in lexical decision experiments is tied to the unsupported claim that the frequency of regular computations and their results do not affect behavior. If the frequency of combination of a stem with a regular past-tense ending affected the speed with which this combination could be computed in the future, then surface frequency effects for regular past-tense forms could be attributed to the stage of processing in a full decomposition model in which the morphemes that result from decomposition of a word are recombined for evaluation as a whole. When brains are monitored with MEG, for example, early correlations of brain activity with properties of morphologically complex words show sensitivity to properties of the constituent morphemes and their relations to other morphemes, not to the surface frequency of the forms, although the latter correlates well with button-pressing in responses (Solomyak & Marantz, 2010). The late timing of surface frequency effects supports Taft's interpretation: that they reflect the frequency of the computation of combination of morphemes, not the frequency of the static whole forms themselves.

Once we understand the necessity of composing morphemes via a syntactic derivation to create words, experiments using words provide a testing ground for general theories of language processing. Neurolinguistic work of the next decades should uncover how the brain accesses representations of morphemes, combines these representations into hierarchical syntactic structures, and realizes these structures in form and meaning. Theories of morphology in linguistics make explicit the types of knowledge that must be manipulated in these computations, as well as specifics about the computations and their constraints and detailed phenomena that any account of language processing must explain. Linguistic morphology, then, should be a key element in the neurobiology of language enterprise.

Syntax and the Cognitive Neuroscience of Syntactic Structure Building

Jon Sprouse¹ and Norbert Hornstein²

¹Department of Linguistics, University of Connecticut, Storrs, CT, USA; ²Department of Linguistics, University of Maryland, College Park, MD, USA

14.1 INTRODUCTION

One goal of cognitive neuroscience, if not *the* goal of cognitive neuroscience, is to uncover how neural systems can give rise to the computations that underlie human cognition. Assuming, as most do, that the relevant biological description can be found at the level of neurons, then another way of stating this is that cognitive neuroscience is (at least) the search for the neuronal computations that underlie human cognition (Carandini, 2012; Carandini & Heeger, 2012). To the extent that this is an accurate formulation of the goal(s) of the field, any research program in cognitive neuroscience will have three components: (i) a cognitive theory that specifies the potential computations that underlie cognition; (ii) a neuroscientific theory that specifies how neurons (or populations of neurons) perform different types of computations; and (iii) a linking theory that maps between the cognitive theory and the neuroscientific theory (Marantz, 2005; Poeppel, 2012; Poeppel & Embick, 2005). We take all of this to be relatively uncontroversial; however, we mention it explicitly because we believe that modern syntactic theories, under a certain conception, are well-positioned to provide the first component (a theory of computations) for a cognitive neuroscientific theory of syntactic structure building. Our goal in this chapter is to make a case for this belief. We hope to demonstrate that the potential for a productive cross-fertilization exists between theoretical syntacticians and neuroscientists, and we suggest that developments in syntactic theory over the past two decades make this an optimal time to engage seriously in this collaboration.

For ease of exposition, we call our view that the theory of syntax can be, and should be, viewed as a theory of

syntactic structure-building computations *the computational view of syntax*. This view is simply that the syntactic operations that have been proposed in syntactic theory (e.g., merge in Minimalism, substitution in Tree-Adjoining Grammar [TAG]) are a plausible cognitive theory of the structure-building computations that neurons must perform to process language. Therefore, a plausible research program for cognitive neuroscience would be to search for a theory of: (i) how (populations of) neurons could perform these computations and (ii) which (populations of) neurons are performing these computations during any given language processing event. As syntacticians, this strikes us as the natural evolution of the goals of the cognitive revolution of the 1950s in general, and of the goals of generative linguistics in particular. However, we are also aware that this is not how many would describe current syntactic theory. Therefore, we attempt to make our case in a series of steps. In Section 14.2, we provide a brief history of the field of syntax. The goal of this section is to contextualize modern syntactic theories such that it becomes clear that modern theories are not simply lists of grammatical rules (although older theories were), but instead theories of cognitive computations. In Section 14.3, we present two concrete examples of potential structure-building computations (from two distinct contemporary syntactic theories) to illustrate the computational view of syntax. In Section 14.4, we lay out several of the properties of modern syntactic theories that we believe make them well-suited for the computational view of syntax. We believe that these properties will be easily recognizable to all cognitive neuroscientists as the properties of a theory of cognitive computations. In Section 14.5, we discuss the large-scale collaboration between syntacticians, psycholinguists, and neuroscientists that will be necessary to construct a cognitive

neuroscience of syntactic structure building. In Section 14.6, we discuss some of the challenges that this collaboration might face. Section 14.7 concludes.

Before making our case for the computational view of syntax, a small clarification about the scope of this chapter is in order. We have explicitly chosen to focus on the issue of *why* syntactic theories will be useful for a cognitive neuroscience of language, and not *how* syntactic theorizing is conducted today. In other words, this chapter is intended to lay out arguments in favor of a large-scale collaboration between syntacticians and neuroscientists and is not intended to be a review chapter on syntax. We assume that if our arguments are successful, then syntacticians within these collaborations can carry the burden of doing the syntax. That being said, for readers interested in reviews of topics in contemporary syntax, we can recommend the review chapters in the recently published *Cambridge Handbook of Generative Syntax* (den Dikken, 2013), which contains 26 excellent review chapters covering everything from the history and goals of syntactic theory, to overviews of several major contemporary theories, to reviews of specific phenomena in syntax.

14.2 A BRIEF HISTORY OF SYNTACTIC THEORY

Syntactic theory starts from two critical observations. The first is that there is no upper bound on the number of possible phrases/sentences within any given language (i.e., languages are, for all practical purposes, “infinite”). This implies that successful language learning is not only the memorization of a set of expressions (otherwise infinity would be impossible) but also the acquisition of a grammar, which is just a finite specification of a recursive set of combinatory rules. The second observation is that any child can acquire any language (e.g., a child born to US citizens living in Kenya will successfully learn Swahili if exposed to Swahili speakers during childhood). Given that the first observation suggests that languages should be viewed as grammars, the second observation translates as any child can acquire any grammar. These two observations lead to the two driving questions for the field of syntax:

1. What are the properties of the grammars of all of the world’s languages?
2. What are the mental mechanisms that allow humans to learn human languages?

The goal of Generative Syntax (GS) over the past 60 years has been to explore the properties of human grammars (question 1) in such a way to make it possible to explore the mental mechanisms that are required

for successful language acquisition (question 2). As with any specialized science, the pursuit of these dual driving questions has led to the development of specific research programs and technical terminology, both of which have at times been opaque to other cognitive scientists working outside of syntax. Our goal in this section is to provide a brief history of the way the field has pursued these driving questions (to contextualize the modern syntactic theories discussed in Section 2.2) and to clarify some of the major points of miscommunication that have historically arisen between syntacticians and other cognitive scientists.

GS began by describing specific rules found in particular languages (and so contained in the grammars of these languages). This is not surprising; if one is interested in the kinds of rules natural language grammars contain, then a good way to begin is by looking for particular examples of such rules. Thus, in the earliest period of GS, syntacticians built mini-grammars describing how various constructions in particular languages were built (e.g., relative clauses in Chamorro, questions in English, topic constructions in German, reflexivization in French, etc.) and how they interacted with one another to generate a reasonably robust “fragment” of the language.

With models of such grammars in hand, the next step was to factor out the common properties of these language particular grammars and organize them into rule types (e.g., movement rules, phrase structure rules, construal rules). This more abstract categorization allowed for the radical simplification of the language that particular rules investigated in the prior period, with constructions reducing to congeries of simpler operations (although analogies are dangerous, this seems similar to the way other sciences often discover that seemingly distinct phenomena are in fact related, such as the unification of planetary motion, projectile motion, and tidal motion as instances of gravitational attraction in physics). By the mid 1980s there were several reasonably well-articulated candidate theories of syntax (e.g., Government and Binding Theory, Lexical-Functional Grammar, Tree-Adjoining Grammar), each specifying various rule types and their properties and each illuminating commonalities across constructions and across languages.

The simplification of grammatical rule types also led to progress on the second driving question. By reducing syntactic theories to only a few rule types, syntacticians could reduce the number of learning mechanisms required to learn human grammars (here we use the term “learning mechanisms” as a cover term for all of the components of learning theories: biases to attend to certain input, specifications of hypothesis spaces, algorithms for searching hypothesis spaces, etc.). With fewer learning mechanisms in the theory, syntacticians

were able to investigate (and debate) the nature of the learning mechanisms themselves. Although there are a number of dimensions along which learning mechanisms might vary, syntactic theory has often focused on two in particular. The first is specificity: the learning mechanisms either can be domain-general, meaning that they are shared by several (or all) cognitive domains, or can be domain-specific, meaning that they are specific to language learning. The second dimension is nativity: the learning mechanisms either can be innate, meaning that they arise due to the genetic makeup of the organism, or can be derived, meaning that they are constructed from the combination of experience and other innate mechanisms. This leads to a 2×2 grid that can be used to classify any postulated learning mechanism (see also [Pearl & Sprouse, 2013](#)):

		Specificity	
		Domain-specific	Domain-general
Nativity	Innate	Universal Grammar	e.g., statistical learning
	Derived	e.g., learning to read	e.g., n-grams

What is particularly interesting about this grid is that it helps to clarify some of the miscommunications that have often arisen between syntacticians and other cognitive scientists surrounding terms like “innate,” “domain-specific,” and, worst of all, “Universal Grammar (UG).” This grid highlights the fact that the classification of any given learning mechanism is an empirical one. In other words, given a rule type X and a learning mechanism Y that could give rise to X , which cell does Y occupy in the grid? It may be the case that one or more of the cells are never used. Second, this grid highlights the fact that a complete specification of all of the rule types underlying human grammars and all of the learning mechanisms deployed to learn human grammars could involve any combination of the four types of learning mechanisms. As cognitive scientists, syntacticians are interested in all of the mechanisms underlying human syntax, not just the ones that get all of the attention in debates. Finally,

this grid clarifies exactly what syntacticians mean when they use the term “Universal Grammar.” Universal Grammar is just a special term for potential learning mechanisms that are simultaneously domain-specific and innate. Despite this rhetorical flourish, we hope it is clear that syntacticians view UG mechanisms (if they exist at all) as only a subset of the learning mechanisms that give rise to human language.¹

The progress made in the 1980s regarding simplifying the rule types in human grammars also laid the foundation for the current research program within modern GS: to distill the computational commonalities found among the various *kinds* of rules (i.e., the computational features common to movement rules, phrase building rules, and construal rules). Here, again, the dimension of domain-generality and domain-specificity plays a role in theoretical discussions, but this time at the level of cognitive computation rather than at the level of learning mechanisms. As syntacticians have made progress distilling the computational properties of grammatical rules, they have found that some of the suggested computations appear similar to computations in other domains of cognition (e.g., the binding, or concatenation, of two mental representations), whereas others still retain some amount of domain-specificity (see Section 14.3 for a concrete example). Current GS work is pursuing this program in full force: attempting to identify the basic computations and determine which are specific to the syntax and which are shared with other cognitive domains.

Note the odyssey described: the field of syntax moved from the study of very specific descriptions of particular rules in particular languages to very general descriptions of the properties of linguistic computations and their relationship, and finally to cognitive computation more generally. This shift in the “grain” of linguistic analysis (in the sense of [Poeppel & Embick, 2005](#)) has had two important effects. First, it has reduced the special “linguistic” character of syntactic computations, making them more similar to the cognitive computations we find in other domains. Second, it has encouraged investigation of

¹As a quick side note on Universal Grammar, the reason that UG receives so much attention, both within the syntax literature and across cognitive science, is that the other three types of learning mechanisms are generally uncontentious. For example, it is widely assumed that learning cannot occur in a blank slate (i.e., every learning system needs some built in biases if there is to be any generalization beyond the input); therefore, at least one learning mechanism must be innate. Nearly every postulated neural architecture (both symbolic and subsymbolic) assumes some form of statistical learning, which is presumably a learning mechanism (or set of mechanisms) that is domain-general and innate. The domain-general/derived cell is likely filled with the more complex statistical learning mechanisms required by different domains of cognition, such as the ability to track the probabilities of different sized sequences (n-grams). Similarly, the domain-specific/derived cell could potentially contain the learning mechanisms tailored to specific areas of higher-order cognition, such as reading (or maybe even language itself), but built from cognitive mechanisms available more broadly. It is the final cell, domain-specific/innate, that is the most contentious (and therefore, to some, the most interesting). In syntax, we call learning mechanisms that potentially fall into this cell Universal Grammar to highlight their significance. Currently, as we note here, a very hot area of syntactic investigation aims to reduce these domain-specific innate mechanisms to a minimum without losing explanations for the linguistic phenomena and generalizations that syntacticians have discovered over the past 60 years of syntactic research.

how syntactic computations might be used in real-time tasks such as parsing, production, and learning. Both these effects have had the consequence of bringing syntactic theory much closer to the empirical interests of others working in cognitive neuroscience.

Unfortunately, this shift in syntactic theory and its implications for cognitive neuroscience has not always been widely appreciated. Although the field of syntax was a central player in the cognitive revolution of the 1950s, in the intervening decades, syntax and the other domains of cognitive science have drifted apart. Some of this drift is the inevitable consequence of scientific specialization, and some of it reflects the internal logic of the different research programs (i.e., that the rule-based theories of the past were a necessary step in the evolution of syntactic theories). However, some of the drift reflects the view that syntactic theory has little to contribute to other domains of language research (including cognitive neuroscience). We worry that part of this problem may be that syntacticians have done a less-than-adequate job of conveying the general computational character of modern syntactic theories. In the absence of such discussions, it would not be surprising to learn that some cognitive neuroscientists still view syntax in terms of the phrase structure rules and transformations that typified syntactic theory in the 1950s and 1960s (and in varying forms up through the 1980s), rather than the more cognitively general computations common in current practice.² In the following sections, we provide two examples of how contemporary syntax might fruitfully make contact with cognitive neuroscience.

14.3 TWO CONCRETE EXAMPLES OF SYNTACTIC STRUCTURE-BUILDING COMPUTATIONS

Although early formulations of syntactic theories postulated complex rules that applied to entire constructions (often permuting, adding, or deleting

multiple words in different positions in the constructions), as noted in Section 2.1, there has been a steady evolution toward theories that postulate a small number of structure-building operations that can be applied mechanistically (or derivationally) to construct more elaborate syntactic structures in a piecemeal fashion. With very few exceptions, the primitives of contemporary syntactic theories are units and the computations that apply to those units. The following are two concrete examples³:

The syntactic theory known as *Minimalism* (or the Minimalist Program) postulates a single structure-building computation called *merge*, which takes two units and combines them to form a third. The units in Minimalism are lexical and sublexical items (something akin to the notion of word or morpheme, although the details can vary by analysis). *Merge* applies to these units directly, and also applies recursively to the output of previous instances of *merge*. In this way, *merge* can be used to iteratively construct complex syntactic structures from a basic inventory of lexical atoms. Of course, *merge* cannot freely concatenate any two units together. This means that restrictions on *merge* must be built into the lexical items themselves (only certain lexical items are compatible with each other), and in the case of merging units with the output of previous merges, this means that the outputs of *merge* must also contain restrictive properties. This is accomplished through a labeling computation, let us call it *label*, that applies a label to the output of *merge*, which can then be used to determine what that output can be merged with in the future.

The goal of syntactic theory is to capture the major properties of human syntactic structures with the proposed units and computations. For concreteness, we illustrate how *merge* and *label* succeed in capturing two such properties. The first is the distinction between local dependencies and nonlocal dependencies. A local dependency is simply the relationship between two adjacent items in a sentence. Local dependencies are

²The rule and transformation view of syntax has other problems as well. This conception of syntax is considered problematic for the computational view of syntax, because there are well-known empirical results from the 1950s and 1960s that appear to demonstrate that rule-based syntactic theories of that sort are poor models for real-time sentence processing (or, more specifically, poor predictors of complexity effects in language processing, as captured by the Derivational Theory of Complexity; for reviews see Fodor, Bever, & Garrett, 1974; but see Phillips, 1996 for a useful reevaluation of these claims). This problem is compounded by the fact that syntactic theories are at best only theories of syntactic structure building, with little to nothing to say about other components that are necessary for a complete theory of sentence processing, such as ambiguity resolution, memory/resource allocation, semantic structure building, and discourse structure building. Therefore, if one views syntactic theory as a rule-based theory, then it might appear to be a poor theory of only one small corner of language processing. Even as syntacticians, we understand why other cognitive scientists might find this version of syntactic theory difficult to engage with.

³There are, of course, a number of other syntactic theories that propose different types of computations (and different types of units). For example, Head-Driven Phrase Structure Grammar (HPSG) proposes a computation similar to *merge*, but without the possibility of internal merge (nonlocal dependencies involve a special slash unit instead). Construction grammar proposes a tree-unification computation similar to substitution in TAG, but operating over much larger units (entire constructions) and with the possibility of multiple unification points in a single construction. We assume that a full-fledged research program on the computational view of syntax would investigate all of these possible theories.

captured by `merge` by concatenating two distinct elements together. A nonlocal dependency is a relationship between two elements that are not adjacent in a sentence, such as the word *what* and *buy* in the question *What did John buy?* Nonlocal dependencies can be modeled by `merge` by concatenating a phrase with an element that is already properly contained within that phrase. Syntacticians call the former instantiation `external merge`, because the two elements are external to each other, and call the latter instantiation `internal merge`, because one element is properly contained within the other (Chomsky, 2004). The second property is the distinction between structures that contain verbs and their arguments (e.g., *eat bananas*) and structures that contain modifiers (e.g., *eat quickly*). The former, which we can call nonadjunction structures, are built from a combination of `merge` and `label`; the latter, which we can call adjunction structures, are built from `merge` alone (no `label`) (Hornstein, 2009). In this way, the two primitive computations `merge` and `label` can be used to construct syntactic structures capable of modeling the variety of structures one finds within natural language.

The syntactic theory known as *Tree-Adjoining Grammar* postulates two structure-building computations called `substitution` and `adjunction`. The units in TAG are small chunks of syntactic structure, or trees (hence the name of the theory). The `substitution` computation allows two elementary trees to be concatenated into locally dependent, nonadjunction structures. The `adjunction` computation, as the name

implies, allows two trees to be concatenated into locally dependent, adjunction structures. TAG captures nonlocal dependencies that are only a single clause in length with a single elementary tree (so, *What did John buy?* is a single tree without any application of `substitution` or `adjunction`). For dependencies that are more than one clause in length, the `adjunction` computation is applied to a special type of tree called an auxiliary tree to extend the dependency length. In this way, the two primitive computations `substitution` and `adjunction` can be used to construct syntactic structures from elementary and auxiliary trees, and they give rise to the important distinctions of human syntax (for accessible introductions to TAG, see Frank, 2002, 2013) (Box 14.1).

Although both theories capture the same set of phenomena in human syntax, and although both theories postulate structure-building computations, they do so using different computations, different units, and different combinations of computations for each phenomenon. For nonadjunction structures that involve only local dependencies, Minimalism uses `external merge` and `label`, whereas TAG uses `substitution` with two elementary trees. For adjunction structures, Minimalism uses `external merge` alone, whereas TAG uses `adjunction` with two elementary trees. For nonlocal dependencies, Minimalism uses `internal merge` and `label`, whereas TAG uses `adjunction` with one elementary tree and one auxiliary tree. The similarities between these two syntactic theories (i.e., both use two basic computations to capture a wide range of characteristics of human syntax) suggest that both are

BOX 14.1

STRUCTURE-BUILDING COMPUTATIONS IN MINIMALISM AND TAG

The structure-building computation in Minimalism is called `merge`. It takes two syntactic objects and concatenates them into a third object. When the two syntactic objects are distinct, it is called `external merge`. When one of the objects is contained within the other, it is called `internal merge`:

External merge: $[eat] + [bananas] = [[eat] [bananas]]$
 Internal merge: $[did\ John\ buy\ what] + [what] = [[what] [did\ John\ buy\ what]]$

The `label` computation determines the properties of the new syntactic object constructed by `merge` by applying a label based on the properties of one of the merged objects (the head). `label` is mandatory for the merge of argument relationships (e.g., verbs and their arguments),

but it appears to be optional for the merge of adjuncts (e.g., verbs and modifiers):

Merge with Label: $[_V\ eat] + [_{NP}\ bananas] = [_{VP}\ [_V\ eat] [_{NP}\ bananas]]$
 Merge without Label: $[[_{VP}\ [_V\ run]]] + [_{AdvP}\ quickly] = [[[_{VP}\ [_V\ run]]] [_{AdvP}\ quickly]]$

TAG proposes two structure-building operations. `Substitution` combines two elementary trees to form argument relationships, whereas `adjunction` combines elementary trees and adjunct trees to form adjunction structures:

Substitution: $[_{DP}\ John] + [_{TP}\ [_{DP}\] [_{VP}\ eats\ bananas]] = [_{TP}\ [_{DP}\ John] [_{VP}\ eats\ bananas]]$
 Adjunction: $[_{TP}\ [_{DP}\ John] [_{VP}\ [_V\ runs]]] + [_{VP}\ [_{VP}\]\ quickly] = [_{TP}\ [_{DP}\ John] [_{VP}\ [_{VP}\ [_V\ runs]]\ quickly]]$

tapping into deeper truths about human structure-building computations. However, the subtle differences in the character of the proposed computations suggest that one might be able to derive competing predictions from each theory about the presence or absence of computations in different constructions. This combination of abstract similarities and subtle differences strikes us as a potentially fruitful starting point for a search for neuronal structure-building computations.

14.4 ADDITIONAL PROPERTIES OF SYNTACTIC THEORIES THAT ONE WOULD EXPECT FROM A THEORY OF COGNITIVE COMPUTATIONS

In addition to focusing on structure-building computations, there are a number of additional properties of contemporary syntactic theories that make them ideal candidates for the computational view of syntax. Here, we review three.

First, contemporary syntactic theories attempt to minimize the number of computations while maximizing the number of phenomena captured by the theory. This is a general desideratum of scientific theories in general (it is sometimes called unification, or reductionism, or just Occam's razor), and syntax, as a science, has adopted it as well. In fact, the name Minimalism was chosen to reflect the fact that years of investigations using earlier theories had yielded enough information about the properties of language as a cognitive system that it was finally possible to fruitfully incorporate unification/reduction/Occam's razor as a core principle of the research program. Other syntactic theories have been less blunt about this in their naming conventions, but the principles are obvious in the shape of the theories. Commitment to Occam has led to syntactic theories based on simple computations with wide applicability across the thousands of syntactic constructions in human languages. One nice side benefit of the ratio of computations to constructions is that it may make the search for neurophysiological correlates of these computations more fruitful, especially given concerns about spurious correlations in high-dimensional neurophysiological data.

Second, syntactic theories attempt to minimize the number of domain-specific computations and maximize the number of domain-general computations (to the extent possible given the overall minimization of the number of computations). This is an important, and often overlooked, point within syntax. The *merge* computation in Minimalism and the *substitution* computation in TAG are both plausibly domain-general computations similar to the binding computations that occur in multiple cognitive domains (vision, hearing, etc.), albeit operating over language-specific representations. The formulation of these plausibly domain-general computations stems directly from the premium that syntactic theories now place on unification/reductionism. In contrast, the *label* computation and the *adjunction* computation are potentially domain-specific, because there are no obvious correlates in other cognitive domains, although that could just be a consequence of our current state of knowledge. The question of whether plausibly domain-specific computations like *label* and *adjunction* can be learned or must be innate is an open area of research in language acquisition.

Finally, syntactic theories have mapped a sizable portion of the potential hypothesis space of syntactic structure-building computations. As we have mentioned, with few exceptions, every contemporary syntactic theory has the potential to serve as a theory of cognitive structure-building computations. Although the sheer number of competing theories may seem daunting from outside of syntax, from inside of syntax we believe this is a necessary step in the research. We need to explore every possible combination of unit-size and computation type that captures the empirical facts of human languages (and to be clear, not every combination does) to provide neuroscientists with a list of possible cognitive computations. To be sure, there is more work to be done on this front. And it goes without saying that syntacticians actively debate the empirical coverage of the different theories, and also how well each theory can achieve empirical coverage without inelegant stipulations. But from the perspective of cognitive neuroscience, the value is in the hypothesis space—each theory represents a different hypothesis about the types of fundamental structure-building computations (and the distribution of those functions across different sentences in any given language).⁴

⁴Inside of the field of syntax there is a recurring debate about whether different syntactic theories (e.g., Minimalism and TAG) are in some sense notational variants of one another. There are various mathematical proofs demonstrating that many theories are identical in terms of weak generative capacity (i.e., the ability to create certain strings of symbols and not others; e.g., [Joshi, Vijay-Shanker & Weir 1991](#); [Michaelis, 1998](#); [Stabler, 1997](#)). However, it is an open question whether these theories are equivalent in other terms, such as strong generative capacity (the types of structures that they can generate) or empirical adequacy for human languages. It is interesting to note that inside of syntax this debate is often couched in terms of theoretical "elegance" (i.e., how elegantly one theory captures a specific phenomenon relative to another theory). However, the research program suggested here would make such debates purely empirical: the "correct" syntactic theory would be the one that specifies the correct distribution of syntactic computations (and therefore their neuronal instantiations) across all of the constructions of a given language.

14.5 THE COLLABORATION NECESSARY TO ENGAGE IN THIS PROGRAM

The research program that the computational view of syntax suggests will require close collaboration between different types of researchers. The first step is for syntacticians to identify the structure-building computations that are deployed at each point in constructions from human syntax. From these analyses, syntacticians could identify two types of interesting cases. The first interesting case would be constructions that predict the same type of structure-building computation at the same location in all theories (e.g., Minimalism predicts merge at the same location in the construction as TAG predicts substitution). These areas of convergence may be fruitful places to begin the search for neuronal computations. A second interesting case would be constructions that require diverging computations across theories (e.g., Minimalism predicts merge but TAG predicts adjunction). If these analyses could be identified across a large number of constructions, then it should be possible to construct a type of comparison/subtractive logic that could uncover neuronal correlates of these computations. It seems to us that phenomena that vary along the major dimensions of human syntax, such as nonadjunction versus adjunction structures, or local versus nonlocal dependencies, will be most likely to lead to these types of convergences and divergences. But over the long-term, every phenomenon of syntax should be investigated (to the extent possible given some of the challenges discussed in Section 14.4).

The second step is for syntacticians and theoretical neuroscientists to figure out how neurons deploy the structure-building computations that underlie the phenomenon in each theory. In practice, this step might require several substeps. For example, the typical form of syntactic theories is “bottom-up”: the most deeply embedded constituents are constructed first, followed by the next most deeply embedded, and so on. This is largely the reverse order from sentence comprehension and production. Given that the empirical studies required by later steps will be based on comprehension (and perhaps production), it may be necessary to convert the “bottom-up” computations of syntactic theories into the “left-to-right” or “top-down” computations of parsing theories. There exist several computational models for how to relate bottom-up grammars with left–right parsers. This step will most likely involve collaboration among mathematical linguists (to rigorously formalize the syntactic computations (Collins & Stabler, 2011; Stabler, 1997)), mathematical psycholinguists to convert those computations into parsing computations (e.g., Berwick & Weinberg, 1984; Marcus, 1980; Stabler, 2011, 2013; and for issues

beyond structure-building: Hale, 2003; Koebele, Gerth, & Hale, 2013), and neuroscientists to identify candidate neurocomputational systems. Although this sounds straightforward, it is likely that the space of possible computations will expand at each step, from syntactic computations to mathematically formalized computations, from formalized computations to parsing computations, and from parsing computations to neuronal computations. It is quite possible that this step will result in hypothesis spaces for the possible neuronal computations for each syntactic theory relevant to each phenomenon.

Once the structure-building computations have been translated into potential neuronal computations (or hypothesis spaces of potential neuronal computations), the final step is to look for evidence of those computations in neural systems. Again, although we state this as a single step in principle, we assume that it will be a multifaceted process in practice, drawing on neuroscientists of all types: electrophysiologists (EEG/MEG), neuroimagers (fMRI), and even neurosurgeons (ECOG). As syntacticians, this step is the furthest beyond our area of expertise, but we could imagine a process like the following. First, (extracranial) electrophysiological work (either EEG or MEG) could be used to identify the gross neuronal signatures in either the amplitude domain (ERP/ERF) or frequency domain (oscillations) that occur at the critical regions in the sentences of interest. Depending on the similarities and differences predicted by the different syntactic theories, and the different classes of neuronal populations that follow from the formalization of those theories in the previous step, the neuronal signatures (ERP/ERFs or oscillations) may be useful in eliminating competing computations from consideration. Recently, there have been exciting examples of work of this type in both syntax and semantics research. For example, Pylkkanen and colleagues have been searching for neurological correlates of fundamental semantic combinatory processes in the time–amplitude domain using MEG, with results pointing to increased activity in left anterior temporal lobe (LATL) and ventromedial prefrontal cortex (vmPFC) (e.g., Bemis & Pylkkänen, 2011; Brennan & Pylkkänen, 2008; and many others). As another example, Bastiaansen and colleagues have been searching for neurological correlates of both syntactic and semantic combinatory processes in the time–frequency domain using EEG, with results pointing to the gamma frequency band (>30 Hz) for semantic processes and the lower beta frequency band (13–18 Hz) for syntactic processes (e.g., Bastiaansen, Magyari, & Hagoort, 2010; Bastiaansen, Van Berkum, & Hagoort, 2002; for a review see Bastiaansen, Mazaheri, & Jensen, 2012).

Once electrophysiological correlates have been identified, localization studies, either with MEG (if the

orientation of the generators is appropriate) or concurrent EEG and fMRI, could be used to identify cortical areas associated with the neuronal activity of interest. There is a large and ever-growing literature on localization in language processing, and we are sure the other chapters in this volume provide more enlightening reviews of that literature. However, we would like to point to [Pallier, Devauchelle, and Dehaene \(2011\)](#) as an example of localization work that shares the same spirit as the program advocated here. Pallier et al. searched for brain areas that respond to the size of the syntactic constituent being processed (from 1 to 12 words), in essence using the number of syntactic computations deployed as a measure of complexity, and finding activity in a number of regions, including left inferior frontal gyrus (LIFG), left anterior superior temporal sulcus (LaPSTS), and left posterior superior temporal sulcus (LpSTS). Finally, when suitable location and electrophysiological hypotheses are established, intracranial recordings (ECoG) could be used to identify the single unit information necessary to begin to identify the specific neuronal computation and observe its implementation.

We admit that the brief sketch of the collaboration suggested by the computational view is based on our incomplete understanding of the various fields that would be part of the collaboration. We also admit that the space of possible neuronal computations is likely much larger than the space of extant structure-building operations, making the search for the actual neuronal computations that much more difficult. But it seems to us that the size of the hypothesis space is irrelevant to the question of how to move the fields of syntax and neuroscience forward (and together). This is either the right hypothesis space to be searching or it is not. It seems to us that multiple domains of cognition are converging on both the need for identifying neuronal computations and the plausibility of conducting such a search in the 21st century ([Carandini, 2012](#); [Poeppel, Emmorey, Hickok, & Pylkkänen, 2012](#)). We believe that the wider field of syntax is ready to join the search that researchers such as Bastiaansen, Dehaene, Pallier, Pylkkänen, and colleagues have begun.

14.6 CHALLENGES TO THIS RESEARCH PROGRAM

Beyond the obvious challenge of engaging in the interdisciplinary work presented in Section 14.5, there are numerous smaller challenges that need to be addressed for the collaboration to be successful. In this section we discuss five, in some cases in an attempt to

dispel the challenge and in others simply to raise the issue for future work.

One obvious challenge is the concern from some cognitive scientists that syntactic theories are not built on solid empirical foundations. This concern has been expressed since the earliest days of syntactic theorizing ([Hill, 1961](#)), and recently with several high-profile publications ([Gibson & Fedorenko, 2010, 2013](#)). This concern is driven by the idea that the typical data collection methods are too informal to provide reliable data; therefore, the theories built on that data are themselves unreliable. The persistence of this concern speaks to a fundamental failure on the part of syntacticians to make the argument either that the data type that they are collecting (acceptability judgments) are robust enough that the informality of the collection methods have no impact or that there are unreported safeguards in the informal methods to prevent the kind of unreliability that they are concerned about (see [Marantz, 2005](#); [Phillips, 2009](#) for discussions of these issues). [Sprouse and Almeida \(2012\)](#) and [Sprouse, Schütze, and Almeida \(2013\)](#) have begun to address this concern directly by exhaustively retesting all of the phenomena in a popular Minimalist textbook using formal methods, and by retesting a large random sample of phenomena from a popular syntax journal using formal methods. These retests have replicated 98% and 95% of the phenomena, respectively, suggesting that the informal methods used in syntax have the reliability that syntacticians claim. Given recent concerns about replicability inside of some areas of psychology, it is heartening to see that large-scale replications inside of syntax yield potential error rates at or below the conventional type I error rate of 5%.

Despite the substantial evidence that the acceptability judgments that form the basis of syntactic theory are reliable, one could imagine potential collaborators being concerned that a theory built on offline data (like acceptability judgments) would be irrelevant for a theory built on real-time language processing data (like the electrophysiological data required by the research program proposed here). We agree that this could be a reasonable concern *a priori*. However, there is also a growing body of research in the sentence processing literature demonstrating that real-time sentence processing behavior respects grammatical conditions on well-formedness. For example, several studies have shown that complex constraints on the formation of nonlocal dependencies (called island constraints in the syntax literature) are respected by the parsing mechanism that form these dependencies in real time ([Stowe, 1986](#); [Traxler & Pickering, 1996](#)). In addition, several studies have demonstrated that these same processing mechanisms respect the sophisticated *exceptions* to these constraints postulated by syntactic theories

(Phillips, 2006; Wagers & Phillips, 2009). Similarly, several studies have demonstrated that complex constraints on the dependencies that give pronouns their referents (called binding constraints in the syntax literature) are also respected by real-time referential processing mechanisms (Kazanina, Lau, Lieberman, Yoshida, & Phillips, 2007; Sturt, 2003; Van Gompel & Liversedge, 2003). Several recent studies also show these effects to be the result of grammatical constraints and not the consequences of nongrammatical processing mechanisms (Dillon & Hornstein, 2013; Kush, Omaki, & Hornstein, 2013; Sprouse, Wagers, & Phillips, 2012; Yoshida, Kazanina, Pablos, & Sturt, 2013). In sum, there is a growing body of convincing evidence that syntactic theories capture structure-building properties that are relevant for real-time sentence processing, despite having initially been empirically based on offline data.

A third potential challenge for the computational view of syntax is that not every syntactician agrees that syntactic theories should serve as a theory of cognitive structure-building computations. The potential for a logical distinction between theories of syntax and theories of cognitive structure-building is clearest in examples of nonmentalistic, or Platonic, linguistic theories, which seek to study the mathematical properties of language without making any claims about how those properties are instantiated in a brain. Even within GS, which is mentalistic, it is not uncommon to hear theories of syntax described as theories of knowledge (or competence) and not theories of use (or performance). The computational view of syntax goes beyond simple knowledge description. The computational view sees syntactic theories as making substantive claims about how syntactic structure building is instantiated in the human brain. It may be the case that there is a one-to-many relationship between syntactic theories and neuronal structure-building computations, but the relationship is there (see Lewis & Phillips, 2014 for a deeper discussion of this challenge).

A final challenge to the computational view of syntax is the problem of isolating structure-building computations from other sentence processing computations in real-time processing data. Real-time language processing data are going to contain signals from both structure-building computations and all of the nonstructure-building computations that syntactic theory abstracts away from (parsing strategies, resource allocation, task specific strategies in the sense of Rogalsky & Hickok, 2011, etc). This means that the actual construction of neurophysiological experiments discussed in Section 14.5 will require quite a bit of ingenuity to isolate the structure-building computations, especially given the high-dimensionality of neural data, and the likelihood of spurious correlations.

And even assuming that *logically* isolating a computation of interest is possible in the experimental stimuli, *physically* isolating a neuronal computation in human neural systems is probably orders of magnitude more difficult. To our knowledge, there are no existing neuronal computations that can be used as a guide (a Rosetta stone of sorts) to mark the beginning or end of a computation being physically performed. We assume that as more and more computations are investigated, combining them in novel ways will eventually allow the physical boundaries of computations to be mapped, but this is currently a promissory note. In summary, the narrow focus of syntactic theories on structure-building computations is in some ways positive, because it provides a hypothesis space for a problem that is potentially tractable, but it is also negative, because the computations left out of that hypothesis space may be either confounds or necessary additions to solve the physical localization problem.

14.7 CONCLUSION

We believe that modern syntactic theory is well-suited to serve as a cognitive theory of syntactic structure-building computations, and that the time is right for a large-scale collaboration between syntacticians, mathematical linguists and psycholinguists, and theoretical and experimental neuroscientists to identify the neuronal instantiations of those computations. Such a research program will be a collaborative project of unprecedented scope and will face numerous theoretical and technological challenges, but in the histories of cognitive science, linguistics, and neuroscience, there has never been a better time to try.

Speech Perception as a Perceptuo-Motor Skill

Carol A. Fowler

Department of Psychology, University of Connecticut, Storrs, CT, USA

15.1 INTRODUCTION

Among theories of phonetic perception, there are “general auditory approaches” (Diehl, Lotto, & Holt, 2004) that contrast with “gesture theories” (Fowler, 1986; Liberman & Mattingly, 1985). These approaches are contrasted in many publications (Diehl et al., 2004; Fowler & Iskarous, 2013). The present chapter focuses on gesture theories, in which the integrality of speech production and perception is central to the accounts.

The best known of the gesture approaches to speech perception, the motor theory (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Liberman & Mattingly, 1985), claims that speech perceivers perceive linguistically significant (“phonetic”) gestures of the vocal tract as immediate perceptual objects (rather than auditory transforms of the acoustic speech signal). Another claim is that perceiving speech necessarily involves speech motor system recruitment. A final claim is that, in these respects, speech perception is special, particularly in relation to other auditorily perceived events in which auditory transforms of acoustic signals are perceptual objects. The present chapter suggests that the first two claims are accurate (except possibly the *necessity* of motor recruitment). However, the third claim is not. Perception of distal events (gestures, for speech) is generally what perceptual systems achieve (Gibson, 1966), and motor system recruitment is widespread in perception and cognition.

An alternative gesture theory, direct realism (Fowler, 1986, 1996), agrees that listeners to speech perceive the distal events of speaking, phonetic gestures, but disagrees that, in regard to perceiving distal events, rather than proximal (e.g., acoustic) stimulation, speech perception is special (see Carello, Wagman, & Turvey, 2005 for a review of “ecological acoustics”; see also Rosenblum, 2008). In direct realism, recruitment of the motor system is not expected for speech perception,

because information for gestures is available in the acoustic speech signal. Required or not, however, evidence shows that recruitment is widespread.

In both gesture theories, speech perception is a perceptuo-motor skill. Understanding why it is and why that does not make it special require embedding its study in a larger context of investigations of the ecology of perceiving and acting. Therefore, the context for the literature reviewed in this chapter is not that of processing in the brain. Rather, it is about language users in their world, in which perceiving and acting are inextricably intertwined. Presumably, the brains of language users, like the rest of language users, will be adapted to such a world. Therefore, findings of speech motor system activation in the brain during ordinary speech perception perhaps should be unsurprising. For an alternative perspective, see Lotto and Holt (Chapter 16).

15.1.1 Perception and Action are Inextricably Integrated

In the econiche, animals’ activities are necessarily perceptually guided. For example, locomotion usually involves visual guidance so that walkers can move along a route toward a goal location while avoiding collision with obstacles (Warren, 2006). Sometimes, however, for example, crossing a street at a curve so that oncoming traffic is not visible (or crossing anywhere for those texting while walking) may involve detecting approaching vehicles by listening. It also involves maintaining postural balance with the help of vestibular systems and proprioceptive detection of the forces exerted by the walker on the support surface and on the walker by the support surface. Walking, like other activities, is a multimodal perceptuo-motor activity.

Sometimes animals' goals are more exploratory than performatory. For example, human sightseers may walk around (as it were) to enable their perceptual systems to intercept new sights or sounds or feels or smells or tastes. In that case, complementarily to performatory actions whereby perception serves action, action systems serve primarily perceptual aims. Either way, acting and perceiving both are perceptuo-motor skills.

Aside from being perceptuo-motor in nature, however, animals' actions and perceptions share something else that is crucial to their lives, namely the *econiche*. The world in which they act and the world in which they obtain perceptual information is the *same world*. Because survival depends on felicitous acting, it also depends on perceptual systems that accurately expose properties of the *econiche* relevant to their actions (the "affordances" of the *econiche*; Gibson, 1979). In short, perceptual systems as well as action systems have to be adapted to the animals' "way of life" (Gibson, 1994). There has to be a strong likelihood of a relation of parity between properties of the *econiche* implied by an animal's actions and properties of the *econiche* perceived in support of those actions.

Most analogous to language use in the world are coordinative social activities (e.g., moving a piece of furniture together, paddling a canoe, playing a duet). The foregoing characterizations are true of these activities as well, but now parity has an additional cross-person dimension. Participants have to perceive social affordances (Marsh, Richardson, Baron, & Schmidt, 2006), and their actions generally should be true to them. In addition, co-participants' perceptions should be shared and co-participants should coordinate their actions in relation to those shared social affordances. Speech perception and production in the *econiche* are coordinative social activities.

15.1.2 Parity in Speech

Because speaking and listening are social activities, much of this discussion applies to them. But they are different from some nonlinguistic, nonsocial actions in a notable way. At one level of description, an aim of speaking is to cause patterning in the air. That is how speaking can get the attention of a listener and how it can get a chance to have its intended impact on him or her. This is different from the activity of locomoting,

for example, which typically is done to get somewhere, not to cause patterning in light or air. However, it is not so different in that respect from performances meant to be seen or heard, such as ballet or competitive diving or musical performances.

Regarding perceiving and acting generally, Liberman and Mattingly (1989) and Liberman and Whalen (2000) have remarked that parity is central to speaking and perceiving speech. For Liberman and Whalen, parity in language use has three essential aspects. One relates to the observation that the same language or languages are involved in a language user's dual roles of talking and of listening to the speech of others. There must be a relation of parity (sometimes called a "common code;" Schütz-Bosbach & Prinz, 2007) between language forms produced and perceived by the same person. That is how perception of one's own speech can guide its production (e.g., Houde & Jordan, 1998).

A second component of parity in language relates to between-person language use. For language use to serve its communicative role in a between-person exchange, there has to be a relation of sufficient parity¹ between forms uttered by a talker and forms intercepted by listeners. For many theorists (Pierrehumbert, 1990), the "common code" within a speaker–hearer and between them is "mental" and not physical. However, for speech perception not to be special, perceptual objects *have* to be physical. Only physical things can causally structure informational media such as light and air and therefore can have effects that *can* be perceived. Language forms as physical events do not prevent their being psychological in nature as well (Ryle, 1949). In the account of Liberman and Mattingly (1985) and others (Browman & Goldstein, 1986; Goldstein & Fowler, 2003), the smallest language forms are phonetic gestures of the vocal tract. They are physical actions that have linguistic and, hence, psychological significance.

The third component of parity for Liberman and Whalen (2000) is that brain systems for production and perception of language forms must have co-evolved, because each is specialized for the unique problems to which coarticulation gives rise, and neither specialized system would be useful without the other. This component is not addressed further here beyond commenting that coarticulation and its effects are not special to speech.

¹The hedge "sufficient" is meant to forestall misunderstanding (Remez & Pardo, 2006). Talkers and listeners do not have to share their dialect, and listeners do not have to detect every phone, even every word, produced by talkers for language to "work" in public use. However, sharing of forms has to be sufficient for the talker's message to get across in events involving talking. Relatedly, at a slower time scale, in a language community, language forms and structures serve as conventions (Millikan, 2003) that *are* conventional just because they are reproduced (with the same hedge: reproduced with sufficient fidelity to count as being reproduced) across community members. The capacity to reproduce perceived forms implies perception–production parity.

The foregoing discussion is meant to underscore that, in the econiche, life, including linguistic life, is perceptuo-motor in nature. Nothing discussed here logically requires that *mechanisms* involved in action must be incorporated in perceptual systems or vice versa. However, it would be surprising if they were not, and in both the linguistic and nonlinguistic domains, they appear to be. A brief review is provided within the domain of speech and then, outside of it showing that evidence for the perceptuo-motor nature of perception and cognition is quite general.

15.2 RESEARCH FINDINGS

15.2.1 Speech

Lieberman and Mattingly (1985) identify their motor theory of speech perception as motor in two respects. First, in the theory, listeners perceive speech gestures. Second, to achieve perception of gestures, they recruit their own speech motor system.

The first claim does not, in fact, make the theory a motor theory. No one would identify a theory of visual perception as a motor theory if it made the (uncontroversial) claim that, when a person walks by in a perceiver's line of sight, the perceiver sees someone walking. Perceiving a motor event when a motor event occurs in the econiche does not require a theoretical account deserving the descriptor "motor." The first claim of motor theorists should imply that there is nothing special about speech perception in regard to perceptual objects (Rosenblum, 2008). Listeners perceive speech gestures as they hear people knocking on doors and see walkers walking, because perceivers intercept structure in media, such as structured air and light that inform about what they need to perceive: the objects and events that compose the econiche.

Although the claim that speech listeners perceive phonetic gestures is controversial in the field of speech perception, within the context of the foregoing discussion of perception in the econiche, phonetic gestures are expected perceptual objects. Compatibly, there is

converging evidence for gesture perception. A sampling is offered here.

Speech perception is a perceptuo-motor skill with respect to its objects of perception. In articles published in 1952 and 1954 (Lieberman, Delattre, & Cooper, 1952; Lieberman, Delattre, Cooper, & Gerstman, 1954), Lieberman and colleagues reported their first findings that led them to develop a motor theory. Suggestions, such as that of Lotto, Hickok and Holt (2009), that the claims of the motor theory were motivated by a theoretical issue, the problem of coarticulation, are mistaken. The theory was motivated by research findings, the first of which were published in 1952. The claim of motor system involvement was *rationalized* in terms of coarticulation later. The first (Lieberman et al., 1952) was a finding that the *same* acoustic pattern (a stop burst centered at 1440 Hz) that had to have been produced by *different* consonantal gestures coarticulated with different vowels was heard as *different* consonants (the "/pi/-/ka/-/pu/" phenomenon). The second (Lieberman et al., 1954) was a finding that *different* acoustic patterns (second formant transitions) that were produced by the *same* (alveolar) consonant constriction gesture of the vocal tract coarticulated with different vowel gestures were heard as the *same* consonants (the "/di/-du/" phenomenon). In both cases, when listeners' perceptual tracking of acoustic "cues" could be dissociated from their tracking of gesture production, listeners were found to track gestures.²

These findings imply that listeners somehow "parse" (Fowler & Smith, 1986) the acoustic signal along gestural lines. That is, to perceive the same consonant, /d/, from different formant transitions for the syllables /di/ and /du/, they must extract acoustic information that supports perceptual separation of temporally overlapping consonantal and vocalic gestures. Many distinct findings support that parsing occurs (Fowler & Brown, 1997; Fowler & Smith, 1986; Pardo & Fowler, 1997; Silverman, 1986, 1987). Perceivers do the same kind of parsing in the visual domain (e.g., in perception of walking and other biological motions; Johanssen, 1973; Runeson & Frykholm, 1981).

²Intuitively, these findings can be explained as pattern learning instead of gesture perception. A pattern learner can learn to classify the very different acoustic patterns for /di/ and /du/ into the same /d/ category while learning to classify the same stop bursts in /pi/ and /ka/ differently. Learning these classifications requires a systematic basis for learning, of course, and the basis must be the articulatory sameness of the consonantal gestures in /di/ and /du/ and differentness in /pi/ and /ka/. By this account, pattern learners acquire the acoustic-articulatory links when they hear the acoustic consequences of their own speech. No presumption that listeners perceive articulation is required. This, in fact, was the earliest motor theory (Lieberman, 1957), with the proposed learning underlying "acquired similarity" of the /d/ s in /di/ and /du/ and "acquired distinctiveness" of the stop bursts of /pi/ and /ka/. The account fails, however, as argued by early opponents of the motor theory, because individuals exist who perceive speech successfully without being able to produce what they perceive (MacNeilage, Rootes, & Chase, 1967). Information about articulation has to come from information in the acoustic signals from others' speech as well as one's own when that is possible.

One such line of investigation is that regarding compensation for coarticulation. This is a finding that listeners make speech judgments that reflect sensitivity to acoustic consequences of coarticulatory gestural overlap. The research line has a long and controversial history. In a seminal finding by Mann (1980), members of a /da/-/ga/ continuum differing only in the third formant (F3) onset frequency of the initial consonant (high for /da/, low for /ga/) were identified differently after a precursor /al/ (high ending F3) than /ar/ (low ending F3) syllable. Listeners identified more continuum syllables as “ga” after /al/ than /ar/. As Mann (1980) explained, this can be interpreted as perceptual compensation for the acoustic consequences of gestural overlap, that is, the coarticulatory fronting/backing pulls that /l/ and /r/ would exert, respectively, on a following /da/ or /ga/ in natural speech production.

However, Mann (1980) also remarked that her findings can be interpreted in another way. They can be seen as evidence for spectral contrast rather than for listeners’ perceptual parsing of coarticulatory gestural overlap. In the contrast account, frequencies in a context segment render the perceptual system temporarily insensitive to frequencies in neighboring speech. For example, a high F3 transition in /al/ makes frequencies in a following syllable that is ambiguous between /da/ (high F3) and /ga/ (low F3) sound lower and therefore more /ga/-like. A preceding /ar/, with a low F3, has the opposite contrastive effect, leading the syllable to sound more /da/-like. This mimics true perceptual parsing of the coarticulatory effects of /l/ and /r/ on /d/ and /g/.

In support of this view, investigators have reported that nonspeech contexts can yield compensation-like perceptual judgments (Kingston et al., 2014; Lotto & Kluender, 1998). For example, in research by Lotto and Kluender (1998), high- and low-frequency tones replaced /al/ and /ar/ syllables and had qualitatively the same effect on /da/-/ga/ judgments as the context syllables had.

However, other findings oppose that account and favor an interpretation that listeners, in fact, track gestural overlap in speech. For example, compensation is achieved perceptually when contrast is ruled out because compensation is cross-modal (Mitterer, 2006). In this study, context syllables were distinguished only visually (in audiovisual presentations), whereas the continuum syllables were distinguished only acoustically. Because a visible speech gesture cannot be the source of spectral contrast on a following acoustic syllable, contrast is not a viable account of the perceptual compensation that occurred in this study. Contrast is also ruled out when the gestural overlap for which listeners compensate has simultaneous, rather than successive, acoustic consequences (Silverman, 1987), because contrast affects perceptual sensitivity of

neighbors of the source of contrast, not of the source itself. Finally, it is ruled out when gestural overlap is both cross-modal and simultaneous (Fowler, 2006). Moreover, in the only two (difficult-to-find) instances in which predictions of gestural parsing and contrast accounts have been dissociated in speech stimuli (Johnson, 2011; Viswanathan, Magnuson, & Fowler, 2010), results supported gestural parsing, not contrast.

As noted, findings most supportive of the contrast account show that nonspeech contexts trigger compensation-like responses in speech. (Lotto & Kluender, 1998). However, Viswanathan, Magnuson, and Fowler (2013) distinguished a contrast from a masking account of nonspeech effects experimentally and found that the nonspeech contexts used in these studies induced energetic masking rather than contrast. Masking cannot explain the speech effects, however.

In a different line of investigation, perceivers are shown to integrate cross-modal information about speech gestures. A striking and seminal finding by McGurk and MacDonald (1976; MacDonald and McGurk, 1978) showed that appropriately selected pairings of acoustic consonant–vowel (CV) syllables and synchronous dubbed, visible mouthings of different CVs led listeners to report hearing a syllable that integrates information across the modalities. For example, acoustic /ma/ dubbed onto mouthed /da/ leads listeners to hear /na/, an integration of the visually specified place of articulation of the consonant with its acoustically specified nasal and voicing properties. A gestural account of the finding is that listeners integrate information about gestures that are specified cross-modally. That is, they experience an event of talking and integrate cross-modal information about that event. Although there can be other accounts of the finding that invoke past experience associating the sights and sounds of talking (Diehl & Kluender, 1989; Stephens & Holt, 2010), these accounts are challenged by findings of cross-modal integration, among others. For example, Gick and Derrick (2009) showed that puffs of air against the neck of listeners transformed their reports of acoustic /ba/ to /pa/ and of /da/ to /ta/. The puff of air is evidence of the aspiration or breathiness in production of voiceless (/p/, /t/) stops. The gestural account is that puffs of air, acoustic signals, reflected light, and more (Fowler & Dekle, 1991) have impacts on perceivers in ways that specify their ecological source.

This is a subset of research that provides converging evidence for gesture perception in speech. This work is consistent with the framework in which perceivers must perceive the econiche as it is specified multimodally (Stoffregen and Bardy, 2001) for perception to support action and for action to support life.

However, nothing in this review indicates that perception of speech gestures reflects recruitment of the motor system as the motor theory of Liberman and colleagues proposes (Liberman et al., 1967; Liberman & Mattingly, 1985; see Scott, McGettigan, & Eisner, 2009). Listeners perceive speech gestures because acoustic signals, having been lawfully and distinctively structured by speech gestures, specify the gestures (Fowler, 1986, 1996)³ just as reflected light that has been lawfully and distinctively structured as the act of walking specifies walking. Even so, there is considerable evidence that the motor system *is* active in effective ways during phonetic perception. The following review is meant to show only that there are effective perceptuo-motor links in speech perception. It does not show that motor involvement is *required* to extract phonetic (gestural) primitives from speech signals.

Speech perception is a perceptuo-motor skill in respect to mechanisms that support it. The following review is restricted to behavioral evidence and is only illustrative. Moreover, summaries of evidence of brain activation patterns that support speech perception and evidence complementary to that provided here showing that perceptual information changes speech production (Houde & Jordan, 1998; Tremblay, Shiller, & Ostry, 2003) are omitted.

A direct connection between the speech perception and action systems is reported by Yuen, Davis, Brysbaert, and Rastle (2010). These investigators collected electropalatographic data as talkers produced syllables starting with /k/ (produced with a constriction gesture of the tongue dorsum against the velum) or /s/ (produced with a narrow constriction between the tongue tip and the alveolar region of the palate). While articulating either of these syllables, the talkers heard either congruent syllables or /t/-initial syllables (/t/, like /s/, is an alveolar consonant; however, because it is a stop, not a fricative like /s/, there is more alveolar contact for /t/). The remarkable finding was that the heard syllable left traces in the production of /k/- and /s/-initial syllables in the form of increased alveolo-palatal contact by the tongue when the distractor was /t/-initial. The effect was absent when distractor syllables were presented in print form. This finding is important because acoustically presented syllables were distractors to which participants did not explicitly respond. The explicit task involved talking, not listening; even so, listening had an impact on articulation, presumably because, in this

experimental set-up, listening automatically and unintentionally involves motor system activation.

The findings are consistent with those of Fadiga and colleagues (Fadiga, Craighero, Buccino, & Rizzolatti, 2002). They found that transcranial magnetic stimulation (TMS) of the tongue region of the speech motor system of the brain leads to more activation of tongue muscles when words or nonwords being perceived include lingual as compared with labial intervocalic consonants. That is, motor activation that occurred during perception of speech was specific to the gestural properties of the words or nonwords to which the listener was exposed.

Compatibly, D'Ausilio and colleagues (D'Ausilio et al., 2009) used TMS either to the tongue or to the lip region of the motor system of the brain as listeners identified stop-initial syllables in noise. Response times were faster and accuracy was higher to identify lingual consonants (/d/, /t/) than labial consonants (/b/, /p/) when TMS was to the lingual region. The pattern reversed when stimulation was to the labial region (see Hickok [2009, 2014] for an alternative interpretation).

Finally, Ostry and colleagues (Ito, Tiede, & Ostry, 2009; Nasir & Ostry, 2009) have shown that changes in the way that talkers produce a vowel also lead to changes in the way that they perceive it. A striking finding in that regard is reported by Nasir and Ostry (2009). In their study, talkers produced monosyllables including the vowel /æ/. Talkers' jaws were perturbed in the direction of protrusion as they produced the monosyllables. This perturbation did not have measurable or audible acoustic consequences, but, despite that, most participants compensated for it. That is, their jaw trajectories after compensation were closer to the preperturbation path than it was before compensation. Before and after the perturbation experience, participants classified vowels perceptually along a *head to had* acoustic continuum (where /æ/ is the vowel in *had*). They showed a boundary shift after compensation identifying fewer vowels as /æ/ than they did before compensation to the jaw perturbations. No shifts in identification were found for control participants who followed the same protocol except that perturbations were never applied during the perturbation phase of the experiment. In addition, among participants in the experimental group, the size of the compensation to perturbation was correlated with the size of the perceptual shift.

³Claims that acoustic signals necessarily lack the required specificity for gestural recovery (Diehl, Lotto, & Holt, 2004, p. 172: "[T]he inverse problem appears to be intractable") are overstated. Most approaches to the inversion problem make simplifying assumptions about the vocal tract that are false and consequential (Iskarous, 2010; Iskarous, Fowler, & Whalen, 2010). Moreover, characteristically approaches are designed to recover individual vocal tract *states*, not gestures, and so cannot take advantage of constraints provided by the tract's history, an analog of the retinal image fallacy in visual perception (Gibson, 1966).

Therefore, clearly, the perceptual shift was tied to the adaptive learning. As talkers changed the way they produced a vowel (in response to perturbations that had no measurable or audible acoustic consequences), they also changed how they extracted acoustic information about that vowel in perception.

As noted, there have been proposals that motor system activation during speech perception may only occur under special circumstances, such as when the signal is noisy or only when special kinds of tasks are being performed (Osnes, Hugdahl, & Specht, 2011). However, the foregoing review suggests that motor activation occurs whether or not the signal is noisy or distorted and in a variety of tasks. Stimuli are sometimes meaningless syllables and sometimes meaningful words; they are sometimes presented in the clear and sometimes in noise. Moreover, the review that follows should lead skeptics to question whether motor activation during speech perception should be limited only to special circumstances. The review shows that motor system recruitment is widespread in other domains of perception and elsewhere in the realm of language. Its pervasiveness likely reflects humans' adaptation to the fundamentally perceptuo-motor nature of life in the econiche.

15.2.2 Nonspeech

15.2.2.1 Nonlanguage

As noted, evidence that perceivers perceive a motor event when one occurs in their vicinity is not in itself evidence for a motor theory. Even so, there *is* evidence for motor activation during visual perception of walking in research by Takahashi, Kamibayashi, Nakajima, Akai, and Nakazawa (2008). They applied TMS to the motor systems of observers' brains to potentiate muscles of their legs as the observers watched actors either walking or standing on a treadmill. Activity in the observers' leg muscles was measured. Findings were analogous to those of Fadiga et al. (2002) for speech perception. Greater muscle activity occurred in muscles of the leg as observers watched walking as contrasted with standing. As it does during speech perception, muscle activation occurs that is specific to the event being perceived during perception of biological motion.

Motor system activation consequent on observing action is not restricted to visual observation. Activation also occurs as listeners hear sounds (in a study by Caetano, Jousmäki, & Hari, 2007, the sound of a drum membrane being tapped with the finger)

that is comparable in some, but not all respects, with activation that occurs when listeners produce the same sounds themselves or see someone else producing them with or without sound.

A finding that is conceptually analogous to that of D'Ausilio et al. (2009) but in the visual domain has been reported as well. D'Ausilio et al. (2009) showed that potentiation of lip or tongue muscles facilitated perception of labial or lingual consonants, respectively, in noise. Blaesi and Wilson (2010) had observers classify facial expressions that had been morphed along a continuum between a smile and a frown. In half of the trials, the observers clenched a pen lengthwise in their mouth to enforce an expression similar to a smile without (directly) evoking the associated emotion. Findings were that "smile" judgments increased in those trials as compared with trials in which the observers' facial expression was not manipulated.

Findings similar to those reported by Blaesi and Wilson (2010) abound in the literature. Barsalou (2008) provides a summary of some of them in the domain of "embodied" or "grounded" cognition.

The studies reviewed so far reveal motor activation in perception. Research by Goldin-Meadow and colleagues (see Goldin-Meadow & Beilock, 2010, for a review) uncovered a role for motor recruitment in problem-solving and thought processes more generally. In their review they show that the manual gesturing that accompanies language use not only reflects thought but also can guide thought. Research with children acquiring Piagetian conservation (Ping & Goldin-Meadow, 2008) showed that children learned more from instruction involving both gestures and speech than from instruction involving speech only and that the advantage accrued whether the containers of liquid used in the conservation problems were present or absent (so that gestures were not points to the critical properties of the objects).

In a study of adults, Beilock and Goldin-Meadow (2010) presented participants with variants of the tower of Hanoi problem.⁴ Participants solved the problem and then were videotaped describing how they had solved it. After that, they solved a variant of the same problem. An important finding was that gestures produced during the description phase that were appropriate to the initial solution of the problem but inappropriate for the solution of the variant were associated with poorer performance on the variant.

⁴The tower of Hanoi tasks present solvers with four disks of different sizes and three pegs on which they may be placed. At the beginning, the four disks are stacked on the left-most peg in order of size, with the smallest disk on top. The solver's task is to shift the disks one at a time so that, eventually, they are stacked in the same size order on the last peg. A constraint is that a larger disk cannot sit above a smaller one.

15.2.2.2 Language, Not Speech

This review shows that motor activation occurs and is effective in perception and cognition outside of language. It is not special to speech perception. One conclusion from this is that motor activation is pervasive in perception and cognition. A second is that the view of Liberman and colleagues (Liberman et al., 1967) that motor recruitment in speech perception solves a problem that is special to speech is not particularly suggested by findings of motor activation in that domain. An explanation that is more likely to be valid for the occurrence of motor activation in speech perception will be one that is shared with explanations for motor activation elsewhere in perception and cognition.

Motor activation within the domain of language is not special to speech perception either. It occurs in word recognition and in language understanding more generally. The generality of motor activation to larger chunks of language than consonants and vowels reflects the fact that language use is a perceptuo-motor activity. It is fundamentally a between-person activity in the world; as such, it is inherently and pervasively perceptuo-motor in its nature (Fowler, 2013). Some examples of findings are presented.

Regarding word recognition, Pulvermüller and Fadiga (2010) reviewed evidence that words with action-related meanings (*grasp* or *kick*) activate the associated part of the motor system (Hauk, Johnsrude, & Pulvermüller, 2004) and do so with a sufficiently short latency that the activation is likely integral to word understanding, not consequent of it (Pulvermüller, Shtyrov, & Ilmoniemi, 2005). Compatibly, a TMS study (Pulvermüller, Hauk, Nikulin, & Ilmoniemi, 2005) showed that stimulation of the arm–hand motor region of the left hemispheres of right-handed participants facilitated lexical decisions (made as lip-movement responses) to words with arm–hand-related meanings compared with words with leg-related meanings, whereas stimulation of leg motor regions had a complementary effect on lexical decision times.

de Zubicaray, Arciuli, and McMahon (2013) challenged these findings, in part, by showing that localizations of motor activations in response to linguistic stimuli in the literature are questionable. They also show that some findings of motor activation to words (and nonwords) reflect sensitivity, not to the words' content but rather to their orthographic and phonological properties that statistically distinguish words by syntactic class. They show that nonwords having the statistical properties of verbs activate the motor system despite being mostly meaningless.

Despite these findings, there is clear behavioral evidence for motor activation specific to actions implied by sentence meanings (see Taylor & Zwaan, 2009, for a

review). These findings are not subject to concerns about where in the brain motor activation occurs, because they show specificity in the motor actions themselves that are primed by linguistic meanings. Moreover, most are not subject to reinterpretation in terms of the orthographic or phonological properties of the stimuli. For example, Glenberg and Kaschak (2002) presented listeners with sentences such as *Andy delivered the pizza to you* or *You delivered the pizza to Andy* (two sentences with identical orthographic and phonological properties but describing different actions). Participants made a speeded response whether each sentence made sense. For one participant group, the *yes* response was a motion toward the body from a home button, whereas the *no* response was a motion in the opposite direction from the same home button. In a second group of participants, the mapping was opposite. Findings were that latencies to respond *yes* to sentences like the first sentence were faster for participants whose responses were toward the body, the same direction as the pizza's motion. Latencies to respond *yes* to sentences like the second sentence were faster for participants whose responses were away from the body. Compatibly, Zwaan and Taylor (2006) presented participants with sentences visually in sequential groups of one to three words (separated here by slashes):

To quench/his/thirst/the/marathon/runner/eagerly/opened/the/water bottle.

Participants turned a knob to see each new word or word sequence. In one block of trials, they turned the knob counterclockwise; in another block, they turned it in the opposite direction. Half of the critical sentences described a clockwise motion; half (as in the example) described a counterclockwise motion. Findings were that reading times for the critical region of the sentence (*opened* in the example) were faster when the direction of the knob turn matched the rotation direction implied by the sentence.

15.3 CONCLUSION

Set in the context of the many recent research findings showing motor system activation and effective involvement in perception, cognition, and language generally, the previously highly controversial claim of Liberman's motor theory (Liberman et al., 1967; Liberman & Mattingly, 1985) that there is motor system recruitment in speech perception appears quite plausible, even mundane. Even so, the associated claim of motor theorists that speech motor system recruitment evolved to solve a perceptual problem that is special to speech recedes in plausibility. Whether acoustic speech

signals present an especially difficult obstacle to perception because of coarticulation (and, most likely it does not; Fowler, 1986, 1996; Fowler & Iskarous, 2013), motor recruitment occurs pervasively in instances in which this obstacle, if it is one, is absent.

The present review suggests that motor recruitment occurs generally in perception and cognition, including in language perception and comprehension. This is likely because life in the econiche is pervasively perceptuo-motor in nature, and animals, including humans, are adapted to that kind of life. Perception generally incorporates exploratory activity as an essential part and performatory actions are perceptually guided. Moreover, for activities of either sort to be felicitous requires both acting and perceiving to be true to the nature of the econiche. Actions have to be appropriate to the affordances of the econiche, and perception has to reveal the affordances. The econiche has to be shared (there must be a relation of parity) between perceiving and acting.

This kind of action–perception parity is required for interpersonal action in which participants in joint activities have to coordinate. Participants in joint actions have to perceive accurately their own participation in the action and their partner’s; complementarily, their actions have to be true to the joint situation and their perception of it. This is no less true for language use than it is for activities such as dancing, paddling a canoe, or playing a duet (Clark, 1996). Perceivers of linguistic utterances produced by others have, in general, to perceive accurately what has been said by themselves and by interlocutors. There has to be a relation of (sufficient) parity between utterances produced and perceived on the parts of all participants in a linguistic interchange. In this case, the shared part of the econiche is the utterance composed at the level of language forms of appropriately sequenced linguistic actions of the vocal tract.

Where does this leave Liberman’s motor theory? Although Liberman was by no means the first motor theorist, he should be recognized as among the earliest theorists to recognize the perceptuo-motor link in the domain of speech (Galantucci, Fowler, & Turvey, 2006). A task for motor theorists of speech perception now is to bring the theory into alignment with developments outside the domain of speech such as those reviewed here.

Speech Perception

The View from the Auditory System

Andrew J. Lotto¹ and Lori L. Holt²

¹Speech, Language, & Hearing Sciences, University of Arizona, Tucson, AZ, USA; ²Department of Psychology and the Center for the Neural Basis of Cognition, Carnegie Mellon University, Pittsburgh, PA, USA

16.1 INTRODUCTION

For much of the past 50 years, the main theoretical debate in the scientific study of speech perception has focused on whether the processing of speech sounds relies on neural mechanisms that are specific to speech and language or whether general perceptual/cognitive processes can account for all of the relevant phenomena. Starting with the first presentations of the Motor Theory of Speech Perception by Alvin Liberman and colleagues (Liberman, Cooper, Harris, MacNeilage, & Studdert-Kennedy, 1964; Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Studdert-Kennedy, Liberman, Harris, & Cooper, 1970) and the critical reply from Harlan Lane (1965), many scientists defended “all-or-none” positions on the necessity of specialized speech processes, and much research was dedicated to demonstrations of phenomena that were purported to require general or speech-specific mechanisms (see Diehl, Lotto, & Holt, 2004 for a review of the theoretical commitments behind these positions). Whereas the “speech-is-special” debate continues to be relevant (Fowler, 2008; Lotto, Hickok, & Holt, 2009; Massaro & Chen, 2008; Trout, 2001), the focus of the field has moved toward more subtle distinctions concerning the relative roles of perceptual, cognitive, motor, and linguistic systems in speech perception and how each of these systems interacts in the processing of speech sounds. The result has been an opportunity to develop more plausible and complete models of speech perception/production (Guenther & Vladusich, 2012; Hickok, Houde, & Rong, 2011).

In line with this shift in focus, in this chapter we concentrate not on whether the general auditory system is sufficient for speech perception but rather on

the ways that human speech communication appears to be constrained and structured on the basis of the operating characteristics of the auditory system. The basic premise is simple, with a long tradition in the scientific study of speech perception: the form of speech (at the level of phonetics and higher) takes advantage of what the auditory system does well, resulting in a robust and efficient communication system. We review here three aspects of auditory perception—discriminability, context interactions, and effects of experience—and discuss how the structure of speech appears to respect these general characteristics of the auditory system.

It should be noted that we include in our conception of the “auditory system” processes and constructs that are often considered to be “cognition,” such as memory, learning, categorization, and attention (Holt & Lotto, 2010). This is in contrast to previous characterizations of “Auditorist” positions in speech perception that appeared to constrain explanations of speech phenomena to peculiarities of auditory encoding at the periphery. Most researchers who have advocated for general auditory accounts of speech perception actually propose explanations within a larger general auditory cognitive science framework (Holt & Lotto, 2008; Kluender & Kiefte, 2006). Recent findings in auditory neuroscience provide support for moving beyond simple dichotomies of perception versus cognition or top-down versus bottom-up or peripheral versus central. There have been demonstrations that manipulation of attention may affect the earliest stages of auditory encoding in the cochlea (Froehlich, Collet, Chanal, & Morgon, 1990; Garinis, Glattke, & Cone, 2011; Giard, Collet, Bouchet, & Pernier, 1994; Maison, Michéyl, & Collet, 2001) and experience with music and language

changes the neural representation of sound in the brain stem (Song, Skoe, Wong, & Kraus, 2008; Wong, Skoe, Russo, Dees, & Kraus, 2007). In line with these findings, we treat attention, categorization, and learning as intrinsic aspects of auditory processing.

16.2 EFFECTS OF AUDITORY DISTINCTIVENESS ON THE FORM OF SPEECH

At the most basic level, the characteristics of the auditory system must constrain the form of speech because the information-carrying aspects of the signal must be encoded by the system and must be able to be discriminated by listeners. Given the remarkable ability of normal-hearing listeners to discriminate spectral-temporal changes in simple sounds such as tones and noises, the resolution of the auditory system does not appear to provide much of a constraint on the possible sounds used for speech communication. The smallest discriminable frequency change for a tone of 1,000 Hz is just over 1 Hz (Wier, Jesteadt, & Green, 1977), and an increment in intensity of 1 dB for that tone will likely be detected by the listener (Jesteadt, Wier, & Green, 1977). However, it is a mistake to make direct inferences from discriminability of simple acoustic stimuli to the perception of complex sounds, such as speech. Speech perception is not a simple detection or discrimination task; it is more similar to a pattern recognition task in which the information is carried through changes in relative patterns across a complex multidimensional space. These patterns must be robustly encoded and perceptually discriminable for efficient speech communication.

To the extent that some patterns are more readily discriminable by the auditory system, they will presumably be more effective as vehicles for communication. Liljencrants and Lindblom (1972) demonstrated that one could predict the vowel inventories of languages relatively well by maximizing intervowel distances within a psychophysically scaled vowel space defined by the first two formant frequencies (in Mel scaling). For example, /i/, /a/, and /u/ are correctly predicted to be the most common set of vowels for a three-vowel language system based on the presumption that they would be most auditorily discriminable given that their formant patterns are maximally distinct in the vowel space. Vowel inventory predictions become even more accurate as one more precisely models the auditory representation of each vowel (Diehl, Lindblom, & Creeger, 2003; Lindblom, 1986). These demonstrations are in agreement with proposals that languages tend to use sounds that maximize auditory distinctiveness in balance with the value of

reducing articulatory effort, such as Stevens' (1972, 1989) Quantal Theory, Lindblom's (1991) H&H Theory (which we return to below), and Ohala's (1993) models of sound change in historical linguistics.

The proposal that auditory distinctiveness is important for effective speech communication was pushed even further by the Auditory Enhancement Theory from Diehl and colleagues (Diehl & Kluender, 1987, 1989; Diehl, Kluender, Walsh, & Parker, 1991). According to Auditory Enhancement, speakers tend to combine articulations that result in acoustic changes that mutually enhance distinctiveness of the resulting sounds for the listener. For example, in English the voicing contrast between /b/ and /p/ when spoken between two vowels, such as *rabid* versus *rapid*, is signaled in part by the duration of a silent interval that corresponds to the lip closure duration, which is shorter for /b/. However, speakers also tend to lengthen the duration of the preceding vowel when producing a /b/. Kluender, Diehl, and Wright (1988) demonstrated that preceding a silent gap with a long-duration sound results in the perception of a shorter silent gap, even for nonspeech sounds; this can be considered a kind of durational contrast. Thus, when talkers co-vary short lip closure durations with longer preceding vowels and vice versa, they produce a clearer auditory distinction between /b/ and /p/. This is just one of numerous examples appearing to indicate that the need for auditory distinctiveness drives the phonetic structure of languages (Diehl, Kluender, & Walsh, 1990; Kingston & Diehl, 1995).

In addition to providing constraints on the global structure of spoken languages, there is good evidence that the *individual* behavior of speakers is influenced by the local needs of listeners for auditory distinctiveness. According to Lindblom's (1991) H(yper) & H(ypo) Theory of speech communication, speakers vary their productions from hyperarticulation to hypoarticulation depending on the contextual needs of the listener. Spoken utterances that are redundant with other sources of information or with prior knowledge may be spoken with reduced effort, resulting in reduced auditory distinctiveness. However, novel information or words that are likely to be misperceived by a listener are produced with greater clarity or hyperarticulation. In accordance with this theory, there have been many demonstrations that speakers modulate productions when speaking to listeners who may have perceptual challenges, such as hearing-impaired listeners or non-native language learners (Bradlow & Bent, 2002; Picheny, Durlach, & Braida, 1985, 1986).

Despite the continued success of the theories described, it remains a challenge to derive a valid metric of "auditory distinctiveness" for complex time-varying signals like speech (and equally difficult to

quantify “articulatory effort”). The classic psychophysical measures of frequency, intensity, and temporal resolution are simply not sufficient. The pioneering work of David Green regarding auditory profile analysis in which listeners discriminate amplitude pattern changes across a multitonal complex (Green, 1988; Green, Mason, & Kidd, 1984) was a step in the right direction because it could conceivably be applied to measuring the ability to discriminate steady-state vowel acoustics. However, vowel acoustics in real speech are much more complex and it is not clear that these measures scale up to predict intelligibility of speech at even the level of words. The future prospects of understanding how the operating characteristics of the auditory system constrain the acoustic elements used in speech communication are brighter given more recent approaches to psychoacoustic research that investigate the roles of context, attention, learning, and memory in general auditory processing (Kidd, Richards, Streeter, Mason, & Huang, 2011; Krishnan, Leech, Aydelott, & Dick, 2013; Ortiz & Wright, 2010; Snyder & Weintraub, 2013).

16.3 EFFECTS OF AUDITORY INTERACTION ON THE FORM OF SPEECH

The patterns of acoustic change that convey information in speech are notoriously complex. Speech sounds like /d/ and /g/ are not conveyed by a necessary or sufficient acoustic cue and there is no canonical acoustic template that definitively signals a linguistic message. Furthermore, variability is the norm. The detailed acoustic signature of a particular phoneme, syllable, or word varies a great deal across different contexts, utterances, and talkers. The inherent multidimensionality of the acoustic signatures that convey speech sounds and the variability along these dimensions presents a challenge for understanding how listeners readily map the continuous signal to discrete linguistic representations. This has been the central issue of speech perception research. Although some researchers have suggested that acoustic variability may serve useful functions in speech communication (Elman & McClelland, 1986; Liberman, 1996), the prevailing approach has been to explore how listeners accommodate or compensate for the messy physical acoustic signal to align it with native-language linguistic knowledge.

Although this framing of speech perception has dominated empirical research and theory, the focus on acoustic variability may lead us to pursue answers to the wrong questions. Like all perceptual systems, the auditory system transforms sensory input; it is not a linear system. It is possible that the nature of auditory

perceptual transformations is such that the challenge of *acoustic* variability is mitigated when analyzed through the lens of *auditory* perception. Some of the more daunting mysteries about the ability of humans to accommodate acoustic variability in speech may arise from a lack of understanding of how the auditory system encodes complex sounds, generally.

Coarticulation is a case in point. As we talk, the mouth, jaw, and other articulators move very quickly, but not instantaneously, from target to target. Consequently, at any point in time the movement of the articulators is a function of the articulatory demands of previous and subsequent phonetic sequences as well as the “current” intended production. As a direct result, the acoustic signature of a speech sound is context-dependent. When /al/ precedes /ga/, for example, the tongue must quickly move from anterior to posterior occlusions to form the consonants. The effect of coarticulation is to draw /ga/ to a more anterior position (toward /al/). This context-sensitive shift in production impacts the resultant acoustic realization, making it more “da”-like because the place of tongue occlusion slides forward in the mouth toward the articulation typical of “da.” Likewise, when /da/ is spoken after the more posteriorly articulated /ar/, the opposite pattern occurs; the acoustics of /da/ become more “ga”-like. This means that, due to coarticulation, the acoustic signature of the second syllables in “alga” and “arda” can be highly similar (Mann, 1980).

Viewed from the perspective of acoustic variability, this issue seems intractable. If the second consonant of “alga” and “arda” is signaled by highly similar acoustics, then how is it that we hear the distinct syllables “ga” and “da”? The answer lies in the incredible context dependence of speech perception; perception appears to compensate for coarticulation. This can be demonstrated by preceding a perceptually ambiguous syllable between /ga/ and /da/ with /al/ or /ar/. Whereas the acoustics of /ga/ produced after /al/ are more “da”-like, a preceding /al/ shifts perception of the ambiguous sound toward “ga.” Similarly, /ar/ shifts perception of the same ambiguous sound toward “da.” This pattern opposes the coarticulatory effects in speech production. In this example and many replications with other tasks and stimuli, coarticulation assimilates speech acoustics, but perception “compensates” in the opposing direction (Mann, 1980; Mann & Repp, 1980).

The traditional interpretation of these findings highlights that theoretical approaches have tended to discount what the auditory system can contribute to the challenges of speech perception. The flexibility of speech perception to make use of so many acoustic dimensions to signal a particular speech sound and the dependence of this mapping on context has

suggested to many that it is infeasible for these effects to arise from auditory processing. This challenge is part of what led to the proposal that motor representations might be better suited to serve as the basis of speech communication. But, by virtue of being sound, acoustic speech necessarily interfaces with early auditory perceptual operations. As noted, these operations are not linear; they do not simply convey raw acoustic input, they transform it. Thus, although acoustics are readily observable and provide a straightforward means of estimating input to the linguistic system, this representation is not equivalent to the *auditory* information available to the linguistic system. What might be gained by considering *auditory*—rather than *acoustic*—information?

Lotto and Kluender (1998) approached this question by examining whether perceptual compensation for coarticulation like that described for “alga” and “arda” really requires information about speech articulation, or whether the context sounds need to be speech at all. They did this by creating nonspeech sounds that had some of the acoustic energy that distinguishes /al/ from /ar/. These nonspeech signals do not carry information about articulation, talker identity, or any other speech-specific details. The result was two nonspeech tone sweeps, one with energy like /al/ and the other with energy mimicking /ar/. Lotto and Kluender found that when these nonspeech acoustic signals preceded /ga/ and /da/ sounds, the tone sweeps had the same influence as the /al/ and /ar/ sounds they modeled. So-called perceptual compensation for coarticulation is observed even for nonspeech contexts that convey no information about speech articulation.

This finding has been directly replicated (Fowler, 2006; Lotto, Sullivan, & Holt, 2003) and extended to other stimulus contexts (Coady, Kluender, & Rhode, 2003; Fowler, Brown, & Mann, 2000; Holt, 1999; Holt & Lotto, 2002) many times. Across these replications, the pattern of results reveals that a basic characteristic of auditory perception is to exaggerate contrast. Preceded by a high-frequency sound (whether speech or nonspeech), subsequent sounds are perceived to be lower-frequency. This is also true in the temporal domain; preceded by longer sounds or sounds presented at a slower rate, subsequent sounds are heard as shorter (Diehl & Walsh, 1989; Wade & Holt, 2005a, 2005b). Further emphasizing the generality of these effects, Japanese quail exhibit the pattern of speech context dependence that had been thought to be indicative of perceptual compensation for coarticulation (Lotto, Kluender, & Holt, 1997).

This example underscores the fact that *acoustic* and *auditory* are not one and the same. Whereas there is considerable variability in speech acoustics, some of this variability is accommodated by auditory perceptual processing. In this way, the form of speech can

have coarticulation and still be an effective communication signal because the operating characteristics of the auditory system include exaggeration of spectral and temporal contrast. Lotto et al. (1997) argue that the symmetry of assimilated speech production and contrastive perception is not serendipitous, but rather is a consequence of organisms having evolved within natural environments in which sound sources are physically constrained in the sounds they can produce. Because of mass and inertia, natural sound sources tend to be assimilative, like speech articulators. Perceptual systems, audition included, tend to emphasize signs of change, perhaps because in comparison with physical systems’ relative sluggishness rapid change is ecologically significant information. Having evolved like other perceptual systems to respect regularities of the natural environment, auditory processing transforms coarticulated acoustic signals to exaggerate contrast and, thus, eliminates some of the apparent challenges of coarticulation. We can communicate efficiently as our relatively sluggish articulators perform acrobatics across tens of milliseconds to produce speech, in part because our auditory system evolved to use acoustic signals from natural sound sources that face the same physical constraints.

These results also highlight the importance of considering higher-level auditory processing in constraining models of speech perception. Subsequent research has shown that the auditory system exhibits spectral and temporal contrast for more complex sound input (Holt, 2005, 2006a, 2006b; Laing, Liu, Lotto, & Holt, 2012). These studies indicate that the auditory system tracks the long-term average spectra (or rate; Wade & Holt, 2005a) of sounds, and that subsequent perception is relative to, and contrastive with, these distributional characteristics of preceding acoustic signals (Watkins, 1991; Watkins & Makin, 1994). These effects, described graphically in Figure 16.1, cannot be explained by low-level peripheral auditory processing; effects persist over more than a second of silence or intervening sound (Holt, 2005) and require the system to track distributional regularity across acoustic events (Holt, 2006a). These findings are significant for understanding talker and rate normalization, which refer to the challenges introduced to speech perception by acoustic variability arising from different speakers and different rates of speech. What is important is that the preceding context of sounds possess acoustic energy in the spectral (Laing et al., 2012) or temporal (Wade & Holt, 2005a, 2005b) region distinguishing the target phonemes, and not that the context carries articulatory or speech-specific information. Here, too, some of the challenges apparent from speech acoustics may be resolved in the transformation from acoustic to auditory.

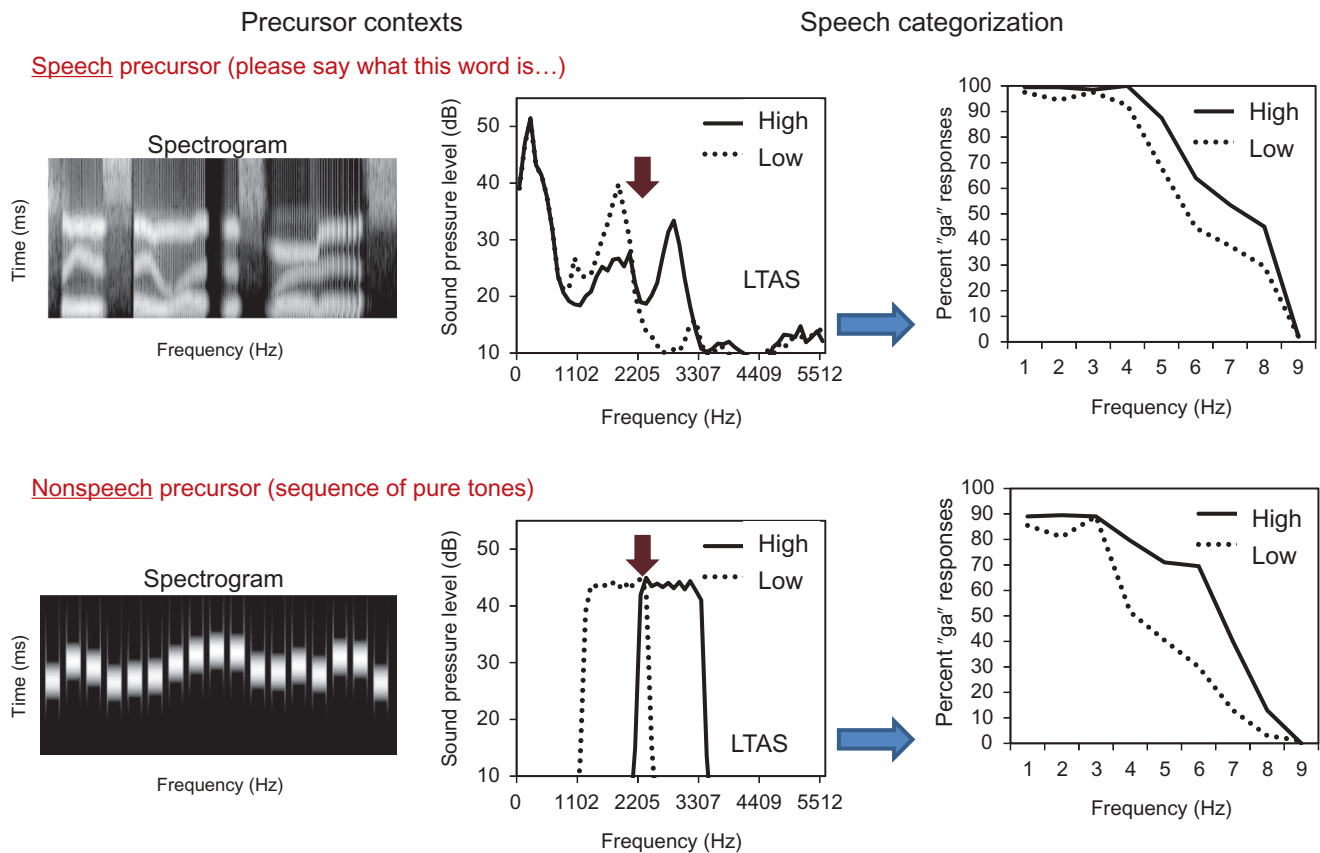

FIGURE 16.1 Precursor contexts and their effect on adult /ga-/da/ categorization. Manipulation of the Long-Term Average Spectrum (LTAS) of both speech (top) and nonspeech (bottom) has a strong, contrastive influence on speech categorization. 16.4 EFFECTS OF LEARNABILITY ON THE FORM OF SPEECH

Auditory representations are influenced greatly by both short-term and long-term experience. Categorical perception, the classic textbook example among speech perception phenomena, exemplifies this. When native-language speech varying gradually in its acoustics is presented to listeners, the patterns of identification change abruptly, not gradually, from one phoneme (or syllable or word) to another. Likewise, there is a corresponding discontinuity in discrimination such that pairs of speech sounds are more discriminable if they lie on opposite sides of the sharp identification boundary than if they lie on the same side of the identification curve's slope, even when they are matched in acoustic difference. Said another way, acoustically distinct speech sounds identified with the same label are difficult to discriminate, whereas those with different labels are readily discriminated. Despite the renown of categorical perception for speech, it is now understood that it is not specific to speech (Beale & Keil, 1995; Bimler & Kirkland, 2001; Krumhansl, 1991; Livingston,

Andrews, & Harnad, 1998; Mirman, Holt, & McClelland, 2004), and that even speech is not entirely "categorical" (Eimas, 1963; Harnad, 1990; Liberman, Harris, Hoffman, & Griffith, 1957; Pisoni, 1973). Infants (Kuhl, 1991; McMurray & Aslin, 2005) and adults (Kluender, Lotto, Holt, & Bloedel, 1998; McMurray, Aslin, Tanenhaus, Spivey, & Subik, 2008) remain sensitive to within-category acoustic variation. Speech categories exhibit graded internal structure such that instances of a speech sound are treated as relatively better or worse exemplars of the category (Iverson & Kuhl, 1995; Iverson et al., 2003; Johnson, Flemming, & Wright, 1993; Miller & Volaitis, 1989).

We have argued that it may be more productive to consider speech perception as *categorization*, as opposed to *categorical* (Holt & Lotto, 2010). This may seem like a small difference in designation, but it has important consequences. Considering speech perception as an example of general auditory categorization provides a means of understanding how the system comes to exhibit relative perceptual constancy in the face of acoustic variability and does so in a native-language-specific manner. The reason for this is that although

there is a great deal of variability in speech acoustics, there also exist underlying regularities in the distributions of experienced native-language speech sounds. This is the computational challenge of categorization; discriminably different exemplars come to be treated as functionally equivalent. A system that can generalize across variability to discover underlying patterns and distributional regularities—a system that can *categorize*—may cope with the acoustic variability inherent in speech without need for invariance. Seeking invariance in the acoustic signatures of speech becomes less essential if we take a broader view that extends beyond pattern matching to consider active auditory processing that involves higher-order and multimodal perception, categorization, attention, and learning.

From this perspective, learning about how listeners acquire auditory categories can constrain behavioral and neurobiological models of speech perception. Whereas the acquisition of first and second language phonetic systems provides an opportunity to observe the development of complex auditory categories, our ability to model these categorization processes is limited because it is extremely difficult to control or even accurately measure a listener's history of experience with speech sounds. However, we are beginning to develop insights into auditory categorization from experiments using novel artificial nonspeech sound categories that inform our understanding about how speech perception and acquisition are constrained by general perceptual learning mechanisms (Desai, Liebenthal, Waldron, & Binder, 2008; Guenther, Husain, Cohen, & Shinn-Cunningham, 1999; Holt & Lotto, 2006; Holt, Lotto, & Diehl, 2004; Ley et al., 2012; Liebenthal et al., 2010).

One example of what this approach can reveal about how auditory learning constrains speech relates to a classic early example of the “lack of invariance” in speech acoustics. If one examines the formant frequencies corresponding most closely with /d/ as it precedes different vowels, then it is impossible to define a single acoustic dimension that uniquely distinguishes the sound as a /d/; the acoustics are greatly influenced by the following vowel (Liberman, Delattre, Cooper, & Gerstman, 1954). This kind of demonstration fueled theoretical commitments that speech perception is accomplished via the speech motor system in the hopes that this would provide a more invariant mapping than acoustics (Liberman et al., 1967). Viewed from the perspective of acoustics, perceptual constancy for /d/ seemed an intractable problem for auditory processing.

Wade and Holt (2005a, 2005b) modeled this perceptual challenge with acoustically complex nonspeech sound exemplars that formed categories signaled only by higher-order acoustic structure and not by any invariant acoustic cue (see Figure 16.2 for a

representation of the stimulus set). Naïve participants experienced these sounds in the context of a videogame in which learning sound categories facilitated advancement in the game but was never explicitly required or rewarded. Within just a half-hour of game play, participants categorized the sounds and generalized their category learning to novel exemplars. This learning led to an exaggeration of between-category discriminability (of the sort traditionally attributed to categorical perception) as measured with electroencephalography (EEG; Liu & Holt, 2011). The seemingly intractable lack of acoustic invariance is, in fact, readily learnable even in an incidental task.

This is proof that the auditory system readily uses multimodal environmental information (modeled in the videogame as sound-object links, as in natural environments) to facilitate discovery of the distributional regularities that define the relations between category exemplars while generalizing across acoustic variability within categories. More than this, however, the approach can reveal details of auditory processing that constrain behavioral and neurobiological models of speech perception. Using the same nonspeech categories and training paradigm, Leech, Holt, Devlin, and Dick (2009) discovered that the extent to which participants learn to categorize nonspeech sounds is strongly correlated with the pretraining to post-training recruitment of left posterior temporal sulcus (pSTS) during presentation of the nonspeech sound category exemplars. This is unexpected because left pSTS has been described as selective for specific acoustic and informational properties of speech signals (Price, Thierry, & Griffiths, 2005). In recent work, Lim, Holt, and Fiez (2013) have found that left pSTS is recruited online in the videogame category training task in a manner that correlates with behavioral measures of learning. These results also demonstrate that recruitment of left pSTS by the nonspeech sound categories cannot be attributed to their superficial acoustic signal similarity to speech or to mere exposure. When highly similar nonspeech sounds are sampled such that category membership is random instead of structured, left pSTS activation is not related to behavioral performance.

As in the examples from the preceding sections, this series of studies demonstrates that there is danger in presuming that speech is fundamentally different from other sounds in either its acoustic structure or in the basic perceptual processes it requires. The selectivity of left pSTS for speech should not be understood to be selectivity for intrinsic properties of acoustic speech signals, such as the articulatory information that speech may carry. Instead, this region seems to meet the computational demands presented by learning to treat structured distributions of acoustically variable sounds as functionally equivalent.

FIGURE 16.2 Schematic spectrograms showing the artificial nonspeech auditory categories across time and frequency. The dashed gray lines show the lower-frequency spectral peak, P1. The colored lines show the higher-frequency spectral peak, P2. The six exemplars of each category are composed of P1 and one of the colored P2 components pictured. Note that unidimensional categories are characterized by an off-set glide that increases (top left) or decreases (top right) in frequency across all exemplars. No such unidimensional cue differentiates the multidimensional categories. From *Wade and Holt (2005a, 2005b)* with permission from the publishers.

Likewise, caution is warranted in presuming that the transformation from acoustic to auditory involves only a static mapping to stable, unchanging linguistic representations. The recruitment of putatively speech-selective left pSTS was driven by category learning in less than an hour (Lim et al., 2013). Thus, the behavioral relevance of the artificial, novel auditory categories drove reorganization of their transformations from acoustic to auditory. The examples we present here illustrate the facile manner by which auditory categories can be acquired. On an even shorter time scale, there is considerable evidence that the mapping of speech acoustics to linguistic representation is “tuned” by multiple information sources in an adaptive manner such as may be required to adapt to foreign accented speech or to speech in adverse, noisy environments (Kraljic, Brennan, & Samuel, 2008; Mehler et al., 1993; Vitela, Carbonell, & Lotto, 2012). The active, flexible nature of auditory processing puts learning in the spotlight and positions questions of speech perception in greater contact with other

neurobiological approaches to understanding perception, cognition, and language.

16.5 MOVING FORWARD

The preceding sections provide a few brief examples of how general auditory processing may influence the perception of speech sounds as well as the structure of phonetic systems. These examples demonstrate that, at the very least, human speech communication appears to take advantage of the things that the auditory system does well—phonetic inventories tend to include sounds whose differences are well-encoded in the auditory system. The acoustic effects of coarticulation are just the types of interactions that the auditory system can accommodate, and the multidimensional structure of speech sounds form just the kinds of categories that are easily learned by the auditory system. Whether there are additional specialized processes required for speech perception, it is likely that the

auditory system constrains the way we talk to and perceive each other to a greater extent than has been acknowledged.

One of the beneficial outcomes of the fact that the auditory system plays a strong role in speech perception is that there is the opportunity for synergy between research of speech and of general auditory processing. Speech perception phenomena shine a light on auditory processes that have remained unilluminated by research of simpler acoustic stimuli. The theories regarding the auditory distinctiveness of speech sounds have inspired the search for better models of auditory encoding of complex stimuli and better functions for computing distinctiveness (Lotto et al., 2003). The existence of perceptual compensation for coarticulation and talker normalization provide evidence for spectral and temporal interactions in general auditory processing that are not evident when presenting stimuli in isolation (Holt, 2006a, 2006b; Holt & Lotto, 2002; Watkins & Makin, 1994). The complexity of speech categories along with the ease with which humans learn them is the starting point for most of the current work on auditory categorization (Goudbeek, Smits, Swingly, & Cutler, 2005; Lotto, 2000; Maddox, Molis, & Diehl, 2002; Smits, Sereno, & Jongman, 2006; Wade & Holt, 2005a, 2005b).

The vitality of auditory and speech cognitive neuroscience depends on continuing this trend of using speech and auditory phenomena to mutually inform and inspire each field.

Understanding Speech in the Context of Variability

Shannon Heald, Serena Klos and Howard Nusbaum

Department of Psychology, The University of Chicago, Chicago, IL, USA

In listening to spoken language, speech perception subjectively seems to be a simple, direct pattern matching system (cf. Fodor, 1983) because of the immediacy with which we understand what is said. This subjective simplicity is misleading given the difficulty of developing speech recognition devices with human-level performance over the range of conditions under which we have little difficulty understanding speech. A typical approach to understanding the mechanisms of human speech perception is to treat the system as if composed of two parts, a simple acoustic–linguistic pattern matcher and some kind of noise reducing filter. However, we argue that this simple form of speech recognition, which is based largely on subjective impression, misconstrues the nature of noise–robust processing in speech. Rather than construe noise robustness as a separate system, we argue that it is intrinsic to the definition of the human speech perception system and suggestive of the processes that are necessary to explain how we understand spoken language. We argue here that understanding the mechanisms of speech perception depends on adaptive processing that can respond to contextual variability that can take a wide range of noise and distortion. Further, what counts as signal and what counts as noise (or contextual variability) may well depend on the listener’s goals at the moment of listening.

17.1 SPEECH AND SPEAKERS

In perceiving speech, we typically listen to understand what someone is saying (the content of their message), as well as to understand something about who is saying it (speaker identity). Of course the message (word by word) changes much faster than

who is delivering the message. But this means that much of speech understanding takes place in the context of a particular speaker, and if the speaker changes, the context changes. Although what is being said changes more frequently in a conversation, there can also be changes between speakers, and such changes are important for the listener to recognize. A shift between talkers can pose a perceptual challenge to a listener due to an increase in the variability of how acoustic patterns map onto phonetic categories. This perceptual challenge is often referred to as the problem of talker variability. For different talkers, a given specific acoustic pattern may correspond to different phonemes perceptually, whereas conversely, across talkers, a given phoneme may be represented in speech by different acoustic patterns (Dorman, Studdert-Kennedy, & Raphael, 1977; Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Peterson & Barney, 1952). For this reason, as well as others, changes in talker are important because they may mark significant changes in how acoustic patterns map onto phonetic categories (cf. Nusbaum & Magnuson, 1997).

Additionally, recognizing a change in speaker may be important because a listener’s attitudes and behavior toward a speaker are often informed by what a listener knows about a speaker (e.g., Thackerar & Giles, 1981). For example, indirect requests are understood in the context of a speaker’s status (Holtgraves, 1994). More directly relevant to speech perception, however, a listener’s belief about the speaker’s social group can alter the perceived intelligibility of the speech (Rubin, 1992). Additionally, dialect (Niedzielski, 1999) and gender (Johnson, Strand, & D’Imperio, 1999) expectations can meaningfully alter phoneme perception, highlighting that social knowledge about a speaker can affect relatively “low-level” perceptual processing of a

speaker's message, much in the same way that knowledge of vocal tract characteristics can (Ladefoged & Broadbent, 1957; although see Huang & Holt, 2012; Laing, Lotto, & Holt, 2012 for an auditory explanation of the mechanism that could underlie this). To understand speech, it is important to know something about the speaker's speech. Of course, speaker recognition is important in its own right, over and above the way that it informs message understanding, although speaker identification for its own sake is much less frequent as a typical listener goal.

In general, there have been two broad views regarding how talker information is used during perception. One account, often called "talker normalization" (Nearey, 1989; Nusbaum & Magnuson, 1997), suggests that listeners use talker information to calibrate or frame the interpretation of a given message to overcome the considerable uncertainty (e.g., acoustic variability, reference resolution) that arises from talker differences. An alternative view suggests that talker information is not used as a context to frame message understanding at all. Rather the alternative view is that speaker recognition is something listeners need to do for social information or just to identify the speaker as a known individual (see Goldinger, 1998). However, this then suggests that there are two general, independent processes for spoken language understanding—word recognition (or phoneme or syllable) and speaker identification.

The kind of knowledge and information that is used during talker normalization is different from the knowledge used to account for phoneme recognition. To carry out talker normalization, it is necessary to derive information about the talker's vocal characteristics. For example, in Gerstman's (1968) model, the point vowels are used to scale the location of the F1-F2 space to infer all the other vowels produced by a given talker. Because the point vowels represent the extremes of a talker's vowel space, they can be used to characterize the talker's vocal tract extremes and therefore bound the recognition space. Similarly, Syrdal and Gopal's (1986) model scales F1 and F2 using the talker's fundamental frequency and F3 because these are considered to be more characteristic of the talker's vocal characteristics than vowel quality (e.g., Fant, 1973; Peterson & Barney, 1952). Thus, talker normalization models use information about the talker rather than information about the specific message or phonetic context, as in models of phoneme perception such as Trace (McClelland & Elman, 1986), Motor Theory (Lieberman,

Cooper, Harris, & MacNeilage, 1962; Liberman, Cooper, Harris, MacNeilage, & Studdert-Kennedy, 1967; Liberman & Mattingly, 1985), analysis-by-synthesis (Stevens & Halle, 1967), or the Fuzzy Logical Model of Perception (Massaro, 1987; Massaro & Oden, 1980).

Traditionally, speech perception has been described as classifying linguistic units (e.g., phonemes, words) from a mixture of detailed acoustic information that contains both phonetically relevant and irrelevant information. In other words, there is an assumed (typical or idealized) pattern that corresponds to linguistic information combined with noise or distortion of that pattern as a consequence of the process of speaking, including aspects of speech production that are specific to the speaker. Given that the acoustic information about a talker (as opposed to the message) might be viewed as noise in relation to the canonical linguistic units on which speech perception relies, it is sometimes assumed that talker information is lost or stripped away during this process of message recognition (e.g., Blandon, Henton, & Pickering, 1984; Disner, 1980; Green, Kuhl, Meltzoff, & Stevens, 1991). Although it is possible that talker information, even in a talker normalization theory, is preserved in parallel representational structures for other listening goals¹ (e.g., Hasson, Skipper, Nusbaum, & Small, 2007), the concern about losing talker-specific information and recognition of the need for this information for other perceptual goals prompted the alternative view. In this view all auditory information in an utterance is putatively represented in a more veridical fashion that maintains talker-specific auditory information along with phonetically relevant auditory information (e.g., Goldinger, 1998) as well as any environmental noise or distortion. In the details of such theories, there is separate coding that represents both talker-specific auditory information such as fundamental frequency and acoustic-phonetic information.² However, because this is an auditory-trace model, there are no specific provisions for the representation or processing of other aspects of talker information such as knowledge about the social group of the talker, the dialect of the talker, or the gender of the talker that might come from glottal waveform or other source information. Further, the echoic encoding account does not explain how talker-specific information that is not acoustic (e.g., visual talker information) can affect speech processing or how other kinds of auditory information (e.g., noise or competing talkers) is filtered out.

¹There are many examples of parallel representations for other sensory systems: there are multiple somatosensory maps (e.g., Kaas, 2004), visual maps (e.g., Bartels & Zeki, 1998), and auditory maps (e.g., Hackett & Kaas, 2004) in the brain.

²As specified, there is no process to determine what is talker-specific information (e.g., glottal waveshape or idiolectal cue combinations) versus phonetically relevant information, nor is there a way of separating noise, although the model suggests that there are separate codes for talker-specific and phonetic-specific information (Goldinger, 1998).

Moreover, and perhaps more importantly, this view privileges speaker differences as a problem for speech perception. But variation in speaking rate within a single talker can have the same kind of effect (Francis & Nusbaum, 1996) such that one acoustic pattern corresponds to different phonemes and one phoneme can be produced with different acoustic patterns (Miller, O'Rourke, & Volaitis, 1997; Miller & Volaitis, 1989). For example, at slow rates of speech, the acoustic pattern of /b/ is similar to /w/ produced at a fast speaking rate, meaning that one acoustic pattern can correspond to either a /b/ or /w/, depending on the rate of speech. Conversely, any phoneme can be produced at a fast or slow speaking rate, resulting in different acoustic patterns. Of course, changes in phonetic and lexical context can restructure the relationship between acoustic patterns and phonetic categories to produce the lack of invariance problem (Liberman, Cooper, Shankweiler, et al., 1967; Nusbaum & Magnuson, 1997). Thus, talker differences are simply one example of the different kinds of variability that can affect the pattern properties of speech.

Noise can also come from environmental sources such as conversations or machinery, and distortion can be introduced by transmission (e.g., cell phone) or room acoustics. These are all modifications of the speech signal that are extrinsic to the utterance that was emitted from the lips of the person talking. However, some signal modifications (that can affect pattern structure) of the speech signal arise within the speaker during speech production, such as varying speaking rate or voice amplitude or fundamental frequency changes. This distinction between extrinsic and intrinsic modifications of speech assumes that there is an idealized acoustic pattern corresponding to a linguistic message and these kinds of signal modifications impair the ability of the listener to recover that putative idealized form from within the noise and distortions. In addition, there is an assumption that the idealized forms of linguistic messages are distinctive in sufficiently differentiating among messages such that once the noise is eliminated, the similarity of a cleaned-up acoustic pattern to known representations of linguistic messages can be determined. While these assumptions underlie almost all theories of speech perception, the problems entailed by these assumptions and how they shape our understanding of the neurobiology of language are seldom examined explicitly.

17.2 THE LACK OF INVARIANCE PROBLEM

In speech perception, the rubric of a lack of invariance between acoustic patterns in speech and the

linguistic interpretation of those patterns is a core challenge to theories of speech perception. Many simple recognition systems assume that given some pattern as input, the features or structure of the input pattern can be compared mathematically to a set of stored representations of patterns and the distance between the input and each can be computed in some Minkowski metric (e.g., city block or Euclidean space). This distance can then serve as the basis for the decision criterion for selecting the recognized interpretation. In other words, when stimulus patterns are sufficiently different, recognition is simply a comparison process between the input pattern and the stored representations with recognition determined by the stored representation that is most similar to the input. However, this kind of approach has traditionally failed for speech recognition.

The problem of lack of invariance in the relationship between the acoustic patterns of speech and the linguistic interpretation of those patterns is a fundamental problem. Although the many-to-many mapping between acoustic patterns of speech and perceptual interpretations is a longstanding, well-known issue (e.g., Liberman, Cooper, Shankweiler, et al., 1967), there are two aspects of this problem—many-to-one versus one-to-many mappings—that are not distinguished, but may be important to understanding the neural architecture of the language processing system. The core computational problem associated with the many-to-many mapping problem only truly emerges when a particular pattern has many different interpretations or can be classified in many different ways. Nusbaum and Magnuson (1997) argued that a many-to-one mapping can be understood with a simple deterministic class of mechanisms, whereas a one-to-many mapping can only be solved by nondeterministic mechanisms. In essence, a deterministic system establishes one-to-one mappings between inputs and outputs and thus can be computed by passive mechanisms such as feature detectors. To achieve many-to-one simply requires a set of one-to-one detectors for different input signals. In other words, a many-to-one mapping (e.g., rising formant transitions signaling a labial stop and diffuse consonant release spectrum signaling a labial stop) can be instantiated as a collection of one-to-one mappings. However, in the case of a one-to-many mapping (e.g., a formant pattern that could signal either the vowel in BIT or BET) there is ambiguity about the interpretation of the input without additional information. One solution is that additional context or information could eliminate some alternative interpretations, such as talker information (Nusbaum & Magnuson, 1997). However, this leaves the problem of determining the nature of the constraining context and how it is processed, which

together are arguably contingent on the nature of the ambiguity itself. This suggests that there is no automatic or passive means of identifying and using the constraining information. Thus, an active mechanism that tests hypotheses about interpretations and tentatively identifies sources of constraining information (see Nusbaum & Schwab, 1986) is needed.

In spoken language understanding, active cognitive processing is vital to achieve flexibility and generativity (Nusbaum & Magnuson, 1997; Nusbaum & Schwab, 1986). Active cognitive processing is contrasted with passive processing in terms of the control mechanisms that organize the nature and sequence of cognitive operations (Nusbaum & Schwab, 1986). A passive process is one in which inputs map directly to outputs with no hypothesis testing or information-contingent operations as in the simple distance-based recognition system already described. Automated cognitive systems (see Shiffrin & Schneider, 1977) behave as though passive, in that stimuli are mandatorily mapped onto responses without flexibility or any demand on cognitive resources. However, it is important to note that cognitive automatization does not have strong implications for the nature of the mediating control system such that different mechanisms have been proposed to account for the appearance of automatic processing (e.g., Logan, 1988). By comparison, active cognitive systems have a control structure that permits “information contingent processing” or the ability to change the sequence or nature of operations in the context of new information or uncertainty. In principle, active systems can generate hypotheses to be tested as new information arrives or is derived (Nusbaum & Schwab, 1986) and thus provide substantial cognitive flexibility to respond to novel situations and demands. Understanding how and why such active cognitive processes are involved in speech perception is fundamental to the development of a theory of speech perception. However, what is important for understanding the neurobiology of speech perception is the notion that an active control system could, in principle, implicate brain regions that are outside the traditional perisylvian language processing regions. This assumes that the active control of speech perception requires changes in attention to pattern information, as well as the recruitment of brain regions involved in long-term memory for nonlinguistic knowledge, and working memory systems to maintain alternative linguistic interpretations.

When there are multiple alternative interpretations for a particular acoustic pattern, the information needed to constrain the selection depends on the source of variability that produced the nondeterminism, and this could arise due to variation in speaking rate, or talker, or linguistic context, or other

signal modifications. Whether the system uses articulatory or linguistic information or other contextual knowledge as a constraint, the perceptual system needs to flexibly use context as a guide in determining the relevant properties needed for recognition (Nusbaum & Schwab, 1986). The process of eliminating or weighing potential interpretations may involve working memory and changes in attention as alternative interpretations are considered, as well as adapting to new sources of lawful variability in context (Elman & McClelland, 1986). Similar mechanisms may be implicated at higher levels of linguistic processing in spoken language comprehension, although the neural implementation of such mechanisms might well differ depending on whether the nondeterminism occurred at the level of the speech signal, the lexical level, or the sentential level.

The involvement of cognitive mechanisms (e.g., working memory, attention) in speech perception remains controversial. In particular, one such mechanism, adaptability or plasticity in processing, has long been a point of theoretical contention. Although much of the controversy about learning in language processing has focused on syntax, there is also some disagreement about the plasticity of speech processing. At the center of this debate is how the long-term memory structures that guide speech processing are modified to allow for this plasticity while at the same time maintaining and protecting previously learned information from being expunged. This is especially important because often newly acquired information may represent irrelevant information to the system in a long-term sense (Born & Wilhelm, 2012; Carpenter & Grossberg, 1988).

17.3 ADAPTIVE PROCESSING AND PERCEPTUAL LEARNING

To overcome this problem, researchers have proposed various theories, and although there is no consensus, a hallmark characteristic of these accounts is that learning occurs in two stages. In the first stage, the memory system is able to use fast learning and temporary storage to achieve adaptability and in a subsequent stage, during an offline period such as sleep, this information is consolidated into long-term memory structures if the information is germane (Ashby, Ennis, & Spiering, 2007; Marr, 1971; McClelland, McNaughton, & O'Reilly, 1995). However, this kind of mechanism does not figure into speech recognition theories despite its arguable importance. Traditionally theories for speech recognition focus less on the formation of category representations and the need for plasticity during recognition than on the

stability and structure of the categories (e.g., phonemes) to be recognized. Theories of speech perception often avoid the plasticity–stability trade-off problem by proposing that the basic categories of speech are established early in life, tuned by exposure, and subsequently only operate as a passive detection system (e.g., Abbs & Sussman, 1971; Fodor, 1983; McClelland & Elman, 1986). However, even these kinds of theories, suggest that early exposure to a phonological system has important effects on speech processing.

Research has established that adult listeners can learn a variety of new phonetic contrasts from outside their native language (Best, McRoberts, & Sithole, 1988; Lively, Logan, & Pisoni, 1993; Logan, Lively, & Pisoni, 1991; Pisoni, Aslin, Perey, & Hennessy, 1982; Yamada & Tohkura, 1992). For example, Francis and Nusbaum (2002) demonstrated that listeners are able to learn to direct perceptual attention to acoustic cues that were not previously used to form phonetic distinctions in their native language. This change in perceptual processing can be described as a shift in attention (Nusbaum & Schwab, 1986), although other descriptions are used as well. Auditory receptive fields may be tuned (e.g., Cruikshank & Weinberger, 1996; Wehr & Zador, 2003; Weinberger, 1998; Znamenskiy & Zador, 2013) or reshaped as a function of appropriate feedback (cf. Moran & Desimone, 1985) or context (Asari & Zador, 2009). This is consistent with theories of category learning (e.g., Schyns, Goldstone, & Thibaut, 1998) in which category structures are related to corresponding sensory patterns (Francis, Kaganovich, & Driscoll-Huber, 2008; Francis, Nusbaum, & Fenn, 2007). This learning could also be described as cue weighting as observed in the development of phonetic categories (e.g., McMurray & Jongman, 2011; Nittrouer & Lowenstein, 2007; Nittrouer & Miller, 1997). Yamada and Tohkura (1992) describe native Japanese listeners as typically directing attention to acoustic properties of /r/-/l/ stimuli that are not the dimensions used by English speakers, and as such are not able to discriminate between these categories. This is because Japanese and English listeners distribute attention in the acoustic pattern space for /r/ and /l/ differently as determined by the phonological function of this space in their respective languages. Perceptual learning of these categories by Japanese listeners suggests a shift of attention to the English phonetically relevant cues. Recently, McMurray and Jongman (2011) proposed the C-Cure model of phoneme classification in which the relative importance of cues varies with context. Although the model does not specify a neural mechanism by which such plasticity is implemented, there are a number of possibilities. This kind of approach to learning or modifying phonetic categories provides a

mechanism that can support adaptation to contextual variability such as talker variability or other kinds of speech distortion.

Given that learning specific phonetic contrasts depends on changes in perceptual attention, learning the phonetic properties of a particular talker (distinct from more typical talkers) is relevant to the kinds of variability that reflect talker differences or might be produced by variation in speaking rate. For this reason, research on the way listeners learn to recognize low-quality synthetic speech produced, by rule, should be informative about the processes that underlie adaptation to talker variability and variation in speaking rate (Schwab, Nusbaum, & Pisoni, 1985). Synthetic speech learning has been demonstrated to generalize beyond the training exemplars to novel spoken words and contexts (Greenspan, Nusbaum, & Pisoni, 1988). Thus, listeners can learn the acoustic-phonetics that are idiosyncratic to a particular talker (Dorman et al., 1977). Furthermore, this kind of perceptual learning of the acoustic phonetics of a particular talker results in changes in attention to the speech signal (Francis, Baldwin, & Nusbaum, 2000). Moreover, this shift in attention between acoustic cues produces a restructuring of the perceptual space for that talker's speech (Francis & Nusbaum, 2002). Perceptual learning of a novel talker's speech results in a reduction in the cognitive load on working memory for recognizing the speech (Francis & Nusbaum, 2009). In other words, systematic experience listening to a novel talker allows a listener to learn the acoustic-phonetic mapping for a given talker. This learning increases the intelligibility of the talker's speech, which results from shifting attention to phonetically more relevant cues, which in turn lowers the working memory demands of speech perception. This is a hallmark of an active processing system—information about perceptual classification can be used to direct attention to improve performance and reduce the demands on working memory. However, although this demonstrates the operation of active cognitive processes during speech perception, it is more about learning the categories of speech or modifying those categories to be specific to improving recognition of that talker's speech.

Taken together, this work demonstrates that listeners are able to detect variance with known acoustic-phonetic patterns and to shift attention to appropriate cues, given feedback, in order to reduce uncertainty in interpretation and provides a computational solution to the one-to-many lack of invariance problem. Given a set of possible interpretations of a particular acoustic pattern, listeners may shift attention to the cues that discriminate among the alternative interpretations. The question, then, is whether such a mechanism seems to operate in circumstances of contextual (e.g., speaker or speaking rate) variability. If it is the case that sources

of variability impose a nondeterministic computational structure on the problem of perception, then it must follow that we can reject all theories that have an inherently passive control structure. In other words, it is our contention that phonetic constancy must be achieved by an active computational system (e.g., Nusbaum & Morin, 1992; Nusbaum & Schwab, 1986).

17.4 EMPIRICAL EVIDENCE FOR ACTIVE PROCESSING IN TALKER NORMALIZATION

Active control systems use a feedback loop structure to systematically modify computation to converge on a single, stable interpretation (MacKay, 1951, 1956). By comparison, passive control structures represent invariant computational mappings between inputs and outputs. In consideration of this distinction, there are two general patterns of behavioral performance that can be taken as empirical evidence for the operation of an active control system (see Nusbaum & Schwab, 1986, for a discussion). First, evidence of load sensitivity in processing should provide an argument for active processing. There are several ways to justify this claim. For example, automatized processing in perception occurs when there is an invariant mapping between targets and responses whereas controlled—load-sensitive—processing occurs when there is uncertainty regarding the identity of targets and distractors over trials or when there is no simple single feature difference to distinguish targets and distractors (e.g., Shiffrin & Schneider, 1977; Treisman & Gelade, 1980). In other words, when there are multiple possible interpretations of a stimulus pattern, processing shows load sensitivity, which may be manifest as an increase in processing time, a decrease in recognition accuracy, or an interaction with an independent manipulation of cognitive load (Navon & Gopher, 1979) such as digit preload (e.g., Baddeley, 1986; Logan, 1979).

Second, the appearance of processing flexibility as demonstrated by the effects of listener expectations, context effects, learning, or other forms of online strategic processing should indicate active processing. Although an active process need not demonstrate this kind of flexibility, a passive process by virtue of its invariant computational mapping certainly cannot. This means, for example, that evidence for the effects of higher-order linguistic knowledge on a lower-level perceptual task such as lexical influence on phonetic recognition (e.g., Samuel, 1986) should implicate an active control system in processing.

There is definitely a great deal of evidence arguing that speech perception is load-sensitive under conditions of talker variability. For example, the accuracy of

word recognition in noise and word recall is reduced when there is talker variability (speech produced by several talkers) compared with a condition in which a single talker produced the speech (Creelman, 1957; Martin, Mullennix, Pisoni, & Summers, 1989; Mullennix, Pisoni, & Martin, 1989). Talker variability also slows recognition time for vowels, consonants, and spoken words in a number of different experiments using a range of different paradigms (Mullennix & Pisoni, 1990; Nusbaum & Morin, 1992; Summerfield & Haggard, 1975). This provides some basic evidence that perception of speech is sensitive to talker variability, but it does not really indicate why this occurs.

Our view is that the evidence regarding the load sensitivity of the human listener when there is talker variability provides strong evidence that speech perception is performed by an active process. Furthermore, evidence of the flexibility of human listeners in processing speech, given talker variability, provides additional support. For example, we have found that listeners shift attention to different acoustic cues when there is a single talker and when there is talker variability (Nusbaum & Morin, 1992). In one condition, subjects monitored a sequence of spoken vowels for a specified target vowel, and the vowels were produced by one talker. In a second condition, a mix of different talkers produced the vowels. Both of these conditions were given with four different sets of vowels that were produced by LPC resynthesis of natural vowels used in our other experiments (Nusbaum & Morin, 1992). One set consisted of intact, four-formant voiced vowels. A second set consisted of the same vowels with voicing turned off to produce whispered counterparts. A third set was produced by filtering all information. A fourth set combined whispering with filtering to eliminate F0 and formant information above F2.

If listeners recognize vowels using a mechanism similar to the one described by Syrdal and Gopal (1986), then fundamental frequency and F3 information (although see Johnson, 1989, 1990a) should be necessary to recognition under all circumstances because their view is this information provides a talker-independent specification of vowel identity. This predicts that in both the single-talker and mixed-talker conditions, the intact voiced vowels should be recognized most accurately with whispering or filtering reducing performance somewhat and the combination reducing performance the most, because these modifications eliminate critical information for vowel recognition. Our results showed that in the single-talker condition, recognition performance was uniformly high across all four sets of stimuli. In the mixed-talker condition, however, accuracy dropped systematically as a function of the modifications of the stimuli with the voiced, intact vowels recognized most accurately and the whispered,

filtered vowels recognized least accurately (Nusbaum & Morin, 1992). If vowel recognition were performed by a passive, talker-independent mechanism (e.g., Syrdal & Gopal, 1986), then the same pattern of results should have been obtained in both the single-talker and mixed-talker conditions. The results we obtained suggest that listeners only direct attention to F0 and F3 when there is talker variability (cf. Johnson, 1989, 1990a). This kind of strategic flexibility in recognition is strong evidence of an active mechanism. Furthermore, it suggests that the reason for the increase in cognitive load given talker variability may be because the listener must distribute attention over more cues in the signal than when there is a single talker. Wong, Nusbaum, and Small (2004) demonstrated that talker variability increased brain activity consistent with an increase in cognitive load and mobilization of attention in superior parietal cortex.

Listener expectations affect talker normalization processes as well. In a previous study, we found that not all talker differences increase recognition time in a mixed-talker condition (Nusbaum & Morin, 1992; also see Johnson, 1990a). When the vowel spaces of talkers are sufficiently similar and their fundamental frequencies are similar, there may be no difference in recognizing targets when speech from these talkers is presented in separate blocks or in the same block of trials. Magnuson and Nusbaum (2007) performed a study designed to investigate more specifically under what conditions talker variability increases recognition time. In this study, two sets of monosyllabic words were synthesized with two different mean F0s differing by 10 Hz. In one condition, a small passage was played to subjects in which two synthetic talkers, differing in F0 by 10 Hz, have a short dialogue. In a second condition, another group of subjects heard a passage in which one synthetic talker used a 10-Hz pitch increment to accent certain words. Both groups then listened to exactly the same set of single-pitch and mixed-pitch recognition trials using the monosyllabic stimuli. The subjects who listened to the dialogue between two talkers showed longer recognition times when there was a mix of the two different F0s in a trial compared to trials that consisted of words produced at a single F0. By comparison, subjects who expected that the 10-Hz pitch difference was not a talker difference showed no difference in recognition times or accuracy between the single-pitch and mixed-pitch trials. This demonstrates two things. First, the effect of increased recognition time in trials with a mix of F0s cannot be attributed to a simple contrast effect (see Johnson, 1990b) because both groups received exactly the same stimuli. Instead, the increased recognition times in the mixed-pitch trials seem to reflect processing specific to the attribution of the pitch difference to a talker difference and not something about

the pitches themselves. Second, and perhaps more important for the present argument, the listeners' expectations affected whether they showed any processing sensitivity to pitch variability. This kind of processing flexibility cannot be accounted for by a simple passive computational system and argues strongly for an active perceptual mechanism (Nusbaum & Schwab, 1986).

17.5 TOWARD AN ACTIVE THEORY OF CONTEXTUAL NORMALIZATION

First and foremost, our view is that contextual normalization—using contextual variability as a perceptual frame for phoneme recognition—is carried out by the normal process of speech perception. In other words, talker or rate normalization is not carried out by a separate module or computational system, but it is a consequence of the basic computational structure of the normal operations of speech perception. This stands in sharp contrast to most previous approaches to normalization that emphasized the problem of computing talker vocal tract limits and scaling vowel spaces or base rates of speaking. It may be more productive to treat the processing of lawful variation as a single perceptual problem and focus on the commonalities rather than separating these problems based on the specific sources of information and knowledge needed to support normalization and recognition.

Second, the effects of talker or rate variability on perceptual processing directly reflect the computational operations needed to achieve phonetic constancy. Increased recognition times and interactions of varying cognitive load with recognition reflect the increased processing demands on capacity that are incurred by talker variability. Contextual variability increases the number of possible alternative interpretations of the signal, thereby increasing the processing demands on the listener. As a corollary of our first point, we predict that the same kinds of processing demands will be observed whenever there is any non-deterministic relationship between acoustic cues and linguistic categories during perceptual processing. Furthermore, even though there may be some relationship between the information used in talker identification and talker normalization, we claim that the perceptual effects of talker variability are not a consequence of talker identification processes competing with speech understanding. This is likely true of any aspect of contextual variability, although listeners are not typically called on to explicitly identify speaking rate or other forms of contextual variability.

Third, to achieve phonetic constancy, given a nondeterministic relationship between cues and categories, different sources of information and knowledge

beyond the immediate acoustic pattern to be recognized must be brought to bear on the recognition problem. For example, if the F1 and F2 extracted from an utterance could have been intended as either of two different vowels given talker variability, information about the vocal tract that produced the vowels (e.g., from F0 and F3) will be used to provide the context for interpretation. Whenever there is a one-to-many mapping between a particular acoustic pattern and linguistic categories, listeners will have to use information outside the specific pattern to resolve the uncertainty. This information could come from other parts of the signal, previous utterances, linguistic knowledge, or subsequent parts of the utterance.

To realize the kind of computational flexibility required for this approach, it is important to reconceptualize the basic process of speech perception. The standard view of speech perception is that phoneme recognition or auditory word recognition is a process of comparing auditory patterns extracted from an utterance with stored mental representations of pattern information associated with linguistic categories. Our view is that speech perception, as an active process, is basically a cognitive process as described by Neisser (1967) and is more akin to hypothesis testing than pattern matching (cf. Nusbaum & Schwab, 1986). Nusbaum and Henly (1992) have argued that linguistic categories need to be represented by structures that are much more flexible than have been previously proposed. They claimed that a particular linguistic category such as the phoneme /b/ might be better represented by a theory of what a /b/ is. This view is an extension of the argument of Murphy and Medin (1985) regarding more consciously processed, higher-order categories. From this perspective, a theory is a set of statements that provide an explanation that accounts for membership in a category. Rather than view a theory as a set of explicit verbal statements, our view is that a theory representation of a linguistic category is an abstract, general specification regarding the identity and function of that linguistic category. Although this could be couched as a set of features, it is more reasonable to think of a theory as something that would generate a set of features given particular contextual constraints.

Recognizing a particular phoneme or word is a process of generating a set of candidate hypotheses regarding the classification of the pattern structure of an utterance. Conjectures about possible categories that could account for a section of utterance are proposed based on the prior context, listener expectations, and information in the signal. Given a set of alternative classifications for a stretch of signal information, the perceptual system may then carry out tests that are intended to diagnose the specific differences among

the alternative classifications. Cognitive load increases as a function of the number of alternatives to be considered and the number of diagnostic tests that must be carried out.

By this view, phonetic constancy is the result of a process of testing hypotheses that have been tailored to distinguish between alternative linguistic interpretations of an utterance. An active control system mediates this process of hypothesis formation and testing. An abstract representation of linguistic categories in terms of theories provides the flexibility to apply diverse forms of evidence to this classification process allowing the perceptual system to resolve the non-deterministic structure produced by talker variability. These components taken together form a complex inferential system that has much in common with conceptual classification (Murphy & Medin, 1985) and other cognitive processes.

17.6 NEUROBIOLOGICAL THEORIES OF SPEECH PERCEPTION

There are a number of recently proposed theories of speech perception that have been framed in terms of brain regions identified as active during speech processing. To the extent that such theories are described as purely bottom-up recognition systems, wherein auditory coding leads to phonetic coding and then word recognition, it is difficult to reconcile that kind of architecture with evidence suggesting active processing in speech perception. Thus, neurobiological theories that are candidates for explaining recognition given contextual variability need to incorporate feedback or possibly feedforward information, although the difference in such models could well be testable in speech perception experiments. Moreover, such models seldom explicitly address the problem of talker or rate normalization, leaving the issues of the lack of invariance out of the domain of explanation. However, recent models have explicitly divided the neural processing of speech into dorsal and ventral streams following the neurobiology of visual processing models (Ungerleider & Mishkin, 1982). The difference among the models is typically in the functions attributed to these streams and their relationship. In considering visual perception, Bar (2003) explicitly proposed that the visual dorsal stream, typically conceived of as functional for object location or use (Milner & Goodale, 1995), may also serve as a fast pathway for coarse object classification, projecting through prefrontal cortex to ultimately connect with the ventral stream for object recognition. This proposal of interacting dorsal and ventral streams, interacting with prefrontal mechanisms for working memory, attention control, memory encoding, and goal and value

maintenance is quite different from some of the neurobiological models of speech perception because it explicitly incorporates both feedback and feedforward active processing using neural networks that are not typically viewed as “perceptual.” By contrast, neurobiological models of speech perception typically stay close to the perisylvian language areas, even when taking into account task effects in speech processing, albeit not explicitly considering active processing involving more general cognitive systems.

For example, [Hickok and Poeppel \(2007\)](#) have proposed a neurobiological model that explicitly separates ventral and dorsal speech processing streams identifying these largely with speech object recognition (ventral) and speech perception-production (dorsal). There is a somewhat unusual distinction made in this theory between speech perception and speech recognition as processes that double dissociate both functionally and cortically. Hickok and Poeppel define speech perception (as dissociated from speech recognition) as any sublexical task that involves the discrimination or categorization of auditory input. It is an active process that requires both working memory and executive control, but it does not necessarily lead to the lexical-sentential understanding of the speech signal. One could posit that such a network could play an important role in resolving the lack of invariance problem. Auditory–phonological representations that are “ambiguous” (in the ventral stream) mappings with more than one linguistic interpretation could, in principle, be resolved using the dorsal projections into auditory working memory and adaptive processing to shift attention between cues. However, this is not how Hickok and Poeppel describe the dorsal stream, which seems more functionally focused on word learning and metalinguistic task performance in speech perception experiments but is not identified as having any role in recognizing spoken language, although the connections are present within the model for this possibility. By contrast, utterances are recognized and understood by the process of speech recognition, which takes place solely within the ventral stream, transforming acoustic signals into mental lexicon representations.

This dual-stream neural network reflects a passive approach to speech recognition. An active process model of speech recognition would suggest that contextual influences processed in the dorsal stream may contribute to this comparison of multiple acoustic cues. However, because the cortical model proposed by Hickok and Poeppel does not explain how the ventral and dorsal streams interact, nor does it make clear how additional conceptual networks cited in the illustration of the model may influence these two pathways, the role of contextually based attentional changes cannot be explained by this model. Elsewhere,

[Hickok \(2012\)](#) has argued that the speech motor system (within the dorsal stream) does not play a causal role in speech perception, despite evidence demonstrating that activity within the putative dorsal stream is affecting speech perception ([Davis & Johnsrude, 2007](#); [Skipper, van Wassenhove, Nusbaum, & Small, 2007](#)).

By contrast, other models (e.g., [Davis & Johnsrude, 2007](#); [Friederici, 2012](#); [Rauschecker & Scott, 2009](#)) propose a more direct interaction between different pathways and brain regions. [Rauschecker and Scott \(2009\)](#) argue for a forward mapping ventral stream and an inverse mapping dorsal stream, which provides more explicitly for active processing. In the forward mapping pathway, the speech signal is decoded into linguistic categories in the inferior frontal cortex (IFC), which are then translated into articulatory/motor movements in premotor cortex (PMC). These articulatory representations of the speech signal are then sent to the inferior parietal lobe (IPL) as an efference copy. The inverse mapping stream essentially follows the same pathway in the reverse direction. Attentional and intentional demands originating in the IPL moderate the context-dependent motor plans that are activated in PMC and prefrontal cortex. These predictive motor plans are then compared with the sensory input processed by the IFC. Rauschecker and Scott posit that these two processing streams are active simultaneously, as the ventral stream solves the lack of invariance problem of the speech signal while the dorsal stream engages in domain-general linguistic processing beyond the maintenance of the phonological–articulatory loop.

[Friederici \(2012\)](#) argues for a more complex system in which four pathways are involved in speech processing. In many respects, this approach adds complexity to the dual-pathway model to account for sentence-level effects and explicit top-down processing as well as cognitive control mechanisms from prefrontal cortex. In doing so, this model goes beyond the more traditional perisylvian networks, but this is largely to accommodate the demands of syntactic complexity and sentence processing rather than the fundamental problems of lack of invariance in speech. This contrasts with [Davis and Johnsrude \(2007\)](#), who focus more on the role of active processing in basic speech perception. They argue that in the ventral pathway, multiple lexical interpretations of the speech input at various levels of representation must be activated in the IFC so that they may be compared with an echoic record of the incoming acoustic signal in the temporal cortex. This constant maintenance of the speech signal at multiple levels of representation allows top-down projections from the IFC to retune the perception of the acoustic signal at lower levels of the auditory pathway. Similarly, somato-motor representations of the acoustic input in the dorsal stream are projected both to the

IFC and downstream to areas of the temporal cortex to further influence perception of the signal at both upper and lower levels of the pathway. In this way, Davis and Johnsrude have created a neural model that definitively depicts speech perception as an active process.

Despite this improvement from the interpretation of speech recognition as a passive process, and the increased specificity and breadth of brain region interactions, perceptual learning of speech is not sufficiently explained. These models also fail to go beyond the cortico-cortical connections of speech processing. The auditory pathway begins well before the acoustic signal even reaches the primary auditory cortex and it has been well-established that there are more descending projections to these components of the peripheral nervous system than ascending projections (Huffman & Henson, 1990). Such evidence would suggest that a complete model of the neural substrates of speech perception should include the interaction between the cortical structures of the network and lower-level areas of the nervous system such as the thalamus, the auditory brainstem, and even the cochlea. To fully understand how speech perception adapts to the many variant cues in the speech signal, all components of the auditory pathway must be included in the neural model.

17.7 SUBCORTICAL STRUCTURES AND ADAPTIVE PROCESSING

The restriction of neural models of speech perception to cortical systems is in sharp contrast to the more cognitive–neurobiological models, such as the Ashby and Maddox (2005) model in which thalamus and striatum play important roles in fast mapping of category representations before slower sensorimotor cortical learning occurs or the complementary learning systems model (McClelland et al., 1995) in which fast learning occurs in the hippocampus and slower learning occurs in neocortical circuits. Acoustic input travels from the cochlea through the cochlear nucleus, the superior olive, the inferior colliculus, and the medial geniculate nucleus in the thalamus before reaching the primary auditory cortex. The connections between these structures contain twice as many descending projections from cortex as ascending projections to cortex. Evidence from animal models suggests that cortical structures utilize the corticofugal system to engage in egocentric selection, whereby they improve their own input from the brainstem through feedback and lateral inhibition (Suga, Gao, Zhang, Ma, & Olsen, 2002). Such processes allow for rapid readjustment of subcortical processing and long-term adjustments in cortex to facilitate associative learning.

In humans, higher-level cognitive functions clearly have an effect on subcortical structures as low as the cochlea, because selective attention has been shown to enhance the spectral peaks of evoked otoacoustic emissions (Giard, Collet, Bouchet, & Pernier, 1994; Maison, Michey, & Collet, 2001) and discrimination training has been directly related to enhanced suppression of click-evoked otoacoustic emissions (de Boer & Thornton, 2008). Despite the growing evidence that the corticofugal system plays an important role in audition, researchers of speech perception continue to overlook this network when delineating the neurobiological underpinnings of speech. If speech perception utilizes the same basic categorization processes as auditory perception in general, then the subcortical structures that play a large role in audition must be included in these neural networks.

The influence of top-down cortical processes on subcortical structures is most apparent in the auditory brainstem. Electrophysiological recordings of the auditory brainstem response have demonstrated that the frequency following response (FFR), a sustained response phase-locked to the fundamental frequency of a periodic stimulus and/or the envelope of the stimulus (Krishnan, 2007), reflects changes in higher-level cognitive processes such as attention and learning. Galbraith and Arroyo (1993) determined that the FFR is modulated by selective attention to dichotic tones, with the attended tone eliciting larger peak amplitudes in the FFR than the ignored tone. The FFR is also affected by the reallocation of attentional resources to another modality. When listeners are presented with auditory and visual stimuli simultaneously but instructed to only attend to the visual stimulus, the signal-to-noise ratio of the FFR to the auditory stimulus decreases compared with when attention is directed to the auditory stimulus (Galbraith, Olfman, & Huffman, 2003). Although in both of these examples the auditory input consisted of tones rather than speech, they clearly establish an attentional influence on the activity of the auditory brainstem, which may modify the signal that ultimately reaches the auditory cortex.

When the FFR is examined in response to speech stimuli, top-down influences of the linguistic categorization processes that occur at the level of the cortex can also be seen. The FFR to synthetic English vowels contains prominent spectral peaks at the first formant harmonics of the signal and smaller peaks at the harmonics between formants (Krishnan, 2002). The enhanced peaks found in the FFR at the first formant suggest that some form of categorization is already occurring at the level of the auditory brainstem. The representation of the input is modified to strengthen the important cues so that they are more prominent than the rest of the signal, indicating that the

translation of signal to lexical representations that occurs in the cortico-cortical connections of the speech network may influence the way in which the auditory brainstem represents the signal as it transfers it to higher points along the auditory pathway. [Krishnan, Xu, Gandour, and Cariani \(2005\)](#) compared the FFRs of Mandarin speakers and English speakers with four lexical tones used in Mandarin. They determined that Mandarin speakers had stronger pitch representations and smoother pitch tracking in their FFRs than did English speakers. They also had stronger representations of the second harmonic (F2) for all four tones. Based on these results, the researchers concluded that language experience may induce changes in the subcortical transfer of auditory input to enhance the representation of relevant linguistic features that are transmitted in the signal. The interaction between experience and brainstem activity is not exclusive to language experience. Musically trained individuals show earlier and larger FFRs and better phase-locking to the fundamental frequency in response to music stimuli as well as speech stimuli from their native language ([Musacchia, Sama, Skoe, & Kraus, 2007](#); [Wong, Skoe, Russo, Dees, & Kraus, 2007](#)).

These studies demonstrate the influence of perceptual experience and training on the responses of the auditory brainstem, a relatively low-level neural structure. However, such effects are currently outside the domain of neurobiological theories of speech perception. These data do, however, demonstrate descending and experiential effects on the processing of speech and other acoustic stimuli and can be taken to reflect an active processing system. Speech input varies in many ways, both between talkers and within a single talker. The top-down control of subcortical structures allows the system to adapt to these changes in the signal by enhancing the most relevant spectral cues in the auditory input before it even reaches the cortical speech recognition networks.

17.8 CONCLUSION

With the increase in neuroimaging methods and studies of speech perception, there are a number of new theories that are grounded in brain regions attempting to explain speech perception. In some respects these theories can be viewed as modifications of the longstanding theory of speech perception proposed in the 1800s by Wernicke focusing mostly on perisylvian brain regions and incorporating aspects of neural architecture from the dorsal-ventral distinction in vision. While these theories may differ in the degree to which there are feedback connections among regions, incorporation of brain regions outside the “traditional” Wernicke language areas, and

specificity of phenomena accounted for, there are two aspects of speech processing that are unaccounted for. First, the basic problem of lack of invariance in mapping acoustic patterns onto perceptual interpretations is not directly addressed. This problem has hindered the development of computer speech recognition systems, and yet neurobiological models of speech perception do not seem to recognize the need for such explanations. Moreover, this is a general problem of language understanding, not just speech perception. A similar many-to-many mapping can also be found between patterns at the syllabic, lexical, prosodic, and sentential level in speech and the interpretations of those patterns as linguistic messages. This is due to the fact that across linguistic contexts, speaker differences (idiolect, dialect, etc.), and other contextual variations, there are no patterns (acoustic, phonetic, syllabic, prosodic, lexical, etc.) in speech that have an invariant relationship to the interpretation of those patterns. For this reason, it could be beneficial to consider how these phenomena of acoustic perception, phonetic perception, syllabic perception, prosodic perception, lexical perception, and others are related computationally to one another and understand the computational similarities among the mechanisms that may subserve them ([Marr, 2010](#)).

Second, the plasticity of human speech perception and language processing, which is likely tied closely to the solution to the lack of invariance problem, is also not taken seriously. Such adaptive processing is at the core of human speech understanding rather than some kind of added-on system and is necessary to explain how listeners cope with talker and rate variability, as well as environmental noise and distortion. Explaining the kinds of neural mechanisms that mediate this kind of adaptive processing is key to explaining human speech perception as well as explaining language understanding more generally. Such explanations are unlikely to reside in exclusively cortical systems and need to take into account the fact that speech perception is carried out within the auditory pathway that has descending projections all the way down to the cochlea. Simply recognizing the need to develop a broader view of speech perception that incorporates brain regions outside the traditional perisylvian network (e.g., prefrontal attention-working memory regions, striatum, thalamus) and the need to explain speech perception in the context of an intrinsically active auditory system that has descending innervation to the cochlea is an advance over theories derived from 1800s neurology. However, now there is a need to develop theories that are explicit and testable based on this broader view that treats the perceptual processing of contextual variability in speech as central to understanding speech recognition rather than as a separable system.

Successful Speaking: Cognitive Mechanisms of Adaptation in Language Production

Gary S. Dell and Cassandra L. Jacobs

Beckman Institute, University of Illinois, Urbana, IL, USA

The language production system works. If a person is older than the age of 4, has no major brain pathology, and has been exposed to linguistic input that accords with their perceptual and motor abilities, then they will have developed a production system that transmits what they want to say. It works when the goal is only to say “hi,” and when the speaker attempts to communicate a complicated novel thought that takes several sentences to convey.

Successful linguistic communication is achieved by a division of labor between the speaker and the listener (Ferreira, 2008). Both the production and comprehension systems have to do their job. The speaker has to say something apt and understandable, and the listener must do the rest, which can include compensating for any of the speaker’s errors or other infelicities.

In this chapter, we focus on how the production system keeps up its end so that the listener is not overly burdened. Our central claim is that the production system benefits from a number of what we call *speaker tuning mechanisms*. Speaker tuning mechanisms are properties of the system that adapt it to current circumstances and to circumstances that are generally more likely. These include *implicit learning* mechanisms that create long-term adaptive changes in the production system, and a variety of short-term adaptive devices, including *error monitoring*, *availability-based retrieval*, *information-density sensitivity*, and, finally, *audience design*. Although we characterize these mechanisms in cognitive rather than neural terms, we include some pointers to relevant neurobiological data and mechanisms. In the following, we describe the production system generally and then focus on the long-term and then short-term speaker tuning mechanisms.

18.1 LANGUAGE PRODUCTION

The production system turns thoughts into sequences of words, which can be spoken aloud, inwardly spoken, or written down. Traditionally (Levelt, 1989), the production process consists of determining the semantic content of one’s utterance (*conceptualization*), translating that content into linguistic form (*formulation*), and *articulation*, as illustrated in Figure 18.1. Here, we focus on the second of these stages, which describes how intended meaning, sometimes called the *message*, is turned into an ordered set of words that are specified for their phonological content. That is, the formulation stage describes how CHASE (CAT1, RAT1, past) becomes /ðə.kæt.ˈtʃest.ðə.ræt/. (The “1” in “CAT1” represents a particular definite CAT). Much of the psycholinguistic and neuroscience research on formulation has concerned three subprocesses: (i) *lexical access*, the retrieval of appropriate words; (ii) *grammatical encoding*, the specification of the order and grammatical forms of those words; and (iii) *phonological encoding*, determining the pronunciation of the sequence of words. These are discussed in turn.

18.1.1 Lexical Access

Most experimental, clinical, and theoretical research on production has concerned lexical access and focuses on the production of single-word utterances. When given a picture that has been identified as the concept CAT, how does the speaker retrieve the word “cat”? Lexical access has been characterized as a two-step process (Garrett, 1975). First, the concept is mapped

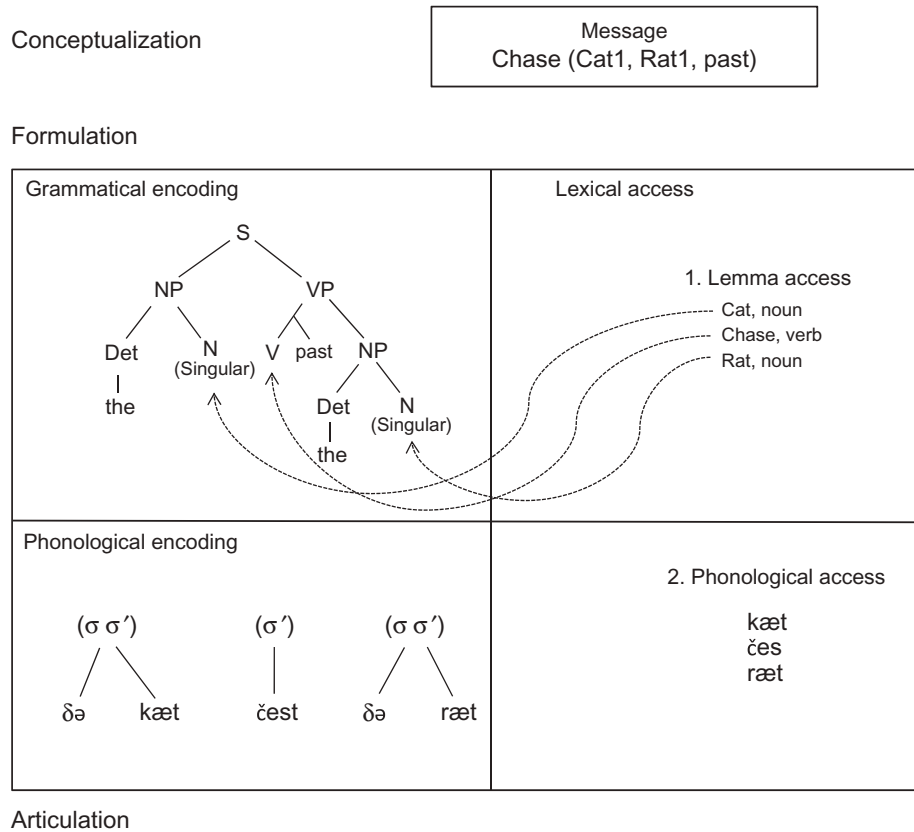

FIGURE 18.1 Components of the language production system.

onto an abstract lexical representation, variously called the *lemma*, the *L-level* representation, or simply the *word node*. This abstraction identifies the grammatical properties of the word such as its syntactic category (e.g., noun) and other grammatically relevant features (e.g., number, grammatical gender). Importantly, this level does not specify anything about pronunciation. That comes in the second step, where the word's phonological form, most often viewed as a sequence of phonemes, is retrieved. Intuitive support for the two-step notion comes from speech errors (Fromkin, 1971). Slips can profitably be divided into those that might have arisen during the first step (e.g., semantic errors such as “dog” for “cat”) and those that could have happened in the second step (e.g., “cap” for “cat”). Furthermore, the tip-of-the tongue state (“I know that word! It’s on the tip of my tongue”) can be characterized as getting stuck between the steps.

Much of the research on lexical access has concerned just how separate the two steps are. For example, the *modular discrete-step* view states that the first step must be completed before the second step can begin (Levelt, Roelofs, & Meyer, 1999). Alternatively, one could allow for *cascading*, which blurs the boundaries between the steps by allowing for phonological properties of potential word candidates to be retrieved before a single

lexical item has been settled on in the first step. Or, one could allow for *interaction*, which blurs the steps even further by allowing for relevant representations at each step to influence one another through the interactive spread of activation (see Dell, Nozari, & Oppenheim, 2014 for a recent review of the evidence for interaction between the steps, and see Dell, Schwartz, Nozari, Faseyitan, & Coslett, 2013 and Ueno, Saito, Rogers, & Lambon Ralph, 2011 for proposals regarding the neural correlates of the steps).

18.1.2 Grammatical Encoding

Although most production research concerns single-word utterances, the hallmark of production is the ability to construct multiword utterances, particularly those that the speaker has never said or even heard before. For example, William Blake famously used the phrase, “fearful symmetry” to characterize the tiger. And it is not just the poets who are linguistically inventive. Since Chomsky (1959) emphasized the creativity of language, it is a psycholinguistic cliché that most of what speakers say is novel. Regardless of whether this claim is strictly true, there is no doubt that theories must explain the production of novel utterances. The usual explanation is that the production system uses

syntactic-sequential abstractions that specify how word categories can combine to express structured messages. For Blake's phrase, the relevant abstractions would dictate that, in English, adjectives (*fearful*) precede nouns (*symmetry*). Production models of grammatical encoding (Bock, 1982; Chang, Dell, & Bock, 2006; Kempen & Hoenkamp, 1987) differ considerably, but all recognize the distinction between categorically specified abstractions and lexical items. Typically, the abstractions are characterized as *frames*, that is, structures that specify the sequence and phrasal membership of syntactically categorized word-sized slots (Dell, 1986; Garrett, 1975). So, there might be a noun-phrase frame with slots for a singular indefinite determiner, an adjective, and a singular count noun. And this frame may occupy a larger slot in a clausal frame, and so on. Because of the separation between words and their slots, the system has the means to encode new phrases (e.g., "a poetic tiger") by putting known words into known frames in new combinations. Evidence for such a system comes from dissociations in aphasia between individuals with lexical retrieval deficits and those with deficits in syntactic-sequential processes (e.g., see Gordon & Dell, 2003, for review), from functional imaging data that identify different brain areas for word-retrieval and word-combination mechanisms (e.g., Hagoort, 2013), and from structural priming studies, which are reviewed later.

18.1.3 Phonological Encoding

The retrieval of the phonological form of a word results in a sequence of phonological segments: k æ t. The segments are then put together with the segments of surrounding words, and the resulting sequence must be characterized in terms of its syllables and how those syllables are stressed (Levelt et al., 1999). These processes must respect the phonological properties of the language being spoken, including how segments combine to make syllables (*phonotactic* knowledge), how syllables are organized into higher-level prosodic structures, and how timing, pitch, and intensity vary as a function of those structures. Ultimately, this organized phonological structure guides the articulatory process. The phonological encoding process has been studied by assessing the response time to produce words and syllables (e.g., Cholin, Dell, & Levelt, 2011; Meyer, 1991), by examining phonological speech errors (Warker & Dell, 2006), by measuring the articulatory and acoustic details of utterances (e.g., Goldrick & Blumstein, 2006; Goldstein, Pouplier, Chen, Saltzman, & Byrd, 2007; Lam & Watson, 2010), and more recently by event-related brain potentials and other imaging techniques (e.g., Qu, Damian, & Kazanina, 2012).

18.2 LONG-TERM SPEAKER TUNING: IMPLICIT LEARNING

The production system does its job because it has learned to do so, and the basis for that learning is experience in comprehending and speaking (Chang et al., 2006). Learning, however, is not just something that children do. The typical adult speaker says approximately 16,000 words per day (Mehl, Vazire, Ramirez-Esparza, Slatcher, & Pennebaker, 2007) and hears and reads many more. This experience adapts the production system so that it is able to make effective choices in the particular circumstances that it finds itself. We refer to this continual process of adaptation as *implicit learning*. We claim that this adaptation is a kind of learning because the changes induced are not short-lived, and that the learning is implicit because it is an automatic consequence of linguistic experience that occurs without any intention to learn or awareness of what has been learned. In the remainder of this section, we review implicit-learning research in each of the three production subprocesses mentioned previously. For lexical access, we consider mechanisms of lexical repetition priming and frequency effects, and the possibility of phrasal frequency effects. For grammatical encoding, we discuss the hypothesis that structural priming in production is a form of implicit learning. And, for phonological encoding, we review studies that find implicit learning of novel phonotactic patterns.

18.2.1 Implicit Learning of Words and Phrases

The production system adapts to make the words that it is most likely to use easier to retrieve and articulate. In particular, words that we have said recently are easier to say than words that we have not said recently (*repetition priming*; e.g., Mitchell & Brown, 1988). We are also, in general, faster and more accurate at producing words that we have more experience saying, that is, frequent words (Caramazza, Costa, Miozzo, & Bi, 2001; Jescheniak & Levelt, 1994). Both repetition priming and frequency effects are thought to arise from and can be explained by implicit learning, which optimizes the production system for situations that are more likely to happen.

One manifestation of implicit learning in word production is *cumulative semantic interference* (e.g., Howard, Nickels, Coltheart, & Cole-Virtue, 2006). When we have to name a picture of the same thing twice (e.g., *crow*), we benefit from repetition priming. But, if instead of repeating the picture's name we next have to name something that is similar in meaning, but not the same word (e.g., *finch*), then we produce this word more slowly and have a greater chance of

error (e.g., Schnur, Schwartz, Brecher, & Hodgson, 2006). This negative effect is semantic interference. Oppenheim, Dell, and Schwartz (2010) investigated the “dark” (semantic interference) and “light” (repetition priming) sides of word production using a computational model, aptly called the “dark-side” model. In the model, each experience with a word tunes the production system by prioritizing words that are recently used and, importantly, deprioritizing their competitors, that is, semantically similar words. This tuning consists of the strengthening of connections to words when they are used, but weakening of connections to these words’ competitors. As a result, when a word is repeated it becomes relatively more active in the lexical network, effectively by leeching activation from similar words. In this way, repeating the word *crow* becomes easier, whereas naming different, but semantically similar, words in a sequence (e.g., *crow*, *finch*, *gull*) becomes increasingly difficult. This effect shows that the production system is adaptive, because words that are used and will likely be used again become easier to say, whereas words that could potentially interfere with those words are rendered less accessible and, hence, less disruptive.

We described how lexical access in production involves two steps, retrieval of the abstract lexical item and then retrieval of the item’s phonological form. We also noted that semantic errors such as “dog” for “cat” can occur at the first step, but phonological errors such as “cap” or “dat” for “cat” occur during the second step. We also said that recently spoken or high-frequency words (e.g., “cat” as opposed to “feline”) are less vulnerable to error because an implicit learning process enhances their retrieval. But does the greater ease associated with common or repeated words apply to both steps or just one of them? Jescheniak and Levelt (1994) proposed that frequency effects in word retrieval are felt largely during the second step. Others (e.g., Knobel, Finkbeiner, & Caramazza, 2008) claim that both steps benefit when the target word is frequent, because implicit learning should have an effect throughout the retrieval process. Kittredge, Dell, Verkuilen, and Schwartz (2008) addressed this question by looking at how target-word frequency affects semantic and phonological errors during picture naming. They presented aphasic participants with pictures to name that varied, among other factors, in their word frequency. They found, as expected, that the odds of saying the right word increased with the frequency of the target, demonstrating that common words are “protected” by their frequency. This protective power was found to prevent both semantic and phonological errors, suggesting that both steps of lexical retrieval benefit from frequency and, more

generally that the production system keeps track of likely events at all levels.

The production system also seems to keep track of and adapts to the degree to which words combine. Janssen and Barber (2012) explored this by looking at whether the frequency of the combination of two words (e.g., *red car* or *red hammer*) predicted how easily that phrase was generated. In particular, they presented participants with pictures of colored objects and had them name the object and its color with an appropriate phrase. They found that frequent phrases had faster naming latencies than would be predicted just by the frequency of the first or second word. This suggests that the production system tunes itself to probable events beyond the word level by keeping track of word combinations as well.

18.2.2 Structural Priming

One of the classic findings in psycholinguistics is structural priming, also known as syntactic priming, or structural repetition. Structural priming is the tendency for speakers to reuse recently experienced structures. Bock (1986a) gave experimental participants pictures that can be described with either of the two kinds of dative structures (double objects, “The woman handed the boy the paint brush,” versus prepositional datives, “The woman handed the paint brush to the boy”). Participants described these pictures after saying an unrelated prime sentence that used either a double-object or prepositional dative structure. Priming was seen in the tendency for speakers to use the structure of the prime when describing the picture. Similar effects were seen for other structural alternations such as active transitive sentences (“Lightning is striking the church”) versus passives (“The church is struck by lightning”). The important aspect of this priming is that it appears to be the persistence of an abstract syntactically characterized structure (e.g., the frame: *Noun_phrase Auxillary_verb Main_verb Prepositional_phrase* for a full passive), and not the lexical content of the utterance, its meaning, or its intonational properties (Bock & Loebell, 1990). As such, structural priming provides evidence for a production process that uses structural abstractions during grammatical encoding.

Bock and Griffin (2000) claimed that structural priming is not just a temporary change to the system, but instead it is a form of implicit learning, akin to the connection weight changes that characterize learning in connectionist models. They provided evidence for this claim by showing that the effect of a prime persists undiminished over at least 10 unrelated sentences (several minutes). If priming were due to temporary activation of a structure, then the prime’s influence

would rapidly decay. The evidence that the learning is implicit is that it occurs in brain-damaged speakers who have no explicit memory of the prime sentence (Ferreira, Bock, Wilson, & Cohen, 2008).

Chang et al. (2006) created a computational model that reflected the idea that structural priming is implicit learning. They trained a connectionist model to simulate a child experiencing sentences one word at a time. The model was also given a representation of the intended meaning of some of the sentences that it experienced, with this meaning presumably having been inferred by the child from context. The model learned by “listening” to each sentence and trying to predict each word. When the actual next word was heard, the model then compared its prediction to that word, thus generating a prediction error signal. This error signal was the impetus for the model to change its connection weights so that its future predictions were more accurate. By using prediction error, the model learned the linguistic patterns in the language (e.g., syntactic structures) and how those patterns mapped onto meaning (e.g., Elman, 1993). After this learning, the model was able to produce because “prediction is production” (Dell & Chang, 2014); generating the next word from a representation of previous words and intended meaning is, computationally, a production process. When given a representation of intended meaning, the model’s sequence of word predictions constituted the production of a sentence. The key aspect of this model, for our purposes, is that it accounted for structural priming through learning. Even after the model attained “adult” status, it continued to learn. When a prime sentence was experienced, the model’s connection weights were changed ever so slightly to favor the subsequent production of sentences with the same structure. Experiencing, for example, a double-object dative inclined the model to produce that structure later. Because the priming was based on weight change, it is a form of learning, thus accounting for Bock and Griffin’s finding that structural priming is undiminished over time. Also, the evidence that the implicit learning that characterizes structural priming is based on prediction error comes from demonstrations that less common, and hence more surprising, prime structures lead to more priming than common ones (e.g., Jaeger & Snider, 2013).

18.2.3 Phonotactic Learning

Young children implicitly learn the phonotactic patterns of their language through experience. Such patterns include knowledge about where certain consonants can occur in the syllables in their language; for example, in English, /h/ only occurs at the beginning of a syllable (the *onset*) and /ng/ occurs only at

the end (the *coda*). Because of their phonotactic knowledge, English speakers can readily produce the phonotactically legal nonword “heng,” but not the illegal “ngeh.” Evidence that the production system actively uses this knowledge comes from the *phonotactic regularity effect* on speech errors: slips tend to be phonotactically legal. One might mistakenly produce “nun” as “nung,” a phonotactically legal nonword, but not as “ngun” (Wells, 1951).

Warker and Dell (2006) and Dell, Reed, Adams, and Meyer (2000) created an experimental analogue to the phonotactic regularity effect in which participants recited four-syllable tongue twisters such as “hes feng kem neg” at a fast pace. Unbeknownst to the participants, the syllables followed artificial phonotactic patterns that were present only in the experimental materials. For example, a participant’s syllables might follow the pattern: *During the experiment, /f/ can only be a syllable onset and /s/ can only be a syllable coda* (as in the example four-syllable sequence above). Participants would recite several hundred of these sequences in each of four experimental sessions on consecutive days. Because of the fast speech rate, slips were reasonably common. Most often, these involved movements of consonants from one place to another, such as “hes feng kem neg” being spoken as “fes feng kem neg,” in which /f/ moved to the first syllable. The crucial feature of the study was whether these slips respected the phonotactics of the experienced syllables. As expected, slips of /h/ and /ng/ respected English phonotactics; /h/ is always moving to an onset position and /ng/ is always moving to a coda position. The crucial finding, though, was that slips of the artificially restricted consonants (/f/ and /s/ in our example) also respected the local phonotactics of the experiment. Notice in the example that /f/ slips to an onset position, that is, the slip is “legal” with regard to the experimental phonotactic patterns. And this was not just a small statistical tendency; 98% of the slips of experimentally restricted consonants were “legal” in this respect, whereas consonants that were not experimentally restricted the way that /f/ and /s/ were often slipped from onset to coda or vice versa (Dell et al., 2000).

Finding that slips respected the experimental distributions of consonants suggests that participants implicitly learned these distributions, and this learning affected their slips. But is this effect truly one of learning, as opposed to some very temporary priming of preexisting knowledge (e.g., priming of a rule that /f/ can be an onset in English)? Evidence that true learning is occurring comes from exposing participants to more complex “second-order” constraints such as: *if the vowel is /ae/, then /f/ must be an onset and /s/ must be a coda, but if the vowel is /I/, then /s/ must be an onset and*

/f/ must be a coda. Warker and Dell (2006) found that participants' slips did *not* follow this vowel-dependent second-order constraint on the first day of a 4-day experiment. On the second and subsequent days, though, the slips did obey the constraint (e.g., more than 90% of slips were legal). This suggests that the effect requires *consolidation*, a period of time (possibly involving sleep; Warker, 2013) in which the results of the experience are registered in a relatively permanent way in the brain. After consolidation, the effects appear to remain at least for 1 week (Warker, 2013). Because the effect requires consolidation and is persistent in time, it appears to be a form of learning. Thus, phonotactic-like knowledge and its expression in speech production errors can be tuned by an implicit learning process.

18.3 SHORT-TERM SPEAKER TUNING

Implicit learning is not the only mechanism that allows the production system to fluently generate appropriate, grammatically correct utterances that listeners can easily interpret. There are several adaptive phenomena in production that involve immediate processing, rather than long-term learning. These short-term tuning mechanisms include error monitoring, availability-based production choices, sensitivity to information density, and audience design.

18.3.1 Error Monitoring

Speakers help their listeners by avoiding making speech errors or, when an error occurs, by attempting to correct it. Catching slips before they happen or fixing them after they do requires that speakers do error monitoring. Studies of monitoring suggest that we detect at least half of our overt slips after they happen, and that we detect and block potential errors before they can occur (Baars, Motley, & MacKay, 1975; Levelt, 1983). Evidence that errors can be detected before they are spoken comes from the existence of very rapid detections of overt errors. Levelt (1983) gave the example of “v—horizontal.” The speaker started to say “vertical,” but quickly stopped and replaced it with the correct “horizontal.” The fact that speech was stopped right away (within 100 msec of the onset of the erroneous /v/) demonstrates that the error was almost certainly detected before articulation began. How is this possible? There are two theories of error detection. One is that speakers detect errors by comprehending their own speech and noting if there is a mismatch with what they intended (Hartsuiker & Kolk, 2001; Levelt, 1983). This view—the *perceptual loop theory*—allows for the comprehension of internal

speech before it is produced to explain the fact that errors can be detected before articulation. The alternative is that error detection occurs within the production system itself. An example of this is the *conflict detection theory* of Nozari, Dell, and Schwartz (2011), which proposes that the production system can assess the extent to which its decisions are conflicted and assumes, when conflict is high, that an error is likely. For example, suppose that during word access, the word CAT was selected during the first lexical-access step, but DOG was also nearly as activated as CAT. That can be taken as a sign that there was a possible error during that step. Similarly, if a particular speech sound, for example, /d/, is selected while another, /k/, is almost as active, again that can be a signal that there may have been a mis-selection, this time during the second access step. Nozari et al. used a computational model to demonstrate that the association between high conflict and error likelihood is a strong one, but also that the association no longer holds when the production system is functioning very poorly. Thus, for some aphasic individuals, conflict would not be an effective predictor of error and such individuals would be expected to have trouble detecting their own errors.

To test the conflict detection theory of monitoring and the competing perceptual loop theory, Nozari et al. (2011) examined how successful aphasic individuals were at detecting their own errors in a picture-naming task. The perceptual loop account predicts that good error detection should be associated with good comprehension because detection is performed by the comprehension system in that theory. In contrast, the conflict detection theory expects good detection to be associated with production rather than comprehension skill. The results supported the conflict detection account. The aphasic patients with higher rates of error detection had relatively good production skills, and comprehension ability was unrelated to error detection rate. Furthermore, Nozari and colleagues showed that patients who were relatively better at the first step of lexical access, but poor at the second step, could detect their first-step errors (e.g., semantic errors) but not their second-step errors (phonological errors). The complement was true as well—doing better on the second step in production implied better detection of second-step errors in particular. These results show that dissociations in production abilities for the lexical-access steps are mirrored in differential abilities to detect errors at the two steps, exactly as expected by the conflict detection theory.

Do the results of Nozari et al. (2011) mean that we do not detect errors by comprehending our own speech? No. These results only point to another possible mechanism for error detection, particularly a mechanism that

can detect errors before they happen. It seems likely that many overtly spoken slips are detected simply by hearing them, as proposed in the perceptual loop theory. In support of this claim, Lackner and Tuller (1979) found that using noise to mask a speaker's speech diminished the speaker's ability to detect their overt phonological errors, demonstrating that perception of the auditory signal plays a role in detection. It is therefore likely that multiple mechanisms contribute to the monitoring process. For example, speakers appear to guard their speech against slips that create taboo words (Motley, Camden, & Baars, 1982; see also Severens, Kühn, Hartsuiker, & Brass, 2012 for an fMRI study of frontal brain regions involved in taboo-word monitoring).

18.3.2 Availability-Based Production

The adage, "think before you speak" advises speakers to fully plan their utterances before saying them. The fact that the adage exists suggests that speakers do not routinely do this. Instead, language production involves some degree of *incrementality* (Kempen & Hoenkamp, 1987): utterances are often constructed and spoken in a piecemeal fashion, with the result that one might start talking before having planned the entire sentence. Because production can be incremental, the retrievability of the various parts of the utterance can influence its structure. For example, when attempting to produce the message illustrated in Figure 18.1, suppose that we are able to retrieve "rat," but have not yet retrieved "cat." We can start the utterance as "The rat..." and then, because English allows for a passive structure, can continue with "was chased by the cat" as we eventually retrieve the other words. Thus, the production system may opportunistically take advantage of the words that are retrieved first and may start with those words. This is the essence of availability-based production. What is retrieved first tends to be said first. More generally, what is available tends to be spoken as soon as it can. Although this strategy occasionally results in false starts, it makes for an efficient production system (Bock, 1982).

Bock (1986b) provided support for availability-based production by asking speakers to describe pictures such as one in which lightning is striking a church. This can be described with either an active ("Lightning is striking a church") or a passive ("The church is struck by lightning") structure. Earlier in this chapter, we showed how this structural choice can be influenced by structural priming. It turns out that this choice is also sensitive to the relative availability of the words "lightning" and "church." Bock found that

participants who had recently experienced the word "thunder," which presumably makes "lightning" more available, were more likely to describe the picture with the active form, making the primed word come out earlier. Similarly, priming "church" made the passive more likely.

One can also see availability-based production at work in choices about optional words. A sentence such as "The coach knew **that** you missed practice" can be produced with no "that," without changing the meaning of the sentence. So, what determines whether you include the "that"? One possibility is that speakers engage in *audience design*: when faced with a production choice, they choose what will make the sentence easier for their listener to understand. Notice that if the "that" is missing, then the sentence has a temporary ambiguity when "you" is heard. The "you" can be either the direct object of "knew" or the subject of a new embedded clause. Including the "that" removes the ambiguity. Ferreira (2008) and Ferreira and Dell (2000) suggested an alternative explanation for when "that" is present in these sentences. It has to do with the availability of the material after "that." If "you" has already been retrieved and is ready to go at the point in the sentence after "The coach knew..." then the speaker is more likely to omit "that." But if the speaker is not quite ready with "you," then including "that" is a convenient way to pause and buy time. As described in the subsequent section on information-density sensitivity, there is evidence that speakers do attempt to stretch time out at certain points in a sentence, and this can be thought of as an example of this. Here the issue is whether speakers produce "that" to disambiguate the utterance for their listeners, or because their production systems naturally produce whatever is available.¹ If the "you" is immediately available after "The coach knew," then the sentence can grammatically continue without the "that." Ferreira and Dell tested these ideas by comparing the production of four kinds of sentences:

- I knew (that) I missed practice.* (embedded pronoun is repeated and unambiguously nominative)
- You knew (that) you missed practice.* (embedded pronoun is repeated and ambiguous)
- I knew (that) you missed practice.* (embedded pronoun is not repeated and ambiguous)
- You knew (that) I missed practice.* (embedded pronoun is not repeated and unambiguously nominative)

The sentences were presented and then recalled in situations in which the participants could not remember whether there had been a "that" in the sentence

¹Of course, the grammar does not always allow you to eliminate "that" as a complementizer; "the girl that saw the boy is here" must have it in Standard American English.

and, hence, they tended to use their natural inclinations about whether to include “that.” The key variable was the percentage of recalled sentences with “that.” The hypothesis that speakers include “that” to help their listeners predicts that the two sentences with the ambiguous embedded “you” will include more instances of “that” than the unambiguous conditions that have the clearly nominative pronoun, “I,” as the embedded subject. The availability hypothesis predicts that because of repetition priming, the embedded pronoun (**I** or **you**) will be more available if it had just been said as the subject of the main clause. Because their embedded pronouns should be quite available, the two conditions with repeated pronouns are expected to have fewer instances of “that.” Across several experiments, there was no tendency for more “that”s in the ambiguous sentences, but repeating the pronoun caused the percentage of “that”s to decrease by approximately 9%. The results clearly supported the availability hypothesis, providing another demonstration that the production system’s decisions are opportunistically guided by what is easily retrieved. In the next section, we approach the question of the production of optional words like “that” from another angle.

18.3.3 Information-Density Sensitivity

One way that people may alter production in the short-term is by monitoring for and adjusting the probabilistic characteristics of what they are about to say. Taking a cue from information theory (Shannon, 1948), it has been proposed that speakers control the *rate of information* conveyed in their utterances so that there are as few as possible points in which the rate is extremely high or extremely low. Recall that, on a formal level, words or structures that are *less* likely contain *more* information and that, in the reverse case, *redundant* or predictable items are associated with less information. The idea is that keeping the information rate constant at a level that listeners can handle maximizes the effective transmission to the listener. Too fast a rate leads to loss of transmission, and too slow a rate wastes time. The hypothesized information constancy in production is termed the *smooth signal redundancy hypothesis* or, alternatively, *uniform information density* (UID). This tendency can be assumed to apply at all levels of language production, including lexical choice (Mahowald, Fedorenko, Piantadosi, & Gibson, 2013), syntactic structure (Jaeger, 2006, 2010), and phonetic and phonological output (Aylett & Turk, 2004).

Lexical, syntactic, phonological, and pragmatic predictability and given-ness, as constrained by the discourse or experiment, strongly influence the durations of individual words as would be expected from the UID. For example, the word *nine* in “A stitch in

time saves *nine*” is shorter than in the phrase “I’d like *nine*” (Lieberman, 1963) because the *nine* in the first example is highly predicted by the previous words. Speakers moderate duration and other prosodic cues in response to these linguistic factors, as has been demonstrated experimentally and in the wild, and this effect is robust even when a large number of other factors are taken into account (Jurafsky, Bell, Gregory, & Raymond, 2001).

Aylett and Turk (2004) examined the relationship between reduction and redundancy, or the contribution of statistical predictability to the short-term manifestation of phonetic output. They modeled the durations of syllables as a function of the degree to which they were predicted by the preceding information and the predictability of the word itself in discourse as well as its frequency of occurrence. They found evidence that individuals regulate the distribution of information in the signal (modulating various prosodic cues like duration, volume, and pitch) in that these cues represent a tradeoff between predictability and acoustic prominence. So, when a word is less predictable, it will carry more information in the sense that it is unexpected, but speakers take this into account by providing additional cues as to the identity of an upcoming word or syllable, such as articulating the word more loudly.

Jaeger (2006, 2010) identified analogous behavior in syntactic flexibility as a function of information density. Using evidence from the optional *that* structure that we introduced in the previous section, he demonstrated that the choice of whether to include a “that” provides the language production system with a means of redistributing information so that information density is more uniform across the utterance. For example, in sentences such as “My boss confirmed/thinks (that) we were absolutely crazy,” speakers were more likely to include “that” when the presence of a complement clause (e.g., “. . .we were absolutely crazy”) is unexpected given the main verb (e.g., “confirmed”). This is because *confirm* is a verb that most often takes a noun as its argument (e.g., “. . .confirmed the result”), and so the presence of a complement clause is less probable and therefore more surprising. In contrast, the verb *think* often takes a complement clause and, because that is more expected, “that” was less likely to be included in the utterance. In general, including a “that” when the complement clause is unexpected makes upcoming linguistic material less surprising for the listener, because “that” very commonly signals for a complement clause. The resulting overall structure is much more even in its syntactic surprisal. In this way, the speaker’s choices about optional *that* are sensitive to the goal of minimizing peaks and valleys in the information conveyed during the incremental production of the sentence.

These choices presumably translate into less effort for the listener. It is also possible that producing sentences with more UID directly aids the fluency of the production process, because what may be highly surprising to a listener may be relatively more difficult for speakers to create.

When we say that speakers “monitor” and “adjust” information density, this implies active online control. But control of information rate is not necessarily the result of an active short-term adaptation. Instead, the mechanisms that achieve good information rates may be learned as speakers gain experience about what production choices lead to effective comprehension (Jaeger & Ferreira, 2013). For example, speakers may consistently include “that” in their complement clauses introduced by main verbs such as “confirm” because they have learned that failure to do so leads to misunderstanding. With this view, there is no active control of information density; only the retention of successful speaking habits.

18.3.4 Audience Design

The language production system adapts to one’s partner, not only by avoiding high information rates but also by considering the partner’s specific needs and abilities; a speaker uses syntax, words, and phonology that the partner will likely understand. As we have outlined throughout this chapter, the production system can adapt to internal moment-by-moment demands, and it can change itself in the long-term as a function of experience. In this final section, we consider how the production system goes beyond what is easy for *it* to do, and instead considers what might best help the other person understand. This consideration is known as *audience design*. We discuss two examples of such design. First, we consider the way individuals use words that result in more effective communication on a cooperative task via a process called *entrainment* (Brennan & Hanna, 2009; Clark & Wilkes-Gibbs, 1986), and then how talkers can change their own pronunciation of words to facilitate understanding in *phonetic convergence* (Pardo, 2006).

Entrainment, or the convergence on a single term between two talkers in a conversation, is a necessary part of communication. It is estimated that approximately 50% of discourse entities are mentioned multiple times in a conversation or text (Recasens, de Marneffe, & Potts, 2013). Given this degree of repetition, it would be useful if speakers could agree on labels for those entities. If one party to a conversation referred to a particular plant as a “bush” and the other called it a “tree,” then confusion is likely. Agreement on terms through entrainment removes the confusion. In experimental settings, entrainment has been examined by looking at

how participants in a cooperative task describe an object and how that description changes as the participants continue to interact. In Clark and Wilkes-Gibbs (1986), participants had to cooperate to sort a set of abstract visual shapes (made up of “tangrams”) often resembling people or animals. Over the course of several turns, both partners came to use similar, eventually convergent terms or short phrases to describe the items. Early on, a speaker might recognize that the other person does not understand their initial description (e.g., “The next one is the rabbit.” “huh?”), requiring that the speaker elaborate (e.g., “That’s asleep, you know, it looks like it’s got ears and a head pointing down.”). As the experiment continues, the objects’ labels become increasingly shorter and the listener’s errors in interpreting what is said become rare, suggesting that talkers have optimized label length and form for communicative efficiency. The description of such a figure can go from the very complex on the first exchange (“looks like a person who’s ice skating, except they’re sticking two arms out in front”) to shorter, multiphrasal (“the person ice skating, with two arms”) to finally a single noun phrase (“the ice skater”). Thus, the entrainment process adapts the production systems of both participants in such a manner that communication success, rather than production ease, is the goal.

Phonetic convergence is a phenomenon where individuals adopt the phonetic and phonological representations of the other talker during a conversation. A person may adopt features of another’s accent, such as the famous US southern “pin-pen” merger or a northern cities vowel shift (e.g., “dawg” becomes “dahg”), or even more subtle features such as differences in voice-onset time. Pardo (2006) demonstrated such convergence experimentally. Participants completed a map task where one partner’s map (the receiver’s) needs to be drawn to look like the other’s (the giver’s). Like the tangram task used by Clark and Wilkes-Gibbs, the map task requires cooperative communication. There were many places on the map with standard names provided to the talkers (e.g., *abandoned monastery*, *wheat field*, etc.). Phonetic convergence of the speech of the talker pairs was assessed by naïve participants who were asked to judge the degree of similarity of the pairs’ pronunciations for these place names as they did the task. Not only did all conversation partners show some degree of convergence, but also these effects arose after very little interaction time—many partners showed convergent phonetics as early as before the halfway point in their dialogue, with convergence persisting into the second half as well. This convergence demonstrates that individuals engage in audience design by adopting the phonetic features of their conversation partner during a cooperative task. Because it is presumably easier for each speaker to use

his or her own accent, phonetic convergence counts as another example in which the adaptation suits the goal of communication, rather than the immediate ease of the production systems of the individual speakers.

18.4 CONCLUSION

Language production is, in one sense, difficult. The speaker has to decide on something worth saying, choose words (out of a vocabulary of 40,000), appropriate syntax, morphology, and prosody, and ultimately has to articulate at the rate of two to three words per second. In another sense, production is easy. We think it takes little effort. Particularly when we are talking about familiar topics, we can at the same time walk, drive, or even play the piano (Becic et al., 2010). The seeming paradox that something so difficult is yet so easy is resolved when we consider the mechanisms presented in this chapter. The production system is continually being tuned by the extraordinary amount of experience we have. We say 16,000 words per day and hear and read a lot more. The implicit learning that results from this input effectively trains the system and tunes it well to its current circumstances. But implicit learning is not the whole story. The production system also makes use of a variety of moment-by-moment mechanisms to compensate for and prevent errors, to promote fluency, and to make the job of the listener easier.

19.1 INTRODUCTION

Speech motor control is unique among motor behaviors in that it is a crucial part of the language system. It is the final neural processing step in speaking, where intended messages drive articulator movements that create sounds conveying those messages to a listener (Levelt, 1989). Many questions arise concerning this neural process we call speech motor control. What is its neural substrate? Is it qualitatively different from other motor control processes? Recently, research into other areas of motor control has benefited from a vigorous interplay between people who study the psychophysics and neurophysiology of motor control and engineers that develop mathematical approaches to the abstract problem of control. One of the key results of these collaborations has been the application of state feedback control (SFC) theory to modeling the role of the higher central nervous system (i.e., cortex, the cerebellum, thalamus, and basal ganglia—hereafter referred to as “the CNS”) in motor control (Arbib, 1981; Guigon, Baraduc, & Desmurget, 2008b; Shadmehr & Krakauer, 2008; Todorov, 2004; Todorov & Jordan, 2002). SFC postulates that the CNS controls motor output by estimating the current state of the thing (e.g., arm) being controlled and by generating controls based on this estimated state. SFC has successfully predicted a great range of the phenomena seen in nonspeech motor control, but as yet it has not received attention in the speech motor control community. Here, we review some of the key characteristics of how sensory feedback appears to be used during speaking and what this says about the role of the CNS in the speech motor control process. Along the way, we discuss prior efforts to model this role, but ultimately we argue that such

models can be seen as approximating characteristics best modeled by SFC. We conclude by presenting an SFC model of the role of the CNS in speech motor control and discuss its neural plausibility.

19.2 THE ROLE OF THE CNS IN PROCESSING SENSORY FEEDBACK DURING SPEAKING

It is not controversial that the CNS plays a role in speech motor output: cortex appears to be a main source of motor commands in speaking. In humans, the speech-relevant areas of motor cortex (M1) make direct connections with the motor neurons of the lips, tongue, and other speech articulators (Jürgens, 1982, 2002; Ludlow, 2004). Damage to these M1 areas causes mutism and dysarthria (Duffy, 2005; Jürgens, 2002). However, it is much less clear what the role of the CNS is in processing the sensory feedback from speaking. Sensory feedback, especially auditory feedback, is critically important for children learning to speak (Borden, Harris, & Raphael, 1994; Levitt, Stromberg, Smith, & Gold, 1980; Oller & Eilers, 1988; Osberger & McGarr, 1982; Ross & Giolas, 1978; Smith, 1975). However, once learned, the control of speech has the characteristics of being both responsive to, yet not completely dependent on, sensory feedback. In the absence of sensory feedback, speaking is only selectively disrupted. Somatosensory nerve block impacts only certain aspects of speech (e.g., lip rounding, fricative constrictions) and, even for these, the impact is not sufficient to prevent intelligible speech (Scott & Ringel, 1971). In postlingually deafened speakers, the control of pitch and loudness degrades rapidly after hearing loss, yet their speech will remain intelligible for decades

(Cowie & Douglas-Cowie, 1992; Lane et al., 1997). Normal speakers also produce intelligible speech with their hearing temporarily blocked by loud masking noise (Lane & Tranel, 1971; Lombard, 1911).

But this does not mean speaking is largely a feedforward control process that is unaffected by feedback. Delaying auditory feedback (DAF) by approximately a syllable's production time (100–200 ms) is very effective at disrupting speech (Fairbanks, 1954; Lee, 1950; Yates, 1963). Masking noise feedback causes increases in speech loudness (Lane & Tranel, 1971; Lombard, 1911), whereas amplifying feedback causes compensatory decreases in speech loudness (Chang-Yit, Pick, Herbert, & Siegel, 1975). Speakers compensate for mechanical perturbations of their articulators (Abbs & Gracco, 1984; Nasir & Ostry, 2006; Saltzman, Lofqvist, Kay, Kinsella-Shaw, & Rubin, 1998; Shaiman & Gracco, 2002; Tremblay, Shiller, & Ostry, 2003), and compensatory changes in speech production are seen when auditory feedback is altered in its pitch (Burnett, Freedland, Larson, & Hain, 1998; Elman, 1981; Hain et al., 2000; Jones & Munhall, 2000a; Larson, Altman, Liu, & Hain, 2008), loudness (Bauer, Mittal, Larson, & Hain, 2006; Heinks-Maldonado & Houde, 2005), formant frequencies (Houde & Jordan, 1998, 2002; Purcell & Munhall, 2006), or, in the case of fricative production, when the center of spectral energy is shifted (Shiller, Sato, Gracco, & Baum, 2007).

Taken together, such phenomena reveal a complex role for feedback in the control of speaking—a role not easily modeled as simple feedback control. Beyond this, however, there are also more basic difficulties with modeling the control of speech as being based on sensory feedback. In biological systems, sensory feedback is noisy due to environment noise and the stochastic firing properties of neurons (Kandel, Schwartz, & Jessell, 2000). Furthermore, when considering the role of the CNS in particular, an even more significant problem is that sensory feedback is delayed. There are several obvious reasons why sensory feedback to the CNS is delayed (e.g., by axon transmission times and synaptic delays; Kandel et al., 2000), but a less obvious reason involves the time needed to process raw sensory feedback into features useful in controlling speech. For example, in the auditory domain, there are several key features of the acoustic speech waveform that are important for discriminating between speech utterances. For some of these features, like pitch, spectral envelope, and formant frequencies, signal processing theory dictates that the accuracy in which the features are estimated from the speech waveform depends on the duration of the time window used to calculate them (Parsons, 1987). In practice, this means such features are estimated from the acoustic waveform using sliding time windows with lengths of approximately 30–100 ms in duration. Such integration-window-based feature estimation methods are slow to

respond to changes in the speech waveform, and thus they will effectively introduce additional delays in the detection of such changes. Consistent with this theoretical account, studies show that response latencies of auditory areas to changes in higher-level auditory features can range from 30 ms to more than 100 ms (Cheung, Nagarajan, Schreiner, Bedenbaugh, & Wong, 2005; Godey, Atencio, Bonham, Schreiner, & Cheung, 2005; Heil, 2003). A particularly relevant example is the long (~100 ms) response latency of neurons in a recently discovered area of pitch-sensitive neurons in auditory cortex (Bendor & Wang, 2005). As a result, while auditory responses can be seen within 10–15 ms of a sound at the ear (Heil & Irvine, 1996; Lakatos et al., 2005), there are important reasons to suppose that the features needed for controlling speech are not available to the CNS until a significant time (~30–100 ms) after they are peripherally present. This is a problem for feedback control models, because direct feedback control based on delayed feedback is inherently unstable, particularly for fast movements (Franklin, Powell, & Emami-Naeini, 1991).

19.3 THE CNS AS A FEEDFORWARD SOURCE OF SPEECH MOTOR COMMANDS

Given these problems with controlling speech via sensory feedback control, it is not surprising that, in some models of speech motor control, the role of the CNS has been relegated to being a pure feedforward source, outputting desired trajectories for the lower motor system to follow (Ostry, Flanagan, Feldman, & Munhall, 1991, 1992; Payan & Perrier, 1997; Perrier, Ostry, & Laboissiere, 1996; Sanguineti, Laboissiere, & Ostry, 1998; Sanguineti, Laboissiere, & Payan, 1997). In these models, it is the lower motor system (e.g., brainstem and spinal cord) that implements feedback control and responds to feedback perturbations. The inspiration for these models comes from consideration of biomechanics and neurophysiology. A muscle has mechanical spring-like properties that naturally resist perturbations (Hill, 1925; Zajac, 1989), and these spring-like properties are further enhanced by somatosensory feedback to the motor neurons in the brainstem and spinal cord that control the muscle (e.g., for the jaw: Pearce, Miles, Thompson, & Nordstrom, 2003; see also the stretch reflex: Hulliger, 1984; Matthews, 1931; Merton, 1951). This local feedback control of the muscle makes it look, on first approximation, like a spring with an adjustable rest-length that can be set by control descending from the higher levels of the CNS (Asatryan & Feldman, 1965). The muscles affecting an articulator's position (e.g., the muscles controlling the position of the tongue tip) always come in opposing

pairs—agonists and antagonists—whose contractions have opposite effects on articulator position. Thus, for any given set of muscle activations, an articulator will always come to rest at an *equilibrium point* where the muscle forces are balanced. In response to perturbations from its current equilibrium point, the articulator will naturally generate forces that return it to the equilibrium point, without any higher-level intervention. This characteristic was the inspiration for models of motor control based on equilibrium point control (EPC) (Bizzi, Accornero, Chapple, & Hogan, 1982; Feldman, 1986; Polit & Bizzi, 1979). EPC models postulate that to control an articulator's movement, the higher-level CNS need only provide the lower motor system with a sequence of desired equilibrium point to specify the trajectory of that articulator. The lower motor system handles responses to perturbations.

In speech, EPC models can explain the phenomenon of “undershoot,” or “carryover,” *coarticulation* (Lindblom, 1963). This can be seen when a speaker produces a vowel in a consonant-vowel-consonant (CVC) context: as the duration of the vowel segment is made shorter, the formants of the vowel do not reach (i.e., they undershoot) their normal steady-state values. This undershoot is easily explained by supposing that successive equilibrium points are generated faster than they can be achieved. In the case of a rapidly produced CVC syllable, undershoot of vowel formants would happen if, while it was still moving toward the equilibrium point for the vowel, the tongue was retargeted to the equilibrium point of the following consonant.

There are, however, several problems with the EPC account of the lower motor system being solely responsible for feedback control. First, although both somatosensory (Jürgens, 2002; Kandel et al., 2000) and auditory (Burnett et al., 1998; Jürgens, 2002) pathways make subcortical connections with descending motor pathways, the latencies of responses to somatosensory and auditory feedback perturbations (approximately 50–150 ms) are longer than would be expected for subcortical feedback loops (Abbs & Gracco, 1983). Instead, such response delays appear sufficiently long enough for neural signals to go to and come from cortex (Kandel et al., 2000). By themselves, such timing estimates do not prove involvement of cortex, but a study by Ito and Gomi using transcranial magnetic stimulation (TMS) gives further evidence (Ito, Kimura, & Gomi, 2005). The authors examined the facilitatory effect of applying a subthreshold TMS pulse to mouth motor cortex on two oral reflexes: the compensatory response by the upper lip to a jaw-lowering perturbation during the production of /ph/ (a soft version of /f/ in Japanese made only with the lips) and a response to upper lip stimulation known to be subcortically mediated called the perioral reflex. The TMS pulse was applied approximately

10 ms before the time of the reflex response (i.e., at the time motor cortex would be activated if it governed the response). The authors found motor TMS only facilitated the response to jaw perturbation during /ph/, implicating cortex involvement specifically in only the task-dependent perturbation response during speaking.

Perhaps a larger problem with ascribing feedback control to only subcortical levels is that responses to sensory feedback perturbations in speaking often look task-specific. For example, perturbation of the upper lip will induce compensatory movement of the lower lip, but only in the production of bilabials. The upper lip is not involved in the production of /f/ and perturbation of the upper lip before /f/ in /afa/ induces no lower lip response. However, the upper lip is involved in the production of /p/ and, here, perturbation of the upper lip before /p/ in /apa/ does induce compensatory movement of the lower lip (Shaiman & Gracco, 2002). Task-dependence is also seen in responses to auditory feedback. The production of vowels in stressed syllables appears to be more sensitive to immediate auditory feedback than vowels in unstressed syllables (Kalveram & Jancke, 1989; Natke, Grosser, & Kalveram, 2001; Natke & Kalveram, 2001), responses to pitch perturbations are modulated by how fast the subject is changing pitch (Larson, Burnett, Kiran, & Hain, 2000), and responses to loudness perturbations appear to be modulated by syllable emphasis (Liu, Zhang, Xu, & Larson, 2007). Such task-dependent perturbation responses cannot be simply explained with pure feedback control by setting stiffness levels (i.e., muscle impedance) for individual articulators (e.g., upper lip or lower lip) and instead suggest that, depending on the task (i.e., the particular speech target being produced), the higher-level CNS uses sensory feedback to couple the behavior of different articulators in ways that accomplish a higher-level goal (e.g., closing of the lip opening) (Bernstein, 1967; Kelso, Tuller, Vatikiotis-Bateson, & Fowler, 1984; Saltzman & Munhall, 1989).

There is also evidence that the CNS is sensitive to the dynamics of the articulators. In controlling fast movements, the CNS behaves as if it does anticipate that the articulators will have dynamical responses to its motor commands. For example, arm movement studies have shown that fast movements are characterized by a “three-phase” muscle activation sequence whereby an initial burst of activation of the agonist muscle accelerates the articulator quickly toward its target, followed by, at approximately mid-movement, a “breaking” burst of antagonist muscle activation that decelerates the articulator, causing it to come to rest near the target (followed, in turn, by a weaker agonist burst to further correct the articulator's position) (Hallett, Shahani, & Young, 1975; Shadmehr & Wise, 2005; Wachholder & Altenburger, 1926). Such activation patterns appear to take advantage of the momentum of the arm. When

equilibrium points are determined for such muscle activations, they appear to follow complex trajectories, initially racing far ahead of the target position before finally converging back to it (Gomi & Kawato, 1996). Yet, in such cases, the actual trajectory of the arm is always a smooth path to the target that greatly differs from the complex equilibrium point trajectory. This mismatch suggests that even if the CNS were outputting “desired” articulatory trajectories to the lower motor system, it does so by taking into account dynamical responses to these trajectory requests, such that a fast smooth motion is achieved.

This ability of the CNS to take articulator dynamics into account can also be seen in speech production. A series of experiments has shown that speakers will learn to compensate for perturbations of jaw protrusion that are dependent on jaw velocity (Nasir & Ostry, 2008, 2009; Tremblay, Houle, & Ostry, 2008; Tremblay et al., 2003). In learning to compensate for such altered articulator dynamics, speakers show that they are formulating articulator movement commands that anticipate and cancel out the effects of those altered dynamics. Thus, the ability to anticipate articulator dynamics is not only a theoretically desirable property of a model of speech motor control but also a property required to account for real experimental results.

Taken together, these several lines of evidence suggest that, rather than simply instructing the lower motor system on what its goals are, the CNS instead likely plays an active role in responding to sensory information about deviations from task goals.

19.4 CURRENT MODELS OF THE ROLE OF THE CNS IN SPEECH MOTOR CONTROL

Current models of speech motor control can trace their lineage back to Fairbanks’ early model. With the advent of cybernetic theory (Wiener, 1948) and the discovery of the effects of DAF soon after (Lee, 1950), it was natural that at conference in 1953, Fairbanks would propose a model of speech motor control based in large part on the principles of feedback control (Fairbanks, 1954). A key element of Fairbanks’ model was a “comparator” that subtracted sensory feedback (including auditory feedback) from a target “input signal,” creating an “error signal” that was used in the control of the vocal tract articulators. However, given the aforementioned phenomena concerning auditory feedback, it is not surprising that current models of speech motor control are significantly more complicated than simple feedback control models. Even Fairbanks appeared to hedge on proposing a model completely based on feedback control. In his model, the “error signal” output of

his feedback control subsystem does not drive the vocal tract directly. Instead, it is first combined with the “input signal” (the output of a feedforward control subsystem) by a “mixer” element to create the “effective driving signal” that directly controls the vocal tract. This combination of feedback and feedforward control subsystems is similar in design to that of the current Directions into Velocities of Articulators (DIVA) model of speech motor control (Guenther, 1995; Guenther, Ghosh, & Tourville, 2006; Guenther, Hampson, & Johnson, 1998; Guenther & Vladusich, 2012), although the feedforward control subsystem in DIVA is implemented as an internal feedback loop, which we describe further.

Feedback control models can be considered the most extreme implementation of the efference copy hypothesis, where the motor-derived prediction functions as the target output, and comparison with this target/prediction results in a prediction error that directly drives the motor control output. In current speech motor control models, the efference-copy/feedback prediction process is still used to create a correction, but that correction does not directly generate output controls. Instead, it is a contributing factor in the generation of output controls. These models retain the concept of feedback control but put the feedback loop inside the CNS, where processing delays are minimal, with actual sensory feedback forming a slower, possibly delayed and intermittent, external loop that updates the internal feedback loop (Guenther & Vladusich, 2012; Hickok, Houde, & Rong, 2011; Houde & Nagarajan, 2011; Price, Crinion, & Macsweeney, 2011; Tian & Poeppel, 2010). It turns out that such models can be described as variations in the general theory of SFC, developed in the domain of modern control engineering theory, which is based on the concept of a dynamic state.

19.5 THE CONCEPT OF DYNAMICAL STATE

A key feature of these current models of speech motor control is their outer sensory processing loops are based on comparing incoming feedback with a prediction of that feedback. To make such sensory predictions, the CNS would ideally base them not on what the current articulatory target was, but instead on the actual articulatory commands currently being sent to the articulators (i.e., true efference copy of the descending motor commands output to the motor units of the articulators). However, without a model of how these motor commands affect articulator dynamics, accurate feedback predictions cannot be made because it is only through their effects on the dynamics of the articulators that motor commands affect articulator positions and velocities, and thus acoustic output and somatosensory feedback from the vocal tract.

But how can we model the effects of motor commands on articulator dynamics? To say that vocal tract articulators have “dynamics” is another way of saying that how they will move in the future and how they will react to applied controls are dependent on their immediate history (e.g., the direction they were last moving in). The past can only affect the future via the present; in engineering terms, the description of the present sufficient to predict how a system’s past affects its future is called the dynamical *state* of the system. It is this concept of dynamical state that is basis for engineering models of systems and how they respond to applied controls.

Based on these ideas, Figure 19.1 illustrates how the problem of controlling speaking can be phrased in terms of the control of vocal tract state. This discrete time description represents a snapshot of the speech motor control process at time t , where the controls \mathbf{u}_{t-1} formulated at the previous timestep $t - 1$ have now been applied to the muscles of the vocal tract, changing its dynamic state to \mathbf{x}_t , which in turn results in the vocal tract outputting \mathbf{y}_t . In this process, \mathbf{x}_t represents an instantaneous dynamical description of the vocal tract (e.g., positions and velocities of various parts of the tongue, lips, or jaw) sufficient to predict its future behavior and $\mathbf{vtdyn}(\mathbf{u}_{t-1}, \mathbf{x}_{t-1})$ expresses the physical processes (e.g., inertia) that dictate what next state \mathbf{x}_t will result from controls \mathbf{u}_{t-1} being applied to prior state \mathbf{x}_{t-1} . The next state \mathbf{x}_t is also partly determined by random disturbances \mathbf{w}_{t-1} (called state noise). A key part of this formulation is that \mathbf{x}_t is not directly observable from sensory feedback. Instead, output function $\mathbf{vtout}(\mathbf{x}_t)$ represents all the physical and biophysical processes causing \mathbf{x}_t to generate sensory consequences \mathbf{y}_t . \mathbf{y}_t is also corrupted by noise \mathbf{v}_t and delayed by \mathbf{z}^{-N} , where \mathbf{N} is a vector of time delays representing the time taken to neurally transmit each element of \mathbf{y}_t to the higher CNS and process it into a control-useable form (e.g., into pitch, formant frequencies, tongue height). Furthermore, certain elements of \mathbf{y}_t can be intermittently unavailable, as when auditory feedback is blocked by noise. Therefore, from this description, the control of vocal tract state can be summarized as follows: how can the

higher CNS correctly formulate the next controls \mathbf{u}_t to be applied to the vocal tract given access only to previously applied controls \mathbf{u}_{t-1} and noisy, delayed, and possibly intermittent feedback \mathbf{y}_{t-N} ?

19.6 A MODEL OF SPEECH MOTOR CONTROL BASED ON STATE FEEDBACK

An approach to this problem is based on the following idealization shown in Figure 19.2: If the state \mathbf{x}_t of the vocal tract is available to the CNS via immediate feedback, then the CNS could control vocal tract state directly via feedback control. For this reason, this control approach is referred to as SFC. However, as discussed, because \mathbf{x}_t is not directly observable from any type of sensory feedback, and because the sensory feedback that comes to the higher CNS is both noisy and delayed, the scheme as shown is unrealizable. As a result, a fundamental principle of SFC is that control must instead be based on a running internal *estimate* of the state \mathbf{x}_t (Jacobs, 1993). The first step toward getting this estimate is another idealization. Suppose, as shown in Figure 19.3, the higher CNS had an internal model of the vocal tract, vocal tract, which had accurate forward models of the dynamics $\mathbf{vtdyn}(\mathbf{u}_{t-1}, \hat{\mathbf{x}}_{t-1})$ and output function $\mathbf{vtout}(\hat{\mathbf{x}}_t)$ (i.e., its acoustics, auditory and somatosensory transformations) of the actual vocal tract. Such an internal model could mimic the response of the real vocal tract to applied controls and provide an estimate $\hat{\mathbf{x}}_t$ of the actual vocal tract state. In this situation, the controller could permanently ignore the feedback \mathbf{y}_{t-N} of the actual vocal tract and perform ideal SFC $\mathbf{U}_t(\hat{\mathbf{x}})$ based only on $\hat{\mathbf{x}}_t$. The controls \mathbf{u}_t thus generated would correctly control both vocal tract and the actual vocal tract.

But this situation is still idealized. The vocal tract state \mathbf{x}_t is subject to disturbances \mathbf{w}_{t-1} , and the forward

FIGURE 19.1 The control problem in speech motor control. The figure shows a snapshot at time t , when the vocal tract has produced output \mathbf{y}_t in response to the previously applied control \mathbf{u}_{t-1} .

FIGURE 19.2 Ideal SFC. If the controller in the CNS had access to the full internal state \mathbf{x}_t of the vocal tract system (red path), then it could ignore feedback \mathbf{y}_{t-N} and formulate an SFC law $\mathbf{U}_t(\mathbf{x}_t)$ that would optimally guide the vocal tract articulators to produce the desired speech output \mathbf{y}_t . However, as discussed in the text, the internal vocal tract state \mathbf{x}_t is, by definition, not directly available.

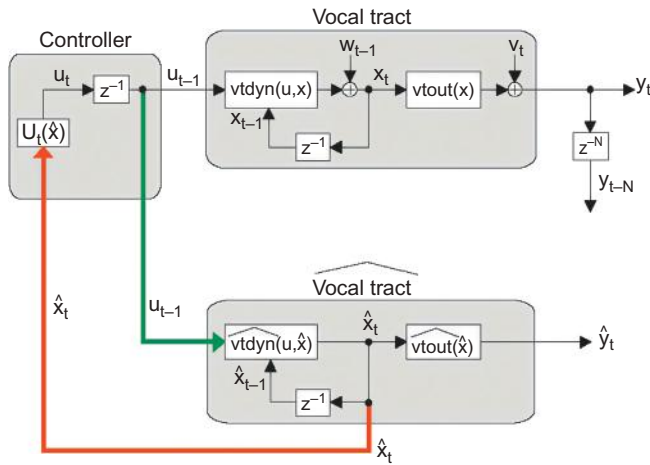

FIGURE 19.3 A more realizable model of SFC based on an estimate \hat{x}_t of the true internal vocal tract state x_t . If the CNS had an internal model of the vocal tract **vocal tract**, comprising dynamics model $\widehat{vtdyn}(u, x)$ and sensory feedback model $\widehat{vtout}(x)$, then it could send efference copy (green path) of vocal tract controls u_{t-1} to the internal model, whose state \hat{x}_t is accessible and could be used in place of x_t in the controller's feedback control law $U_t(\hat{x})$ (red path). However, this scheme only works if \hat{x}_t always closely tracks x_t , which is not a realistic assumption.

models $\widehat{vtdyn}(u_{t-1}, \hat{x}_{t-1})$ and $\widehat{vtout}(\hat{x}_t)$ could never be assumed to be perfectly accurate. Furthermore, **vocal tract** could not be assumed to start out in the same state as the actual vocal tract. Thus, without corrective help, \hat{x}_t will not, in general, track x_t . Unfortunately, only noisy and delayed sensory feedback y_{t-N} is available to the controller, and y_{t-N} is not tightly correlated with the current vocal tract state x_t . Nevertheless, because y_{t-N} is not completely uncorrelated with x_t , it carries some information about x_t that can be used to correct \hat{x}_t . Figure 19.4 shows how this can be done by augmenting the idealization shown in Figure 19.3 to include the following prediction/correction process. First, in the prediction (green) direction, efference copy of the previous vocal tract control u_{t-1} is input to forward dynamics model $\widehat{vtdyn}(u_{t-1}, \hat{x}_{t-1})$ to generate a prediction $\hat{x}_{t|t-1}$ of the next vocal tract state. $\hat{x}_{t|t-1}$ is then delayed by $\frac{z^{-N}}{z^{-1}}$ to match the actual sensory delays. The resulting delayed state estimate $\hat{x}_{(t|t-1)-\hat{N}}$ is input to forward output model $\widehat{vtout}(\hat{x}_t)$ to generate a prediction $\hat{y}_{t-\hat{N}}$ of the expected sensory feedback y_{t-N} . The resulting sensory feedback prediction error $\hat{y}_{t-\hat{N}} = y_{t-N} - \hat{y}_{t-\hat{N}}$ is a measure of how well \hat{x}_t is currently tracking x_t (note, for example, if \hat{x}_t was perfectly tracking x_t , then $\hat{y}_{t-\hat{N}}$ would be approximately zero). Next, in the correction (red) direction, feedback prediction error $\hat{y}_{t-\hat{N}}$ is converted into state estimate correction \hat{e}_t by the function $K_t(\hat{y})$. Finally, \hat{e}_t is added to the original next state prediction $\hat{x}_{t|t-1}$ to derive the corrected state estimate \hat{x}_t . By this process, therefore, an accurate estimate of the true vocal

tract state x_t can be derived in a feasible way and used by the SFC law $U_t(\hat{x}_t)$ to determine the next controls u_t output to the vocal tract.

As Figure 19.4 indicates, the combination of **vocal tract** plus this feedback-based correction process is called an *observer* (Jacobs, 1993; Stengel, 1994; Tin & Poon, 2005; Wolpert, 1997), which in this case, because it includes allowances for feedback delays, is also a variant of a *Smith Predictor* (Mehta & Schaal, 2002; Miall, Weir, Wolpert, & Stein, 1993; Smith, 1959). Within the observer, $K_t(\hat{y})$ converts changes in feedback to changes in state. When it is optimally determined, $K_t(\hat{y})$ is a feedback gain proportional to how correlated the feedback prediction error $\hat{y}_{t-\hat{N}}$ is with the state prediction error $(x_t - \hat{x}_{t|t-1})$. Thus, if $\hat{y}_{t-\hat{N}}$ is highly uncorrelated with $(x_t - \hat{x}_{t|t-1})$, as happens with large feedback delays or feedback being blocked, $K_t(\hat{y})$ largely attenuates the influence of feedback prediction errors on correcting the current state estimate. When $K_t(\hat{y})$ is so optimally determined, it is referred to as the *Kalman gain function* and the observer is referred to as a *Kalman filter* (Jacobs, 1993; Kalman, 1960; Stengel, 1994; Todorov, 2006). We also refer to $K_t(\hat{y})$ as the *Kalman gain function* because we assume the speech motor control system would seek an optimal value for this function.

Therefore, SFC is the combination of a control law acting on a state estimate provided by an observer. This is a relatively new way to model speech motor control, but SFC models are well-known in other areas of motor control research. Interest in SFC models of motor control has a long history that can trace its roots all the way back to Nikolai Bernstein, who suggested that the CNS would need to take into account the current state of the body (both the nervous system and articulatory biomechanics) to know the sensory outcomes of motor commands it issued (Bernstein, 1967; Whiting, 1984). Since then, the problem of motor control has been formulated in state-space terms like those discussed (Arbib, 1981), and observer-based SFC models of reaching motor control have been advanced to explain how people optimize their movements (Guigon et al., 2008b; Shadmehr & Krakauer, 2008; Todorov, 2004; Todorov & Jordan, 2002).

19.7 SFC MODELS MOTOR ACTIONS AS AN OPTIMAL CONTROL PROCESS

Experiments show that people appear to move optimally, not just on average, but in each movement, making optimal responses to perturbations of their movements that take advantage of task constraints (Guigon, Baraduc, & Desmurget, 2008a; Guigon et al., 2008b; Izawa, Rane, Donchin, & Shadmehr, 2008; Kording, Tenenbaum, & Shadmehr, 2007; Li, Todorov, & Pan, 2004; Liu & Todorov, 2007; Shadmehr & Krakauer, 2008;

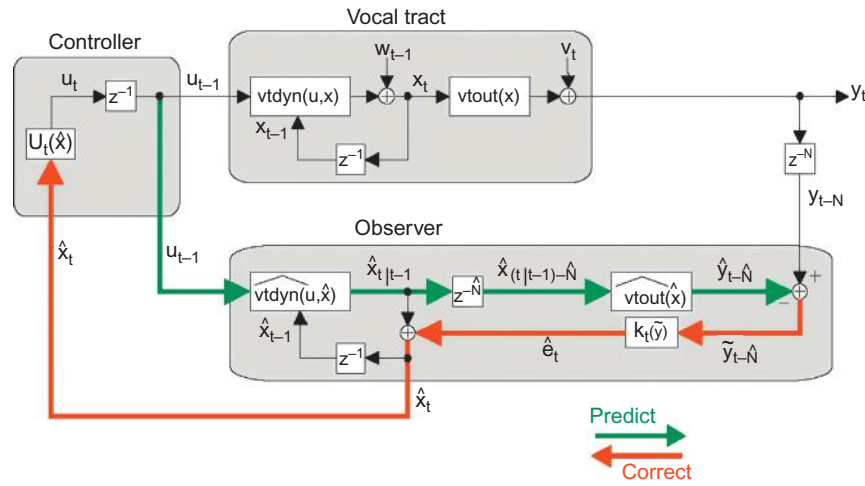

FIGURE 19.4 SFC model of speech motor control. The model is similar to that depicted in Figure 19.4 (i.e., the forward models $vtdyn(u_{t-1}, \hat{x}_{t-1})$ and $vtout(\hat{x}_t)$ constitute the internal model of the vocal tract shown in Figure 19.4), but here sensory feedback y_{t-N} is used to keep the state estimate \hat{x}_t tracking the true vocal tract state x_t . This is accomplished with a prediction/correction process in which, in the prediction (green) direction, efference copy of vocal motor commands u_{t-1} are passed through dynamics model $vtdyn(u_{t-1}, \hat{x}_{t-1})$ to generate the next state prediction $\hat{x}_{t|t-1}$, which is delayed by z^{-N} . z^{-N} outputs the next state prediction $\hat{x}_{(t|t-1)-N}$ from N seconds ago to match the sensory transduction delay of N seconds. $\hat{x}_{(t|t-1)-N}$ is passed through sensory feedback model $vtout(\hat{x}_t)$ to generate feedback prediction \hat{y}_{t-N} . Then, in the correction (red) direction, incoming sensory feedback y_{t-N} is compared with prediction \hat{y}_{t-N} , resulting in sensory feedback prediction error \tilde{y}_{t-N} . \tilde{y}_{t-N} is converted by Kalman gain function $K_t(\tilde{y})$ into state correction \hat{e}_t , which is added to $\hat{x}_{t|t-1}$ to make corrected state estimate \hat{x}_t . Finally, as in Figure 19.4, \hat{x}_t is used by SFC law $U_t(\hat{x}_t)$ in the controller to generate the controls u_t that will be applied at the next timestep to the vocal tract.

Todorov, 2007; Todorov & Jordan, 2002). Furthermore, people quickly reoptimize their movements as task requirements change. They flexibly discover and adaptively adjust control of different aspects of their movements (e.g., contact force, final velocity) to take advantage of any aspect of the task that lets them reduce control effort (e.g., reaching to a target they must stop in front of versus reaching to a target when they can use impact with the target to slow their reach; Liu & Todorov, 2007).

19.8 SPEAKING BEHAVES LIKE AN OPTIMAL CONTROL PROCESS

Like learning to reach, the process of learning to speak could be described as an *optimization* process, with the speaker attempting to learn articulatory controls that strike a balance between the idiosyncrasies of his/her own vocal tract and the sounds demanded by his/her language. The reason speakers can, in general, find such an optimal balance is that the speaking task, if defined only as “be understood by the listener,” is underspecified with respect to the available articulatory degrees of freedom. This is especially true because of the many-to-one nature of the articulatory–acoustic relationship. For example, during the initial closure portion of /b/, the lips are closed and phonation has not

begun; the position of the tongue at this time is therefore acoustically irrelevant and thus unconstrained by the task.

Many studies have shown that speakers appear to systematically take advantage of this underspecification in their articulation of speech. This is manifest in the trading relations seen in the production of /u/, with tongue position being made similar to the surrounding phonetic context and lip rounding accommodating the resulting tongue position (Perkell, Matthies, Svirsky, & Jordan, 1993). This same context-dependent choice of tongue position is also seen in the production of /r/, with the bunched articulation used in velar contexts (e.g., /grg/) and the retroflex articulation used in alveolar contexts (e.g., /drd/) (Espy-Wilson & Boyce, 1994; Guenther et al., 1998; Guenther et al., 1999; Zhou, 2008). These effects of phonetic context on the articulation of a speech sound are broadly referred to as coarticulation—a term introduced in the discussion of the undershoot as a phenomenon that the equilibrium point hypothesis can explain. However, coarticulation is often more complicated than this simple undershoot. In their running speech, speakers appear to anticipate the future need of currently noncritical articulators by moving them in advance to their ultimately needed positions: in the production of /ba/, the tongue is already moved to the position for /a/ during the production of /b/ (Farnetani & Recasens, 1999). How critical an articulator

is for a given speech target is also often language-dependent; for example, in English, nasalization of vowels is not a critical perceptual distinction, leaving speakers free in the production of /am/ to begin in advance the nasalization needed for /m/ (i.e., the opening of the velo-pharyngeal port) during the production of /a/. However, in French, where nasalization of vowels is critical distinction, this advance nasalization of /m/ is not seen (Clumeck, 1976). Coarticulation has also been shown to vary widely across different native speakers of the same language (Kühnert & Nolan, 1999; Lubker & Gay, 1982; Perkell & Matthies, 1992). Even within the same speaker, the instruction to speak “clearly” reduces undershoot coarticulation (Moon & Lindblom, 1994), showing that speaking style controls some types of coarticulation (but not all types; see Matthies, Perrier, Perkell, & Zandipour, 2001).

These observations suggest that coarticulation is partly a learned phenomenon, but what exactly is learned is a matter of debate that distinguishes theories of coarticulation. One theory explains coarticulation purely in terms of “phonological” rules (i.e., rules based on the assumption that speech sounds are stored in memory as groups of discreet valued features) (Chomsky & Halle, 1968). For example, the representation of the /a/ includes the binary tongue features [+high] and [+back], whereas these features are left unspecified in /b/. In the look-ahead model of coarticulation, there is a feature spreading process that considers the full utterance to be spoken and that fills all unspecified features with any values they take on in the future (Henke, 1966). Thus, in the case of /ba/, the unspecified [high] and [back] features would be set to [+high] and [+back], based on looking ahead to the features specified for /a/. Unfortunately, not all coarticulation phenomena can be accounted for as an all-or-nothing feature spreading to unspecified features (remember the example of partial undershoot coarticulation described), and rule-based theories have been expanded to include learning of continuously variable, target-specific coarticulation resistance values (Bladon & Al-Bamerni, 1976). Another attempt to explain the continuous nature of coarticulation dismisses the idea of discreet feature targets in speech, instead postulating speakers learn whole trajectories (timecourses) for different features (e.g., lip opening or tongue-tip height) called gestures; coarticulation then naturally results when these gestures overlap in time (Browman & Goldstein, 1986; Fowler & Saltzman, 1993). Unfortunately, not all coarticulation can be modeled as the linear overlap of such feature time courses, necessitating once again the supposition that speakers learn a resistance to coarticulation (in this case, called blending strength) for different speech targets.

An alternative to explaining coarticulation with such explicit rules is to model it as resulting from

an optimization process, like that postulated for non-speech movements. This was first suggested by Lindblom in 1983 (Lindblom, 1983), and later more fully elaborated in his “H&H” theory of speech production (Lindblom, 1990). In it, Lindblom explains phenomena observed in speech production as variations between “hyperspeech” (speech determined by demanding constraints on acoustic output) and “hypospeech” (speech more determined by production system [e.g., minimal effort] constraints). Acoustic output demands are determined by two things: (i) acoustic distinctiveness (i.e., how confusable a given speech sound is with nearest neighbors in “acoustic space”) and (ii) how easily the listener can predict the next sound to be produced based on any number of sources of information the listener has available (e.g., semantic, linguistic, or phonetic contextual constraints). These factors can be approximately summarized by the more general constraint, mentioned previously, that what the speaker says should be understood by the listener. In this way, the complexities of coarticulation are explained as a “tug-of-war” between acoustic output and production system constraints, with coarticulated speech resulting when acoustic distinctiveness constraints are sufficiently lax that production system constraints can determine a minimal effort articulation. The acoustic output constraint accounts for the language-dependent nature of coarticulation, whereas production system constraint accounts for variations in coarticulation across speakers, because what counts as “minimal effort” depends on an individual speaker’s vocal tract geometry and musculature. A variant of this idea that makes the listener-oriented acoustic distinctiveness constraints more explicit is Keating’s window theory of coarticulation (Keating, 1990). The theory postulates that speech targets are not single-valued, but instead are specified as windows—permissible ranges for different speech features, where these permissible feature ranges are learned by a speaker from listening to other speakers of the language. Coarticulation happens because articulatory trajectory planning in speaking is a process of satisfying a language constraint that features bounds for speech targets must be respected and a minimal effort constraint.

Historically, the problem with explaining the control of speaking as resulting from an optimization process (i.e., that speaking is an *optimal control* process) is that, by itself, this is only a descriptive theory; qualitatively, speakers do behave as if they are working to minimize different movement cost terms, but this does not explain how this minimization is accomplished. This incompleteness of the theory makes it difficult to use it as a model of the role of the CNS in speaking. As a result, for example, in early versions of the DIVA model, one of the best current attempts at providing a

mechanistic account of speech motor control, the optimization process was implemented by adopting a specific version of Keating's window theory; the phonetic feature ranges on speech targets provide an explicit rule for specifying how targets are achieved (i.e., the articulatory trajectory must pass within the target's feature ranges), and the minimal effort constraint is replaced with an explicit rule that says that minimal distance trajectories in phonetic feature space will be followed between successive phonetic targets (Guenther, 1995).

Without resorting to such explicit rules, however, the more general question about speech motor control remains unanswered: just how could the CNS choose the next articulatory control to be output in ongoing speech, such that, ultimately, some overall movement cost constraints are satisfied? How does a distal goal, whose achievement is only known after a word is produced, guide the selection of the next articulatory control at a given point in the ongoing production of the word? Optimal control theory provides a solution: the algorithms at the heart of the theory provide mechanisms for translating an overall movement goal into moment-by-moment controls (Stengel, 1994). In this framework, overall movement goals are expressed as cost functions to minimize (Todorov, 2004, 2006; Todorov & Jordan, 2002; Scott, 2004). These cost functions are a composite of terms reflecting the competing constraints governing movements; for example, one term (accuracy) could express the constraint that the listener should understand what was said (e.g., it could be obtained by an evaluation of the probability that the listener confuses what was said with a different utterance during the state corresponding to movement finished). Another term (effort) could express the fact that actions incur a metabolic cost depending on the forces the articulator muscles are commanded to generate (e.g., cost as the sum of all force magnitudes over the whole movement). The total cost is then a weighting of these cost terms, where the weighting is determined by the current task (e.g., high weighting of accuracy and low weighting of effort for clear speech, and low weighting of accuracy and high weighting of effort for casual speech).

To find the control law that minimizes a given cost function, the concept of state is crucial. Intuitively, if you knew exactly how the system being controlled would respond to your commands (i.e., if you knew its state), you could choose one that minimized the need for future corrective commands and thus minimize control efforts. This intuitive idea is the principle behind the algorithms that determine optimal controls. Perhaps the most understandable versions of these algorithms are those based on dynamic programming and reinforcement learning, in which each state has a cost-to-go, which is the movement cost incurred if only optimal control

actions are taken after that state. Control actions also have a cost (as discussed) and, in one optimal control algorithm (dynamic programming), the optimal next control action for the current state is chosen to minimize the cost of that action plus the cost-to-go of the state it leads to (Bellman, 1957; Bertsekas, 2000). That minimal cost also becomes the new cost-to-go for the current state. Thus, over repeated utterance variations, costs-to-go for later states are propagated backward to earlier states, with the cost-to-go for the end state defined as the probability that the listener will misunderstand what was said. And, in this process of back-propagating costs-to-go, an optimal next control action is chosen for every state visited. In this way, the complete control law mapping states to output controls is eventually learned.

This process for learning a control law is of particular interest because neurophysiological processes appear to be in the CNS that mimics it. The basal ganglia (BG) in particular appear to represent several of the needed quantities, which is significant because the BG are thought to be involved in action selection. Dopaminergic neurons have been implicated in both reward prediction (Hollerman & Schultz, 1998; Schultz, Dayan, & Montague, 1997) and the detection of novel sensory outcomes of actions (Redgrave & Gurney, 2006). Interestingly, these neurons also display a back-propagation of their responses: they initially respond vigorously to delivery of a reward but soon habituate and instead respond to earlier sensory cues that predict the reward (Schultz, 1998). If it can be considered rewarding to improve the outcome of a movement (i.e., minimize its cost), then the behavior of dopaminergic neurons suggests the possibility of a back-propagation of state cost-to-go values would be a way for the CNS to learn control laws (Daw & Doya, 2006; Doya, 2000). Several studies have shown that neurons in the BG striatum appear to represent and retain expected reward returns for different possible future actions (Samejima, Ueda, Doya, & Kimura, 2005; Wang, Miura, & Uchida, 2013)—characteristics that are well-suited for representing costs-to-go of different states. In addition, other studies have shown that GPi output appears to represent movement effort (Desmurget, Grafton, Vindras, Grea, & Turner, 2003; Grafton, Vindras, Grea, & Turner, 2004; Turner, Desmurget, Grethe, Crutcher, & Grafton, 2003). And although many of the detailed studies of the role of BG in action learning have been done at a relatively high level of discreet action choice, the BG are also likely involved in the learning of new "lower level" sensorimotor skills. The subthalamic nucleus (STN) has been shown to react more strongly to more successful movement outcomes in the production of simple movements (Brown et al., 2006). Taken together, there is ample evidence to implicate the BG in the learning of state-based control laws, and studies have modeled is

role as a “critic” that uses cost-to-go values to learn movement control laws (Barto, 1995; Berthier, Rosenstein, & Barto, 2005).

19.9 SFC EXPLAINS THE TASK-SPECIFIC ROLE OF THE CNS IN SPEECH FEEDBACK PROCESSING

Besides providing a mechanistic explanation for how optimal control laws could be learned, the SFC framework also provides an explanation for how and why the CNS would process sensory feedback during ongoing speaking. This is because, in its most general form, the process of estimating the current state of the system being controlled relies on more than just tracking the sequence of controls sent to the system. Crucially, it also relies on sensory feedback to correct errors in the state estimate, as is described here. This full state estimation process not only serves as a model of the role of CNS in feedback processing but also explains how task-specific responses to feedback perturbations would occur: In SFC, such perturbations cause corrections to the current state estimate, and the corrected state, if it has been visited before, has a task-specific optimal control law associated with it. If the state has not been visited before, then the process updating the cost-to-go for that state will begin the process of learning a task-optimal control response in that state.

In this way, a state estimation process that includes sensory feedback explains how task-specific responses to feedback perturbations could be learned without recourse to assuming speech is perceived in terms of certain specialized features. This is important because experiments that test whether speakers use task-relevant feature representations often have mixed results, with some speakers behaving as if they use a certain representation and others behaving as if they do not. To return to an earlier example, it is often reported that speakers exhibit trading relations in the production of /u/, with variations in tongue height being compensated by covariations in lip extension (and vice versa) such that an acoustic representation of their /u/ production (i.e., its formant pattern) is preserved. And when such covariation has been looked for in experiments, it is observed in many speakers (Perkell et al., 1993), consistent with their use of an acoustic representation to constrain their /u/ productions. Critically, however, it is not observed in other speakers. Related experiments have looked for acoustic /u/ representations by examining how speakers produce /u/ when required to hold tubes at their lips. These tubes function as artificial perturbations of a speaker’s lip extension, requiring compensatory adjustment of other articulators like the tongue to maintain the original /u/ formant pattern. Some speakers

compensated for the lip tubes, suggesting they worked to maintain an acoustic /u/ representation, whereas others did not (Savariaux, Perrier, & Orliaguet, 1995). Because these other speakers nevertheless had normal speech and hearing, what explains their results? It could be that unknown experimental factors confounded the results for these speakers, but another distinct possibility is that there are many viable solutions to the speech motor control problem, and that different speakers learn different solutions. Thus, it may be that the control solution based on an acoustic representation of /u/ is only discovered and used by some speakers. An optimal SFC model of speaking can explain such variability across speakers because it specifies only the way that speakers learn task-dependent perturbation responses rather than the specific representations of the task that different speakers learn.

19.10 IS SFC NEURALLY PLAUSIBLE?

For speech, the SFC model suggests not only that auditory processing is used by the CNS for comprehension during listening, but also that the CNS uses auditory information in a distinctly different way during speech production; it is compared with a prediction derived from efference copy of motor output, with the resulting prediction error used to keep an internal model tracking the state of the vocal tract. There are a number of lines of evidence supporting the neural plausibility of this second, production-specific mode of sensory processing. First, even in other primates, there appear to be at least two distinct pathways, or streams, of auditory processing. The concept of multiple sensory processing streams in both the auditory (Deutsch & Roll, 1976; Evans & Nelson, 1973; Poljak, 1926) and visual (Held, 1968; Ingle, 1967) systems of the brain has been around for decades, but the idea gained most attention when it was advanced as an organizational principle of the cortical regions involved in visual information processing. A dorsal “where” stream leading to parietal cortex that was concerned with object location and a ventral “what” stream leading to the temporal pole was concerned with object recognition were hypothesized (Mishkin, Ungerleider, & Macko, 1983; Ungerleider & Mishkin, 1982). Subsequently, studies of the auditory system found a match to this visual system organization (Romanski et al., 1999). Neurons responding to auditory source location were found in a dorsal pathway leading up to parietal cortex, and neurons responding to auditory source type were found in a ventral pathway leading down toward the temporal pole (Rauschecker & Tian, 2000). More recent evidence, however, has refined the view of the dorsal stream’s task to be one of sensorimotor integration. The dorsal

visual stream was found to be closely linked with non-speech motor control systems (e.g., reaching, head, and eye movement control) (Andersen, 1997; Rizzolatti, Fogassi, & Gallese, 1997) while in humans, the dorsal auditory stream was found to be closely linked with the vocal motor control system. In particular, a variety of studies have implicated the posterior superior temporal gyrus (STG) (Zheng, Munhall, & Johnsrude, 2010) and the superior parietal temporal area (Spt) (Buchsbaum, Hickok, & Humphries, 2001; Hickok, Buchsbaum, Humphries, & Muftuler, 2003) as serving auditory feedback processing specifically related to speech production. Consistent with this, studies of stroke victims have shown a double dissociation between ability to perform discreet production-related perceptual judgments and ability to understand continuous speech that depends on lesion location (dorsal and ventral stream lesions, respectively) (Baker, Blumstein, & Goodglass, 1981; Miceli, Gainotti, Caltagirone, & Masullo, 1980). This has led to refined looped and “dual stream” models of speech processing (Hickok et al., 2011; Hickok & Poeppel, 2007; Rauschecker & Scott, 2009), with a ventral stream serving speech comprehension and a dorsal stream serving feedback processing related to speaking. This two-stream model is in fact a close match with that originally proposed by Wernicke more than 100 years earlier (Wernicke, 1874/1977).

When the production-oriented auditory processing of the dorsal stream is disrupted, a number of speech sensorimotor disorders appear to result (Hickok et al., 2011). Conduction aphasia is a neurological condition resulting from stroke in which production and comprehension of speech are preserved but the ability to repeat speech sound sequences just heard is impaired (Geschwind, 1965). Conduction aphasia appears to result from damage to area Spt in the dorsal auditory processing stream (Buchsbaum et al., 2011). Consistent with this, the impairment is particularly apparent in the task of repeating nonsense speech sounds, because when the sound sequences do not form meaningful words, the intact speech comprehension system (the ventral stream) cannot aid in remembering what was heard. More speculatively, stuttering may also result from impairments in auditory feedback processing in the dorsal stream. It is well-known that altering auditory feedback (e.g., altering pitch (Howell, El-Yaniv, & Powell, 1987), masking feedback with noise (Maraist & Hutton, 1957), and DAF (Soderberg, 1968)) can make many persons who stutter speak fluently. Evidence for dorsal stream involvement in these fluency enhancements comes from a study relating DAF-induced fluency to structural MRIs of the brains of persons who stutter (Foundas et al., 2004). The planum temporale (PT) is an area of temporal cortex encompassing dorsal stream areas like Spt, and the study found that right PT was aberrantly larger than left

PT in those stutterers whose fluency was enhanced by DAF. Several other anatomical studies have also implicated dorsal stream dysfunction in stuttering, including studies showing impaired white matter connectivity in this region (Cykowski, Fox, Ingham, Ingham, & Robin, 2010) as well as aberrant gyrification patterns (Foundas, Bollich, Corey, Hurley, & Heilman, 2001).

19.11 SFC ACCOUNTS FOR EFFERENCE COPY PHENOMENA

There are a number of studies that have found evidence that production-specific feedback processing involves comparison of incoming feedback with a feedback prediction derived from motor efference copy. Nonspeech evidence for this is seen when a robot creates delay between the tickle action subjects produce and when they feel it on their own hand (Blakemore, Wolpert, & Frith, 1998, 1999, 2000). With increasing delay, subjects report a more ticklish sensation, as expected if the delay created mismatch between a sensory prediction derived from the tickle action and the actual somatosensory feedback. By using different neuroimaging techniques, an analogous effect can be seen in speech production; the response of a subject's auditory cortices to his/her own self-produced speech is significantly smaller than their response to similar but externally produced speech (e.g., tape playback of the subject's previous self-productions). This effect, which we call speaking-induced suppression (SIS), has been seen using positron emission tomography (PET) (Hirano et al., 1996; Hirano, Kojima et al., 1997; Hirano, Naito et al., 1997), electroencephalography (EEG) (Ford et al., 2001; Ford & Mathalon, 2004), and magnetoencephalography (MEG) (Curio, Neuloh, Numminen, Jousmaki, & Hari, 2000; Heinks-Maldonado, Nagarajan, & Houde, 2006; Houde, Nagarajan, Sekihara, & Merzenich, 2002; Numminen & Curio, 1999; Numminen, Salmelin, & Hari, 1999; Ventura, Nagarajan, & Houde, 2009). An analog of the SIS effect has also been seen in nonhuman primates (Eliades & Wang, 2003, 2005, 2008). Our own MEG experiments have shown that the SIS effect is only minimally explained by a general suppression of auditory cortex during speaking and that this suppression is not happening in the more peripheral parts of the CNS (Houde et al., 2002). We have also shown that the observed suppression goes away if the subject's feedback is altered to mismatch his/her expectations (Heinks-Maldonado et al., 2006; Houde et al., 2002), as is consistent with some of the PET study findings. Finally, if SIS depends on a precise match between feedback and prediction, then precise time alignment of prediction with feedback would be critical for complex rapidly changing productions (e.g., rapidly speaking

“ah-ah-ah”), and less critical for slow or static productions (e.g., speaking “ah”). Assuming a given level of time alignment inaccuracy, the prediction/feedback match should therefore be better (and SIS stronger) for slower, less dynamic productions, which is what we found in a recent study (Ventura et al., 2009).

By itself, evidence of feedback being compared with a prediction derived from efference copy implies the existence of predictive forward models within the CNS, but another line of evidence for forward models comes from sensorimotor adaptation experiments (Ghahramani, Wolpert, & Jordan, 1996; Wolpert & Ghahramani, 2000; Wolpert, Ghahramani, & Jordan, 1995). Such experiments have been conducted with speech production, where subjects are shown to alter and then retain compensatory production changes in response to extended exposure to artificially altered audio feedback (Houde & Jordan, 1997, 1998, 2002; Jones & Munhall, 2000a, 2000b, 2002, 2003, 2005; Jones, Munhall, & Vatikiotis-Bateson, 1998; Purcell & Munhall, 2006; Shiller, Sato, Gracco, & Baum, 2009; Villacorta, Perkell, & Guenther, 2007) or altered somatosensory feedback (Nasir & Ostry, 2006, 2008, 2009; Tremblay et al., 2003; Tremblay et al., 2008). For example, in the original speech sensorimotor adaptation experiment, subjects produced the vowel /ε/ (as in “head”), first hearing normal audio feedback and then hearing their formants shifted toward /i/ (as in “heed”). Over repeated productions while hearing the altered feedback, subjects gradually shifted their productions of /ε/ in the opposite direction (i.e., they shifted their produced formants toward /α/, as in “hot”). This had the effect of making the altered feedback sound more like /ε/ again. These changes in the production of /ε/ were retained even when feedback was subsequently blocked by noise (Houde & Jordan, 1997, 1998, 2002). The retained production changes are consistent with the existence of a forward model making feedback predictions that are modified by experience. In addition to providing evidence for forward models, such adaptation experiments also allow investigation of the organization of forward models in the speech production system. By examining how compensation trained in the production of one phonetic task (e.g., the production of /eh/) generalizes to another untrained phonetic task (e.g., the production of /ah/), such experiments can determine if there are shared representations like forward models used in the control of both tasks. Some of these experiments have found generalization of adaptation across speech tasks (Houde & Jordan, 1997, 1998; Jones & Munhall, 2005), but other experiments have not found such generalization (Pile, Dajani, Purcell, & Munhall, 2007; Tremblay et al., 2008), suggesting that, in many cases, forward models used in the control of different speech tasks are perhaps not shared across tasks.

19.12 NEURAL SUBSTRATE OF THE SFC MODEL

Based partly on the discussion here, Figure 19.5 suggests a putative neural substrate for the SFC model. Basic neuroanatomical facts dictate the neural substrates on both ends of the SFC prediction/correction processing loop. On one end of the loop, motor cortex (M1) is the likely area where the feedback control law $U_t(\hat{x}_t)$ generates neuromuscular controls applied to the vocal tract. Motor cortex is the main source of motor fibers of the pyramidal tract, which synapse directly with motor neurons in the brainstem and spinal cord and enable fine motor movements (Kandel et al., 2000). As mentioned, damage to the vocal tract areas of motor cortex often results in mutism (Duffy, 2005; Jürgens, 2002). On the other end of the loop, auditory and somatosensory information first reaches the higher CNS in the primary auditory (A1) and somatosensory (S1) cortices, respectively (Kandel et al., 2000). Based on our SIS studies, we hypothesize this end of the loop is where the operation comparing the feedback prediction with incoming feedback occurs. Between these endpoints, the model also predicts the need for an additional area that mediates the prediction (green) and correction (red) processes running between motor and the sensory cortices. The premotor cortices are ideally placed for such an intermediary role: premotor cortex is both bidirectionally well-connected to motor cortex (Kandel et al., 2000) and, via the arcuate and longitudinal fasciculi (Glasser & Rilling, 2008; Schmahmann et al., 2007; Upadhyay, Hallock, Ducros, Kim, & Ronen, 2008), bidirectionally connected to the higher order somatosensory (S2/inferior parietal lobe [IPL]) and auditory (Spt/PT) cortices, respectively. In this way, the key parts of the SFC model are a good fit for a known network of sensorimotor areas that are, in turn, well-placed to receive task-dependent, modulatory connections (blue dashed arrows in Figure 19.5) from other frontal areas.

What evidence is there for premotor cortex playing such an intermediary role in speech production? First, reciprocal connections with sensory areas suggest the possibility that premotor cortex could also be active during passive listening to speech, and this appears to be the case. Wilson et al. found the superior ventral premotor area (svPMC), bilaterally, was activated by both listening to and speaking meaningless syllables, but not by listening to nonspeech sounds (Wilson, Saygin, Sereno, & Iacoboni, 2004). In a follow-up study, Wilson et al. found that this area, bilaterally, showed greater activation when subjects heard non-native speech sounds than they did when they heard native sounds. In this same study, auditory areas were also activated more for speech sounds rated least producible, and that svPMC

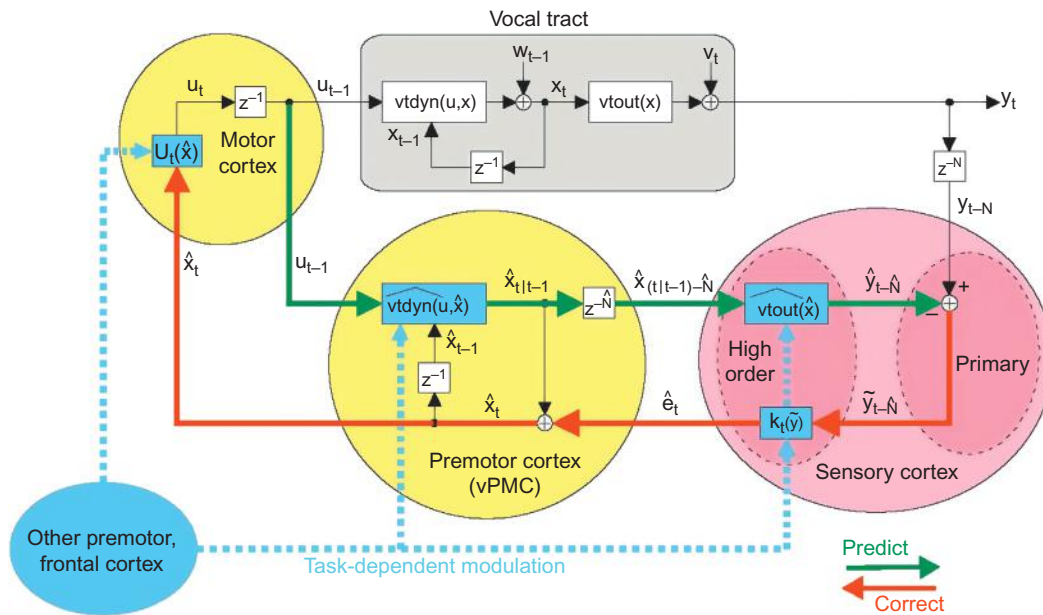

FIGURE 19.5 SFC model of speech motor control with putative neural substrate. The figure depicts the same operations as those shown in Figure 19.5, but with suggested cortical locations of the operations (motor areas are in yellow, sensory areas are in pink). The current model is largely doubtful regarding hemispheric specialization for these operations. Also, for diagrammatic simplicity, the operations in the auditory and somatosensory cortices are depicted in the single area marked “sensory cortex,” with the understanding that it represents analogous operations occurring in both of these sensory cortices, that is, the delayed state estimate $\hat{x}_{(t|t-1)-\hat{N}}$ is sent to both high-order somatosensory and auditory cortex, each with separate feedback prediction modules ($\mathbf{vtout}(\hat{x}_t)$ for predicting auditory feedback in high-order auditory cortex and $\mathbf{vtout}(\hat{x}_t)$ for predicting somatosensory feedback in high-order somatosensory cortex). The feedback prediction errors $\tilde{y}_{t-\hat{N}}$ generated in auditory and somatosensory cortex are converted into separate state corrections \hat{e}_t based on auditory and somatosensory feedback by auditory and somatosensory Kalman gain functions $\mathbf{K}_t(\tilde{y})$ in the high-order auditory and somatosensory cortices, respectively. The auditory-based and somatosensory-based state corrections are then added to $\hat{x}_{t|t-1}$ in premotor cortex to make the next state estimate \hat{x}_t . Finally, the key operations depicted in blue are all postulated to be modulated by the current speech task goals (e.g., what speech sound is currently meant to be produced) that are expressed in other areas of frontal cortex.

was functionally connected to these auditory areas during listening (Wilson & Jacoboni, 2006). This activation of premotor cortex when speech is heard has also been seen in other functional imaging studies (Skipper, Nusbaum, & Small, 2005) and studies based on TMS (Watkins & Paus, 2004).

Second, altering sensory feedback during speech production should create feedback prediction errors in sensory cortices, increasing activations in these areas, and the resulting state estimate corrections should be passed back to premotor cortex, increasing its activation as well. A study that tested this prediction was performed by Tourville et al., who used fMRI to examine how cortical activations changed when subjects spoke with their auditory feedback altered (Tourville, Reilly, & Guenther, 2008). In the study, subjects spoke simple CVC words with the frequency of first formant occasionally altered in their audio feedback of some of their productions. When they looked for areas more active in altered feedback versus nonaltered trials, Tourville et al. found auditory areas (pSTG, including Spt in both hemispheres), and they also found areas in the right frontal cortex: a motor area (vMC), a premotor area (vPMC), and an area (IFt) in the inferior

frontal gyrus, pars triangularis (Broca’s) region. When they looked at the functional connectivity of these right frontal areas, they found that the presence of the altered feedback significantly increased the functional connectivity only of the left and right auditory areas, as well as the functional connectivity of these auditory areas with vPMC and IFt. The result suggests that the auditory feedback correction information from higher auditory areas has a bigger effect on premotor/pars triangularis regions than motor cortex regions, which is consistent with our SFC model if we expand the neural substrate of our state estimation process beyond premotor cortex to also include Broca’s area. The results of Tourville et al. are partly confirmed by another fMRI study. Toyomura et al. had subjects continuously phonate a vowel and, in some trials, the pitch of the subjects’ audio feedback was briefly perturbed higher or lower by two semitones (Toyomura et al., 2007). In examining the contrast between perturbed and unperturbed trials, Toyomura et al. found premotor activation in the left hemisphere and a number of activations in the right hemisphere, including auditory cortex (STG) and frontal area BA9, which is near the IFt activation found by Tourville et al.

19.13 CONCLUSION

In this review, the applicability of SFC to modeling speech motor control has been explored. The phenomena related to the role of CNS in speech production, especially its role in processing sensory feedback, are complex and suggest that speech motor control is not an example of pure feedback control or feedforward control. The task-specificity of responses to feedback perturbations in speech further argues that feedback control is not only a function of the lower motor system but also one in which CNS plays an active role in the online processing of sensory feedback during speaking. Current models of this role are described as variations of concept of SFC from engineering control theory. Thus, SFC is put forth as an appropriate and neurally plausible model of how the CNS processes feedback and controls the vocal tract.

Spoken Word Recognition: Historical Roots, Current Theoretical Issues, and Some New Directions

David B. Pisoni¹ and Conor T. McLennan²

¹Department of Psychological and Brain Sciences, Indiana University, Bloomington, IN, USA; ²Department of Psychology, Cleveland State University, Cleveland, OH, USA

20.1 INTRODUCTION

This is an exciting time to be working in the field of human *spoken word recognition* (SWR). Many long-standing assumptions about spoken language processing are being reevaluated in light of new experimental and computational methods, empirical findings, and theoretical developments (Gaskell, 2007a, 2007b; Hickok & Poeppel, 2007; McQueen, 2007; Pisoni & Levi, 2007). Moreover, recent findings on SWR also have direct applications to issues related to hearing impairment in deaf children and adults, non-native speakers of English, bilinguals, and older adults.

The fundamental problems in the field of SWR, such as invariance and variability, neural coding, representational specificity, and perceptual constancy in the face of diverse sensory input, are similar to the perceptual problems studied in other areas of cognitive psychology and neuroscience. Although these well-known theoretical problems have occupied speech research since the early 1950s, until recently research and theory on spoken language processing have been intellectually isolated from mainstream developments in neurobiology and cognitive science (Arlinger, Lunner, Lyxell, & Pichora-Fuller, 2009; Dahan & Magnuson, 2006; Hickok & Poeppel, 2007; Magnuson, Mirman, & Harris, 2012; Magnuson, Mirman, & Myers, 2013; Rönnberg et al., 2013). The isolation of speech communication evolved because speech scientists and communication engineers relied heavily on linguistically motivated theoretical assumptions about the core properties of speech and the computational processes

underlying spoken language processing (see Chomsky & Miller, 1963). These assumptions embodied the *conventional segmental linguistic view*, which assumes that speech signals consist of a linear sequence of abstract, idealized, context-free segments ordered temporally in time much like the discrete letters of the alphabet or bricks on the wall (Halle, 1985; Hockett, 1955; Licklider, 1952; Peterson, 1952). The assumption that the continuously varying speech signal can be represented as a sequence of discrete units has played a central role in all theoretical accounts of spoken language research (Lindgren, 1965a, 1965b).

The present chapter is organized into four sections. First, we briefly review the historical roots of the field of SWR. Second, we discuss the principle theoretical issues and contemporary models of SWR. Third, we contrast the conventional segmental view of speech and SWR with an alternative proposal that moves beyond abstract linguistic representations. Finally, we briefly consider how basic research in SWR has led to several new research directions and additional challenges.

20.2 HISTORICAL ROOTS AND PRECURSORS TO SWR

This is a chapter about human SWR. However, before jumping right into our discussion of SWR, some brief historical background is necessary to place the current research and theory into a broader historical context. By discussing some older theoretical issues and empirical findings from research on speech and

hearing, we are able to illustrate important changes in the way researchers think about representational and processing issues in SWR today. There are, of course, also some connections and parallels with studies of visual word recognition (Carreiras, Armstrong, Perea, & Frost, 2014) and neuroimaging methods of language processing (Price, 2012; Sharp, Scott, & Wise, 2004), which are discussed in other chapters of this book.

The field of speech and hearing science has a well-documented history dating back to the end of the 19th century when researchers began to use electrically recorded audio signals to assess hearing loss supplementing traditional clinical measures that relied on simple acoustical signals (Flanagan, 1965; Fletcher, 1929; Miller, 1951; Wilson & McArdle, 2005). Except for the seminal, but otherwise obscure, early findings reported by Bagley (1900) on SWR using a novel experimental methodology involving mispronunciation detection (see Cole, 1973; Cole & Rudnicky, 1983), most of what we currently know about the basic acoustical and perceptual foundations of speech and hearing comes from pioneering research performed at Bell Telephone Laboratories in the 1920s (Flanagan, 1965; Fletcher, 1929, 1953; Fletcher & Galt, 1950). This extensive body of research established the minimal necessary and sufficient acoustical conditions for effective and highly reliable speech transmission and reception over conventional telephone circuits and provided an enormous body of empirical data and acoustic measurements on the foundations of hearing and speech communication under limited telephone bandwidth conditions (Allen, 1994, 2005; Fletcher, 1953).

20.2.1 Speech Intelligibility

Most of the quantitative experimental methods developed for assessing speech intelligibility routinely used today can be traced directly back to these early empirical studies (Fletcher, 1929, 1953; Hirsh, 1947; Konkle & Rintelmann, 1983; Wilson & McArdle, 2005). The primary focus of this research was on speech intelligibility; there was little interest in describing the human listener's perceptual and cognitive abilities to recognize spoken words (Allen, 1994, 2005). Further applied research on speech communication in noise was performed at the Psycho-Acoustic Laboratory at Harvard University during World War II (WW II) (see Hudgins, Hawkins, Karlin, & Stevens, 1947; Licklider & Miller, 1951; Rosenzweig & Stone, 1948 for reviews). Although these two applied research programs provided much of the core knowledge about hearing and speech communication, almost all of these investigations were focused on practical telephone and military-related communications issues. Little effort was devoted

to broader theoretical and conceptual issues in SWR. One exception was a brief theoretical work by Licklider (1952) on *process models* of human speech perception. Surprisingly, several ideas proposed by Licklider are still relevant to current theoretical issues today. After WW II, speech and hearing scientists and acoustical engineers turned their attention to the human listener. Several research programs were initiated to understand how SWR is performed so efficiently under highly impoverished conditions (Cooper, Delattre, Liberman, Borst, & Gerstman, 1952). Efforts were also begun to develop methods for speech synthesis-by-rule that could be used in reading machines for blind veterans returning from the war (Allen, Hunnicutt, & Klatt, 1987; Cooper et al., 1952; Klatt, 1987).

20.2.2 Source-Filter Theory and Speech Cues

The development of the source-filter theory of speech acoustics at MIT (Stevens, Kasowski, & Fant, 1953) and the well-known *pattern playback* studies of speech cues using highly simplified hand-painted spectrographic patterns of synthetic speech at Haskins Laboratories (Cooper et al., 1952) provided the foundations of modern speech science and acoustic-phonetics. The modeling work at MIT focused on the acoustic nature of the speech signal (Stevens, 1998); research at Haskins investigated listeners' perceptual skills in making efficient use of minimal acoustic-phonetic cues as central components in the *speech chain* (Denes & Pinson, 1963; Liberman, 1996; Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Moore, 2007a, 2007b).

These early studies were directly responsible for uncovering many core theoretical problems in spoken language processing, especially problems related to the articulatory dynamics of speech production and the context-dependent nature of the acoustic cues to speech perception that have remained among the major theoretical issues in the field (see Klatt, 1979; Liberman, 1996; Pisoni, 1978; Studdert-Kennedy, 1974; and see chapters in Gaskell, 2007a; Pisoni & Remez, 2005 for additional reviews and discussion).

20.3 PRINCIPLE THEORETICAL ISSUES IN SWR

In this section, we discuss the principle theoretical issues in SWR and then briefly review several contemporary models of SWR (for more detailed reviews, see Jusczyk & Luce, 2002; Magnuson et al., 2012, 2013; Marslen-Wilson, 1989; Pisoni & Levi, 2007). The fundamental problem in SWR is to understand how listeners recover the talker's intended message from the complex time-varying speech waveform. This problem is

typically broken-down into a series of more manageable subquestions (Pisoni, 1978; Studdert-Kennedy, 1974). What stages of perceptual analysis intervene between the presentation of the speech signal and recognition of the talker's intended linguistic message? What types of processing operations occur at each stage of analysis? What are the primary processing units of speech? What is the nature of the neural and cognitive representations of spoken words? Finally, what specific perceptual, neurocognitive, and linguistic processing operations are used in SWR, and how are they coordinated into an integrated system?

Although many of these questions have remained basically the same since the early 1950s, the answers have changed, reflecting new theoretical and methodological developments and novel ways of thinking about sensory and neurocognitive processes used to recognize spoken words (Hickok & Poeppel, 2007; Luce & Pisoni, 1998; Moore, 2007a, 2007b; Scott & Johnsrude, 2003). As discussed, applied research on hearing and speech performed at Bell Labs and Harvard was primarily concerned with assessing the adequacy of telephone communication equipment and investigating factors that affected speech intelligibility in noise. Other research focused on methods to improve speech intelligibility in military combat conditions (Black, 1946). Although these applied research programs were created to address practical real-world problems, many theoretically important empirical findings were uncovered. The significance of these discoveries for theories of human SWR were discussed only briefly in numerous research reports from Harvard in the early 1940s (Abrams et al., 1944; Karlin, Abrams, Sanford, & Curtis, 1944; Wiener & Miller, 1946). Many of these empirical observations played substantial roles in theoretical accounts and models of perceptual and cognitive processes (Lindgren, 1965a, 1965b, 1967). Next, we briefly consider three theoretically significant findings originally uncovered by speech scientists at Harvard: (i) word frequency effects; (ii) word length effects; and (iii) sentence context effects. These findings, among others, later played central roles in theoretical discussions of SWR (Broadbent, 1967; Morton, 1979), have shaped the direction of the field, and need to be accounted for in any model of SWR.

20.3.1 Word Frequency, Word Length, and Sentence Context Effects

Numerous investigations have reported that high-frequency words presented in noise are identified more accurately than low-frequency words (Howes, 1954, 1957; Savin, 1963). At the time the word frequency effect was first discovered in the late 1940s, researchers

believed that word frequency was equivalent to *experienced frequency* and that word counts of printed text of English (Francis & Kucera, 1964; Thorndike-Lorge, 1944) could serve as a good proxy for word frequency. Experienced frequency reflects how often a listener encountered a specific word form. Significant theoretical work was performed by Broadbent (1967) and many others to understand the basis of frequency effects. The word frequency effect is one of the distinctive hallmarks of SWR and has played a central role in research and theory development for many years (Forster, 1976; Morton, 1979; Oldfield, 1966).

Computational analyses and theoretical work performed by Landauer and Streeter (1973) suggested that although *experienced frequency* may play a role in word recognition processes, frequency effects may also reflect more subtle underlying differences in the structural properties of high- and low-frequency words, and that *experienced frequency* may simply be a byproduct of the statistical regularities of the sound patterns of words in the language. In an unpublished seminal study using phonotactically legal nonwords, Eukel (1980) demonstrated frequency effects for novel sound patterns. These results suggested that phonotactics—the frequency and patterning of sound segments and syllables within words—may be responsible for the robust perceptual differences observed between high- and low-frequency words in English (Pisoni, Nusbaum, Luce, & Slowiaczek, 1985; Vitevitch & Luce, 1999).

Computational and behavioral studies performed by Luce and Pisoni (1998) revealed that the sound similarity neighborhoods of high- and low-frequency words differed significantly, and that spoken words are recognized *relationally* in the context of other phonetically similar words in the mental lexicon. Spoken words are not recognized left-to-right segment-by-segment in serial order as traditionally assumed by the conventional linguistic view of speech perception. Instead, spoken words are recognized by processes involving activation and competition among word form candidates or *lexical neighbors* of spoken words (Pisoni & Luce, 1986).

Results from one of the earliest studies on word length effects are illustrated in Figure 20.1. The data from this study, described by Wiener and Miller (1946), demonstrate effects of word length on SWR scores. In marked contrast to word length effects observed in visual perception and memory, which consistently show that longer words are more difficult to recognize and recall, word length effects in SWR show precisely the opposite result—longer words are easier to perceive and recognize (Rosenzweig & Postman, 1957; Savin, 1963). Wiener and Miller's results also demonstrate that the longer a spoken word, the less often it will be confused with phonetically similar sounding words (Savin, 1963).

FIGURE 20.1 The word length effect in SWR illustrating the improvement in speech articulation as the average number of speech sounds per word is increased. Adapted from Wiener and Miller (1946) with permission from the publisher.

Word frequency and word length effects suggest that spoken words are recognized *relationally* in the context of other words in lexical memory and are not processed in a left-to-right fashion segment-by-segment as many theorists had assumed. In *open-set* speech intelligibility tests in which no response alternatives are given to the listener, spoken words are recognized in relation to other perceptually similar words the listener knows that serve as potential lexical candidates for responses (Pollack, Rubenstein, & Decker, 1959, 1960). When listeners receive compromised sensory information, they make use of *sophisticated guessing* strategies, generating lexical candidates and strongly biased responses in a systematic manner reflecting the sound similarity relations among words in lexical memory (Broadbent, 1967; Morton, 1969; Savin, 1963; Treisman, 1978a, 1978b).

When words occur in meaningful sentences, listeners also make use of additional knowledge and linguistic constraints that are unavailable when the same words are presented in isolation (Marks & Miller, 1964; Miller, Heise, & Lichten, 1951; Miller & Isard, 1963). SWR is an active and highly automatized process that takes place very rapidly with little conscious awareness of the underlying sensory, cognitive, and linguistic processes. Many different sources of knowledge are used to recognize words depending on the context, test materials, and specific task demands (Jenkins, 1979). One of the most important and powerful sources of contextual constraint comes from sentences. Figure 20.2 shows the pioneering speech intelligibility results obtained by Miller et al. (1951). In one condition, Miller et al. presented sentences containing key words mixed in noise. In a second

FIGURE 20.2 The effects of sentence context on the intelligibility of spoken words in noise as a function of signal-to-noise ratio in decibels. The filled circles show percentage of words correct in meaningful English sentences. The open circles show percentage of words correct for the same words presented in isolation. Adapted from Miller et al. (1951) with permission from the publisher.

condition, the same words were presented in isolation. The results in Figure 20.2 illustrate that spoken words are much more difficult to recognize in isolation than in meaningful sentences.

These results establish that sentence context constrains word recognition and demonstrate the contributions of the listener's prior linguistic knowledge to SWR (Miller, 1962; Miller & Selfridge, 1950). When words are encoded in sentences, multiple sources of information automatically become available and their associated brain circuits are recruited to support the recognition process (Scott, Blank, Rosen, & Wise, 2000).

20.3.2 Contemporary Approaches to SWR

One of the most important changes in research on spoken language processing over the past 40 years has been a dramatic shift from a focus on the perception of individual speech sounds in isolated nonsense syllables to the study of the underlying cognitive and linguistic processes involved in SWR. For many speech scientists, the domain of speech perception was narrowly confined to the study of the perception of speech features and phonetic segments in highly controlled experimental contexts using simplified synthesized nonsense syllables (Liberman, 1996). The widespread view at the time was that speech perception was a necessary prerequisite for SWR. In most discussions in the early 1950s, the linguistic construct of the phoneme was considered to be the central elementary building block of speech (Peterson, 1952). The theoretical assumption was that if we can understand the processes used to

recognize individual phonemes in nonsense syllables, then this knowledge could be scaled up to SWR. Such a narrow reductionist research strategy is not surprising; researchers in all areas of science typically work on tractable problems that can be studied with existing paradigms and experimental methodologies. Despite the voluminous literature on isolated phoneme perception in the 1950s, 1960s, and 1970s, until the mid-1970s very little was known about how listeners use acoustic-phonetic information in the speech signal to support SWR (Marslen-Wilson, 1975).

Several reasons can be identified for the shift in research efforts from the study of phonetic segments to SWR. First, the number of speech scientists and psycholinguists increased. Second, the cost of performing speech research decreased significantly with the widespread availability of low-cost digital computers and high-powered sophisticated digital signal processing techniques. Third, with more interest in the field of speech perception and more powerful research tools, younger investigators were able to turn their attention and creative efforts to a wider range of challenges related to how acoustic-phonetic information in the speech signal makes contact with stored lexical representations in memory. Importantly, new studies on SWR also used novel experimental paradigms and techniques that required listeners to actively use phonological, lexical, syntactic, and semantic knowledge in assigning a meaningful interpretation to the input. The shift in emphasis from perception of phonetic segments to SWR was also motivated by the belief that by investigating SWR, new insights would be obtained about the role of context, lack of acoustic-phonetic invariance, linearity, and the interaction of multiple sources of knowledge in spoken language processing (Miller, 1962).

20.3.3 Theoretical Accounts of SWR

Early theories of SWR were based on models and research findings in visual word recognition. Three basic families of models have been proposed to account for mapping of speech waveforms onto lexical representations. One approach, represented by the Autonomous Search Model developed by Forster (1976, 1989), is based on the assumption that words are accessed using a *frequency-ordered* search process. In this model, the initial search is performed based on frequency, with high-frequency words searched before low-frequency words. Search theories are no longer considered viable models of SWR and are not considered any further in this chapter.

The second family of models assumes that words are recognized through processes of activation and competition. Early pure activation models like Morton's Logogen Theory assumed that words are recognized based on

sensory evidence in the input signal (Morton, 1969). Passive sensing devices called logogens were associated with individual words in the lexicon. These *word detectors* collected information from the input. Once a Logogen reached a threshold, it became activated. To account for frequency effects, common high-frequency words had lower thresholds than rare low-frequency words. There were a number of problems with the Logogen model. It failed to specify precisely the perceptual units used to map acoustic phonetic input onto logogens or how different sources of linguistic information are combined together to alter the activation levels of individual logogens. Finally, the Logogen model was also unable to account for lexical neighborhood effects and the effects of lexical competition among phonetically similar words because the logogens for individual words are activated independently and have no input from other phonetically similar words in memory.

The third family of models combined assumptions from both search and activation models. One example of a hybrid model of SWR is Klatt's Lexical Access From Spectra (LAFS) model (Klatt, 1979), which relies extensively on real-speech input in the form of power spectra that change over time, unlike other models of SWR that rely on preprocessed coded speech signals as input. Klatt argued that earlier models failed to acknowledge the important role of fine phonetic detail because they uniformly assumed the existence of an intermediate abstract level of representation that eliminated potentially useful acoustic information from the speech signal (Klatt, 1986). Based on a detailed analysis of the design architecture of the HARPY speech recognition system (Lowerre & Reddy, 1980), Klatt suggested that intermediate representations may not be optimal for human or machine SWR because they are always potentially error-prone, especially in noise (Klatt, 1977). Instead, Klatt suggested that spoken words could be recognized directly from an analysis of the input power spectrum using a large network of diphones combined with a "backward beam search" technique like the one originally incorporated in HARPY that eliminated weak lexical candidates from further processing (Klatt, 1979). LAFS is the only model of SWR that attempted to deal with fine phonetic variation in speech, which in recent years has come to occupy the attention of many speech and hearing scientists as well as computer engineers who are interested in designing psychologically plausible models of SWR that are robust under challenging conditions (Moore, 2005, 2007b).

20.3.4 Activation and Competition

Almost all current models of SWR assume two fundamental processes: activation and competition

(Gaskell & Marslen-Wilson, 2002; Luce & Pisoni, 1998; McClelland & Elman, 1986; Norris, 1994). Although there is widespread agreement that acoustic-phonetic input activates a set of lexical candidates that are subsequently selected as a response, the precise details of activation and competition remain a matter of continuing debate (Magnuson et al., 2012). As we discuss similarities and differences between activation-competition models of SWR, it is important to emphasize that all of these SWR models deal with somewhat different theoretical issues and empirical findings, making it difficult to draw direct comparisons among specific models. This is a problem that needs to be addressed in the future because all of the current models target different problems and often focus on specific issues (i.e., the role of top-down feedback, competition dynamics, or representational specificity; see Magnuson et al., 2013 for further discussion). Moreover, none of the current models of SWR deal satisfactorily, if at all, with the indexical channel of information encoded in the speech signal, especially vocal source information about the speaker's voice quality, vocal tract transfer function, and environmental context conditions.

Logogen, TRACE, Shortlist, PARSYN, and the Distributed Cohort Model (DCM) all assume that form-based lexical and sublexical representations can be activated at any point in the speech signal, referred to as *radical activation* (Luce & McLennan, 2005). Radical activation differs from the earlier proposal of *constrained activation* in the original Cohort Theory in which the initial activation of a set of lexical candidates was strictly limited to word initial onsets (Marslen-Wilson & Welsh, 1978). The original Cohort Theory was based on the hypothesis that the beginnings of words played a special role in activating a set of word initial lexical candidates or *cohorts*. As more sensory information is acquired, words that became inconsistent with the input signal were dropped from the cohort until only one word remained. Although the first version of the Cohort Theory was quite influential and generated many novel studies that shaped the field of SWR (see papers in Altman, 1990), the model has been significantly revised and updated in the DCM described below.

In current models of SWR, a central defining feature is the assumption of competition among multiple activated lexical candidates. Lexical competition is one of the major areas of current research and theory on SWR (see Hannagan, Magnuson, & Grainger, 2013; Scharenborg & Boves, 2010). Although there is now considerable evidence for competition in SWR, debate continues over the precise cognitive and neural mechanisms underlying lexical competition dynamics (see Magnuson et al., 2013). In TRACE, Shortlist, and PARSYN, competition involves lateral inhibition

among lexical representations. Lateral inhibition refers to competition within the same *level* (e.g., words competing with words or segments competing with segments). In contrast, in the DCM, lateral inhibition among local units is replaced by an active process that results from the *blending* of multiple representations distributed across processing levels (Gaskell & Marslen-Wilson, 2002).

20.3.5 TRACE

TRACE is a highly influential interactive-activation localist connectionist model of SWR (McClelland & Elman, 1986). Localist models of processing assume the existence of discrete stand-alone representations or processing units that have meaning and can be interpreted directly, whereas distributed models make use of patterns of activation across a collection of representations that are dependent on each other and cannot be interpreted alone by looking at individual units in the network. TRACE contains three types of processing units corresponding to features, phonemes, and words (Elman & McClelland, 1986; McClelland & Elman, 1986). Connection weights raise or lower activation levels of the nodes at each level depending on the input and activity of the system. Although TRACE has had considerable influence in the field, the model has several weaknesses and relies extensively on a psychologically and neurally implausible processing architecture. One weakness is that TRACE is only concerned with the recognition of isolated spoken words and has little to say about the recognition of spoken words in connected fluent speech. Furthermore, nodes and connections in TRACE are reduplicated to deal with the temporal dynamics of SWR. Recently, Hannagan et al. (2013) developed a new model called TISK that combines time-specific representations with higher-level representations based on string kernels. TISK reduces the number of units and connections by several orders of magnitude relative to TRACE.

20.3.6 Shortlist, Merge, and Shortlist B

Shortlist is another localist connectionist model of SWR (Norris, 1994). First, a short list of lexical candidates is activated consisting of word forms that match the speech signal. In the second stage, a subset of hypothesized lexical items enters a smaller network of word units. Lexical units then compete with one another for recognition via lateral inhibition. Shortlist also attempts to account for segmentation of words in fluent speech via lexical competition. Shortlist simulates the temporal dynamics of SWR without having to rely on the unrealistic processing architecture of

TRACE. Shortlist is also an autonomous model of SWR. Unlike TRACE, Shortlist does not allow for any top-down lexical influences to affect the initial activation of its phoneme nodes. In Merge, an extension of Shortlist, the flow of information between phoneme and word levels is unidirectional and strictly bottom-up (Norris, McQueen, & Cutler, 2000). A revised version of the Shortlist model, Shortlist B, retains many key assumptions of the original model but differs radically in two ways (Norris & McQueen, 2008). First, Shortlist B is based on Bayesian principles. Second, input to Shortlist B is a sequence of phoneme probabilities obtained from human listeners, rather than discrete phonemes. Two other closely related models, SpeM and Fine-Tracker, have been developed recently to accept real speech waveforms (Weber & Scharenborg, 2012).

20.3.7 NAM and PARSYN

One of the most successful models of SWR is the Neighborhood Activation Model (NAM) developed by Luce and Pisoni (1998). NAM was designed to confront the acoustic-phonetic invariance problem in speech perception. NAM assumes that listeners recognize spoken words *relationally* in the context of other phonetically similar words rather than by strictly bottom-up processing of a sequence of abstract phonetic segments. NAM uses a simple similarity metric for estimating phonological distances of spoken words based on the one-phoneme deletion, addition, or substitution rule developed by Greenberg and Jenkins (1964). This computational method of assessing lexical similarity provides an efficient and powerful way of quantifying the *relations* between spoken words.

The approach embodied in NAM avoids the long-standing intractable problem of trying to recognize individual context-free abstract idealized sound segments (e.g., phonemes) from bottom-up linguistic analysis of invariant acoustic-phonetic properties in the speech waveform. The search for unique acoustic-phonetic invariants for phonemes is no longer a necessary prerequisite when the primary recognition problem is viewed as lexical discrimination and selection among similar sounding words in memory rather than context-independent identification of phonetic segments. Perceptual constancy and lexical abstraction emerge naturally in NAM and are an automatic byproduct of processing interactions between initial sensory information in the signal and lexical knowledge the listener has about possible words and phonological contrasts (also, see Grossberg, 2003; Grossberg & Myers, 2000).

PARSYN, another localist model of SWR, is a connectionist instantiation of the design principles originally incorporated in NAM. The model contains three levels of interconnected processing units: (i) input

allophones; (ii) pattern allophones; and (iii) words (Luce, Goldinger, & Vitevitch, 2000). Lateral connections between nodes are mutually inhibitory. PARSYN was originally developed to account for lexical competition and probabilistic phonotactics in SWR studies motivated by predictions based on NAM (Vitevitch & Luce, 1999). Unlike TRACE and Shortlist, however, PARSYN assumes the existence of an intermediate allophonic level of representation in the network that encodes fine content-dependent phonetic details (see Wickelgren, 1969).

20.3.8 Distributed Cohort Model

In the DCM, unlike the original Cohort Theory, activation corresponding to a specific word is distributed over a large set of simple processing units (Gaskell & Marslen-Wilson, 2002). In contrast to the three localist SWR models discussed, the DCM assumes distributed representations in which featural input is *projected* onto simple semantic and phonological units. Because the DCM is a distributed model of SWR, there are no intermediate or sublexical units of representation. Moreover, in contrast to lateral inhibition used by TRACE, Shortlist, and PARSYN, lexical competition in DCM is expressed as a *blending* of multiple lexical items that are consistent with the input.

The differences that exist among the four models of SWR reviewed here are relatively modest. Some unresolved issues need to be explored further, such as segmentation of words in sentences and connected fluent speech, the contributions of sentence and discourse context, and the interaction of other sources of knowledge used in spoken language understanding. These issues are known to affect SWR in normal-hearing listeners and in clinical populations with hearing loss, language delay, and cognitive aging. Because the current group of SWR models are all very similar, it is doubtful that these issues will prove to be critically important in deciding which model provides the most realistic and valid account of SWR.

In many ways, it appears that the field of SWR research has reached a modeling plateau. Although there remain numerous unresolved empirical issues, it is also clear that substantial progress has already been made in dealing with many long-standing foundational issues surrounding SWR and how information in the speech signal is mapped onto lexical representations. Given recent findings documenting the increasingly important role of fine phonetic variation and representational specificity on SWR, especially in hearing-impaired populations, it is likely that several of the unconventional design features of the LAFS architecture may find their way into revised versions

of these four basic models of SWR in the near future (see recent models developed by Moore, 2007a, 2007b; Rönnerberg et al., 2013).

20.4 SWR AND THE MENTAL LEXICON

One solution to long-standing problems associated with the lack of acoustic-phonetic invariance, segmentation, and the context-conditioned nature of speech has been to reframe the perceptual invariance issue by proposing that the primary function of speech perception is the recognition of spoken words rather than the recognition and identification of phonetic segments (Luce & Pisoni, 1998). The proposal to recast research on speech perception and SWR as a lexical selection problem has had a significant influence in the field because it drew attention away from traditional studies of *speech cues* in isolated nonsense syllables to somewhat broader theoretical and empirical issues related to SWR, the mental lexicon and the organization of spoken words in lexical memory (Marslen-Wilson, 1975; Marslen-Wilson & Welsh, 1978). It also emphasized the central role of SWR in language comprehension and production, topics that had been ignored by previous work focused exclusively on phonetic perception of speech sounds.

20.4.1 The Conventional View

The conventional view of speech assumes a bottom-up sensory-based approach to speech perception and SWR in which segments are first recognized from elementary cues and distinctive features in the speech signal are then parsed into words (see Lindgren, 1965a, 1965b for reviews of early theories). Historically, within the conventional *segmental linguistic* approach, variability in speech was treated as an undesirable source of *noise* that needed to be reduced in order to reveal the *hidden* idealized linguistic message (Chomsky & Miller, 1963; Halle, 1985; Miller & Chomsky, 1963). Many factors known to produce acoustic-phonetic variability were deliberately eliminated or systematically controlled for by speech scientists in experimental protocols used to study speech. As a consequence, very little basic research was specifically devoted to understanding how variability in the speech signal and listening environment is encoded, processed, and stored, especially in noise and under adverse listening conditions.

20.4.2 Linearity, Invariance, and Segmentation

Several aspects of the conventional view of speech are difficult to reconcile with the continuous nature of the acoustic waveform produced by a speaker.

Importantly, the acoustic consequences of coarticulation, as well as other sources of contextually conditioned variability, result in the failure of the acoustic signal to meet two formal conditions: linearity and invariance. This failure gives rise to a third problem: the absence of explicit segmentation of the acoustic speech signal into discrete units (Chomsky & Miller, 1963). The linearity condition requires that each segment corresponds to a stretch of sound in the utterance. The linearity condition is not met in speech because extensive coarticulation and other contextual effects *smear* acoustic features for adjacent segments. The smearing or *parallel transmission* of acoustic features results in stretches of the speech waveform in which acoustic features of more than one segment are present simultaneously (Liberman, 1996). Acoustic-phonetic invariance means that every segment must have a specific set of defining acoustic attributes in all contexts. Because of coarticulatory effects in speech production, the acoustic properties of a particular speech sound vary as a function of the phonetic environment it is embedded in. Acoustic-phonetic invariance is absent due to within-speaker variation as well as when we look across different speakers (Peterson & Barney, 1952). The absence of acoustic-phonetic invariance is inconsistent with the theoretical assumption that speech can be represented as an idealized context-free linear sequence of discrete linguistic segments. A large body of research over the past 60 years demonstrates clearly that the speech signal cannot be reliably segmented into discrete acoustically defined units; in fluent connected speech, especially casual or reduced speech, it is impossible to identify where one word ends and another begins using acoustic criteria alone. Precisely how the continuous speech signal is mapped onto discrete segmental representations by the listener still remains one of the most important and challenging problems in speech research today and suggests the existence of additional representations that encode and process the graded continuous properties of the speech signal (McMurray & Jongman, 2011).

20.4.3 An Alternative Proposal

Theoretical developments in neurobiology, cognitive science, and brain modeling along with the availability of powerful new computational tools and large digital speech databases have led researchers to reconceptualize the major theoretical problems in speech perception and how they should be approached in light of what we now know about neural development and brain function (Sporns, 1998, 2003; Sporns, Tononi, & Edelman, 2000). In particular, several new *exemplar-based* approaches to SWR have emerged in recent years from independent developments in the field of human

categorization (Kruschke, 1992; Nosofsky, 1986), phonetics and laboratory phonology (Johnson, 2002, 2006), and frequency-based phonology in linguistics (Bybee, 2001; Pierrehumbert, 2001). These novel approaches to SWR offer new insights into many traditional problems related to variability and the lack of acoustic-phonetic invariance in speech perception (Moore, 2007a, 2007b; Pisoni, 1997).

Research findings over the past 25 years provide converging support for an approach to SWR that is compatible with a large and growing body of literature in cognitive science dealing with *episodic* models of categorization and *multiple-trace* models of human memory (Erickson & Kruschke, 1998; Hintzman, 1986, 1988; Kruschke, 1992; Nosofsky, 1986; Shiffrin & Steyvers, 1997). This theoretical approach emphasizes the importance of temporal context and the encoding of specific instances in memory. Such accounts of SWR assume that highly detailed stimulus information in the speech signal and listening environment is encoded, processed, and stored by the listener and subsequently becomes an inseparable component of rich and highly detailed lexical representations of spoken words (Port, 2010a, 2010b).

A critical assumption of this approach to speech perception and SWR is that variability in speech is useful and *highly informative* to the listener, rather than being a source of noise that degrades the underlying idealized abstract linguistic representations (Elman & McClelland, 1986). Exemplar-based views assume that listeners encode and store highly detailed *records* of episodic experiences, rather than prototypes or abstractions (Kruschke, 1992; Nosofsky, 1986). According to these accounts, abstraction and categorization occur but they are assumed to *emerge* from computational processes that take place at retrieval not at encoding. Thus, the fine-grained continuous acoustic-phonetic and indexical details of speech and episodic contextual information are not discarded as a consequence of early sensory processing and perceptual encoding of spoken words into lexical representations.

20.4.4 Indexical Properties of Speech

Numerous studies on the perception of talker variability in SWR have shown that *indexical* information in the speech (Abercrombie, 1967), including details about vocal sound source and optical information about the speaker's face, as well as highly detailed contextual information about speaking rate, speaking mode, and other detailed episodic properties, such as the acoustic properties of the listening environment, are encoded into lexical representations (Brandewie & Zahorik, 2010; Lachs, McMichael, & Pisoni, 2003). These additional sources of information are assumed to become an

integral part of the long-term representations that a listener stores about the sound patterns of spoken words in his or her language and the talkers he or she has been exposed to (Pisoni, 1997; Port, 2010a, 2010b; Remez, Fellows, & Nagel, 2007; Remez, Rubin, Pisoni, & Carrell, 1981). Viewed from this approach, speech variability is an important theoretical problem to study and understand because it has been ignored by speech scientists over the years despite its central role in all aspects of speech communication, cognition, learning, and memory (Jacoby & Brooks, 1984; Klatt, 1986, 1989; Stevens, 1996). Until recently, very little was known about the contribution of the indexical properties of speech to speech perception and the role these complementary attributes play in SWR (see Van Lancker & Kreiman, 1987).

An example of the parallel encoding of linguistic and indexical information in speech is displayed in Figure 20.3. The absolute frequencies of the vowel formants shown by peaks in the spectrum provide cues to speaker identification (A), whereas the relative differences among the formants specify information

FIGURE 20.3 (A) Vowel projections at the auditory periphery reveal that information for speaker identification and (B) perception of vowel quality is carried simultaneously and in parallel by the same acoustic signal. The tonotopic organization of the absolute frequencies using a bark scale provides reliable cues to speaker identification, whereas the relations among the formant (F1, F2, and F3) patterns in terms of difference from F0 in barks provide reliable cues to vowel identification. Adapted from Hirahara and Kato (1992) with permission from the publisher.

used for vowel identification (B). Both channels are carried simultaneously by the same acoustic signal and both sources of information are encoded by the peripheral and central auditory mechanisms used to process speech signals.

Despite recent evidence in favor of episodic approaches to speech perception and SWR, we believe a hybrid account of SWR that also incorporates abstract representations espoused in the conventional view is a promising direction for future research (see proposals by Moore, 2007a, 2007b; Rönnberg et al., 2013). Substantial evidence has been reported for both abstract and episodic coding of speech by human listeners. The challenge for the future is to identify the conditions under which these types of representations are used in SWR. For example, there is mounting evidence in support of the time course hypothesis of SWR (Luce & Lyons, 1998; Luce & McLennan, 2005) that posits that during the process of recognizing spoken words, abstract linguistic information is typically processed prior to vocal sound source information and other types of indexical and episodic information in speech (Krestar & McLennan, 2013; Mattys & Liss, 2008; McLennan & Luce, 2005; Vitevitch & Donoso, 2011). Time course data on SWR are also consistent with hemispheric differences demonstrating that abstract information is processed more efficiently in the left hemisphere and more specific episodic details of speech, including indexical information, are processed more efficiently in the right hemisphere. There are data in support of such hemispheric differences in the visual domain as well, both for visual words (Marsolek, 2004) and nonlinguistic information (Burgund & Marsolek, 2000), and in the auditory domain for spoken words (González & McLennan, 2007), talker identification (González, Cervera-Crespo, & McLennan, 2012), and nonlinguistic environmental sounds (González & McLennan, 2009). Given that hemispheric differences have been observed in the visual and auditory domains—and for both linguistic and nonlinguistic stimuli—these results suggest that having both abstract and more detailed specific representations may be a general property of cognition and the human information processing system. Finally, controlled attention and other neurocognitive and linguistic factors also affect listeners' processing of abstract and indexical information in speech (Maibauer, Markis, Newell, & McLennan, 2014; McLennan, 2006; Theodore & Blumstein, 2011).

20.5 SOME NEW DIRECTIONS AND FUTURE CHALLENGES

After more than 50 years of research on human speech perception, many of the foundational assumptions of the conventional segmental linguistic view of speech

have turned out to be misguided, given our current understanding of how the peripheral and central auditory system work and how the brain and nervous system function to recognize spoken language (Davis & Johnsruide, 2003; Hickok & Poeppel, 2007; Scott et al., 2000; Scott & Johnsruide, 2003). Long-standing assumptions about SWR are being critically reevaluated (Luce & McLennan, 2005). Deeper theoretical insights have also emerged in recent years, encouraging further empirical research on normal-hearing populations, as well as clinical populations with hearing loss (Niparko et al., 2009; Pichora-Fuller, 1995) and language delays (Beckage, Smith, & Hills, 2011).

We have suggested that speech should no longer be viewed as just a linear sequence of idealized abstract context-free linguistic segments (see Port, 2010a, 2010b). It is also becoming clear that any principled theoretically motivated account of SWR will also have to be compatible with what we currently know about human information processing, including episodic memory and learning (Pisoni, 2000). SWR does not take place in a vacuum isolated from the rest of cognition; core computational processes used in SWR are inseparable from basic memory, learning, and cognitive control processes that reflect the operation of many separate neurobiological components working together as a functionally integrated system (Belin, Zattore, Lafaille, Ahad, & Pike, 2000). As Nauta said more than 50 years ago, “no part of the brain functions on its own but only through the other parts of the brain with which it is connected” (Nauta, 1964, p. 125). In other words, it takes a whole brain to recognize words and understand spoken language—the ear is connected to the brain and the brain is connected to the ear.

Research on how early sensory information in speech is *mapped* onto lexical representations of spoken words and how these detailed representations are accessed in SWR tasks has numerous clinical implications for listeners with hearing loss, especially hearing-impaired children and adults who have received cochlear implants (Kirk, 2000; Kirk & Choi, 2009; Kronenberger, Pisoni, Henning, & Colson, 2013; Niparko et al., 2009; Pisoni, 2005).

In addition to clinical implications related to hearing impairment, basic research in SWR has led to other new directions. Research on the recognition of foreign-accented speech contributes to our understanding of lexical activation and selection processes (e.g., Chan & Vitevitch, 2015) and provides new insights into the circumstances under which variability in indexical information affects listeners' ability to recognize words by non-native speakers (McLennan & González, 2012).

SWR in bilinguals represents another promising area of research. Studies with bilinguals make important contributions to our understanding of basic representational and processing issues in SWR (Vitevitch, 2012).

For example, a recent study with bilinguals demonstrates that it is easier to learn to recognize the voices of previously unfamiliar talkers in a language learned early in life (Bregman & Creel, 2014). Studies of bilingual SWR can also be used as a tool to investigate differences in cognitive control processes between monolinguals and bilinguals (Kroll & Bialystok, 2013; however, see de Bruin, Treccani, & Della Sala, 2015).

Finally, scientists have extended SWR studies to investigations of the aging lexicon and the decline in language processes (e.g., Ben-David et al., 2011; Meister et al., 2013; Sommers, 2005; Yonan & Sommers, 2000). Many aspects of language processing are less likely to show age-related declines—and some show improvements—as a consequence of normal aging compared with many other perceptual and cognitive domains (Taler, Aaron, Steinmetz, & Pisoni, 2010).

20.6 SUMMARY AND CONCLUSIONS

Listeners bring an enormous amount of prior knowledge to every spoken language task they are asked to perform in the research laboratory, clinic, or daily life. In this chapter, we have argued that it is important to keep these broad observations in mind in understanding how spoken words are recognized so efficiently and how listeners manage to reliably recover the talker's intended linguistic message from highly degraded sensory inputs under challenging conditions. The findings reviewed in this chapter suggest that SWR processes are highly robust because listeners are able to make use of multiple sources of information encoded in the speech signal—the traditional linguistic pathway that encodes acoustic-phonetic information specifying the talker's intended message, the indexical pathway that encodes and carries detailed episodic contextual attributes specifying the vocal sound source such as the talker's gender, regional dialect, and mental and physical states, as well as other downstream sources of linguistic knowledge that support word prediction strategies, sentence parsing, and linguistic interpretation. Variability in the speech signal was once considered an undesirable source of noise and signal degradation that needed to be eliminated or normalized away to recover the idealized abstract segmental content of the talker's intended linguistic message. We now realize that this long-standing conventional view of speech perception and SWR is fundamentally incorrect and that variability in speech is highly informative and an extremely valuable source of contextual information that listeners encode, process, and routinely make use of in recognizing spoken words, especially in noise and under other adverse listening conditions.

We suggested that the field of SWR appears to have reached a plateau in terms of major theoretical or modeling advancements. However, there have been a number of important new empirical and methodological contributions. Among these include time course findings, due in large part to innovative techniques such as eye-tracking using the visual world paradigm (Alloppenna, Magnuson, & Tanenhaus, 1998) and, more recently, mouse-tracking (Spivey, Grosjean, & Knoblich, 2005). Moving forward into the future, these new methodologies should contribute to improved theories and more precise models of SWR. We also expect to see increases in the number of studies investigating the recognition of casually spoken phonetically reduced words (e.g., Ernestus, Baayen, & Schreuder, 2002) and novel approaches to modeling SWR, including the integration of current computational models with existing hybrid frameworks that incorporate the roles of both abstract and indexical information in SWR (Luce et al., 2000). Finally, there is a rapidly growing body of research on lexical organization and lexical connectivity of words using theory and methodology developed in the field of complex networks and graph theory that has provided additional new insights into spoken language processing and holds promise for dealing with more global aspects of SWR in typical and atypical populations (Altieri, Gruenenfelder, & Pisoni, 2010; Beckage et al., 2011; Kenett, Wechsler-Kashi, Kenett, Schwartz, & Ben-Jacob, 2013; Vitevitch, 2008; Vitevitch, Chan, & Goldstein, 2014).

Acknowledgments

Preparation of this chapter was supported, in part, by research grants R01 DC-000111 and R01 DC-009581 to Indiana University from NIH NIDCD. We are grateful to Luis Hernandez for his dedication, help, and continued assistance and advice over many years in maintaining our research laboratory and contributing to the creation of a highly productive and stimulating research environment at Indiana University in Bloomington. We also thank Terren Green for her help and assistance in the preparation of the present manuscript. Finally, D.B.P. expresses his thanks and deepest appreciation to Professor Kenneth N. Stevens, his postdoctoral mentor in the Speech Communications Group at the Research Laboratory of Electronics, MIT, who passed away last year. As everyone in our field knows, Ken Stevens was one of the early pioneers and major architects in the field of speech communications research, speech acoustics, acoustics-phonetics, and speech perception, and he provided wonderful guidance and advice to many graduate students and postdocs during his more than 50 years as a member of the faculty at MIT. Ken—this one's for you! We'll miss you.

Visual Word Recognition

Kathleen Rastle

Department of Psychology, Royal Holloway, University of London, Egham, Surrey, UK

Reading is one of the most remarkable of our language abilities. Skilled readers are able to recognize printed words and compute their associated sounds and meanings with astonishing speed and a great deal of accuracy. Yet, unlike our inborn capacity for spoken language, reading is not a universal part of the human experience. Reading is a cultural invention and a learned skill, acquired only through years of instruction and practice. Understanding the functional mechanisms that underpin reading and learning to read has been a question of interest since the beginnings of psychology as a scientific discipline (Cattell, 1886; Huey, 1908) and remains a central aim of modern psycholinguistics. This chapter considers one aspect of the reading process—visual word recognition—which is the process whereby we identify a printed letter string as a unique word and compute its meaning. I focus on the understanding of this process that we have gained through the analysis of *behavior* and draw particular attention to those aspects of this process that have been the object of recent debate.

21.1 THE ARCHITECTURE OF VISUAL WORD RECOGNITION

Although the earliest theories of visual word recognition claimed that words were recognized as wholes on the basis of their shapes (Cattell, 1886), there is a strong consensus among modern theories that words are recognized in a hierarchical manner on the basis of their constituents, as in the interactive-activation model (McClelland & Rumelhart, 1981; Rumelhart & McClelland, 1982) shown in Figure 21.1 and its subsequent variants (Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001; Grainger & Jacobs, 1996; Perry, Ziegler, & Zorzi, 2007).

Information from the printed stimulus maps onto stored representations about the visual features that make up letters (e.g., horizontal bar), and information from this level of representation then maps onto stored representations of letters. Some theories assert that letter information goes on to activate higher-level subword representations at increasing levels of abstraction, including orthographic rimes (e.g., the -and in “band”; Taft, 1992), morphemes (Rastle, Davis, & New, 2004), and syllables (Carreiras & Perea, 2002), before activating stored representations of the spellings of known whole words in an orthographic lexicon. Representations in the orthographic lexicon can then activate information about their respective sounds and/or meanings. The major theories of visual word recognition posit that word recognition is achieved when a unique representation in the orthographic lexicon reaches a critical level of activation (Coltheart et al., 2001; Grainger & Jacobs, 1996; Perry et al., 2007).

In recent years, a different class of theory based on distributed-connectionist principles has made a substantial impact on our understanding of processes involved in mapping orthography to phonology (Plaut, McClelland, Seidenberg, & Patterson, 1996) and mapping orthography to meaning (Harm & Seidenberg, 2004). This chapter highlights some of the most important insights that these models have offered to our understanding of reading. However, although these models have been very effective in helping us to understand the acquisition of quasi-regular mappings (as in spelling-to-sound relationships in English), they have been less successful in describing performance in the most frequently used visual word recognition tasks. They offer no coherent account of the most elementary of these tasks—deciding whether a letter string is a known word (i.e., visual lexical decision). Therefore, this chapter assumes a theoretical perspective based on the interactive-activation model and its

FIGURE 21.1 The interactive-activation model of visual word recognition (McClelland & Rumelhart, 1981; Rumelhart & McClelland, 1982).

subsequent variants but directs the reader to further discussion of this issue in relation to distributed-connectionist models (Coltheart, 2004; Rastle & Coltheart, 2006).

21.2 ORTHOGRAPHIC REPRESENTATION

21.2.1 Letters and Letter Position

There is widespread agreement that stored representations of letters are *abstract letter identities*, meaning that they are activated independently of font, size, case, color, or retinal location (Bowers, 2000). This abstraction is a key part of skilled reading because it permits rapid recognition of words presented in unfamiliar surface contexts (e.g., handwriting, typeface). In addition to encoding information about abstract letter *identities*, letter representations must also encode information about letter position. Otherwise, the visual word recognition system would not be able to distinguish words like SALT and SLAT, which share the same letters but in different positions. The classical solution to this problem implemented in the interactive-activation model (McClelland & Rumelhart, 1981; Rumelhart & McClelland, 1982) and its subsequent variants (Coltheart et al., 2001; Grainger & Jacobs, 1996; Perry et al., 2007) involves slot-based coding. In this scheme, there are slots for each position in a letter string, and a full set of letters within each of those positions. Thus, SALT is coded as $S_1A_2L_3T_4$ and is therefore easy to distinguish from SLAT ($S_1L_2A_3T_4$), because these stimuli overlap only in the initial and final letters (S_1T_4).

However, recent research has demonstrated convincingly that information about letter position is not represented through this type of slot-based coding. The general problem with slot-based coding is that words such as SLAT and SALT are judged by skilled readers to be perceptually very similar, despite the fact that their slot-based codes overlap by only 50% (S_1T_4). In fact, the slot-based codes for SLAT and SALT overlap to the same degree as do those for SPIT and SALT (S_1T_4), which are judged to be much less similar. The following e-mail message, which was circulated globally some years ago, demonstrates this principle very well:

Accodrning to rseearch at Cmabrigde Uinervtisy, it deosn't mttair in waht oredr the ltteers in a wrod are, the olny iprmoetnt tihng is taht the frist and lsat ltteer be at the rghit pclae.

Indeed, the reason that we can read this passage so easily is that words with transposed letters are perceived as being very similar to their base words. This issue has been studied experimentally using the masked form priming technique (Forster & Davis, 1984) in which a target stimulus presented for recognition is preceded by a consciously imperceptible prime stimulus. For example, Schoonbaert and Grainger (2004) demonstrated that recognition of a target stimulus like SERVICE is faster when it is preceded by a masked transposed-letter prime like *sevrice* than when it is preceded by a masked substitution prime stimulus like *sedlice*. This result is important because according to slot-based coding, transposed-letter prime *sevrice* and substitution prime *sedlice* have equivalent perceptual overlap with target SERVICE, and thus should speed target recognition to the same degree. Similar results are observed when transpositions are nonadjacent; for example, the recognition of CASINO is speeded by the prior masked presentation of the prime *caniso* relative to the prime *caviro* (Perea & Lupker, 2003). Finally, these kinds of results extend to even more extreme modifications; for example, the recognition of SANDWICH is speeded by the prior masked presentation of the prime *snawdcih* relative to the prime *skwogpah* (Guerrera & Forster, 2008).

These and other findings highlight an intriguing problem in visual word recognition. Readers are clearly able to distinguish anagram stimuli such as SNAWDICIH and SANDWICH, so letter representations must be coded for position. However, classical theories of how this is achieved (McClelland & Rumelhart, 1981) are clearly inadequate. The evidence now seems to suggest that orthographic representations must code position in a *relative* rather than *absolute* manner, and probably with some degree of uncertainty or sloppiness, as in the spatial coding scheme used by the SOLAR model (Davis, 2010). Further, while these kinds of effects motivating

position uncertainty have been reported across a variety of alphabetic languages, it is also important to observe that they are not universal. Primes with transposed letters do not facilitate recognition of their base words (relative to substitution primes) in Hebrew, for example (Velan & Frost, 2009). The reasons for this are not yet well-understood, but it seems likely that the greater the density of the orthographic space, the greater the pressure to develop very precise orthographic representations (Frost, 2012). Further research is necessary to determine the exact nature of orthographic coding and why position uncertainty appears to vary as a function of the nature of the writing system.

21.2.2 Frequency, Cumulative Frequency, and Age of Acquisition

There is a broad consensus that an individual's previous experience with a word is the most powerful determinant of how rapidly that word is identified. But what is meant by "an individual's previous experience"? The most common proxy for this is word frequency—the number of times a particular word occurs in some large corpus of text (Baayen, Piepenbrock, & van Rijn, 1993; New, Brysbaert, Veronis, & Pallier, 2007). Effects of word frequency have been reported in lexical decision (Balota, Cortese, Sergent-Marshall, Spieler, & Yap, 2004; Forster & Chambers, 1973) along with every other speeded task thought to reflect access to orthographic representations, including perceptual identification (Broadbent, 1967), reading aloud (Balota & Chumbley, 1984), and eye-fixation times in sentence reading (Schilling, Rayner, & Chumbley, 1998). Provided frequency estimates are derived from a suitably large corpus of text (approximately half of the frequency effect occurs for words between 0 and 1 occurrences per million; van Heuven, Mandera, Keuleers, & Brysbaert, 2014), word frequency estimates can explain more than 40% of the variance in lexical decision time (Brysbaert & New, 2009). In light of these data, there is wide agreement that one's experience with words is somehow encoded in the orthographic representations of those words and influences the ease with which they can be identified. One long-standing theory is that orthographic representations for high-frequency words have higher resting levels of activation than those for lower-frequency words, making them easier to reach a critical recognition threshold (McClelland & Rumelhart, 1981).

Recently, an interesting debate has emerged over whether the age at which a word is acquired might also be an important aspect of lexical experience, with words acquired earlier processed more easily in visual word recognition tasks. Although several studies claim to have observed independent effects of frequency and

age-of-acquisition on visual word recognition when these factors are manipulated orthogonally (Gerhand & Barry, 1999; Morrison & Ellis, 1995), these claims have been very difficult to assess for a number of reasons. For one, the age-of-acquisition metrics used in these studies are typically *subjective estimates* given by adults of the age at which they acquired particular words. It is not unlikely that the frequency with which a word occurs influences those subjective estimates provided by adults. Further, word frequency and age-of-acquisition are very tightly correlated (i.e., high-frequency words are typically the ones acquired earliest; $r = -0.68$; Carroll & White, 1973), making it extremely difficult to design experiments that examine independent effects of these variables, particularly given that there are multiple corpora from which to draw both of these metrics. Finally, it has been proposed that word frequency and age-of-acquisition are just two dimensions of a single variable—cumulative frequency (i.e., the frequency with which a word occurs over an individual's lifetime; e.g., Zevin & Seidenberg, 2002).

Although it is now fairly well-accepted that cumulative frequency provides a better description of our experience with words than printed word frequency (Brysbaert & Ghyselinck, 2006), the more difficult question is whether the age-of-acquisition effects observed on visual word recognition can be accounted for by cumulative frequency. It now seems that the answer is "no." Recent empirical work has demonstrated that the impact of age-of-acquisition on a number of word processing tasks is greater than would be predicted by cumulative frequency (Ghyselinck, Lewis, & Brysbaert, 2004). Further, work using connectionist models has shown that age-of-acquisition effects may be a fundamental property of models that learn incrementally over time (Monaghan & Ellis, 2010). This computational work has also suggested that age-of-acquisition effects may be more prevalent when input-to-output mappings are less systematic—the reason being that the solution space for early-acquired items will be less helpful for later-acquired items when the mapping is more arbitrary (Monaghan & Ellis, 2010). This observation is consistent with the empirical literature that finds particularly robust effects of age-of-acquisition in tasks that require semantic involvement such as object naming (Ghyselinck, Lewis et al., 2004), translation judgment (Izura & Ellis, 2004), and living versus nonliving decisions (Ghyselinck, Custers, & Brysbaert, 2004).

21.2.3 Morphology

The majority of words in English, and in virtually all of the world's languages, are built by combining

and recombining a finite set of morphemes. These combinatorial processes in English start with a small number of stem morphemes (e.g., *trust*) and pair them with other stem morphemes to form compound words (e.g., *trustworthy*), or with derivational (e.g., *trusty*, *dis-trust*) or inflectional (e.g., *trusted*, *trusts*) affixes to form the much larger proportion of the words that we use. Despite the fact that words with just a single morpheme (e.g., *trust*) are in the extreme minority, the major computational models of visual word recognition (Coltheart et al., 2001; Grainger & Jacobs, 1996; Perry et al., 2007) have focused on those. Even when affixed words are included in these models, they are treated in exactly the same way as are nonaffixed words. This treatment is likely to be inadequate, because there is now substantial evidence that words comprising more than one morpheme are recognized in terms of their morphemic constituents.

One of the main sources of evidence for this claim comes from studies that investigate whether the frequency of the stem in a morphologically complex word (e.g., the *trust* in *dis-trust*) plays any role in the time taken to recognize that morphologically complex word. The answer is virtually unequivocal that it does. For example, Taft and Ardasinski (2006) demonstrated that visual lexical decisions for prefixed words with high-frequency stems (e.g., *rediscover*) were significantly faster than those for prefixed words with low-frequency stems (e.g., *refuel*), despite the fact that these two sets of words were matched on whole-word frequency (e.g., Ford, Davis, & Marslen-Wilson, 2010). This result appears to indicate that participants access the stems of these words during the recognition process, or alternatively that the representation for morphologically complex words like *rediscover* is somehow strengthened during acquisition by experience with their constituent stems (in this case, *discover*). Interestingly, the findings of Taft and Ardasinski (2006) held even in cases in which the nonword fillers for the lexical decision task comprised a prefix attached to a real-word stem (e.g., *relaugh*), which, if anything, should have biased participants against segmenting the stimuli into their morphemic constituents.

The other major source of evidence for the claim that printed words are recognized in terms of their morphemic constituents comes from masked priming data. Multiple studies have now demonstrated that the recognition of a stem target (e.g., DARK) is speeded by the prior masked presentation of a morphologically related prime (e.g., *darkness*). The locus of this facilitation appears to reside in orthographic representations, because the recognition of stem targets is speeded to the same degree by the prior presentation of morphologically simple masked primes that have the appearance of morphological complexity (e.g., the prime

corner speeds recognition of CORN). Critically, this facilitation cannot be ascribed to overlap in letter representations between primes and targets, because masked primes that share letters but no apparent morphological relationship with targets (e.g., *brothel*-BROTH; -el is not a possible suffix in English) yield no facilitation (Rastle et al., 2004; see Rastle & Davis, 2008 for review and relevant neural evidence). These data again indicate that readers activate representations of the stems of morphologically structured words during the recognition process.

21.3 PROCESSING DYNAMICS AND MECHANISMS OF SELECTION

The discussion thus far has described a hierarchical theory of visual word recognition that involves multiple layers of orthographic representation. Representations of the features are used to make letters map onto representations that code abstract letter identity and letter position. There is evidence that these representations then activate representations of sublexical units (e.g., morphemes) before activating representations of the spellings of known words in an orthographic lexicon. This section considers how information flows through this architecture, and how amidst activation of multiple candidates a unique word representation reaches a recognition threshold. This discussion is based largely on principles of the interactive-activation model (McClelland & Rumelhart, 1981; Rumelhart & McClelland, 1982), which many still consider to be the cornerstone of our understanding of visual word recognition.

21.3.1 Interactive Processing

One of the key principles of the interactive-activation model and its subsequent variants is interactive, or bidirectional, processing. In the hierarchical model described, there are assumed to be connections between adjacent levels of representation, which are both excitatory and inhibitory. Information flows in a bidirectional manner across these connections (e.g., letter representations activate word representations, and word representations activate letter representations), and this is what allows the model to explain how higher-level knowledge can influence processing at a lower level.

Two empirical effects were particularly important in identifying the role of bidirectional processing in visual word recognition—the word superiority effect (Reicher, 1969; Wheeler, 1970) and the pseudoword superiority effect (Carr, Davidson, & Hawkins, 1978; McClelland & Johnston, 1977). In the Reicher–Wheeler

word superiority experiments, a letter string was flashed very briefly and then replaced by a pattern mask. Participants were then asked to decide which of two letters, positioned below or above the previous target letter, were in the original target stimulus. The key manipulation was whether the original target was a word (e.g., WORD) or nonword (e.g., OWRK). Results revealed that letter identification was far superior when the original flashed target was a word. These data suggest that letter representations receive top-down support through bidirectional connections from whole-word representations activated on presentation of the target stimulus. Intriguingly, a similar letter identification benefit is observed when the stimulus is a pronounceable pseudoword (e.g., TARK) as opposed to a nonpronounceable string (e.g., ATRK) (Carr et al., 1978; McClelland & Johnston, 1977). Even though pseudowords like TARK are not represented in the orthographic lexicon, this result indicates that they may activate whole-word representations for similar words (e.g., DARK, TALK, PARK), which then feed activation back to the letter level, thus explaining the letter identification benefit observed. Overall, these effects support the notion of interactive processing, because they suggest that a decision based on activation at the letter level is influenced by higher-level information from the orthographic lexicon. More recent research has revealed top-down influences of semantic and phonological variables on visual lexical decision, which can only be explained through interactive processing in the reading system. These semantic and phonological effects are discussed in [Section 21.4](#).

21.3.2 Competition as a Mechanism for Selection

The explanation of the pseudoword superiority effect suggests that printed letter strings activate multiple candidates at the word level. Thus, a letter string like WORD may activate the whole-word representation for WORD, along with whole-word representations for WORK, WARD, CORD, LORD, and others. In the interactive-activation model, the activation of multiple candidates is achieved through *cascaded processing* (McClelland, 1979). Representations at every level excite and inhibit representations at adjacent levels continuously, without having to reach some threshold (as was the case in the “logogen” model; Morton, 1969). However, the situation in which multiple candidates are activated from a single printed stimulus raises the question of how the recognition system selects a unique representation corresponding to the target. The interactive-activation model

solves this problem through competition. In addition to connections between levels of representation, the interactive-activation model posits intralevel inhibitory connections. These lateral inhibitory connections between whole-word representations allow the most active unit (typically that of the target) to drive down activation of its competitors. Of course, representations for any competing alternative candidates will also be exerting inhibition, which will serve to drive down activation of other competitors as well as the representation of the target, making it more difficult for the target to reach a recognition threshold.

21.3.2.1 Neighborhood Effects

One way in which this prediction has been tested is by looking at the impact of lexical similarity on visual word recognition. If a letter string is similar to many words (and thus activates multiple candidates), then it should be more difficult to recognize than a letter string that is similar to few words (and thus does not activate multiple candidates). Before describing the literature around this prediction, it is important to consider what is meant by the phrase “similar to many words.” This is a key point: what counts as similar depends entirely on the nature of the scheme adopted for coding letter position (see [Section 21.2.1](#)). Two stimuli that have large orthographic overlap according to one scheme for coding letter position may have much less overlap according to another scheme. This principle is nicely illustrated by considering the example words BLAND and LAND. In the slot-based coding scheme described on [Section 21.2.1](#), these stimuli share no overlap whatsoever. However, in a letter coding scheme based on relative position, such as the spatial coding scheme of the SOLAR model (Davis, 2010), these stimuli share substantial overlap. Thus, research on the consequences of lexical similarity for visual word recognition is impeded by the lack of consensus around the nature of orthographic input coding.

Until recently, much of the work regarding the impact of lexical similarity on visual word recognition has been based on a metric known as Coltheart’s N (Coltheart, Davelaar, Jonasson, & Besner, 1977). N is defined as the number of words of the same length that can be created by changing one letter of a stimulus, such that a word like CAKE has a very large neighborhood (e.g., BAKE, LAKE, CARE, CAVE) and a word like TUFT has no neighbors. Coltheart et al. (1977) reported that participants rejected high-N nonwords (e.g., PAKE) more slowly than low-N nonwords (e.g., PLUB) in a lexical decision task, an effect replicated several times (Forster & Shen, 1996; McCann, Besner, & Davelaar, 1988). High-N nonwords are thought to be more difficult to reject in lexical decision because they activate many units at the word level,

and this activation makes it difficult to decide that the stimulus is not a word. The situation is more complicated for word targets, however. In contrast to the predictions of competitive models, Coltheart et al. (1977) reported no effect of N on lexical decisions to word targets. Andrews (1989) then went on to report that words with many neighbors are responded to more *quickly* than words with few neighbors. The same year, however, Grainger, O'Regan, Jacobs, and Segui (1989) reported that words with at least one higher-frequency neighbor are recognized more slowly than words with no higher-frequency neighbors. This latter result makes the Andrews (1989) findings particularly perplexing given that words with many neighbors will almost certainly have at least one higher-frequency neighbor.

Although some investigators have continued to report facilitatory effects of N on recognition latency (Balota et al., 2004; Forster & Shen, 1996), most reports are in line with the prediction from competitive models (i.e., inhibitory effects of N) (Carreiras, Perea, & Grainger, 1997; Grainger & Jacobs, 1996; Perea & Pollatsek, 1998). Grainger and Jacobs (1996) put forward one of the most compelling explanations for these divergent effects, arguing that the inhibitory pattern is the "true" pattern and that facilitatory effects might be the result of strategic processes involved in making lexical decisions. Specifically, they argued that participants in the lexical decision task may be able to make a fast "YES" response if the *total* activation in the orthographic lexicon is high. The idea is that a large neighborhood is likely to lead to high total activation (i.e., because of the large number of word units activated), and hence it is through this fast guess mechanism that facilitatory effects of neighborhood are deemed to arise. This explanation has received support from studies showing that the direction of the neighborhood size effect can be influenced by instructions that stress speed or accuracy (De Moor, Verguts, & Brysbaert, 2005; Grainger & Jacobs, 1996). When participants need to be very accurate, inhibitory neighborhood effects are observed, presumably because their decisions are based on the activation of a single orthographic unit (which will be influenced by lateral inhibition). Conversely, when participants need to be very fast, facilitatory effects are observed, presumably because participants' decisions can be based on the fast guess mechanism that does not require access to an individual orthographic unit.

21.3.2.2 Masked Form Priming Effects

Masked form priming effects have been another powerful source of evidence in support of models that use competition as the mechanism for selection. In the interactive-activation model, priming is conceptualized as a balance between facilitation and inhibition. Primes activate visually similar targets, thus producing

savings in the time taken for those targets to reach a recognition threshold. However, primes can also activate orthographic units for whole words, which compete with targets for recognition. Davis (2003) therefore argued that the lexical status of a prime should be an important factor in determining the magnitude of form priming effects. Nonword primes (e.g., azle-AXLE) should yield facilitation, because primes activate units for their corresponding targets without also activating any units for competing words. Conversely, word primes (e.g., able-AXLE) should yield inhibition, because although the prime will still activate the target, it will activate the orthographic unit for itself much more strongly, which will compete with the target for recognition. Results strongly favor competitive models. Nonword masked primes always facilitate recognition of visually similar targets (e.g., azle-AXLE), whereas word masked primes typically inhibit or yield no effect on the recognition of visually similar targets (e.g., able-AXLE; see Davis & Lupker, 2006 for review). The only exception is when word primes appear morphologically related to targets (e.g., darker-DARK); in these cases, primes clearly facilitate rather than inhibit recognition of their targets (Rastle et al., 2004; see Section 21.2).

21.4 VISUAL WORD RECOGNITION AND THE READING SYSTEM

This chapter has put forward an understanding of visual word recognition based on a hierarchical analysis of visual features, letters, subword units (e.g., morphemes), and, ultimately, orthographic representations of whole words. Although visual word recognition is typically regarded in modern theories as based on the analysis of orthography, this system is embedded in a larger reading system that comprises processes to compute the sounds and meanings associated with known spellings. Further, although visual word recognition *remains possible* in the face of severe semantic and/or phonological impairment due to brain damage (Coltheart, 2004; Coltheart & Coltheart, 1997), it is undisputed that semantic and phonological information *can contribute* to visual word recognition.

One computational model that may help us to understand semantic and phonological influences on visual word recognition is the DRC model (Coltheart et al., 2001) shown in Figure 21.2.

This model postulates three processing pathways: (i) one pathway in which a printed letter string is translated to sound in the absence of lexical information; (ii) one pathway in which the phonological form of a word is retrieved directly after its activation in the orthographic lexicon; and (iii) one pathway in which

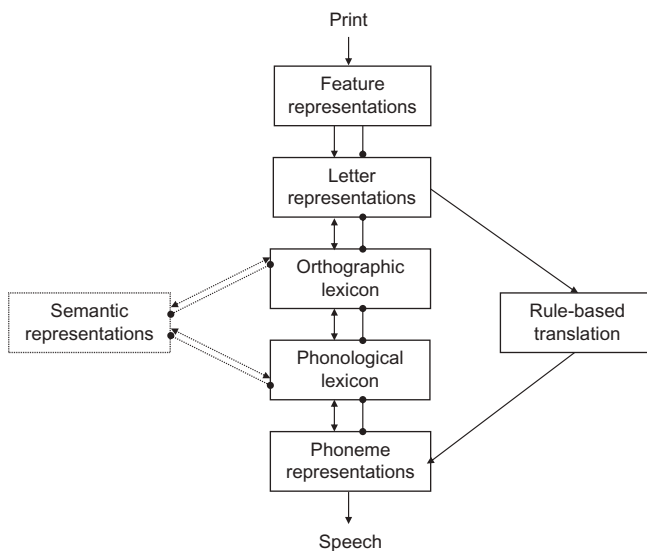

FIGURE 21.2 The DRC model (Coltheart et al., 2001).

the phonological form of a word is retrieved via its meaning representation. The architecture of this model maps fairly well to our understanding of the neural underpinnings of reading (see Taylor, Rastle, & Davis, 2013 for review).

The activation of orthographic whole-word units in the DRC model is based on the interactive-activation model (McClelland & Rumelhart, 1981; Rumelhart & McClelland, 1982). Because information about the printed stimulus flows through all three pathways in cascade, it is entirely possible in this model that information about the semantic and phonological characteristics of a letter string will be activated before any unit in the orthographic lexicon reaches a critical recognition threshold. Further, and critically, there are bidirectional connections between semantic, phonological, and orthographic bodies of knowledge, which make it possible for semantic and phonological information to impact on the activation of units in the orthographic lexicon.

21.4.1 Phonological Influences on Visual Word Recognition

It has been apparent for more than 40 years (actually, going all the way back to Huey, 1908) that the sounds associated with a printed letter string can influence its recognition. Huey (1908) described reading as involving auditory imagery or a “voice in the head,” and empirical effects reported during the cognitive renaissance (Rubenstein, Lewis, & Rubenstein, 1971) led theorists of reading to consider that phonological representations may be not only *involved* in visual word recognition but also a *requirement* of it (Frost, 1998; Lukatela & Turvey, 1994). Although this *strong*

phonological theory of visual word recognition (Frost, 1998) has fallen out of favor in more recent years, the evidence is unequivocal that sound-based representations are computed as a matter of routine during reading (see Rastle & Brysbaert, 2006 for review).

The use of homophones and pseudohomophones (i.e., nonwords that sound like words; e.g., BRANE) has proven especially useful in delineating the role of phonological representations in visual word recognition. Rubenstein et al. (1971) observed that YES responses in lexical decision were slower for homophones than for nonhomophones (e.g., recognition of MAID slower than PAID), and that NO responses were slower for pseudohomophones than for nonpseudohomophones (e.g., KOAT slower than FOAT). Both of these effects have been replicated and are well-accepted (e.g., homophone effect: Pexman, Lupker, & Hino, 2002; pseudohomophone effect: Ziegler, Jacobs, & Kluppel, 2001). Both of these effects are easy to understand in the light of bidirectional connections in the reading system. The homophone effect arises because after presentation of the stimulus MAID, activation of the phonological unit corresponding to MAID goes on to activate the competitor MADE in the orthographic lexicon, thus slowing recognition of MAID. The pseudohomophone effect arises because the stimulus KOAT will be translated nonlexically to a phonological representation that will activate a unit in the phonological lexicon. This phonological unit will then send activation back to the orthographic unit for COAT, making it difficult to classify the stimulus as a nonword.

Pseudohomophones have also been used extensively in the context of masked form priming to elucidate the role of phonology in visual word recognition. There are now a number of studies showing that the recognition of a target stimulus (e.g., COAT) is facilitated by the prior presentation of a masked pseudohomophone prime (e.g., KOAT) relative to an orthographic control prime (e.g., POAT; Ferrand & Grainger, 1992). This masked phonological priming effect arises in lexical decision, reading aloud, perceptual identification, and eye-movement paradigms, although a meta-analysis conducted by Rastle and Brysbaert (2006) revealed that the effect is small. These effects suggest not only that phonological representations can play a role in visual word processing but also that phonology is activated remarkably quickly in the recognition process. It was these demonstrations of “fast phonology” that led to excitement around the strong phonological theory of reading (Frost, 1998), although modern theorizing suggests that these effects can be explained within *weak phonological theories* like the DRC model (Figure 21.2), in which visual word recognition is characterized by an orthographic analysis that *can be influenced by* phonological representations (Rastle & Brysbaert, 2006).

21.4.2 Semantic Influences on Visual Word Recognition

The DRC model (Coltheart et al., 2001) asserts that skilled readers can recognize printed words in the absence of semantic information, and this claim is backed by evidence that brain-damaged patients with severe semantic impairments can nevertheless recognize printed words accurately (Coltheart, 2004). However, as in the case of phonological information, there is a broad consensus that semantic information can influence visual word recognition. Multiple studies now suggest that words that have particularly rich semantic representations are recognized more quickly than words with more impoverished semantic representations. Visual word recognition is speeded by high imageability (e.g., Balota et al., 2004), high semantic neighborhood density (Locker, Simpson, & Yates, 2003), a large number of meanings (Hino & Lupker, 1996) and related meanings (Azuma & Van Orden, 1997), and a large number of related senses (Rodd, Gaskell, & Marslen-Wilson, 2002). Here, again, bidirectional connections provide the mechanism for explaining these kinds of effects. Printed words activate their semantic representations, and activation at this level feeds back to support orthographic representations for word targets.

Priming studies also reveal semantic influences on visual word recognition. In a seminal study, Meyer and Schvaneveldt (1971) observed that lexical decisions to words (e.g., DOCTOR) were speeded by the prior presentation of semantically related primes (e.g., NURSE) relative to unrelated primes (e.g., BREAD). This finding has been replicated numerous times and has motivated a literature all of its own (e.g., see Hutchison, 2003; Lucas, 2000 for reviews). Semantic priming is usually conceptualized in terms of spreading activation between localist units (Collins & Loftus, 1975), overlap in distributed featural representations (McRae, de Sa, & Seidenberg, 1997), or Euclidean distance between high-dimensional vectors derived from lexical co-occurrence matrices (Landauer & Dumais, 1997). Bidirectional connections between semantic and orthographic levels of representation also play a role in explaining the semantic priming effect. If semantic information about the target is activated after presentation of the prime (e.g., information about *doctor* activated after presentation of *nurse*), then this activation can feed back to the orthographic unit for the target (e.g., DOCTOR), thus speeding recognition time.

21.5 CONCLUSION

Humans are born to speak, but they have to learn to read. This fact is part of what makes visual word

recognition in the literate adult such an astonishing ability. Readers are faced with considerable variability in the forms of the symbols presented to them, and the density of the orthographic space (particularly in writing systems such as Hebrew) renders words highly confusable. Further, the reading system must develop in such a way that it is closely linked to phonological and semantic bodies of knowledge, and there is substantial evidence that this stored knowledge is activated very soon after presentation of a printed letter string. Research over the past 40 years on the functional mechanisms that underpin visual word processing has been a great success story. This research provides a sound basis for which to discover how the brain supports the mind in regard to this remarkable human achievement.

Sentence Processing

Fernanda Ferreira¹ and Derya Çokal²

¹Department of Psychology and Center for Mind and Brain, University of California, Davis, CA, USA; ²Institute for Brain and Mind, University of South Carolina, Columbia, SC, USA

The existence of a field called “sentence processing” attests to the implicit agreement among most psycholinguists that the sentence is a fundamental unit of language. In addition, by convention, the term “processing” in this context tends to refer to comprehension rather than production, and thus the topic of this chapter is people’s interpretations of sentences. Our goal is to provide an overview of the findings, theories, and debates that are discussed in more detail in the chapters in this volume comprising the section on “Sentence Processing” (Chapters 47–52). The relevant issues include syntactic and semantic processing, the time-course of interpretation, and the role of other cognitive systems such as working memory in forming sentence interpretations. In this chapter, we begin by examining the sources of information that are used during sentence processing. We then review the major theoretical controversies and debates in the field: the incremental nature of interpretation, serial versus parallel processing, and the extent of interaction among information sources during online processing. Then, we go over the major models of sentence processing, including syntax-based models, constraint-based models, the good-enough approach, and the very recent rational analysis approaches. We end with a few conclusions and speculations concerning future research directions.

22.1 SOURCES OF INFORMATION FOR SENTENCE PROCESSING

Since the 1980s, when psycholinguistics experienced a renaissance (Clifton, 1981) and returned to the question of how to relate formal and psychological approaches to language, the field of sentence processing has been associated with a commitment to the idea that syntactic information is critical to

successful language comprehension. Not all theorists agree on the nature of those syntactic representations or the relative importance of information sources that are nonsyntactic, but almost all assume that structure-building operations are essential for successful comprehension (Fodor, Bever, & Garrett, 1974; Frazier & Rayner, 1990). One key component is phrase-structure parsing, which refers to the process of identifying constituents and grouping them into a hierarchical structure. For example, in a sentence such as *While Mary bathed the baby played in the crib*, the parser must create a structural analysis that postulates the existence of a subordinate and a main clause; moreover, the main verb of the subordinate clause must be analyzed as intransitive and reflexive, and the subject of the main clause must be identified as *the baby*. With this analysis, the correct meaning can be derived, which is that Mary is bathing herself, and the baby is the agent of playing.

As the same example makes clear, one of the challenges to the parser is syntactic ambiguity. At various points in a sentence, a sequence of words can be given more than one grammatical analysis. In the example, the phrase *the baby* appears to be the object of *bathed*, but in fact it turns out to be the subject of *played*. The result is a so-called “garden-path.” The parser first builds an incorrect analysis, and reanalysis processes are triggered on receipt of a constituent that cannot be incorporated into the existing structure. Because the parser obeys the rules of the grammar, including the rule mandating overt subjects, the parse will fail at *played*, and the sentence processing system must locate the alternative analysis in which *the baby* is a subject. How this happens is another point of divergence between competing sentence processing models, as is discussed in Section 22.2.

An additional complication regarding the syntactic analysis of a sentence is that the grammar allows

constituents to be moved from their canonical positions. One classic example is the passive, in which the theme of an action is also the sentential subject, contrary to the general preference to align agency and subjecthood (Fillmore, 1968; Grimshaw, 1990; Jackendoff, 1990). Another type of moved constituent is wh-phrases; in English, as in many other languages, wh-phrases must be moved from their canonical position to a position at the beginning of the clause, leaving behind a trace or “gap.” For example, in *Which man did the dog bite?*, the phrase *which man* receives its thematic role from *bite*. The job of the parser is to find the gap and relate it to the wh-phrase so that the sentence can receive a correct interpretation. This task is made difficult by two challenges. First, the gap is a phonetically null element in the string, and therefore the parser must identify the gap based on the application of a range of linguistic constraints. The second challenge concerns ambiguity. Because many verbs have multiple argument structures, the parser may end up postulating a gap incorrectly. The result is so-called decoy gaps, as illustrated in *Who will the zombie eat with?* The parser initially assumes that *who* was moved from the direct object position after *eat*, and then must reanalyze that structure when *with* is encountered.

Studies investigating the processing of filler-gap dependencies have found evidence for a filled-gap effect, which is closely related to decoy gaps. Consider the example *Which patient did the doctor expect the nurse to call?* Most comprehenders will assume that *which patient* is the object of *expect*, but the noun phrase (NP) *the nurse* occupies that position, which means that the parser must look further along for the correct gap (located after *call*). The existence of filled-gap effects has led researchers to postulate two parsing preferences for creating filler-gap dependencies. One is that the parser adopts an active or early filler strategy (Frazier, Clifton, & Randall, 1983; Frazier & Flores D’Arcais, 1989), according to which a gap is postulated at the first syntactically permissible location. The second is that the parser makes use of verb argument structure information to guide the postulation of gaps. If a verb has a strong intransitive bias, then the parser is less likely to postulate a gap after it; if the verb is strongly transitive, then a postverbal gap will be more compelling.

As we have been discussing the importance of syntactic information for parsing, we have had numerous occasions to refer to lexical information as well. This is because lexical information is the fundamental bottom-up information source for sentence processing. In lexicalist theories, syntactic information is attached to specific words so that when a word is retrieved, its associated structural possibilities become available as

well (Joshi & Schabes, 1997; MacDonald, Pearlmutter, & Seidenberg, 1994). For example, retrieval of the verb *bathe* would bring up not only information associated with the syntactic category and meaning of that word but also the word’s syntactic dependents in the form of what are known as argument structures. An optionally transitive verb like *bathe* would have at least two argument structures, one specifying an agent and a patient and the other specifying an agent and an obligatory reflexive null element. Nonlexicalist theories also assume a major role for this type of information; however, in contrast with lexicalist theories, argument structures are used not to generate a parse, but rather to filter or reinforce a particular analysis and to facilitate recovery from a garden-path.

Another type of lexical information that can be critical for parsing relates to semantic features such as number and animacy. Number information can affect how an ambiguous phrase is attached during online processing; for example, in a sentence such as *While John and Mary kissed the baby slept*, the verb *kissed* is interpreted as intransitive because the plural subject triggers a reciprocal reading of *kissed*. A singular subject does not license this reciprocal interpretation (Ferreira & McClure, 1997; Patson & Ferreira, 2009). Similarly, animacy can help the parser avoid a garden-path, or help it recover more easily (Ferreira & Clifton, 1986; Trueswell, Tanenhaus, & Kello, 1993). Specifically, if a subject is inanimate, then it is unlikely to be an agent, and that analysis, in turn, might lead the parser to adopt a less frequent passive or reduced relative parse (e.g., *The evidence examined by the lawyer*). These examples also show how word properties such as number and animacy interact with lexical argument structures, because those features can lead the parser to select one argument structure (e.g., a reciprocal one for a verb such as *kiss*) over another.

Next, let us consider the question of how prosodic information might influence sentence processing. The starting point for most studies published on this topic is that syntactic and prosodic structures are related and, in particular, major syntactic boundaries such as those separating clauses are usually marked by phrase-final lengthening and changes in pitch (Ferreira, 1993). Some clause-internal phrasal boundaries are also marked, although much less reliably (Allbritton, McKoon, & Ratcliff, 1996); for example, in the sentence *John hit the thief with the bat*, the higher attachment of *with the bat*, which supports the instrument interpretation, is sometimes (but not always) associated with lengthening of *thief*. The logic of the research enterprise is to see whether prosodic “cues” can signal syntactic structure and help the parser to avoid going down a garden-path. One of the earliest

studies to consider this question was conducted by Beach (1991), who demonstrated that meta-linguistic judgments about sentence structure are influenced by the availability of durational and pitch information linked to the final structures of the sentences. A few decades later, more sensitive online techniques including recording of event-related potentials (ERPs) and eye-tracking have yielded a wealth of information about the comprehension of spoken sentences, and one of the ideas on which there is now a general consensus is that prosody does influence the earliest stages of parsing (Nakamura, Arai, & Mazuka, 2012).

Another potentially influential source of information for sentence processing is context, both discourse and visual. An early analysis of the role of discourse context is known as Referential Theory (Crain & Steedman, 1985). It has been observed that many of the sentence forms identified as syntactically dispreferred by the two-stage model are also presuppositionally more complex. For example, the sentence *John hit the thief with the bat* allows for two interpretations: the *with*-phrase may be interpreted as an instrument or a modifier; the latter interpretation requires a more complex structure (on some theories of syntax). The “confound” here is that the more complex structure also involves modification, whereas the simpler analysis does not. Moreover, a modified phrase such as *the thief with the bat* presupposes the existence of more than one thief, and thus the difficulty of the more complex structure might not be due to its syntax, but rather to the lack of a context to motivate the modified phrase. Crain and Steedman predicted that sentences processed in presuppositionally appropriate contexts would be easy to process, a prediction that Ferreira and Clifton (1986) examined using eye movement monitoring in reading. Their data were consistent with the idea that context did not affect initial parsing decisions: Supportive contexts led to shorter global reading times and more accurate question-answering behavior, but early measures of processing revealed that processing times were longer for structurally complex sentences compared with their structurally simpler counterparts.

The potential role of visual context became a topic of intense interest in the 1990s with the emergence of the Visual World Paradigm (VWP) for studying sentence processing. The idea behind the paradigm is simple. From reading studies, it was known that fixations are closely tied to attention and processing (Rayner, 1977). The VWP extends this logic to spoken language processing by pairing spoken utterances with simple displays containing mentioned and unmentioned objects. The “linking hypothesis” (Tanenhaus, Magnuson, Dahan, & Chambers, 2000) is that as a word is heard, its

representation in memory becomes activated, which triggers eye movements toward the named object as well as objects semantically and even phonologically associated with it (Huettig & McQueen, 2007). The widespread adoption of the VWP occurred in part because the idea of multimodal processing was also catching on, with many cognitive scientists wanting to understand the way different cognitive systems might work together—in this case, the auditory language processing system and the visuo-attention system associated with object recognition (Henderson & Ferreira, 2004; Jackendoff, 1996). There was also a growing interest in auditory language processing generally, and in the investigation of how prosodic information might be used during comprehension, as discussed previously. By now, hundreds of studies have been reported making use of it in one way or another (Ferreira, Foucart, & Engelhardt, 2013; Huettig, Olivers, & Hartsuiker, 2011; Huettig, Rommers, & Meyer, 2011).

The reports that triggered the widespread use of the VWP are those by Spivey, Tanenhaus, Eberhard, and Sedivy (2002) and Tanenhaus, Spivey-Knowlton, Eberhard, and Sedivy (1995). This study adapted the ideas of Crain and Steedman (1985) concerning presuppositional support to the domain of visual contexts and spoken sentences that could be evaluated against them. To illustrate, consider the sentence *Put the apple on the towel in the box*. At the point at which the listener hears *on the towel*, two interpretations are possible: either *on the towel* is the location to which the apple should be moved or it is a modifier of *apple*. The phrase *into the box* forces the latter interpretation because it is unambiguously a location. Referential Theory specifies that speakers should provide modifiers only when modification is necessary to establish reference. It follows that if two apples are present in the visual world and one of them is supposed to be moved, then right from the earliest stages of processing, the phrase *on the towel* will be taken to be a modifier, because the modifier allows a unique apple to be identified. The listener faced with this visual world containing two referents should therefore immediately interpret the phrase as a modifier and avoid being garden-pathed (Farmer, Cargill, Hindy, Dale, & Spivey, 2007; Novick, Thompson-Schill, & Trueswell, 2008; Spivey et al., 2002; Tanenhaus et al., 1995). Recently, however, the interpretation of these findings has been challenged. Ferreira et al. (2013) conducted three experiments manipulating properties of the utterances and the visual worlds. They concluded that listeners engage in a fairly atypical mode of processing in VWP experiments with simple visual worlds and utterances that are highly similar to each other in all experimental trials. Rather than processing utterances normally, they instead form a skeleton, underspecified

representation of what they are likely to hear based on the content of the display, and then they evaluate that prediction against the utterance itself. These issues concerning the use of the VWP require additional investigation.

In summary, a range of sources of information is used for successful sentence processing. Lexical and syntactic constraints are central for defining the structural alternatives considered by the language processing system, and information associated with the prosody of the sentence as well as the discourse and visual context in which the sentence occurs helps to reinforce some interpretations and flesh out the full meaning of the sentence. In the following section, we consider some of the theoretical controversies concerning the architecture of the language system and the way these sources of information are coordinated. This discussion sets the stage for our discussion of theoretical models of sentence processing.

22.2 THEORETICAL CONTROVERSIES

In this section, we consider four issues that help distinguish among competing models of sentence processing: (i) incremental interpretation; (ii) serial versus parallel processing; (iii) interactivity versus modularity; and (iv) sources of complexity in comprehension, including those that arise due to working memory constraints.

Incremental interpretation refers to whether the sentence processing system builds the meaning of a sentence word-by-word, as the input unfolds, or whether the system either falls behind or gets ahead of the input. Falling behind the input would indicate delays in interpretation; getting ahead would indicate anticipation or prediction. Essentially all current models of processing assume that interpretations are built incrementally and, in particular, that there are no delays in incorporating new words into the ongoing representation of sentence meaning. In addition, there is some evidence that comprehenders engage in prediction (Levy, 2008; Rayner, Li, Juhasz, & Yan, 2005; Van Berkum, Brown, Zwitterlood, Kooijman, & Hagoort, 2005). The classic demonstration of prediction comes from Altmann and Kamide (1999), who used the VWP and semantically constrained sentences such as *The boy will eat the cake*. They observed that listeners made anticipatory eye movements to a depicted cake prior to hearing the word *cake*, indicating that they predicted that continuation. In the structural domain, Staub and Clifton (2006) found that when readers processed a clause beginning with the word *either*, they predicted an upcoming *or*-clause based on the syntactic constraint that the latter must follow the former.

These and other studies have been taken as evidence that the sentence processing system is not just an incremental, but actually a predictive, anticipating structure and even specific lexical content.

At the same time, there is some evidence that additional processing takes place at major syntactic boundaries. So-called end of sentence wrap-up refers to the finding that reading times at the ends of clauses and sentences are longer than in other sentential positions (Aaronson & Scarborough, 1976; Just & Carpenter, 1980; Rayner, Kambe, & Duffy, 2000; Rayner, Sereno, Morris, Schmauder, & Clifton, 1989). Wrap-up effects indicate that some elements of meaning are computed over a more global domain. In addition, clause boundaries might be the locations where the comprehension system evaluates the entire structure to ensure that all relevant constraints are satisfied, for example, to check that a verb has all its obligatory arguments. Evidence for underspecified representations also suggests some tendency on the part of the processing system to delay interpretations (for an excellent summary, see Frisson, 2009). Words with multiple senses (e.g., *book* as an object versus its content) seem to be processed by initially activating an underspecified meaning, and then by filling out the semantics once contextually disambiguating information becomes available. Some syntactic ambiguities may also be handled in a similar manner, for example, comprehenders leave open the interpretation of ambiguous relative clauses (*the servant of the actress who was on the balcony*), making a specific attachment decision only once it is necessary to do so (Swets, Desmet, Clifton, & Ferreira, 2008). Pronouns are also often not assigned specific antecedents (McKoon, Greene, & Ratcliff, 1993).

The second theoretical issue in which theories of sentence processing differ is serial versus parallel processing, which typically refers to assumptions about whether the system considers only one interpretation at a time or multiple interpretations. For example, consider *The defendant examined by the lawyer turned out to be unreliable* (Ferreira & Clifton, 1986). The sequence *the defendant examined* could mean that the defendant examined something or that the defendant is the thing being examined (the ultimately correct analysis). The issue is whether only one of these interpretations is built and evaluated at any one time, or whether all the interpretations are simultaneously activated and assessed. In the serial view, first the system considers one analysis—in most theories, the one that assumes that the defendant is the agent of examining, given that this analysis is syntactically simpler and more frequent—and then reanalyzes it if a revision signal is encountered. The sentence processing system then goes into “reanalysis mode,” attempting to adjust

the syntactic structure that has been built to create a grammatical analysis (Ferreira & Henderson, 1991; Fodor & Ferreira, 1998; Fodor & Inoue, 1994). Ease of reanalysis depends on the extent to which the sentence processing system can find lexical and grammatical information that motivates an alternative structure.

The parallel view assumes that the sentence processing system activates all grammatically licensed analyses simultaneously. Considering our example, both the incorrect and the ultimately correct interpretations of *the defendant examined* would be available in parallel, initially weighted by their frequency. The agent analysis of *defendant* is more frequent; therefore, at first, it will be stronger than the ultimately correct analysis. But when the word *by* is encountered, the sentence processing system must shift to the other activated interpretation. Ease of reanalysis depends on the relative activation levels of the two interpretations. If the ultimately correct interpretation is infrequent, then it will be difficult to retrieve and reanalysis might even fail. If the right interpretation has some strength based on the extent to which it conforms to a wide range of linguistic and nonlinguistic constraints, then reanalysis will be easier, and so will overall comprehension of the sentence.

A careful reader might have noticed subtle differences in the terminology used in our discussion of serial versus parallel processing. For the former, interpretations are typically described as being “built,” whereas for the latter they are often referred to as being “activated” or “retrieved.” These different terms reflect fundamentally different ideas about how interpretations are stored in memory and accessed during sentence processing. The serial view tends to assume that syntactic rules are stored in memory and then used online to create a structural representation bit by bit. Reanalysis processes are a matter of editing the structure. The parallel view tends to assume that structures are stored in chunks, typically corresponding to an argument-taking word such as a verb and its arguments. Online processing involves not so much building a structure as much as activating one. These issues are raised again when we consider models of sentence processing.

The third issue in which theories of processing differ is interactivity versus modularity. Almost since the earliest days of psycholinguistics, debate has centered around the issue of whether the system considers only linguistic (and possibly even only syntactic) information when parsing a sentence versus a system that considers all potentially relevant sources of information. Modular models assume sentence structures are assigned to words at least initially without any consideration of whether the structure will map to a sentence interpretation that makes sense given prior knowledge or given the contents of the immediate linguistic, visual, or social context. For example, the sentence

processing system would be garden-pathed not only by *the defendant examined by the lawyer* but also by *the evidence examined by the lawyer*, even though *evidence* is inanimate and therefore cannot engage in an act of examination. In contrast, interactive models assume the immediate use of all relevant constraints. At this stage, there is widespread belief in the field that the preponderance of evidence supports interactive models, although it is possible to argue that this conclusion goes somewhat beyond the evidence (Ferreira & Nye, in progress).

Thus far we have mainly focused on structural ambiguity, which is certainly one source of difficulty or complexity in processing. But structure-building processes independent of ambiguity resolution are also a potential source of complexity, as first argued by Gibson (1991). One source of complexity is structural frequency. All things being equal, a structure encountered more frequently will be easier to comprehend than one that is rare (Ferreira, 2003; Gibson, 1991, 1998; MacDonald et al., 1994). The demands that structures place on working memory are an additional source of processing difficulty for both ambiguous and unambiguous structures (Chomsky & Miller, 1963; Gibson, 1991, 1998, 2000; Lewis & Vasishth, 2005; Yngve, 1960). For example, nested structures (*The reporter who the senator who John met attacked disliked the editor*) are harder to process than right-branching structures (*John met the senator who attached the reporter who disliked the editor*), a generalization that holds across typologically different languages (e.g., English, which is a subject verb object [SVO] language, and Japanese, which is subject object verb [SOV]). This contrast between nested and right-branching structures can be explained by appealing to the greater demands the former structures place on working memory. More specifically, two kinds of demands increase processing complexity for unambiguous as well as ambiguous structures: (i) storage costs and (ii) distance-based integration costs. Storage costs are incurred when incomplete materials must be held in working memory, for example, a verb that needs its arguments (Chen, Gibson, & Wolf, 2005; Gibson, 1998; Nakatani & Gibson, 2010). Distance-based costs are those that arise from attempts to integrate a word into the structure already built and seem to be proportional to the difficulty of reactivating an earlier word, for example, an argument that must be linked back to its verb (Gibson, 1998, 2000; Gordon, Hendrick, & Johnson, 2001, 2004; Grodner & Gibson, 2005; Lewis & Vasishth, 2005; Lewis, Vasishth, & Van Dyke, 2006). Distance-based costs also account for the well-known preference for subject-extracted over object-extracted relative clauses (Grodner & Gibson, 2005) and arise in part due to similarity-based interference in working memory (Gordon et al., 2001).

22.3 CLASSES OF MODELS OF SENTENCE PROCESSING

We begin with the so-called two-stage model or garden-path model, first developed by Lyn Frazier (Ferreira & Clifton, 1986; Frazier & Fodor, 1978; Rayner, Carlson, & Frazier, 1983). The model assumes that a single parse is constructed for any sentence based on the operation of Minimal Attachment, which constrains the parser to construct no potentially unnecessary syntactic nodes, and Late Closure, which causes the parser to attach new linguistic input to the current constituent. In addition, the model assumes that the only information that the parser has access to when building a syntactic structure is its database of phrase-structure rules; therefore, the parser cannot consult information associated with lexical items. For example, in the sequence *Mary knew Bill*, the noun phrase *Bill* would be assigned the role of direct object because that analysis is simpler than the alternative subject-of-complement-clause analysis, and the information that *know* takes sentence complements more frequently than direct objects could not be used to inform the initial parse.

The two-stage model has evolved over the past three decades to take into account changes in linguistic theory and significant findings in psycholinguistics. One important addition is the notion of “Construal” (Frazier & Clifton, 1997; Frisson & Pickering, 2001), which allows some constituents to be merely associated with a specific thematic domain in a sentence rather than definitively attached to the structure. Evidence for Construal comes from the finding that readers process sentences with ambiguous relative clauses more quickly than those that have a unique attachment (e.g., *the servants of the actress who was on the balcony*), unless the sentence is followed by a question that forces the reader to provide a specific interpretation; in that case, readers take longer to read the ambiguous versions, presumably because they are trying to choose between the attachment options. Another important revision of the two-stage model is that, now, prosody plays an essential role in determining how parsing proceeds from the earliest stages of processing (Millotte, Wales, & Christophe, 2007; Nakamura et al., 2012; Price, Ostendorf, Shattuck-Hufnagel, & Fong, 1991). Pitch and durational information associated with different kinds of prosodic and intonational phrasing are used to constrain the parser’s syntactic analyses and assist in the construction of semantic meanings such as focus and presupposition. Nonetheless, the essential features of the two-stage model remain. The model assumes that (i) information is used incrementally to build an interpretation; (ii) different possible interpretations are

built and evaluated serially, rather than in parallel; and (iii) only certain kinds of information can be used during the initial stages of sentence processing, particularly information stated in the syntactic and prosodic vocabulary of the sentence processing module.

The two-stage model was soon challenged by researchers in sentence processing who were strongly influenced by the connectionist architectures popular in the 1980s and 1990s (Rumelhart & McClelland, 1985, 1986; Seidenberg & McClelland, 1989). These architectures contrast with the assumptions of the two-stage model in two defining ways. First, in connectionist systems, alternative possibilities are activated and evaluated in parallel; second, any relevant source of information can be used to modulate the activation levels and allow one possible analysis to win at the expense of the others (MacDonald et al., 1994). Applying these ideas to sentence processing, the connectionist alternative assumed the following principles. First, rather than analyses being built with the help of grammatical rules, a great deal of the burden of syntactic representation is put into the lexicon. Adapting ideas that were then timely in linguistic theory (Pesetsky, 1995), lexical representations were assumed to activate not only words and word meanings but also syntactic frames. In this view, syntactic rules are redundant because almost all the necessary information is already stated in the lexicon. Thus, with syntactic structures being stored rather than built, it is easy to imagine an architecture in which all possible analyses are considered in parallel, weighted by their frequency of use. Lexical, contextual, and pragmatic constraints can be used to further modulate the activation levels. With this approach the sentence processing system is incremental, but different possible interpretations are activated in parallel. In addition, any potential source of information can be used at any stage of sentence processing, making the system interactive rather than modular.

Other classes of models emphasize the role of complexity in sentence processing (Gibson, 1991, 1998). The significance of these models is two-fold. First, they highlight sources of information that lead to processing costs for both ambiguous and unambiguous structures and thus capture well-known findings such as the preference for subject- over object-relative clauses (Gibson, 1991, 1998, 2000; Grodner & Gibson, 2005; Lewis & Vasishth, 2005; Yngve, 1960). Second, these models are specifically designed to take into account the role of working memory in sentence processing, with an emphasis on how costs associated with maintaining and integrating items in working memory affect complexity and, therefore, processing difficulty. These models make important predictions about phenomena in sentence processing

that are of particular interest to researchers attempting to uncover the neural mechanisms that underlie sentence comprehension, including structures such as passives and relative clauses.

In the past 15 years or so, a new class of models has emerged with roots in all the approaches that have been described thus far. There are many variants with important distinctions among them, but what they share is the idea that comprehenders sometimes end up with an interpretation that differs from the actual input received—the interpretation is simpler (Construal), somewhat distorted (Late Assignment of Syntax Theory (LAST); Good-Enough Processing), or outright inconsistent (Noisy Channel Approaches) with the sentence's true content. Let us begin with the models that assume representations that reduce the input in some way. One implementation is to allow representations to be underspecified (Sanford & Sturt, 2002). Consider Construal. As mentioned, this model assumes that syntactic structures are not always fully connected and adjunct phrases in particular (e.g., relative clauses, modifying prepositional phrases) may instead simply get associated with a certain processing domain, “floating” until disambiguating information arrives. The parser thus remains uncommitted (Pickering, McElree, Frisson, Chen, & Traxler, 2006) concerning the attachment of the relative clause and the interpretation that would follow from any particular attachment (Frisson & Pickering, 2001; Sanford & Graesser, 2006; Sturt, Sanford, Stewart, & Dawydiak, 2004). Other studies support the idea of underspecified representations for global syntactic structures (Tyler & Warren, 1987), semantic information (Frazier & Rayner, 1990), and coercion structures (Pickering et al., 2006).

More radical variants of shallow processing models allow the comprehension system to generate an interpretation that is even more discrepant from the input. Researchers in the field of text processing have shown that readers are sometimes remarkably insensitive to contradictions in text (Otero & Kintsch, 1992), and they also often fail to update their interpretations when later information undermines a fact stated previously (Albrecht & O'Brien, 1993). These ideas from text processing were exported to the sentence processing literature in a series of experiments showing that people do not seem to fully recover from garden-paths (Christianson, Hollingworth, Halliwell, & Ferreira, 2001). Participants read sentences such as *While the woman bathed the baby played in the crib* and then answered a question such as *Did the woman bathe the baby?* The surprising finding was that most people answered “yes,” even though the meaning of the reflexive verb *bathe* requires that the object be interpreted as coreferential with the subject (see also Slattery, Sturt, Christianson, Yoshida, & Ferreira, 2013).

It appears that comprehenders are not entirely up to the task of syntactic reanalysis and sometimes fail to revise either all pieces of the syntactic structure or all elements of the semantic consequences of the initial, incorrect parse. And the more semantically compelling the original misinterpretation, the more likely people are to want to retain it.

Townsend and Bever's (2001) model implements an architecture similar to what has been suggested for decision-making (Gigerenzer, 2004; Kahneman, 2003), where researchers sometimes distinguish between so-called System 1 and System 2 (or Type 1 and Type 2) reasoning. System 1 is fast, automatic, and operates via the application of simple heuristics. System 2, however, is slow and attention-demanding, and it consults a wide range of beliefs—essentially anything the organism knows and has stored in memory. In Townsend and Bever's (2001) LAST, sentences are essentially processed twice. First, heuristics are accessed that yield a quick meaning, and then syntactic computations are performed on the same word string to yield a fully connected, syntactic analysis. The second process ensures that the meaning that is obtained for a sentence is consistent with its actual form. Townsend and Bever also assume that the first stage is nonmodular and that the second is modular; this is to account for the use of semantics in the first stage and the use of essentially only syntactic constraints in the second.

Two models similar in spirit to LAST but that assume a modular architecture for the first stage have been proposed by Ferreira (2003) and by Garrett (2000). The Ferreira model assumes that the first stage consults just two heuristics—a version of the noun verb noun (NVN) strategy in which people assume an agent–patient mapping of semantic roles to syntactic positions and an animacy heuristic, in which animate entities are biased toward subjecthood. The 2003 Ferreira model explains comprehenders' tendencies to misinterpret passive sentences, particularly when they express an implausible event with reversible semantic roles, as in *the dog was bitten by the man*. The application of heuristics in the first stage yields the dog-bit-man interpretation; a proper syntactic parse will deliver the opposite, correct interpretation, but the model assumes that it is fragile and susceptible to interference. Garrett (2000) offers a more explicitly analysis-by-synthesis model that incorporates the production system to generate what are generally thought of as top-down effects. A first pass, bottom-up process uses syntactic information to create a simple parse that, in turn, allows for a rudimentary interpretation. Then, the language production system takes over and uses that representation to generate the detailed syntactic structure that would support the initial parse and interpretation.

Finally, a family of models has recently been proposed that assume people engage in rational behavior over a noisy communication channel. The channel is noisy because listeners sometimes mishear or misread due to processing error or environmental contamination, and because speakers sometimes make mistakes when they communicate. Thus, a rational comprehender whose goal is to recover the intention behind the utterance will normalize the input according to Bayesian priors. A body of evidence from research using ERPs helped to motivate these ideas (Kim & Osterhout, 2005; Van Herten, Kolk, & Chwilla, 2005). In these experiments, it is reported that subjects who encounter a sentence such as *The fox that hunted the poachers stalked through the woods* experience a P600 rather than an N400 on encountering the semantically anomalous word, even though an N400 might be expected given that it is presumed to reflect problems related to meaning. There is still not a great deal of consensus regarding what triggers P600s, but an idea that has been gaining traction is that it reflects a need to engage in some type of structural reanalysis or revision. The conclusion, then, is that when a person encounters a sentence that seems to say that the fox hunted the poachers, that person “fixes” it so it makes sense, resulting in a P600. Other models have taken this idea and developed it further (Gibson, Bergen, & Piantadosi, 2013; Levy, 2011; Levy, Bicknell, Slattery, & Rayner, 2009). These models are generally interactive, because the information that is accessed to establish the priors can range from biases related to structural forms and all the way to beliefs concerning speaker characteristics (Van Berkum, Van den Brink, Tesink, Kos, & Hagoort, 2008). However, these noisy channel models have not yet been rigorously tested using a methodology that allows early processes to be distinguished from later ones. For example, it remains possible that comprehenders create a simple parse in a manner compatible with modularity and then consult information outside the module to revise that interpretation, right down to actually normalizing the input. Models designed to explain the comprehension of sentences containing self-repairs and other disfluencies (*turn left uh right at the light*) assume mechanisms that allow input to be deleted so that the speaker’s intended meaning can be recovered (Ferreira, Lau, & Bailey, 2004).

22.4 CONCLUSION

The field of sentence processing has changed significantly since the 1980s. Current models emphasize more detailed, context-specific information such as speaker, and there is a great deal of interest in

mechanisms that allow the input to be rationally evaluated and corrected. Future work will continue to make use of behavioral techniques as well as methods from neuroscience to expand our understanding of these topics. The critical next stage is to determine how the processes assumed in models of sentence processing are actually implemented in the human brain. Our view is that the field is well-positioned for this challenge given the sophistication of extant sentence processing models.

Gesture's Role in Learning and Processing Language

Özlem Ece Demir¹ and Susan Goldin-Meadow²

¹Department of Communication Sciences and Disorders, Northwestern University, Evanston, IL, USA;

²Department of Psychology, University of Chicago, Chicago, IL, USA

In all cultures and at all ages, speakers move their hands when they talk—they gesture. Even congenitally blind individuals who have never seen anyone gesture move their hands when they talk (Iverson & Goldin-Meadow, 1998), suggesting that gesturing is a robust part of speaking. Moreover, gesture and speech form an integrated system for expressing meaning. Gesture conveys the visual component of the meaning and uses imagistic and analog devices to do so; speech conveys the linguistic component and uses the linear-segmented, hierarchical devices characteristic of language (McNeill, 1992, 2008). Our goal in this chapter is to introduce neuroscientists interested in the neurobiology of language to gesture and the role it plays in language learning and language processing. We focus primarily on behavioral studies and include findings from neuroimaging studies only when relevant (we direct the reader interested in the neurobiology of gesture to Chapter 32 by Dick and Broce). We begin by briefly reviewing evidence showing that gesture can provide a unique window into the mind of a speaker—not only does gesture reflect a speaker's thoughts but also it can play a role in changing those thoughts. We then explore in detail the role gesture plays in how language is learned and how it is processed.

23.1 GESTURE NOT ONLY REFLECTS THOUGHT, IT CAN PLAY A ROLE IN CHANGING THOUGHT

Although gesture may seem like handwaving, it in fact conveys substantive information, often information that is not found in the speaker's words. For example,

consider a child who is shown two rows of checkers. The child is first asked to verify that the two rows have the same number of checkers and is then asked whether the rows still have the same number after one row is spread out. The child says “no” and justifies his response by saying, “They are different because you moved them.” But at the same time, the child produces the following gestures—he moves his finger between the first checker in row 1 and the first checker in row 2, then the second checker in rows 1 and 2, and so on. In his gestures, the child is demonstrating an understanding of one-to-one correspondence, a central concept underlying the conservation of number that does not appear in his speech (Church & Goldin-Meadow, 1986).

Two additional points are worth noting about gesture. The information conveyed uniquely in a speaker's gestures is often accessible *only* to gesture, that is, it is encapsulated knowledge not yet accessible to speech (Goldin-Meadow, Alibali, & Church, 1993). Speakers who produce gestures that convey information not found in their speech when explaining a task are ready to learn that task—when given instruction in the task, they are more likely to profit from that instruction than speakers whose gestures convey the same information as their speech, whether the speakers are children (Church & Goldin-Meadow, 1986; Perry, Church, & Goldin-Meadow, 1988; Pine, Lufkin, & Messer, 2004) or adults (Perry & Elder, 1997; Ping, Decatur, Larson, Zinchenko, & Goldin-Meadow, under review).

Gesture can thus reflect the state of a speaker's knowledge. But there is now good evidence that gesture can do more than display what speakers know and can play a role in changing what they know. Gesture can change thinking in at least two ways.

First, the gestures we see others produce can change our minds. Learners are more likely to profit from instruction when it is accompanied by gesture than when that same instruction is not accompanied by gesture (Perry, Berch, & Singleton, 1995; Valenzeno, Alibali, & Klatzky, 2003), even when the gestures are not directed at objects in the immediate environment (Ping & Goldin-Meadow, 2008). Gesture has been found to be particularly helpful in instruction when it conveys a correct strategy for solving a math problem that is different from the (also correct) strategy conveyed in the accompanying speech (Singer & Goldin-Meadow, 2005).

Second, the gestures that we ourselves produce can change our minds. To determine whether gesture can bring about change, we need to teach speakers to gesture in particular ways. If speakers can extract meaning from their gestures, then they should be sensitive to the particular movements in those gestures and change their minds accordingly. Alternatively, all that may matter is that speakers move their hands. If so, then they should change their minds regardless of which gestures they produce. To investigate these alternatives, Goldin-Meadow, Cook, and Mitchell (2009) manipulated gesturing during a math lesson. They found that children required to produce *correct* gestures learned more than children required to produce *partially correct* gestures, who in turn learned more than children required to produce *no* gestures. After the lesson, the children who had gestured were able to express in their own words the information that they had conveyed only in their gestures during the lesson (and that the teacher had not conveyed at all), that is, they had learned from their hands. These findings suggest that the gestures speakers produce can have an impact on what they learn.

Having found that gesture has cognitive significance in many contexts, we are now in a position to explore the role of gesture in learning and processing language.

23.2 ROLE OF GESTURE IN LANGUAGE LEARNING

Just like adults, children gesture as they speak. Children start communicating through gestures even before they are able to speak. In this section, we review the role gesture plays in developing vocabulary, syntax, and discourse skills in language comprehension and production.

23.2.1 Vocabulary

23.2.1.1 Vocabulary Comprehension

Children rely on gesture to help them comprehend words starting from approximately 8 to 12 months of

age (Bates, 1976). Gesture affects children's language comprehension over both short and long periods of time. When seeing an experimenter label an object, infants look longer if the named object is not at the location indicated by the experimenter's gesture but instead is on the other side of the display, suggesting that infants expect concurrently occurring labels and deictic gestures to indicate the same referent (Gliga & Csibra, 2009). Not surprisingly, then, gesture can help children learn new object labels (Namy & Waxman, 1998). Infants are more likely to associate a label with an object if the label is accompanied by a pointing gesture to the object than if it is not (Woodward, 2004). When the newly learned object label needs to be retrieved, less scaffolding by pictures or gestures is needed if the labels were initially taught with accompanying gestures than if they were taught without gestures (Capone & McGregor, 2004). Parental gesture thus has the potential to facilitate children's language comprehension by providing nonverbal support. In naturalistic situations, parents frequently gesture when talking to their children, and most of these gestures reinforce the information conveyed in the accompanying speech (Iverson, Capirci, Longobardi, & Caselli, 1999). Moreover, when infants misunderstand their parents, their parents often provide additional gesture cues (e.g., through pointing) that repair the misunderstanding and enable the dyad to reach a consensus (Zukow-Goldring, 1996).

Looking over longer periods of time, early parent gesture use has been found to predict the size of children's comprehension vocabularies years later. Rowe and colleagues (Rowe, Özçalışkan, & Goldin-Meadow, 2008) found that the number of different meanings parents convey in their gestures to a child at age 14 months is a significant predictor of that child's vocabulary comprehension at age 42 months. However, early parent gesture did not have a direct effect on later child comprehension—early parent gesture was related to early child gesture, which, in turn, was related to later child comprehension. This study suggests that parent gesture might be indirectly related to children's vocabulary development through encouraging the child's own gestures. The relation between parent gesture and child vocabulary has been replicated by Pan and colleagues in a low-income sample and extended to language production—early parent pointing predicted their children's vocabulary production growth between 14 and 36 months of age (Pan, Rowe, Singer, & Snow, 2005). In an experimental manipulation, Goodwyn, Acredolo, and Brown (2000) trained a group of parents to use baby signs in addition to words when talking to their children. The children showed greater gains in vocabulary and used more gestures themselves than children of parents who were encouraged to use only words or who did not receive any training at all.

23.2.1.2 Vocabulary Production

In the earliest stages of language learning, infants produce few, if any, words. Their referential communication is primarily through gestures. Children start using gesture to communicate even before they say their first words, which are usually accompanied by meaningless vocalizations (Bates, 1976). For example, children point to places, people, or objects, they hold up an object to show it to others, or they extend their hands to request an object (Bates, 1976). Children in the United States are also often taught to communicate using “baby signs” (Acredolo, Goodwyn, & Gentieu, 2002).

Not much is known about whether producing a gesture helps children to actually produce a word (although this is an interesting question). But we do know that early gesture use is a strong predictor of later vocabulary production. Children’s use of gesture for specific objects (e.g., pointing to a ball) predicts the appearance of verbal labels for these objects in their lexicon (e.g., producing the word “ball”) (Iverson & Goldin-Meadow, 2005). More remarkably, the number of meanings children convey through gesture at 14 months predicts not only the size of their comprehension vocabularies but also the size of their production vocabularies at 54 months (Rowe & Goldin-Meadow, 2009a). Moreover, early gestures can also be used to predict developmental trajectories of clinical populations. Sauer and colleagues showed that children with unilateral focal brain injury whose gesture production at 18 months is within the typical range (but whose speech production is below the range) will catch up to their peers and achieve production (and comprehension) spoken vocabularies later in development that are within the typical range. Importantly, children with brain injury whose gesture rate is below the typical range at 18 months continue to display delays in both their production and comprehension vocabularies (Sauer, Levine, & Goldin-Meadow, 2010).

23.2.2 Syntax

23.2.2.1 Syntactic Comprehension

Children rely on gesture to comprehend sentences from a very early age. Morford and Goldin-Meadow (1992) showed that comprehension of simple sentences, such as “give the clock,” is facilitated either by a pointing gesture at the clock or by a *give* gesture (hand extended, palm up) in 15- to 29-month-olds. In fact, children who were unable to produce two-word utterances were able to understand a “two-word idea” if one of those ideas was presented in gesture. For example, children responded appropriately to “give” plus a point at a clock significantly more often than they responded to the message when it was produced entirely in speech (i.e., “give the clock”).

The role of gesture varies depending on the complexity of the spoken message—gesture is most beneficial when the listeners are young and the message is complex. For example, in a referential communication game, preschool children were given instructions to select a certain set of blocks from an array of blocks. Instructions were accompanied by a reinforcing gesture (saying “up” and producing an *up* gesture), a contradicting gesture (saying “up” and producing a *down* gesture), or no gesture. The spoken messages varied in complexity and that complexity influenced the impact the gestures had on comprehension. Reinforcing gestures facilitated comprehension only when the spoken message was complex. Interestingly, no gesture and contradicting gesture had a similar impact on comprehension and did not facilitate comprehension as much as reinforcing gestures (McNeil, Alibali, & Evans, 2000).

23.2.2.2 Syntactic Production

Gesture paves the way for children’s ability to form sentences. Starting from approximately 10 months of age, children produce gestures along with single words. Children use three types of gesture–speech combinations during the one-word period. Gestures are used to *reinforce* the meanings conveyed in speech (e.g., pointing to a ball and saying “ball”), to *disambiguate* the meanings conveyed in speech (e.g., pointing to a ball and saying “it”), or to *add* to the meanings conveyed in speech (e.g., pointing to a ball and saying “want”).

Interestingly, using gesture–speech combinations to convey sentence-like ideas seems to set the stage for children’s earliest sentences. The age at which children first produce combinations in which gesture conveys one idea and speech conveys another (e.g., point at bird + “nap” to describe a sleeping bird) predicts the age at which they first produce their two-word combinations (e.g., “bird sleep”) (Iverson & Goldin-Meadow, 2005). Moreover, the number of these gesture–speech combinations that children produce at 18 months selectively predicts their syntactic skill, as measured by the Index of Productive Syntax (Scarborough, 1990) at 42 months (the measure does not predict vocabulary size at this age, Rowe & Goldin-Meadow, 2009b).

Gesture thus gives children a means to convey complex ideas before they are able to convey the same ideas entirely in speech. In fact, particular constructions produced across gesture and speech predict the emergence of the same constructions entirely in speech several months later. For example, saying “bird” in speech and producing a flying gesture (an argument + verb combination) precedes and predicts the onset of argument + verb combinations in speech (i.e., saying “bird fly”) (Özçalışkan & Goldin-Meadow, 2005). Once a construction is produced in speech, children do not seem to rely on gesture to further expand that construction.

For example, once children acquire the ability to produce a verb and one argument in a single utterance, they do not produce additional arguments first in gesture, that is, a two-argument + verb construction is just as likely to appear first in speech alone as in speech + gesture (Özçalışkan, Goldin-Meadow, & Özçalışkan, 2009).

23.2.3 Discourse

23.2.3.1 Discourse Comprehension

With age, children face increasingly complex language tasks, such as understanding indirect requests or listening to stories. Gesture continues to support children's language comprehension in later stages of language learning. For example, 3- to 5-year-old children understand indirect requests better if those requests are accompanied by a gesture, for example, saying "It's going to get loud in here" is more easily understood as a request to close the door if the words are accompanied by a pointing gesture to the door than if they are not accompanied by gesture (Kelly, 2001).

Gesture can also have an impact on children's comprehension of longer stretches of discourse. In a recent study, Demir and colleagues (Demir, Fisher, Goldin-Meadow, & Levine, 2014) compared children's ability to retell a story presented to them under different conditions: a wordless cartoon; an audio recording of a storyteller (like listening to a story on radio); an audiovisual presentation of a storyteller who does not produce cospeech gestures (like listening to a storyteller holding a book while reading it); and an audiovisual presentation of a storyteller producing cospeech gestures while talking (like listening to an oral storyteller). Children told better-structured narratives in the gesture condition than in any of the other three conditions, consistent with findings that cospeech gesture can scaffold comprehension of complex language. The gestures were particularly beneficial to children who had difficulty telling a well-structured narrative, suggesting that gesture might be most helpful when language skill is low.

23.2.3.2 Discourse Production

With age, children start producing longer and more frequent utterances that need to be sensitive to more sophisticated discourse-pragmatic principles. As in earlier stages of language learning, gesture reveals that children have more understanding of discourse-pragmatics than they express in speech. For example, when a referent is new to the discourse, or is not perceptually available, proficient speakers know that the referents must be explicitly expressed and they use a noun to do so; conversely, if the referent is available in perceptual context or retrievable from discourse, then the referent can be

expressed in a pronoun or omitted entirely. Although English-, Chinese-, and Turkish-speaking 4-year-olds do not have control of this discourse principle in speech, they do display an understanding of the principle in gesture—they produce more gestures when referring to referents that are new to the perceptual or discourse context, particularly when those referents are underspecified or ambiguous in speech (Demir, So, Ozyürek, & Goldin-Meadow, 2012; So, Demir, & Goldin-Meadow, 2010).

The gestures children produce in complex discourse early in their development have been found to predict their discourse skills in speech later in development. For example, age 5 to 6 years marks a transitional stage in narrative development. Children produce narratives on their own but rarely include the goal of the story or the perspective of the story characters in those narratives. However, some 5- to 6-year-olds use gesture to portray a character from a first person perspective (e.g., moving the arms back and forth to describe a character who is running from the character's point of view) as opposed to a third-person perspective (e.g., wiggling the fingers to describe the character from an observer's point of view). Whether children use character-viewpoint gestures in their narratives at age 5 predicts the structure of their spoken narratives 3 years later, controlling for early narrative structure in speech and language skill (Demir, Levine, & Goldin-Meadow, under review). Thus, gesture continues to be a harbinger of change in speech even in later stages of language development.

23.2.4 Does Gesture Play a Causal Role in Language Learning?

We have seen that the early gestures children produce reflect their cognitive potential for learning particular aspects of language. But early gesture could be doing more—it could be helping children realize their potential. Child gesture could have an impact on language learning in at least two ways.

First, gesture gives children an opportunity to practice producing particular meanings by hand at a time when those meanings are difficult to express by mouth. To accurately determine whether child gesture is playing a causal role in language learning, we need to manipulate the gestures children produce. LeBarton, Goldin-Meadow and Raudenbush, (2013) studied 15 toddlers (beginning at 17 months) in an 8-week at-home intervention study (6 weekly training sessions plus follow-up 2 weeks later) in which all children were exposed to object words, but only some were told to point at the named objects. Before each training session and at follow-up, children interacted naturally with their parents to establish a baseline against which changes in communication were measured. Children who were told to gesture

increased the number of gesture meanings they conveyed not only when interacting with the experimenter during training but also when later interacting naturally with their parents. Critically, these experimentally induced increases in gesture led to larger spoken repertoires at follow-up, and thus suggest that gesturing can have an impact on language learning through the cognitive effect it has on the learner.

The second way in which child gesture could play a role in language learning is more indirect—child gesture could elicit timely speech from listeners. Supporting this view, Goldin-Meadow and colleagues (Goldin-Meadow, Goodrich, Sauer, & Iverson, 2007) found that when their children are in one-word stage, mothers translate the child's gestures into speech. For example, on seeing her child point to a ball and say "kick," a mother might say, "Do you want to kick the ball?," thus modeling for the child a two-word sentence that expresses the ideas the child conveyed in gesture + speech. Importantly, these maternal translations are reliable predictors of children's subsequent word and sentence learning, suggesting that gesturing can have an impact on language through the communicative effect it has on the learning environment.

23.3 ROLE OF GESTURE IN LANGUAGE PROCESSING

Children continue to use gesture long after they become proficient users of their native language(s). The tight relation between speech and gesture increases with development (Thompson & Massaro, 1986). In this section, we first describe the role gesture plays in how language is processed once language has been mastered, and then we describe the functions gesture serves for both listeners and speakers.

23.3.1 Gesturing is Involved in Language Processing at Every Level

23.3.1.1 Phonology

Gesture is linked to spoken language at every level of analysis. At the phonological level, producing gestures influences the voice spectra of the accompanying speech for deictic gestures (Chieffi, Secchi, & Gentilucci, 2009), emblem gestures (Barbieri, Buonocore, Dalla Volta, & Gentilucci, 2009; Bernardis & Gentilucci, 2006), and beat gestures (Krahmer & Swerts, 2007). When phonological production breaks down, as in stuttering or aphasia, gesture production stops as well (Mayberry & Jaques, 2000; McNeill, Pedelty, & Levy, 1990). There are phonological costs to producing gestures with speech—producing

words and pointing gestures together leads to long initiation times for the accompanying speech, relative to producing speech alone (Feyereisen, 1997; Levelt, Richardson, & Laheij, 1985). Viewing gesture also affects voicing in listeners' vocal responses to audiovisual stimuli (Bernardis & Gentilucci, 2006).

23.3.1.2 Lexicon

At the lexical level, gesturing increases when the speaker is searching for a word (Morsella & Krauss, 2004). More generally, gestures reflect and compensate for gaps in a speaker's verbal lexicon. Gestures can package information in the same way that information is packaged in the lexicon of the speaker's language. For example, when speakers of English, Japanese, and Turkish are asked to describe a scene in which an animated figure swings on a rope, English speakers overwhelmingly use the verb "swing" along with an arced gesture (Kita & Özyürek, 2003). In contrast, speakers of Japanese and Turkish, languages that do not have single verbs that express an arced trajectory, use generic motion verbs along with the comparable gesture, that is, a straight gesture (Kita & Özyürek, 2003). But gesture can also compensate for gaps in the speaker's lexicon by conveying information that is not encoded in the accompanying speech. For example, complex shapes that are difficult to describe in speech can be conveyed in gesture (Emmorey & Casey, 2002).

23.3.1.3 Syntax

At the syntactic level, gestures are influenced by the structural properties of the accompanying speech. For example, English expresses manner and path within the same clause, whereas Turkish expresses the two in separate clauses. The gestures that accompany manner and path constructions in these two languages display a parallel structure—English speakers produce a single gesture combining manner and path (a rolling movement produced while moving the hand forward), whereas Turkish speakers produce two separate gestures (a rolling movement produced in place, followed by a moving forward movement) (Kita & Özyürek, 2003; Kita, Özyürek, Allen, Brown, Furman, & Ishizuka, 2007). A recent event-related potential (ERP) study illustrates how gesture can influence syntactic processing (Holle, Obermeier, Schmidt-Kassow, Friederici, Ward, & Gunter, 2012). Listeners were presented with two types of sentences, one with a less-preferred syntactic structure. Less-preferred syntactic structures commonly elicit P600 waves, which is usually associated with syntactic reanalysis. When the less-preferred syntactic structures were accompanied by rhythmic beat gestures, the P600 was eliminated, suggesting that gesture can reduce the processing cost associated with hearing a syntactically

complex sentence. Supporting this finding, gesture has been found to play a greater role in language comprehension when the spoken message is syntactically complex than when it is simple (McNeil et al., 2000). Gesture production also reflects the amount of information encoded in a syntactic structure. Speakers gesture more when producing an unexpected (and, in this sense, more informative) syntactic structure than when producing an expected structure (Cook, Jaeger, & Tanenhaus, 2009).

23.3.1.4 Discourse

At the discourse level, speakers use recurring gestural features (e.g., the same hand shape or location) throughout a narrative when referring to a particular character, thus creating linkages across the narrative (McNeill, 2000). In terms of narrative comprehension, when listening to stories containing gestures, listeners activate regions that are responsive to semantic manipulations in speech (triangular and opercular portions of the left inferior frontal gyrus; left posterior middle temporal gyrus). However, the level of activation in these areas differs as a function of semantic relation between gesture and speech—stories in which gesture conveys information that differs from, but complements, the information conveyed in speech (e.g., a flying gesture produced along with a story about a “pet”) activates the regions more than stories in which gesture conveys the same information as speech (e.g., a flying gesture produced along with a story about a “pet”) (Dick, Mok, Beharelle, Goldin-Meadow, & Small, 2014).

23.3.2 Gesture Serves a Function for Both Listeners and Speakers

23.3.2.1 Impact of Gesture on Listeners

Speakers' gestures reveal their thoughts. Accordingly, one function that gesture could serve is to convey those thoughts to listeners. There is, in fact, considerable evidence that listeners can use gesture as a source of information about the speaker's thinking (e.g., Goldin-Meadow & Sandhofer, 1999; Graham & Argyle, 1975; McNeil et al., 2000). The ability of listeners to glean information from a speaker's gestures can be seen most clearly when the gestures convey information that cannot be found anywhere in the speaker's words (e.g., Cook & Tanenhaus, 2009). Gesture can even affect the information listeners glean from the accompanying speech. Listeners are quicker to identify a speaker's referent when speech is accompanied by gesture than when it is not (Silverman, Bennetto, Campana, & Tanenhaus, 2010). Moreover, listeners are *more* likely to glean the message from speech when that speech is accompanied by gesture conveying the same information than when the speech is

accompanied by no gesture (Beattie & Shovelton, 1999, 2002; Graham & Argyle, 1975; McNeil et al., 2000; Thompson & Massaro, 1994). Conversely, listeners are *less* likely to glean the message from speech when the speech is accompanied by gesture conveying different information than when the speech is accompanied by no gesture (Goldin-Meadow & Sandhofer, 1999; Kelly & Church, 1998; McNeil et al., 2000). In addition, more incongruent gestures lead to greater processing difficulty than congruent gestures (Kelly, Özyürek, & Maris, 2010). The effect that gesture has on listeners' processing is thus linked to the meaning relation between gesture and speech. Moreover, listeners cannot ignore gesture even when given explicit instructions to do so (Kelly, Özyürek, & Maris, 2010; Langton, O'Malley, & Bruce, 1996), suggesting that the integration of gesture and speech is automatic.

23.3.2.2 Impact of Gesture Impact on Speakers

But gesture can also have an impact on the speakers themselves. Gestures have long been argued to help speakers “find” words, that is, to facilitate lexical access (Rauscher, Krauss, & Chen, 1996). Studies supporting this view show that gesture production increases when lexical retrieval is made difficult (Morsella & Krauss, 2004), and speakers are more successful in resolving tip of the tongue states when they are permitted to gesture than when they are prevented from gesturing (Frick-Horbury & Guttentag, 1998). Gestures have also been hypothesized to reduce demands on conceptualization, and speakers have been found to gesture more on problems that are conceptually difficult, even when lexical demands are equated (Alibali, Kita, & Young, 2000; Hostetter, Alibali, & Kita, 2007; Melinger & Kita, 2007). For example, adults were asked to describe complex geometric shapes under two different conditions. In the easy condition, the shapes that the adults were supposed to describe were outlined by dark lines; in the hard condition, the shapes were obscured by lines outlining alternative organizations. The adults produced more gestures in the hard condition than in the easy condition (Kita & Davies, 2009).

Although findings of this sort are consistent with the idea that gesturing reduces demands on conceptualization, to be certain that gesturing is playing a causal role in reducing demands (as opposed to merely reflecting those demands), we need to manipulate gesture and demonstrate that the manipulation reduces the demands on conceptualization. This type of manipulation has been done in some cases, and gesturing has been found to reduce demand on speakers' working memory (Goldin-Meadow, Nusbaum, Kelly, & Wagner, 2001; Wagner, Nusbaum, & Goldin-Meadow, 2004), to activate knowledge that speakers have but do not express

(Broaders, Cook, Mitchell, & Goldin-Meadow, 2007), and to build new knowledge (Goldin-Meadow, Cook, & Mitchell, 2009).

23.4 IMPLICATIONS FOR THE NEUROBIOLOGY OF LANGUAGE

Our review reveals that gesture can play a role in language learning and processing. Going forward, we suggest that the right question to ask is not *whether* gesture helps language processing, but rather *when* and *how* it does so to explore the mechanisms by which gesture exerts its influence on communication. In this regard, neural levels of analyses have the potential to provide insight into unanswered questions that behavioral analyses cannot. Behavioral studies reflect the combined influence of multiple processes in how gesture affects communication and cognition. By localizing brain networks underlying different cognitive functions and examining their contribution during various language tasks, neuroimaging studies may be able to help us tease apart the contribution of different cognitive processes.

There are a number of important neurobiologic questions that can be raised about gesture's role in communication and cognition. For example, does the neural basis for gesture–speech integration vary as a function of the content of speech or the linguistic skills of the listener? In this regard, it is important to point out that many neuroimaging studies examine the effects of gestures conveying information that contradicts the information conveyed in speech (e.g., Willems, Ozyürek, & Hagoort, 2007). Although these studies can offer important insights into what is possible, we note that contradictory gestures (i.e., gestures that convey information that contradicts, and therefore cannot under any conditions be integrated with, the information conveyed in speech) are *not* commonly observed in naturalistic, spontaneous conversation. We therefore encourage researchers to include in their studies gestures conveying information that is different from, but has the potential to be integrated with, the information conveyed in speech (as in Dick et al., 2014).

In sum, the gestures that we produce when we talk are not mindless handwaving. Gesture takes on significance simply because it can convey information about a speaker's thoughts that are not found in the speaker's words. Moreover, the information conveyed in gesture forecasts subsequent changes in a speaker's thinking and can even play a causal role in changing that thinking. Gesture thus offers a unique lens through which we can explore the mechanisms that underlie language learning and processing at the behavioral and the neurobiological levels.

Pathways and Streams in the Auditory Cortex

An Update on How Work in Nonhuman Primates has Contributed to Our Understanding of Human Speech Processing

Josef P. Rauschecker^{1,2} and Sophie K. Scott³

¹Laboratory of Integrative Neuroscience and Cognition, Georgetown University Medical Center, NW, Washington, DC, USA; ²Institute for Advanced Study, TU München, München-Garching, Germany; ³Institute of Cognitive Neuroscience, University College London, London, UK

24.1 HUMAN SPEECH PERCEPTION

Human speech is a sound of immensely spectrotemporal complexity, reflecting the intricacy of the articulatory movements that produce it. The aim of this chapter is to outline the contributions that the study of nonhuman primates has made to our understanding of the neural basis of human speech perception. However, this needs to be set in the context of insights about the neural basis of human speech processing that has arisen from the contribution by studies of patients with a receptive aphasia, often known as Wernicke's aphasia, which was first described by German neurologist Carl Wernicke.

24.2 WHERE IS "WERNICKE'S AREA"?

"Wernicke's area" is often defined as the posterior one-third of the superior temporal gyrus (STG), sometimes including the contiguous region of the inferior parietal lobule (IPL; in particular angular gyrus and supramarginal gyrus). However, the exact location of "Wernicke's area" has undergone various transformations since its initial discovery (Bogen & Bogen, 1976; Rauschecker & Scott, 2009). Wernicke himself (Wernicke, 1881) defined the speech-receptive region simply as the whole STG. Later neurologists, typically investigating single-case studies, shifted the emphasis to posterior STG and IPL, and "Wernicke's area" came to be identified with those posterior regions. Several highly popular and widely distributed textbooks in the early half of the 20th century disseminated this version.

Norman Geschwind depicted the site of "Wernicke's area" as the "posterior language region" (in relation to the "anterior language region" of Broca's considered important for speech production). Although Broca's area was in the frontal lobe, both Broca's area and Wernicke's area were termed as "perisylvian" with regard to the Sylvian fissure, separating the temporal and frontal lobe. Both sides of the Sylvian fissure are often damaged together in stroke cases and are often recorded together as a single source in electroencephalogram (EEG) studies. The role of the STG as a whole, including its anterior portions, in speech perception was all but forgotten until the linguist Harry Whitaker (1971) and the neurosurgeon Wilder Penfield (Penfield and Roberts, 1959) separately noted the shift from Wernicke's original work.

Detailed neuropsychological studies involving quantitative lesion analysis have recently confirmed that the anterior STG makes a more significant contribution to speech perception than the posterior STG (Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004). At the phonological level, phonemic discrimination between real words and nonsense syllables was little affected after lesions of posterior STG, whereas this ability was severely impaired in aphasics with lesions of anterior STG (Blumstein, Baker, & Goodglass, 1977) but not in Broca aphasics, for which the anterior STG was spared. Generally, infarcts in bilateral anterior STG cause auditory agnosias, in which people fail to identify familiar sounds (Clarke, Bellmann, Meuli, Assal, & Steck, 2000; Vignolo, 1982), and the anterior temporal lobe is the location of atrophy in "semantic dementia" (Mummery et al., 2000; Patterson et al., 2006). Functional neuroimaging

studies also demonstrate anterior superior temporal (ST) regions to be activated more than posterior regions when subjects listen to speech (Obleser et al., 2006; Scott, Blank, Rosen, & Wise, 2000). Finally, in a meta-analysis by DeWitt and Rauschecker (2012) that was specific to syllables, words, and phrases, syllables were represented just lateral to Heschl's gyrus, words were antero-lateral (AL) to that, and short standard phrases were even more anteriorly in the ST.

24.3 DUAL PROCESSING STREAMS AND HIERARCHICAL ORGANIZATION IN THE AUDITORY CORTEX OF THE MONKEY

24.3.1 “What” and “Where” Pathways in Vision and Audition

The aim of the current chapter is to address the neural basis of human speech perception in light of neuroanatomical and neurophysiological evidence from nonhuman primate studies. A decade and a half ago it was suggested that auditory cortical processing pathways are organized in a dual fashion similar to those in the visual cortex (Figure 24.1) (Rauschecker, 1998; Rauschecker & Tian, 2000), with one major pathway projecting into the posterior parietal cortex (PPC) and another pathway into the anterior temporal cortex. As in the visual system (Mishkin, Ungerleider, & Macko, 1983), the posterior parietal pathway was

FIGURE 24.1 Dual-processing scheme for auditory “what” and “where” proposed for nonhuman primates on anatomical and physiological grounds (Rauschecker, 1998; Rauschecker & Tian, 2000) combined with the analogous scheme from the visual system (Mishkin et al., 1983). V1, primary visual cortex; A1, primary auditory cortex; IT, inferior temporal region; ST, superior temporal region; PPC, posterior parietal cortex; VLPFC, ventrolateral prefrontal cortex; DLPFC, dorsolateral prefrontal cortex.

considered to subserve spatial processing, and the temporal pathway was considered to participate in the decoding of complex patterns and identification of objects. Because the orientation of the projections in the auditory system differs from those in the visual system, these auditory pathways were referred to as the postero-dorsal and antero-ventral streams, respectively.

This anterior/posterior projection scheme in auditory cortex (AC) has been supported by anatomical tracing studies (Hackett, Stepniewska, & Kaas, 1998; Kaas & Hackett, 2000), with long-range projections originating from the belt areas surrounding the primary-like core areas. Projections were found from anterior belt directly to ventrolateral prefrontal cortex (VLPFC), and from the caudal (posterior) belt to dorso-lateral prefrontal cortex (DLPFC) (Romanski et al., 1999). This finding provided clear evidence for the existence of ventral and dorsal processing streams within AC, with strong anatomical and functional implications (Goldman-Rakic, 1996; Petrides, 2005).

Can comparisons be made between human and nonhuman primates? We have argued that they can (Rauschecker & Scott, 2009). Modern noninvasive neuroanatomical tract-tracing techniques in humans on the basis of high-resolution magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) have revealed that the projections from the core and belt areas of AC follow the same route as in the monkey: The main projection runs anteriorly from Heschl's gyrus to anterior STG, and then crosses the divide to the inferior frontal regions, including Broca's area (Brodmann's area 44/45), via the uncinate fascicle and extreme capsule (Frey, Campbell, Pike, & Petrides, 2008). The connection from posterior STG to Broca's area via the arcuate fascicle, assumed by Geschwind (1965) to be all important for connecting Wernicke's and Broca's areas, is much sparser, if it exists at all, as a direct connection. Most projections from posterior STG go (via the superior longitudinal fascicle) to the IPL and the frontal eye fields (BA 6), consistent with a role of the posterior STG in spatial functions.

24.3.2 Functional Dual Pathways

The anatomical finding of a dual pathway from auditory to prefrontal cortex (PFC) (Romanski et al., 1999) was paralleled by direct functional evidence for an auditory dual-processing scheme from single-unit studies in the lateral belt areas of macaques. Species-specific communication sounds were presented in varying spatial locations, and Tian, Reser, Durham, Kustov, and Rauschecker (2001) discovered that neurons in the antero-lateral belt (area AL) were more

specific for the type of monkey call. Reversing the call abolished the response in AL neurons (B. Tian et al., unpublished), but not in the core or caudal belt (Recanzone, 2008). By contrast, neurons in the caudo-lateral belt (area CL) were more sensitive to spatial location than neurons in core or anterior belt. These data indicate that “what” and “where” processing dissociate in rhesus monkey AC.

The concept of dual-streams in auditory perceptual systems has found support from other studies (Recanzone & Sutter, 2008; Schreiner & Winer, 2007). Recanzone, Guard, Phan, and Su (2000) reported a correlation between spatial tuning of neurons and behavioral performance and found a tighter correlation of neuronal activity and sound localization in caudal belt than in primary AC, supporting a functional role for the posterior auditory stream in spatial processing of sound. Lewis and Van Essen (2000) described a direct auditory projection from the posterior ST (pST) region to area ventral intraparietal area (VIP) in the PPC of the monkey. Functional specialization was seen in single-unit studies as well as imaging studies in monkeys (Bendor & Wang, 2005; Poremba et al., 2003; Rauschecker & Tian, 2004; Rauschecker, Tian, & Hauser, 1995; Tian & Rauschecker, 2004).

Research using functional magnetic resonance imaging (fMRI) in nonhuman primates has identified tonotopic maps on the ST plane and gyrus (Petkov, Kayser, Augath, & Logothetis, 2006), and then a “voice region” in the anterior part of the right STG (Petkov et al., 2008), which projects further to the anterior superior temporal sulcus (STS) and VLPFC (Petkov et al., *in press*). An auditory voice region was also subsequently found in the AC of dogs (Andics, Gacsi, Farago, Kis, & Miklosi, 2014). Cortical cooling, which leads to reversible cortical inactivation, has been used in cat AC (Lomber & Malhotra, 2008) to show that cooling anterior areas caused a deterioration of auditory pattern discrimination, whereas cooling of posterior areas impaired spatial discrimination. These studies all suggest that an antero-ventral processing stream forms the substrate for the recognition of auditory objects, within which communication sounds may form an important category, whereas a postero-dorsal stream includes spatial perception as one of its functions.

Hierarchical processing is an organizational property of cortical perceptual systems, combining elements of serial as well as parallel processing (Bizley & Cohen, 2013). Thus, “lower” cortical areas with simpler receptive-field organization (Tian, Kusmierek, & Rauschecker, 2013), such as sensory core areas, project to “higher” areas with increasingly complex response properties, such as belt, parabelt, and PFC regions. These properties are generated by convergence and summation. Parallel processing principles in hierarchical organizations are evident if

one considers that specialized cortical areas (“maps”) with related functions (corresponding to submodalities or modules) are bundled into parallel processing “streams.” As an alternative to hierarchical processing structures, neural networks have been proposed that are highly interconnected and dynamically modulated by different task demands or contexts. Feedback connections, although well-known from neuroanatomy, are often not sufficiently accounted for in hierarchical models.

24.3.3 “What” and “How” Pathways: The Perception–Action Cycle

In contrast to the “what/where” model in vision (Mishkin et al., 1983), Goodale and Milner (1992) proposed that two pathways differentially subservise behaviors related to perception and action. The ventral pathway’s role in perception is largely consistent with a “what” pathway, whereas the dorsal pathway takes on a sensorimotor role involved in action (“how”), including spatial analysis. Fuster (2008) advocates a similar distinction with regard to PFC and unites the two pathways into a perception–action cycle. We argue here that the “what/where” and “perception/action” theories differ mainly as a matter of emphasis. The morphing of a “where” to a “how” pathway has largely to do with the addition of a temporal component, turning spatial into spatio-temporal information. Recent neurophysiological recordings in monkey caudal belt areas that have given more attention to the latency and temporal precision of responses to sounds have come up with surprising results. First, the latency of neurons in the caudo-medial belt area (CM) is significantly shorter than even in primary AC (Bendor & Wang, 2008; Kusmierek, Ortiz, & Rauschecker, 2012). Furthermore, fine-grained auditory information is better represented in the caudo-medial belt (Camalier, D’Angelo, Sterbing-D’Angelo, de la Mothe, & Hackett, 2012; Scott, Malone, & Semple, 2011). By contrast, spatially fine-grained information (i.e., narrow spatial tuning) is mostly a domain of caudo-lateral area CL, as would be expected from previous studies (Tian et al., 2001). Therefore, it is possible that substreams of the postero-dorsal stream exist early on and are later combined into a whole spatio-temporal main stream. Alternatively, the emphasis on different aspects of dorsal-stream processing may be maintained, or a split into substreams could occur later. For instance, Kravitz, Saleem, Baker, and Mishkin (2011) recently presented a model of the visual dorsal stream wherein three different functions (spatial working memory, visually guided actions, and spatial navigation) are performed by anatomically distinct components of the dorsal stream, all originating from parietal cortex.

24.4 DUAL PROCESSING STREAMS IN THE AUDITORY CORTEX OF HUMANS

The concepts of auditory streams of processing have proved to be extremely powerful as a framework for understanding functional imaging studies of speech perception (Scott, 2005; Scott & Johnsrude, 2003; Scott, McGettigan, & Eisner, 2009), and for understanding the aphasic stroke (Wise, 2003). Human studies also confirm the role of the postero-dorsal stream in the perception of auditory space and motion (see Rauschecker (2007) and Recanzone & Sutter (2008) for review). However, the question remains justified whether multiple (i.e., more than two) processing streams exist (Kaas & Hackett, 1999). In particular, the posterior STG and inferior parietal cortex have long been implicated in the processing of speech and language, so it would seem inappropriate to assign an exclusively spatial function to the postero-dorsal auditory stream. It is therefore essential to discuss how the *planum temporale* (PT), the temporo-parietal junction (TPJ), and the inferior (IP) parietal cortex are involved in speech and language, and whether we can assign a common computational function to the postero-dorsal stream that encompasses both spatial and language functions.

24.4.1 Role of Antero-Ventral Auditory Pathway in Object Identification and Speech Perception

24.4.1.1 Hierarchical Organization

Binder et al. (2000), as part of a meta-analysis of imaging studies of speech processing, confirmed that an AL gradient can be established, along which the complexity of preferred stimuli increases from tones and noise bursts to words and sentences. As in non-human primates, frequency responses demonstrate tonotopy, whereas core regions responding to tones were surrounded by belt areas preferring bandpass noise bursts (Wessinger et al., 2001). Using high-field scanners, multiple tonotopic fields (Formisano et al., 2003) and multiple processing levels (core, belt, and parabelt) (Chevillet, Riesenhuber, & Rauschecker, 2011) can be identified in human AC. This notion was extended in a meta-analysis by DeWitt and Rauschecker (2012) specific to syllables, words, and phrases. In a clear hierarchy, syllables were represented just lateral to Heschl's gyrus, words AL to that, and short standard phrases even more anteriorly. This confirms both the functional organization in monkeys as well as the organization of speech in humans found earlier.

24.4.1.2 Auditory Object Identification

Hierarchical organization in the antero-ventral auditory pathway of humans is important in auditory pattern recognition and object identification. As in animal models, preferred features of lower-order neurons are combined to create selectivity for increasingly complex sounds (Patterson, Uppenkamp, Johnsrude, & Griffiths, 2002; Zatorre, Bouffard, & Belin, 2004), and regions can be seen that are specialized in different auditory object classes (Leaver & Rauschecker, 2010; Obleser et al., 2006). Although speech sounds are found more lateral and more prominently in the left hemisphere, musical instrument sounds were concentrated more anterior in the right hemisphere. Animal sounds are less consistently represented as a distinct category and may depend on expert training (Leaver & Rauschecker, 2010). Developments in how we conceive the structure of auditory objects (Kumar, Stephan, Warren, Friston, & Griffiths, 2007; Shamma, 2008) will help extend these kinds of investigations. Like their visual counterparts, auditory objects coexist based on a multitude of attributes, such as timbre, pitch, and loudness, that give each its distinctive perceptual identity (Shamma, 2008).

24.4.1.3 Speech and Voice Perception

Within speech perception, there is evidence that speech sounds are hierarchically encoded because anterior portions of ST cortex respond as a function of speech intelligibility, and not stimulus complexity alone (Narain et al., 2003; Scott et al., 2000; Scott, Rosen, Lang, & Wise, 2006). Similarly, Liebenthal, Binder, Spitzer, Possing, and Medler (2005) and Obleser, Wise, Alex Dresner, and Scott (2007) showed that the left middle and anterior STS is more responsive to consonant–vowel syllables than auditory baselines. Thus, regions within the “what” stream show the first clear responses to abstract, linguistic information in speech. These findings culminated in the postulate for an auditory word form area (AWFA) in the left anterior STS analogous to the visual word form area (VWFA) (DeWitt & Rauschecker, 2012, 2013), confirming earlier suggestions by Cohen, Russ, Gifford, Kiringoda, and MacLean (2004). Within the speech-specific regions of aST, subregions are beginning to emerge that are selective for particular speech-sound classes, such as vowels (Obleser et al., 2006; Obleser, Zimmermann, Van Meter, & Rauschecker, 2007), raising the possibility of phonetic maps having some anatomical implementation in anterior temporal lobe areas. However, speech-sound categories, such as consonants, for which fine differences in articulation play an important role, may be represented in dorsal-stream areas of (e.g., premotor cortex [PMC])

(Chevillet, Jiang, Rauschecker, & Riesenhuber, 2013) (see next section). This could lead to dissociations of speech processing in patients with corresponding lesions (Caramazza, Papagno, & Rumel, 2000).

Speaker recognition has also been shown to be represented in AL temporal lobe areas (Belin & Zatorre, 2003), sometimes extending into mid-temporal regions as well (Leaver & Rauschecker, 2010). These human voice regions may be homologous, according to crude topological criteria, to the areas in the monkey (Petkov et al., 2008) mentioned previously. The human “voice area” in the anterior auditory fields processes detailed spectral properties of talkers (Warren, Scott, Price, & Griffiths, 2006). Notably, speech perception and voice discrimination dissociate clinically, suggesting that the two are supported by different systems within the anterior and middle temporal lobes.

24.4.1.4 Invariance, Categorization

An important problem to be solved in speech perception is the problem of invariance against distortions in the scale of frequency (e.g., pitch changes) or time (e.g., compressions). Comparing spectrograms of clear speech and of noise-vocoded speech, the latter is quite coarse in its spectrotemporal representation (Shannon, Zeng, Kamath, Wygonski, & Ekelid, 1995), yet it is readily intelligible after a brief training session. Perceptual invariance is important in the perception of normal speech because the “same” phoneme can be acoustically very different (due to coarticulation) while still being identified as the same sound (Bailey & Summerfield, 1980). The sound /s/ is different at the start of “sue” than at the start of “see,” but remains an /s/.

These examples of perceptual constancy appear relatively simple; however, they are computationally difficult to solve. The ability to deal with invariance problems is not unique to speech or audition, being a hallmark of all higher perceptual systems. The structural and functional organization of the anterior/ventral streams in both the visual and auditory systems could illustrate how the cerebral cortex solves this problem. For example, it has been suggested that visual categories are formed in the lateral PFC (Freedman, Riesenhuber, Poggio, & Miller, 2001), which receives input from higher-order object representations in the anterior temporal lobe (Goldman-Rakic, 1996). In the auditory domain, using species-specific communication sounds, Romanski, Averbeck, and Diltz (2005) found clusters of neurons in the macaque ventrolateral PFC encoding similar complex calls, and category-specific cells encoding single semantic categories have also been reported (Russ, Ackelson, Baker, & Cohen, 2008). In humans, rapid adaptation studies with functional MRI in the visual system have recently led to similar conclusions

(Jiang et al., 2007). Potentially, the invariance problem in speech perception is solved in the inferior frontal cortex (IFC) or by interactions between IFC and aST.

24.4.1.5 Hemispheric Asymmetry

Speech perception and production are left-lateralized in the human brain (Dhanjal, Handunnetthi, Patel, & Wise, 2008; Scott et al., 2000; Wise, 2003), and there is considerable interest in the neural basis of this (Boemio, Fromm, Braun, & Poeppel, 2005). Hemispheric specialization is an important feature of the human brain, particularly in relation to speech, attention, and spatial processing, and linguistic phenomena have long been considered to be left-lateralized in most adult humans. Recent work in speech perception has argued that hemispheric asymmetries in human speech perception are driven by functional rather than acoustic properties (McGettigan & Scott, 2012; Scott & McGettigan, 2013): selective activation of left auditory fields is typically only seen for linguistic material rather than particular acoustic properties of sounds. In contrast, right auditory fields show selective responses to longer stimuli, to stimuli with pitch variation, as well as to stimuli with voice or talker cues. Further studies will elaborate on the extent animal models can develop our understanding of these asymmetries, although there is evidence that the right temporal lobe voice areas (Latinus, McAleer, Bestelmeyer, & Belin, 2013) have non-human primate homologues, which are also right-dominant (Perrodin, Kayser, Logothetis, & Petkov, 2011).

24.4.2 Role of Postero-Dorsal Auditory Pathway in Space Processing

Evidence for a role of the postero-dorsal stream in auditory spatial processing is just as strong in the human as in nonhuman primates. Classical stroke studies as well as modern neuroimaging have shown that spatial processing in the temporo-parietal cortex is often right lateralized in humans (i.e., contralateral to speech and language). For instance, spatial neglect is more frequent and severe after damage to the right hemisphere (see Rauschecker (2007) and Recanzone and Sutter (2008) for review).

The auditory “where” stream may originate in the brainstem, perhaps as early as the dorsal cochlear nucleus (Rauschecker, 1997; Yu & Young, 2000), and ultimately reaches PPC via areas in posterior ST (pST), which serve as a transformation stage between primary core areas and PPC. Studies of the macaque cited previously (Lewis & Van Essen, 2000) are paralleled by functional–anatomical studies in the human (Bremmer et al., 2001; Lewis, Beauchamp, & DeYoe, 2000).

A meta-analysis of 38 human imaging studies provided evidence that the majority of auditory spatial studies involved activation of the postero-dorsal pathway (pST, IPL, and superior frontal sulcus [SFS]), whereas only two activated antero-ventral areas (aST, IFC) (Arnott, Binns, Grady, & Alain, 2004; see also Rauschecker, 2007 for review). Likewise, studies of patients with lesions in the posterior auditory pathway have shown deficits in the processing of auditory space (Clarke et al., 2000; Griffiths et al., 1998).

Imaging studies in humans have also demonstrated specific activation in pST with auditory motion (Griffiths et al., 1998; Warren, Zielinski, Green, Rauschecker, & Griffiths, 2002) near the location of visual motion areas, the middle temporal area (MT) and the medial superior temporal area (MST). Imaging studies that have tested moving auditory stimuli in addition to stationary ones have reported that auditory motion leads to activation in areas of pST and PPC that are adjacent to each other, with motion being the more powerful stimulus (Krumbholz et al., 2005).

24.4.3 Role of Postero-Dorsal Auditory Pathway in Speech Processing

The pST region (or *PT*) in humans (and the dorsal stream emanating from it) has classically been assigned a role in speech perception (Geschwind, 1965). The apparent contradiction of this view with that of a spatial role for pST (as well as with the evidence for speech-sound decoding in aST), as mentioned, needs to be discussed.

One unifying view is that the PT is generally involved in the processing of spectro-temporally complex sounds (Obleser, Zimmermann, et al., 2007), which also includes the processing of music (Hyde, Peretz, & Zatorre, 2008). Following this view, it has been suggested that the PT operates as a “computational hub” (Griffiths & Warren, 2002). More specifically, one could argue, following some of the more recent monkey data, that the postero-dorsal stream contains fine details in both the spatial and temporal domains. These two representations could be combined in specific ways for either of its main functions of space and speech (as well as music).

The IPL, particularly the angular and supramarginal gyri (or Brodmann areas 39/40), has also been linked to linguistic functions (Caplan, Rochon, & Waters, 1992), such as the “phonological-articulatory loop” (Baddeley, Lewis, & Vallar, 1984). Functional imaging has confirmed this role, although the activity seen varies with the working memory task used (Buchsbam & D’Esposito, 2008; Gelfand & Bookheimer, 2003). However

the IPL does not seem to be driven by acoustic processing of speech; the angular gyrus (together with extensive prefrontal activation) is recruited when higher-order linguistic factors improve speech comprehension (Obleser, Wise, et al., 2007) rather than by acoustic influences on intelligibility.

Thus, the parietal cortex is associated with more domain-general, linguistic factors in speech comprehension, rather than acoustic-phonetic processing. Bornkessel-Schlesewsky and colleagues (2013, 2015) extend this view by postulating that the dorsal stream as a whole engages in the time-dependent combination of elements, subserving both syntactic structuring and a linkage to action. This unified spatio-temporal perspective has language rooted in mechanisms for spatial processing, which have been generalized to apply to other domains.

24.4.4 Multisensory Responses and Sensorimotor Integration

There is now neurophysiological evidence that auditory caudal belt areas are not solely responsive to auditory input but show multimodal responses (Fu et al., 2003; Kayser, Petkov, Augath, & Logothetis, 2007). This has been extended to show that both caudal medial and lateral belt fields receive input from somatosensory and multisensory cortex, as well as thalamic input. Thus, any spatial transformations conducted in the posterior-dorsal stream may be based on a multisensory reference frame (Andersen & Buneo, 2002; Colby & Goldberg, 1999).

These multisensory responses in caudal auditory areas have been extended into some functional specificity in humans. Several studies of silent articulation (Wise et al., 2001) and nonspeech auditory stimuli (Hickok, Buchsbam, Humphries, & Muftuler, 2003) have identified activation in a posterior medial PT region within the postero-dorsal stream. Following this, the medial PT in humans (Warren, Wise, & Warren, 2005) has been associated with the representation of templates for “doable” articulations and sounds (not limited to speech sounds). This approach can be compared with the “affordance” model of Gibson (Gibson, 1977; Rizzolatti, Ferrari, Rozzi, & Fogassi, 2006), in which objects and events are described in terms of action possibilities. Such a sensorimotor role for the dorsal stream is consistent with the notion of an “action” stream in vision (Goodale & Milner, 1992). The concept can be extended to auditory-motor transformations in verbal working memory tasks (Hickok & Poeppel, 2000, 2007) that involve articulatory representations (Baddeley et al., 1984; Jacquemot & Scott, 2006). The postero-medial PT area has also been identified as

a key node for the control of speech production (Dhanjal et al., 2008) because it shows a response to somatosensory input from articulators.

24.4.4.1 Speech Perception-Production Links

There is considerable neural convergence for the speech perception and production systems. For example, the postero-medial PT area described in the previous section is an auditory area that is important in the motor act of articulation. Conversely, activation by real or imagined speech sounds and music has been described within premotor areas important in overt production of speech (Wilson, Saygin, Sereno, & Jacoboni, 2004) and music (Chen, Penhune, & Zatorre, 2008; Leaver, Van Lare, Zielinski, Halpern, & Rauschecker, 2009). Within auditory areas, monkey studies have shown that auditory neurons are suppressed during the monkey's own vocalizations (Eliades & Wang, 2008; Müller-Preuss & Ploog, 1981). This finding is consistent with results from humans that indicate that auditory perception in (anterior) ST areas is suppressed by an audio-motor efference-copy signal during speech production (Houde, Nagarajan, Sekihara, & Merzenich, 2002; Numminen, Salmelin, & Hari, 1999) and even during silent lip-reading (Kauramäki et al., 2010). As a result, the response to one's own voice is always lower than that to someone else's.

At one level these findings may simply reflect the ways that sensory responses to actions caused by oneself are always differently processed to those caused by the actions of others (Blakemore, Wolpert, & Frith, 1998), and this may support mechanisms important in differentiating between one's own voice and the voices of others. However, in primate studies, auditory neurons that are suppressed during vocalizations are often more activated if the sound of the vocalizations is distorted (Eliades & Wang, 2008). This might indicate a specific role for these auditory responses in the comparison of feed-forward and feedback information from the motor and auditory system during speech production (Guenther, 2006). Distorting speech production in real time reveals enhanced activation in bilateral (posterior temporal) auditory fields to distorted feedback (Tourville, Reilly, & Guenther, 2008). New work using high-resolution DTI in humans has revealed that there are direct projections from the pars opercularis of Broca's area (BA44) to the IPL (Frey et al., 2008) in addition to the ones from the ventral premotor (vPM) cortex (Petrides & Pandya, 1984). With the known connections between parietal cortex and posterior auditory fields, this could form the basis for feed-forward connections between speech production areas and posterior temporal auditory areas (Figure 24.2).

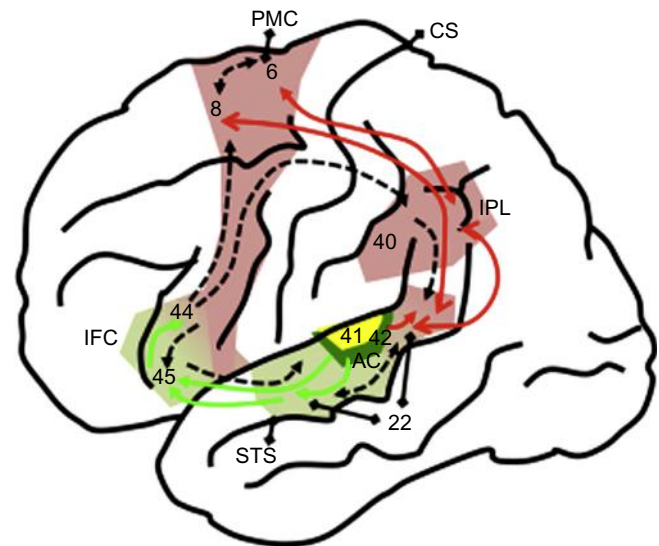

FIGURE 24.2 Dual auditory processing scheme of the human brain incorporating current understanding of the role of internal models in sensory systems (modified from Rauschecker & Scott, 2009). This model closes the loop between speech perception and production and proposes a common computational structure for space processing and speech control in the auditory dorsal stream. AC, auditory cortex; STS, superior temporal sulcus; IFC, inferior frontal cortex; PMC, premotor cortex; IPL, inferior parietal lobule; CS, central sulcus. Numbers correspond to Brodmann areas.

24.5 CONCLUSIONS: A COMMON COMPUTATIONAL FUNCTION FOR THE POSTERO-DORSAL STREAM?

The dual-stream processing model in audition (Rauschecker, 1998; Rauschecker & Tian, 2000; Rauschecker & Scott, 2009) has been a useful construct in hearing research, perceptual physiology, and, in particular, psycholinguistics, where it has spawned a number of further models (Hickok & Poeppel, 2000, 2007) that have tried to accommodate specific results from this field. Although we recognize the theoretical importance of dual-stream models in linguistics, we emphasize the importance of a firm grounding of such models in the anatomy and physiology of the AC, particularly as it has been worked out in nonhuman primates. Precursors of speech and language are bound to exist in nonhuman animals, and the consistency of linguistic models with such animal models is a *conditio-sine-qua-non*.

The role of a ventral stream in hierarchical processing of objects, as in the visual system, is now widely accepted, thanks to both individual and meta-analytic data. Specifically for speech, anterior regions of the ST respond to native speech sounds and intelligible speech, and these sounds are mapped along

phonological parameter domains. By contrast, early posterior regions in and around the *PT* are involved in the processing of many different types of complex sounds. CL areas seem to concentrate more on spatial aspects of sounds, whereas caudo-medial areas process timing of sounds most efficiently. Later posterior regions participate in the processing of auditory motion-in-space but seem to integrate input from several modalities as well.

Thus, whereas evidence is strong for the role of the dorsal pathway (including posterior ST) in space processing, the dorsal pathway is in an excellent position to accommodate speech and language functions as well. Spatial transformations may be one example of fast adaptations used by “internal models” or “emulators,” as first developed in motor control theory. Within these models, “forward models” (predictors) can be used to predict the consequences of actions, whereas “inverse models” (controllers) determine the motor commands required to produce a desired outcome (Wolpert, Doya, & Kawato, 2003). More recently, forward models have been used to describe the predictive nature of perception and imagery (Grush, 2004). The inferior parietal cortex (IPL) could provide an ideal interface where feed-forward signals from motor preparatory networks in the inferior frontal (IFC) and premotor (PMC) cortices are matched with feedback signals from sensory areas (Rizzolatti et al., 2006).

In speech perception and production, projections from articulatory networks in Broca’s area and PMC to the IPL and pST interact with signals from AC (Figure 24.2). The feed-forward projection from BA44 (and ventral PMC) may provide an efference copy in the classical sense of von Holst and Mittelstaedt (1950), informing the sensory system of planned motor articulations that are about to happen. The activity arriving in the IPL and pST from frontal areas anticipates the sensory consequences of action. The feedback signal coming to the IPL from pST, however, could be considered an “efference copy” (Hershberger, 1976) with relatively short latencies and high temporal precision (Jääskeläinen, Ahveninen, Bonmassar, Dale, & Ilmoniemi, 2004)—a sparse but fast primal sketch of ongoing sensory events (Bar et al., 2006) that are compared with the predictive motor signal in the IPL at every instance.

“Internal model” structures in the brain are generally thought to enable smooth sequential motor behaviors from visuo-spatial reaching to articulation of speech. The goal of these models is to minimize the resulting error signal by adaptive mechanisms. At the same time, these motor behaviors also support aspects of motor control in perceptual processing, such as stabilization of the retinal image and disambiguation of phonological

information, thus switching between forward and inverse modes. As Indefrey and Levelt (2004) point out, spoken language “constantly operates a dual system, [processing] and producing utterances. These systems not only alternate, but in many cases they partially or wholly operate in concert.” What is more, both spatial processing and real-time speech processing make use of the same internal model structures.

In summary, our new model of the auditory cortical pathways builds on the previous model of dual-processing pathways for object identification and spatial analysis (Mishkin et al., 1983; Rauschecker & Tian, 2000), but it integrates the spatial (dorsal) pathway with findings from speech and music processing as well. The model is based on neuroanatomical data from nonhuman primates, operating under the assumption that mechanisms of speech and language in humans have built on structures available in other primates. The pivotal factor is the simultaneous processing of space and time, which combines dorsal-stream function into a homogeneous space–time continuum. Finally, our new model extends beyond language processing (Hickok & Poeppel, 2007), and applies in a very general sense to both vision and audition, in its relationship with prior models of perception and action (Fuster, 2008; Goodale & Milner, 1992) by using the notion of internal models as its common denominator.

25.1 INTRODUCTION

The mind/brain must figure out at least two things when faced with the task of learning a natural language. One is how to transform the sound patterns of speech into a representation of the meaning of an utterance. The other is how to reproduce those sound patterns with the vocal tract (or in the case of signed languages with manual and facial gestures). Put differently, speech information must be processed along two different routes, an auditory-conceptual route and an auditory-motor route. These two processing streams involve partially segregated circuits in the brain and form the basis of the dual route model of speech processing (Hickok & Poeppel, 2000, 2004, 2007), which traces its routes to the classical model of Wernicke (Wernicke, 1874/1977) and parallels analogous proposals in the visual (Milner & Goodale, 1995) and somatosensory (Dijkerman & de Haan, 2007) systems. Thus, the division of labor proposed in dual route models, wherein one route is sensory-conceptual and the other is sensory-motor, appears to be a general organizational property of the cerebral cortex.

This chapter outlines the dual route model as a foundation for understanding the functional anatomy of speech and language processing.

25.2 THE DUAL ROUTE MODEL OF SPEECH PROCESSING

The dual route model (Figure 25.1) holds that a ventral stream, which involves structures in the superior and middle portions of the temporal lobe, is involved in processing speech signals for comprehension. A dorsal stream, which involves structures in the posterior planum temporale region (at the parietal-temporal junction) and

the posterior frontal lobe, is involved in translating acoustic-based representations of speech signals into articulatory representations, essential for speech production. In contrast to the canonical view that speech processing is mainly left hemisphere-dependent, a wide range of evidence suggests that the ventral stream is bilaterally organized (although with important computational differences between the two hemispheres). The compelling extent to which neuroimaging data implicate both hemispheres has recently been reviewed (Price, 2012; Schirmer, Fox, & Grandjean, 2012; Turkeltaub & Coslett, 2010). The dorsal stream, however, is traditionally—and in the model outlined here—held to be strongly left-dominant.

25.2.1 Ventral Stream: Mapping from Sound to Meaning

25.2.1.1 Bilateral Organization and Parallel Computation

The ventral stream is bilaterally organized, although not computationally redundant, in the two hemispheres. This may not be obvious based on a cursory evaluation of the clinical data. After all, left hemisphere damage yields language deficits of a variety of sorts, including comprehension impairment, whereas, in most cases, right hemisphere damage has little effect on phonological, lexical, or sentence-level language abilities. A closer look tells a different story. In particular, research in the 1980s showed that auditory comprehension deficits in aphasia (caused by unilateral left hemisphere lesions) were not caused primarily by impairment in the ability to perceive speech sounds, as Wernicke and later Luria proposed (Luria, 1970; Wernicke, 1874/1969). For example, when Wernicke's aphasics are asked to match pictures to auditorily presented words, their overall performance is well above chance, and when they do

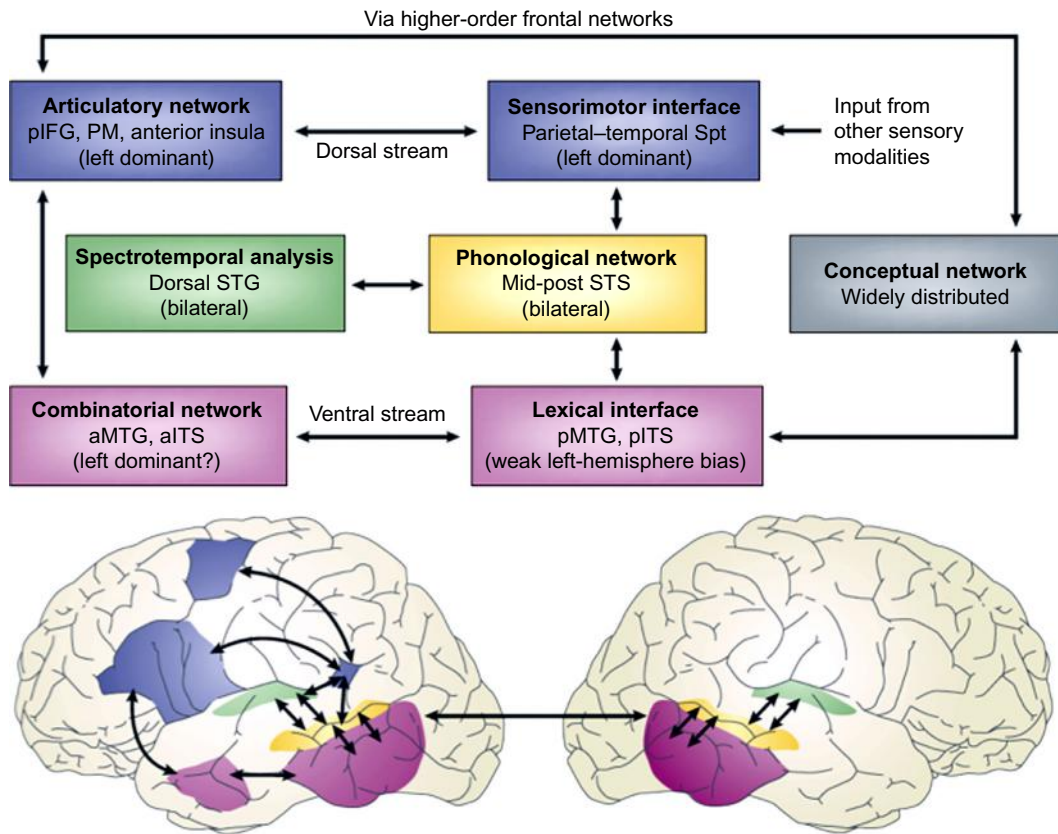

FIGURE 25.1 Dual stream model of speech processing. The dual stream model (Hickok & Poeppel, 2000; Hickok & Poeppel, 2004; Hickok & Poeppel, 2007) holds that early stages of speech processing occurs bilaterally in auditory regions on the dorsal STG (spectrotemporal analysis; green) and STS (phonological access/representation; yellow), and then diverges into two broad streams: a temporal lobe ventral stream supports speech comprehension (lexical access and combinatorial processes; pink), whereas a strongly left-dominant dorsal stream supports sensory-motor integration and involves structures at the parietal-temporal junction (Spt) and frontal lobe. The conceptual network (gray box) is assumed to be widely distributed throughout cortex. IFG, inferior frontal gyrus; ITS, inferior temporal sulcus; MTG, middle temporal gyrus; PM, premotor; Spt, Sylvian parietal-temporal; STG, superior temporal gyrus; STS, superior temporal sulcus. From Hickok and Poeppel (2007) with permission from the publisher.

make errors they tend to confuse the correct answer with *semantically* similar alternatives more often than with *phonemically* similar foils (Baker, Blumstein, & Goodglass, 1981; Miceli, Gainotti, Caltagirone, & Masullo, 1980; Rogalsky, Pitz, Hillis, & Hickok, 2008; Rogalsky, Love, Driscoll, Anderson, & Hickok, 2011). A similar pattern of performance has been observed after acute deactivation of the entire left hemisphere in Wada procedures (Figure 25.2) (Hickok et al., 2008). “Speech perception” deficits can be identified in left-injured patients, but only on metalinguistic tasks such as syllable discrimination that involve some level of conscious attention to phonemic structure and working memory; the involvement of the left hemisphere in these tasks likely follows from the relation between working memory and speech articulation (Hickok & Poeppel, 2000, 2004, 2007). In contrast to the (minimal) effects of unilateral lesions on the processing of phoneme level information during auditory comprehension, bilateral lesions involving the superior temporal lobe can have a

devastating effect, as cases of word deafness attest (see Chapter 37) (Buchman, Garron, Trost-Cardamone, Wichter, & Schwartz, 1986; Poeppel, 2001).

Data from neuroimaging have been more controversial. One consistent and uncontroversial finding, however, is that, when contrasted with a resting baseline, listening to speech activates the STG bilaterally, including the dorsal STG and superior temporal sulcus (STS). But, when listening to connected, intelligible speech is contrasted against various acoustic baselines, some studies have reported left-dominant activation patterns (Narain et al., 2003; Scott, Blank, Rosen, & Wise, 2000), leading some authors to argue for a fully left-lateralized network for speech perception (Rauschecker & Scott, 2009; Scott et al., 2000). Other studies report bilateral activation even when acoustic controls are subtracted out of the activation pattern (Okada et al., 2010) (for a review see Hickok and Poeppel, 2007). The issue is still being actively debated within the functional imaging literature, although recent reviews and meta-analyses

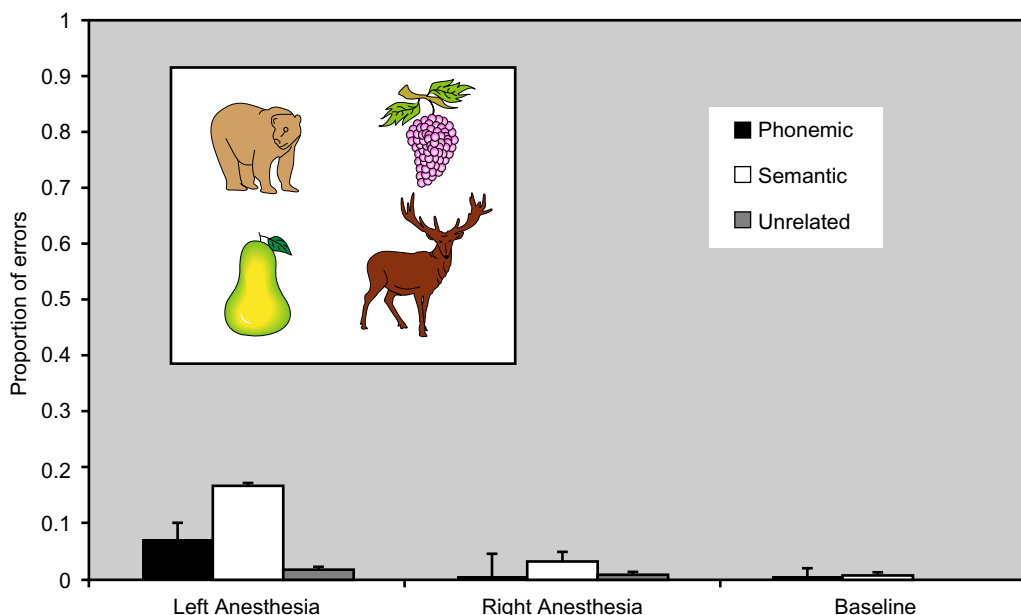

FIGURE 25.2 Auditory comprehension performance during Wada procedure. Data show mean error rate on a four-alternative forced choice auditory comprehension task with phonemic, semantic, and unrelated foils (inset shows sample stimulus card for the spoken target word, *bear*) in 20 patients undergoing clinically indicated Wada procedures. Error rate is shown as a function error type and amytal condition: left hemisphere injection, right hemisphere injection, and baseline. Note overall low error rate, even with left hemisphere injection, and the dominance of semantic mis-selections when errors occur. *Modified from Hickok et al. (2008).*

support the conjecture of bilateral STG/STS involvement (Price, 2012; Schirmer et al., 2012; Turkeltaub & Coslett, 2010).

25.2.1.2 Computational Asymmetries

The hypothesis that sublexical-level processes in speech recognition are bilaterally organized does not imply that the two hemispheres are computationally identical. In fact, there is strong evidence for hemispheric differences in the processing of acoustic/speech information (Abrams, Nicol, Zecker, & Kraus, 2008; Boemio, Fromm, Braun, & Poeppel, 2005; Giraud et al., 2007; Hickok & Poeppel, 2007; Zatorre, Belin, & Penhune, 2002). The basis of these differences is currently being debated. One view, arguing for a domain-general perspective for all sounds, is that the difference turns on the selectivity for temporal (left hemisphere) versus spectral (right hemisphere) resolution (Obleser, Eisner, & Kotz, 2008; Zatorre et al., 2002). That is, the left hemisphere may be particularly well-suited for resolving rapid acoustic change (such as a formant transition), whereas the right hemisphere may have an advantage in resolving spectral frequency information. A closely related proposal is that the two hemispheres differ in terms of their preferred “sampling rate,” with left auditory cortical regions incorporating a bias for faster rate sampling (25–50 Hz) and the right hemisphere for slower rate

sampling (4–8 Hz) (Poeppel, 2003). These two proposals are not incompatible because there is a relation between sampling rate and spectral versus temporal resolution; rapid sampling allows the system to detect changes that occur over short timescales but sacrifices spectral resolution, and vice versa (Zatorre et al., 2002).

Further research is needed to address these hypotheses. For the present purposes, the central point is that this asymmetry of function indicates that spoken word recognition involves parallel pathways—at least one in each hemisphere—in the mapping from sound to lexical meaning (Hickok & Poeppel, 2007), similar to well-accepted dual-route models of reading (phoneme-to-grapheme conversion and whole-word routes) (Coltheart, Curtis, Atkins, & Haller, 1993). Although the parallel pathway view differs from standard models of speech recognition (Luce & Pisoni, 1998; Marslen-Wilson, 1987; McClelland & Elman, 1986), wherein the processor proceeds from small to larger units in serial stages, it is consistent with the fact that speech contains redundant cues to phonemic information (e.g., in the speech envelope and fine spectral structure cues) and with behavioral evidence suggesting that the speech system can take advantage of these different cues (Remez, Rubin, Pisoni, & Carrell, 1981; Shannon, Zeng, Kamath, Wygonski, & Ekelid, 1995). It is worth bearing in mind that such computational asymmetries apply to all sounds that the auditory system analyzes.

They reflect properties of neuronal ensembles that are like filters acting on any incoming signal. Specialization is likely to occur at the next stage at which signals are translated into a format suitable for lexical access (given that words are stored in some format).

25.2.1.3 Phonological Processing and the STS

Beyond the earliest stages of speech recognition there is accumulating evidence that portions of the STS are important for representing and/or processing phonological information (Binder et al., 2000; Hickok & Poeppel, 2004, 2007; Indefrey & Levelt, 2004; Liebenthal, Binder, Spitzer, Possing, & Medler, 2005; Price et al., 1996). The STS is activated by language tasks that require access to phonological information, including both the perception and production of speech (Indefrey & Levelt, 2004), and during active maintenance of phonemic information (Buchsbaum, Hickok, & Humphries, 2001; Hickok, Buchsbaum, Humphries, & Muftuler, 2003). Portions of the STS seem to be relatively selective for acoustic signals that contain phonemic information when compared with complex nonspeech signals (yellow shaded portion of Figure 25.1) (Hickok & Poeppel, 2007; Liebenthal et al., 2005; Narain et al., 2003; Okada et al., 2010). STS activation can be modulated by the manipulation of psycholinguistic variables that tap phonological networks (Okada & Hickok, 2006), such as phonological neighborhood density (the number of words that sound similar to a target word), and this region shows neural adaptation effects to phonological level information (Vaden, Muftuler, & Hickok, 2009).

One currently unresolved question concerns the relative contribution of anterior versus posterior STS regions in phonological processing. Lesion evidence indicates that damage to posterior temporal lobe areas is most predictive of auditory comprehension deficits (Bates et al., 2003) and a majority of functional imaging studies targeting phonological processing in perception have identified regions in the posterior half of the STS (Hickok & Poeppel, 2007). Other studies, however, have reported *anterior* STS activation in perceptual speech tasks (Mazoyer et al., 1993; Narain et al., 2003; Scott et al., 2000; Spitsyna, Warren, Scott, Turkheimer, & Wise, 2006). These studies typically involved sentence-level stimuli, raising the possibility that anterior STS regions may be responding to some other aspect of the stimuli such as its syntactic or prosodic organization (Friederici, Meyer, & von Cramon, 2000; Humphries, Binder, Medler, & Liebenthal, 2006; Humphries, Love, Swinney, & Hickok, 2005; Humphries, Willard, Buchsbaum, & Hickok, 2001; Vandenberghe, Nobre, & Price, 2002). Recent electrophysiological work supports the hypothesis that left anterior temporal lobe (ATL) is critical to elementary structure building (Bemis & Pylkkanen, 2011), in

line with the view that intelligibility tasks tap into additional operations beyond speech recognition. It will, in any case, be important in future work to understand the role of various portions of the STS in auditory speech perception and language processing.

25.2.1.4 Lexical-Semantic Access

During auditory comprehension, the goal of speech processing is to use phonological information to access words: conceptual-semantic representations that are critical to comprehension. The dual stream model holds that conceptual-semantic representations are widely distributed throughout the cortex. However, a more focal system serves as a computational interface that maps between phonological-level representations of words or morphological roots and distributed conceptual representations (Hickok & Poeppel, 2000, 2004, 2007; Lau, Phillips, & Poeppel, 2008). This interface is not the site for storage of conceptual information. Instead, it is hypothesized to store information regarding the *relation* (or correspondences) between phonological information and conceptual information. Most authors agree that the temporal lobe(s) play a critical role in this process, but again there is disagreement regarding the role of anterior versus posterior regions. The evidence for both of these viewpoints is briefly presented here.

Damage to posterior temporal lobe regions, particularly along the MTG, has long been associated with auditory comprehension deficits (Bates et al., 2003; Damasio, 1991; Dronkers, Redfern, & Knight, 2000), an effect confirmed in a large-scale study involving 101 patients (Bates et al., 2003). We infer that these deficits are primarily postphonemic in nature because phonemic deficits after unilateral lesions to these areas are mild (Hickok & Poeppel, 2004). Data from direct cortical stimulation studies corroborate the involvement of the MTG in auditory comprehension and also indicate the involvement of a much broader network involving most of the superior temporal lobe (including anterior portions) and the inferior frontal lobe (Miglioretti & Boatman, 2003). Functional imaging studies have also implicated posterior middle temporal regions in lexical-semantic processing (Binder et al., 1997; Rissman, Eliassen, & Blumstein, 2003; Rodd, Davis, & Johnsrude, 2005). These findings do not preclude the involvement of more anterior regions in lexical-semantic access, but they do make a strong case for significant involvement of posterior regions. Electrophysiological studies have successfully used paradigms building on the N400 response to study lexical-semantic processing. This response is very sensitive to a range of variables known to implicate lexical-level properties. A review of that literature (including source localization studies of the N400) also suggests that posterior MTG plays a key role, although

embedded in a network of anterior temporal, parietal, and inferior frontal regions (Lau et al., 2008).

ATL regions have been implicated both in lexical-semantic and sentence-level processing (syntactic and/or semantic integration processes). Patients with semantic dementia, who have been used to argue for a lexical-semantic function (Scott et al., 2000; Spitsyna et al., 2006), have atrophy involving the ATL bilaterally along with deficits in lexical tasks such as naming, semantic association, and single-word comprehension (Gorno-Tempini et al., 2004). However, these deficits are not specific to the mapping between phonological and conceptual representations and appear to involve more general semantic integration (Patterson, Nestor, & Rogers, 2007). Further, because atrophy in semantic dementia involves a number of regions in addition to the lateral ATL, including bilateral inferior and medial temporal lobe, bilateral caudate nucleus, and right posterior thalamus, among others (Gorno-Tempini et al., 2004), linking the deficits specifically to the ATL is difficult.

Higher-level syntactic and compositional semantic processing might involve the ATL. Functional imaging studies have found portions of the ATL to be more active while subjects listen to or read sentences rather than unstructured lists of words or sounds (Friederici et al., 2000; Humphries et al., 2001; Humphries et al., 2005; Mazoyer et al., 1993; Vandenberghe et al., 2002). This structured versus unstructured effect is independent of the semantic content of the stimuli, although semantic manipulations can modulate the ATL response somewhat (Vandenberghe et al., 2002). Recent electrophysiological data (Brennan & Pytkkanen, 2012; Bemis & Pytkkanen, 2013) also implicate left ATL in elementary structure building. Damage to the ATL has also been linked to deficits in comprehending complex syntactic structures (Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004). However, data from semantic dementia are contradictory, because these patients are reported to have good sentence-level comprehension (Gorno-Tempini et al., 2004).

In summary, there is strong evidence that lexical-semantic access from auditory input involves the posterior lateral temporal lobe. In terms of syntactic and compositional semantic operations, neuroimaging evidence is converging on the ATL as an important component of the computational network (Humphries et al., 2005; Humphries et al., 2006; Vandenberghe et al., 2002); however, the neuropsychological evidence remains equivocal.

25.2.2 Dorsal Stream: Mapping from Sound to Action

The earliest proposals regarding the dorsal auditory stream argued that this system was involved in spatial

hearing, a “where” function (Rauschecker, 1998), similar to the dorsal “where” stream proposal in the cortical visual system (Ungerleider & Mishkin, 1982). More recently, there has been some convergence on the idea that the dorsal stream supports auditory-motor integration (Hickok & Poeppel, 2000, 2004, 2007; Rauschecker, 2011; Rauschecker & Scott, 2009; Scott & Wise, 2004; Wise et al., 2001). Specifically, the idea is that the auditory dorsal stream supports an interface between auditory and motor representations of speech, a proposal similar to the claim that the dorsal visual stream has a sensory-motor integration function (Andersen, 1997; Milner & Goodale, 1995).

25.2.2.1 The Need for Auditory-Motor Integration

The idea of auditory-motor interaction in speech is not new. Wernicke’s classic model of the neural circuitry of language incorporated a direct link between sensory and motor representations of words and argued explicitly that sensory systems participated in speech production (Wernicke, 1874/1969). More recently, research on motor control has revealed why this sensory-motor link is critical. Motor acts aim to hit sensory targets. In the visual-manual domain, we identify the location and shape of, say, a cup visually (the sensory target) and generate a motor command that allows us to move our limb toward that location and shape the hand to match the shape of the object. In the speech domain, the targets are not external objects but rather internal representations of the sound pattern (phonological form) of a word. We know that the targets are auditory in nature because manipulating a speaker’s auditory feedback during speech production results in compensatory changes in motor speech acts (Houde & Jordan, 1998; Larson, Burnett, Bauer, Kiran, & Hain, 2001; Purcell & Munhall, 2006). For example, if a subject is asked to produce one vowel and the feedback that she hears is manipulated so that it sounds like another vowel, then the subject will change the vocal tract configuration so that the feedback sounds like the original vowel. In other words, talkers will readily modify their motor articulations to hit an auditory target, indicating that the goal of speech production is not a particular motor configuration but rather a speech *sound* (Guenther, Hampson, & Johnson, 1998). The role of auditory input is nowhere more apparent than in development, where the child must use acoustic information in the linguistic environment to shape vocal tract movements that must reproduce those sounds.

A great deal of progress has been made in mapping the neural organization of sensorimotor integration for speech. Early functional imaging studies identified an auditory-related area in the left planum temporale region as involved in speech *production* (Hickok et al., 2000;

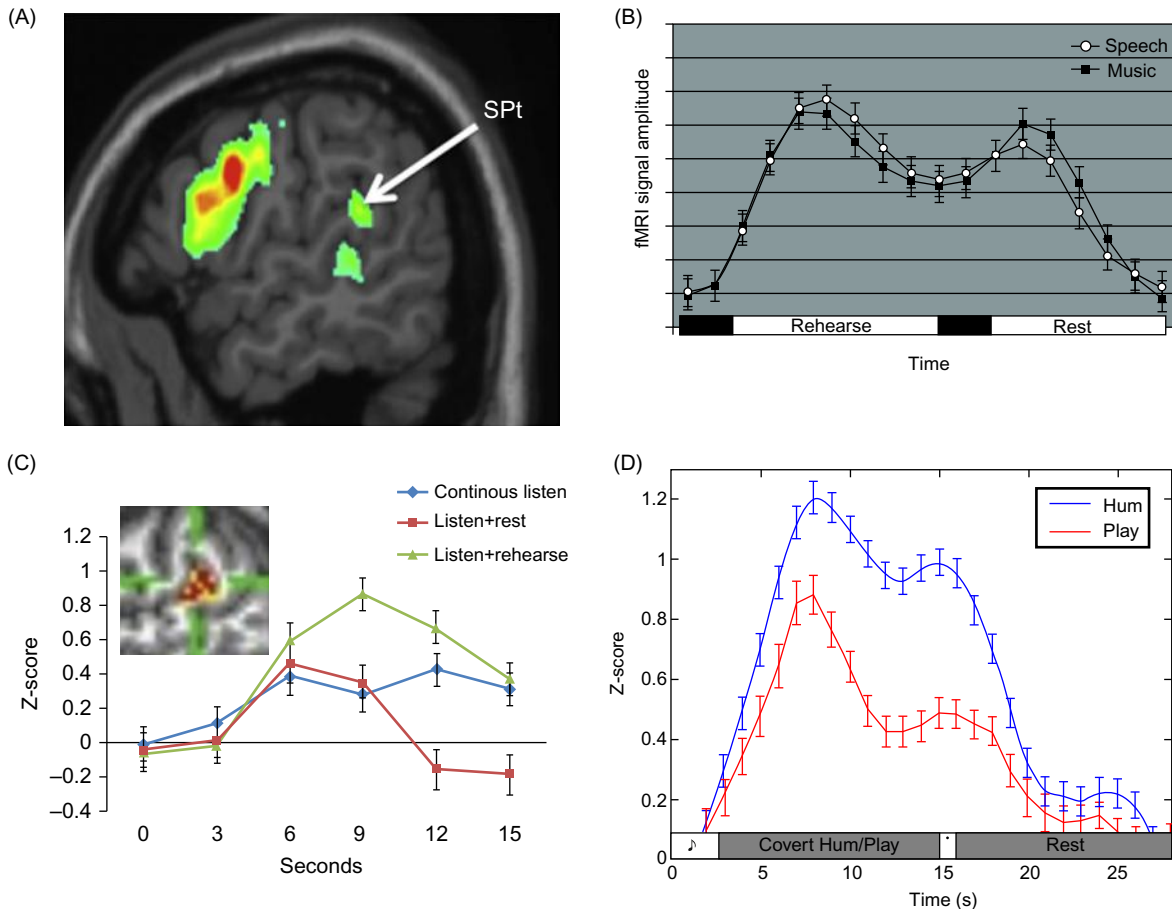

FIGURE 25.3 Location and functional properties of area Spt. (A) Activation map for covert speech articulation (rehearsal of a set of non-words). (B) Activation timecourse (fMRI signal amplitude) in Spt during a sensorimotor task for speech and music. A trial is composed of 3 s of auditory stimulation, followed by 15 s of covert rehearsal/humming of the heard stimulus, followed by 3 s of auditory stimulation, followed by 15 s of rest. The two humps represent the sensory responses; the valley between the humps is the motor (covert rehearsal) response and the baseline values at the onset and offset of the trial represent resting activity levels. Note similar response to both speech and music. (C) Activation timecourse in Spt in three conditions: continuous speech (15 s, blue curve), listen + rest (3 s speech, 12 s rest, red curve), and listen + covert rehearse (3 s speech, 12 s rehearse, green curve). The pattern of activity within Spt (inset) was found to be different for listening to speech compared with rehearsing speech assessed at the end of the continuous listen versus listen + rehearse conditions despite the lack of a significant signal amplitude difference at that time point. (D) Activation timecourse in Spt in skilled pianists performing a sensorimotor task involving listening to novel melodies and then covertly humming them (blue curve) versus listening to novel melodies and imagining playing them on a keyboard (red curve). This indicates that Spt is relatively selective for vocal tract actions. (A) From *Hickok and Buchsbaum (2003)* with permission from the publisher. (B) Adapted from *Hickok et al. (2003)*. (C) Adapted from *Hickok, Okada, and Serences (2009b)*. (D) From *Hickok (2009)* with permission from the publisher.

Wise et al., 2001). Subsequent studies showed that this left-dominant region, dubbed Spt for its location in the Sylvian fissure at the parietal-temporal boundary (Figure 25.3A) (Hickok et al., 2003), exhibited a number of properties characteristic of sensorimotor integration areas such as those found in macaque parietal cortex (Andersen, 1997; Colby & Goldberg, 1999). Most fundamentally, Spt exhibits sensorimotor response properties, activating both during the passive perception of speech and during covert (subvocal) speech articulation (Buchsbaum et al., 2001; Buchsbaum, Olsen, Koch, & Berman, 2005; Hickok et al., 2003); further, the different subregional patterns

of activity are apparent during the sensory and motor phases of the task (Hickok, Okada, & Serences, 2009a), likely reflecting the activation of different neuronal subpopulations (Dahl, Logothetis, & Kayser, 2009) (some sensory-weighted and others motor-weighted). Figure 25.3B–D shows examples of the sensory-motor response properties of Spt and the patchy organization of this region for sensory-weighted versus motor-weighted voxels (25.3C, inset).

Spt is not speech-specific; its sensorimotor responses are equally robust when the sensory stimulus consists of tonal melodies and (covert) humming is the motor task (see the two curves in Figure 25.3B) (Hickok et al., 2003).

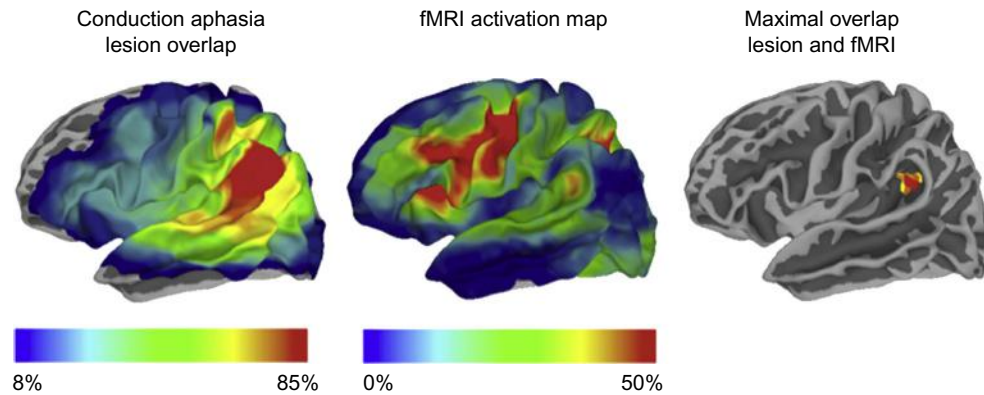

FIGURE 25.4 Relation between lesions associated with conduction aphasia and the cortical auditory-motor network. A comparison of conduction aphasia, an auditory-motor task (listening to and then repeating back speech) in fMRI, and their overlap. The uninflated surface in the left panel shows the regional distribution lesion overlap in patients with conduction aphasia (maximum is 12/14 or 85% overlap). Middle panel shows the auditory-motor network in the fMRI analysis. The right panel shows the area of maximal overlap between the lesion and fMRI surfaces (lesion >85% overlap and significant fMRI activity). *Modified from Buchsbaum et al. (2011).*

Activity in Spt is highly correlated with activity in the pars opercularis (Buchsbaum et al., 2001; Buchsbaum et al., 2005), which is the posterior sector of Broca's region. White matter tracts identified via diffusion tensor imaging suggest that Spt and the pars opercularis are densely connected anatomically (for review see Friederici, 2009, Rogalsky and Hickok, 2011). Finally, consistent with sensorimotor integration areas in the monkey parietal lobe (Andersen, 1997; Colby & Goldberg, 1999), Spt appears to be motor-effector-selective, responding more robustly when the motor task involves the vocal tract than when it involves the manual effectors (Figure 25.2D) (Pa & Hickok, 2008). More broadly, Spt is situated in the middle of a network of auditory (STS) and motor (pars opercularis, premotor cortex) regions (Buchsbaum et al., 2001; Buchsbaum et al., 2005; Hickok et al., 2003), perfectly positioned both functionally and anatomically to support sensorimotor integration for speech and related vocal tract functions.

Lesion evidence is consistent with the functional imaging data implicating Spt as part of a sensorimotor integration circuit. Damage to auditory-related regions in the left hemisphere often results in speech production deficits (Damasio, 1991, 1992), demonstrating that sensory systems participate in motor speech. More specifically, damage to the left temporal-parietal junction is associated with conduction aphasia, a syndrome that is characterized by good comprehension but frequent phonemic errors in speech production (Baldo, Klosternann, & Dronkers, 2008; Damasio & Damasio, 1980; Goodglass, 1992), and the lesion distribution overlaps with the location of functional area Spt (Figure 25.4) (Buchsbaum et al., 2011). Conduction aphasia has classically been considered to be a disconnection syndrome involving damage to the arcuate

fasciculus. However, there is now good evidence that this syndrome results from cortical dysfunction (Anderson et al., 1999; Hickok et al., 2000). The production deficit is load-sensitive: errors are more likely on longer, lower-frequency words and verbatim repetition of strings of speech with little semantic constraint (Goodglass, 1992, 1993). In the context of this discussion, the effects of such lesions can be understood as an interruption of the system that serves at the interface between auditory target and the motor speech actions that can achieve them (Hickok & Poeppel, 2000, 2004, 2007).

Recent theoretical work has clarified the computational details underlying auditory-motor integration in the dorsal stream. Drawing on advances in understanding motor control generally, speech researchers have emphasized the role of internal forward models in speech motor control (Golfinopoulos, Tourville, & Guenther, 2010; Hickok, Houde, & Rong, 2011; Houde & Nagarajan, in press; Houde & Nagarajan, 2011). The basic idea is that to control action the nervous system makes forward predictions about the future state of the motor articulators and the sensory consequences of the predicted actions. The predictions are assumed to be generated by an internal model that receives copies of motor commands and integrates them with information about the current state of the system and past experience (learning) of the relation between particular motor commands and their sensory consequences. This internal model affords a mechanism for detecting and correcting motor errors (i.e., motor actions that fail to hit their sensory targets).

Several models have been proposed with similar basic assumptions but slightly different architectures (Golfinopoulos et al., 2010; Guenther et al., 1998; Hickok et al., 2011; Houde & Nagarajan, in press; also

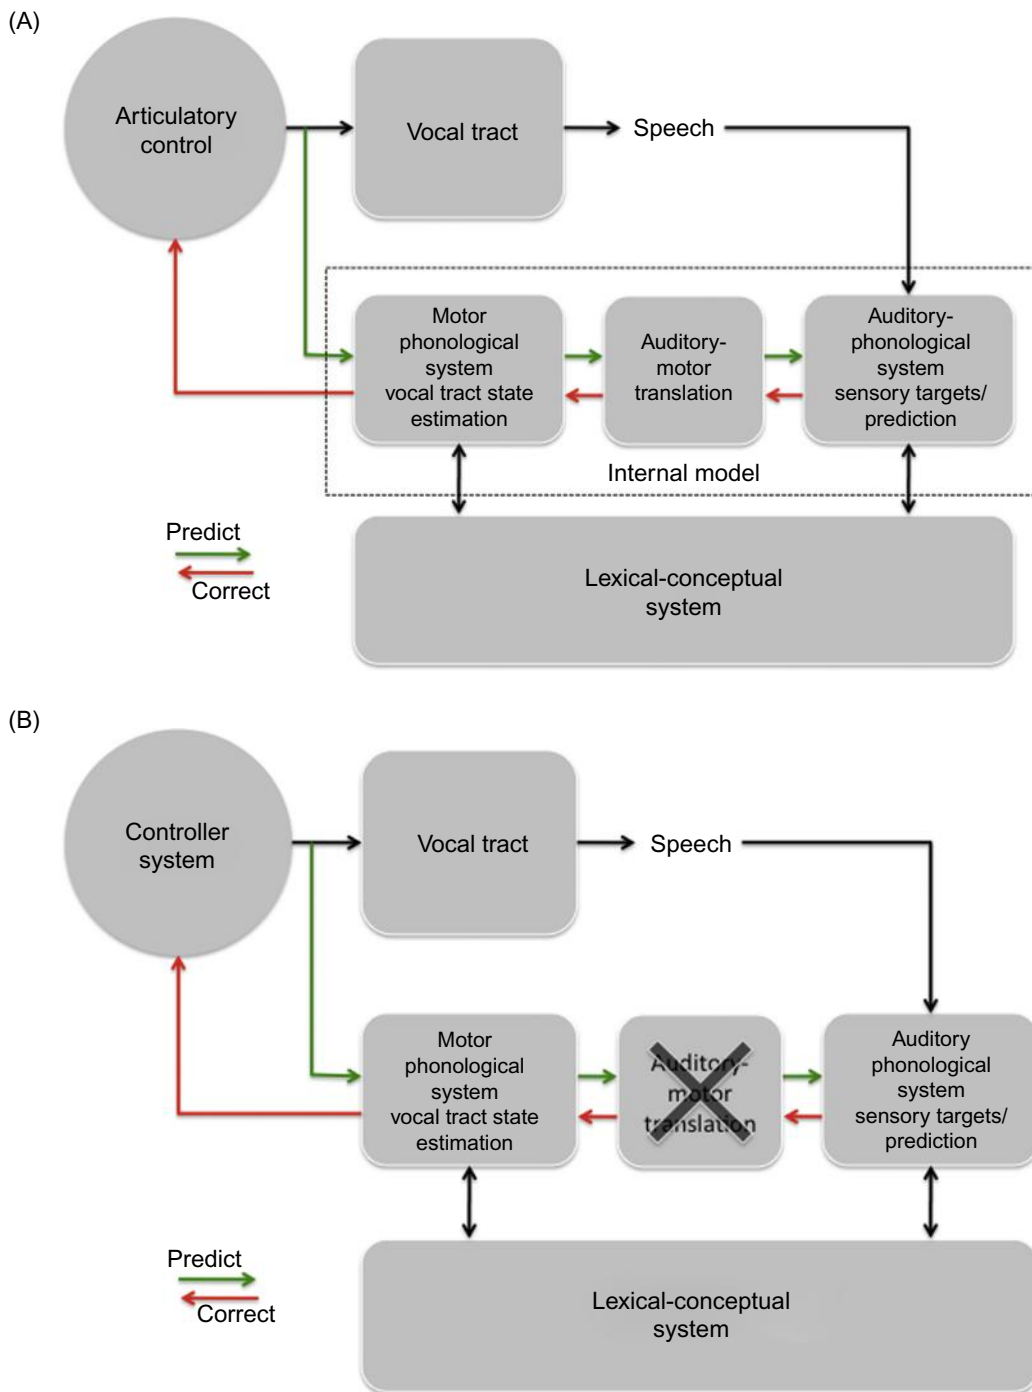

FIGURE 25.5 An integrated state feedback control (SFC) model of speech production. (A) Speech models derived from the feedback control, psycholinguistic, and neurolinguistic literatures are integrated into one framework, presented here. The architecture is fundamentally that of an SFC system with a controller, or set of controllers (Haruno, Wolpert, & Kawato, 2001), localized to primary motor cortex, which generates motor commands to the vocal tract and sends a corollary discharge to an internal model, which makes forward predictions about the dynamic state of the vocal tract and about the sensory consequences of those states. Deviations between predicted auditory states and the intended targets or actual sensory feedback generate an error signal that is used to correct and update the internal model of the vocal tract. The internal model of the vocal tract is instantiated as a “motor phonological system,” which corresponds to the neurolinguistically elucidated *phonological output lexicon*, and is localized to premotor cortex. Auditory targets and forward predictions of sensory consequences are encoded in the same network, namely the “auditory phonological system,” which corresponds to the neurolinguistically elucidated *phonological input lexicon* and is localized to the STG/STS. Motor and auditory phonological systems are linked via an auditory-motor translation system localized to area Spt. The system is activated via parallel inputs from the lexical-conceptual system to the motor and auditory phonological systems. (B) Proposed source of the deficit in conduction aphasia: damage to the auditory-motor translation system. Input from the lexical-conceptual system to motor and auditory phonological systems are unaffected, allowing for fluent output and accurate activation of sensory targets. However, internal forward sensory predictions are not possible, leading to an increase in error rate. Further, errors detected as a consequence of mismatches between sensory targets and actual sensory feedback cannot be used to correct motor commands. From Hickok et al. (2011) and Hickok and Poeppel (2004) with permission from the publisher.

see Chapter 58, this volume). One such model is shown in Figure 25.5 (Hickok et al., 2011). Input to the system comes from a lexical-conceptual network, as assumed by psycholinguistic models of speech production (Dell, Schwartz, Martin, Saffran, & Gagnon, 1997; Levelt, Roelofs, & Meyer, 1999). In between the input/output system is a phonological system that is split into two components, corresponding to sensory input and motor output subsystems and mediated by a sensorimotor translation system, which corresponds to area Spt (Buchsbbaum et al., 2001; Hickok et al., 2003; Hickok et al., 2009a). Parallel inputs to sensory and motor systems are needed to explain neuropsychological observations (Jacquemot, Dupoux, & Bachoud-Levi, 2007), such as conduction aphasia, as shown here. Inputs to the auditory phonological network define the auditory targets of speech acts. As a motor speech unit (ensemble) begins to be activated, its predicted auditory consequences can be checked against the auditory target. If they match, then that unit will continue to be activated, resulting in an articulation that will hit the target. If there is a mismatch, then a correction signal can be generated to activate the correct motor unit.

This model provides a natural explanation of conduction aphasia. A lesion to Spt would disrupt the ability to generate forward predictions in auditory cortex and thereby the ability to perform internal feedback monitoring, making errors more frequent than in an unimpaired system (Figure 25.5B). However, this would not disrupt the activation of auditory targets via the lexical-semantic system, thus leaving the patient capable of detecting errors in their own speech, a characteristic of conduction aphasia. Once an error is detected, however, the correction signal will not be accurately translated to the internal model of the vocal tract due to disruption of Spt. The ability to detect but not accurately correct speech errors should result in repeated unsuccessful self-correction attempts, again a characteristic of conduction aphasia.

25.3 CLINICAL CORRELATES OF THE DUAL STREAM MODEL

The dual stream model, like the classical Wernicke-Lichtheim model, provides an account of the major clinical aphasia syndromes (Hickok & Poeppel, 2004). Within the dual stream model, Broca's aphasia and conduction aphasia are considered to be dorsal stream-related syndromes, whereas Wernicke's aphasia, word deafness, and transcortical sensory aphasia are considered ventral stream syndromes. We have already noted that conduction aphasia can be conceptualized as a disruption of auditory-motor integration resulting from damage to area Spt. Broca's aphasia can

be viewed as a disruption to representations that code for speech-related actions at multiple levels from coding low-level phonetic features, to sequences of syllables, to sequences of words in structured sentences. Although Broca's area and Broca's aphasia are widely considered to be associated with deficits in *receptive* syntactic processing (Caramazza & Zurif, 1976; Grodzinsky, 2000), this issue is now being seriously questioned and remains debatable (Rogalsky et al., 2011).

Word deafness is the "lowest-level" ventral stream syndrome according to the dual stream model, affecting the processing of phonemic information during speech recognition. This differs from classic interpretations of word deafness as a disconnection syndrome (Geschwind, 1965). Due to the key role that auditory systems play in speech production, as discussed, we should expect that disruption to auditory speech systems, as in word deafness, will impact production as well. Although the canonical description of word deafness is a syndrome in which speech production is preserved, the majority of case descriptions that provide information on the speech output of word deaf patients report the presence of paraphasic errors (Buchman et al., 1986).

Wernicke's aphasia is explained in terms of damage to multiple ventral stream processing levels in the dual stream model. Given the rather extensive posterior lesions that are typically required to yield a chronic Wernicke's aphasia (Dronkers & Baldo, 2009), it is likely that this syndrome results from damage to auditory-motor area Spt, left hemisphere auditory areas, and posterior middle temporal lexical-semantic interface systems. Such damage can explain the symptom complex: relatively good phonological level speech recognition (due to the bilateral organization as described above), poor comprehension at the higher semantic level (due to damage to lexical-semantic interface systems), fluent speech (due to preserved motor speech systems), poor repetition (due to disruption of auditory-motor interface network), and paraphasic errors (due to disruption of auditory-motor interface network).

Transcortical sensory aphasia, which is similar to Wernicke's aphasia but with preserved repetition, is conceptualized as a functionally more focal deficit involving the lexical-semantic interface network but sparing the auditory-motor network. Damage to the lexical-semantic interface explains the poor comprehension, whereas sparing of the auditory-motor interface explains the preserved repetition.

25.4 SUMMARY

Dual stream models of cortical organization have proven useful in understanding both language and visual-related systems, and have been a recurrent

theme in neural models stretching back more than a century (Wernicke, 1874/1977). Thus, the general concept underlying the model—that the brain must interface sensory information with two different systems, conceptual and motor—not only is intuitively appealing but also has a proven track record across domains. In the language domain, the dual stream model provides an explanation of classical language disorders (Hickok et al., 2011; Hickok & Poeppel, 2004) and provides a framework for integrating and unifying research across psycholinguistic, neurolinguistic, and neurophysiological traditions. Recent work has shown that still further integration with motor control models is possible (Hickok et al., 2011). All of this suggests that the dual stream framework is on the right track as a model of language organization and provides a rich context for guiding future research.

26.1 INTRODUCTION

Brain language theory can build on well-established wisdom and principles known from neuroscience research. A huge body of knowledge is available about the structure and function of the brain and, more specifically, the human cortex, which is probably the most important device for language. Fundamental neuroscience knowledge can be systematized and summarized by general neurobiological principles. For example, an important *neuroanatomical principle* is that of rich local but more selective and specific long-distance connectivity. Neighboring neurons in the same cubic millimeter of cortex have a relatively high probability of being connected with each other, neuron pools in adjacent areas are still likely to exhibit a direct next-neighbor between-area projection, but areas far apart are linked in a highly specific and selective fashion (Braitenberg & Schüz, 1998; Young, Scannell, Burns, & Blakemore, 1994). A general *physiological principle* is that of Hebbian learning, whereby neurons that fire together wire together and strengthen their mutual connections and, vice versa, neurons out of sync delink (Hebb, 1949; O'Reilly, 1998). Such activity-dependent synaptic plasticity results in a structural mapping of functional relationships. Correlated activity leads to stronger connections, given the necessary connections are available in the first place. Correlation learning is one of the main neurobiological mechanisms believed to underlie learning, language learning included. Neuroanatomical connectivity sets the stage for such learning and mapping of correlations, whereby cortical connectivity structure not only enables such learning but also limits it. Where there are no connections in the first place, no learning can occur.

Likewise, the available structural and functional knowledge about specific features of the human brain is very detailed. Figure 26.1 shows a recently discovered specific feature of human cortical anatomy, which is of special relevance to language: the dorsal fiber bundle connecting temporal and inferior-frontal cortex called the *arcuate fascicle*. This bundle is not available in monkeys, weakly developed in apes, and strong only in humans (Figure 26.1A–C). Because it is also strongly lateralized to the left hemisphere—the language-dominant hemisphere in most of us—it appears as a prime candidate for specifically human language mechanisms (Rilling, Glasser, Jbabdi, Andersson, & Preuss, 2011; Rilling et al., 2008).

Taking into account neuroscience principles and knowledge—including the correlation learning principle and detailed information about, in part, genetically determined cortical neuroanatomy—it becomes possible to deduce from them those mechanisms that underlie language processing and representation. The difference between this theory-driven neuroscience-grounded perspective and approaches that remain at the level of boxes and arrows and abstract labels for cortical areas (Hickok & Poeppel, 2007) is two-fold. First, there is the *neuromechanistic aspect*: mechanisms are being specified in terms of neuronal assemblies and connections, because the level of boxes is obviously not concrete enough and that of areas is too crude. Second, there is the *explanatory aspect*: explanations are offered regarding how the specified mechanisms come about. In our opinion, the progression from abstract descriptive to explanatory-neuromechanistic theories is essential in current brain language science.

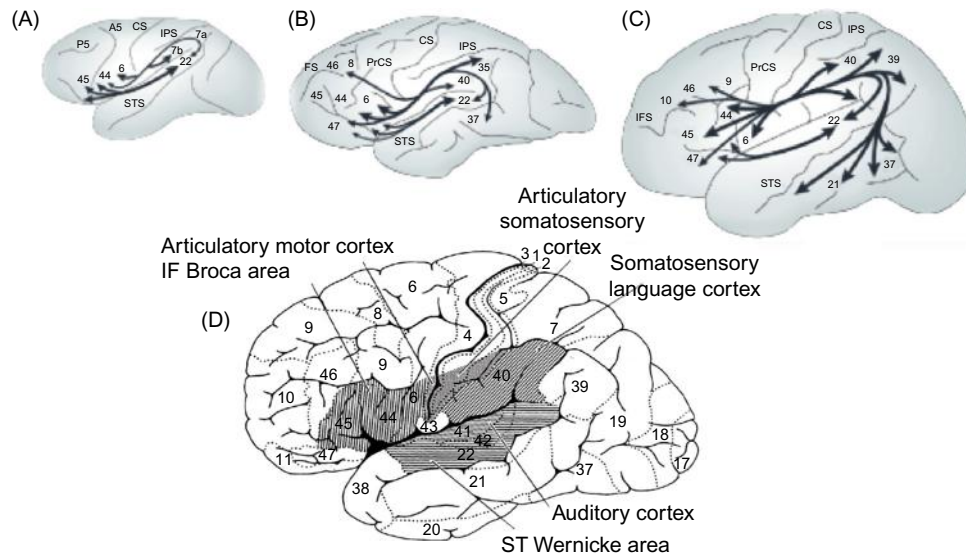

FIGURE 26.1 Major long-distance cortico-cortical connections in (A) macaques, (B) chimpanzees, and (C) humans (from Rilling et al., 2008 with permission from the publisher). Note the strong dorsal connection from inferior-frontal, precentral, and central sulcus (IFS, PrCS, SC) regions to areas around the inferior-parietal and superior-temporal sulcus (IPS, STS) of the arcuate fascicle, which is only present in humans. (D) Language core areas of the left cortical hemisphere surrounding the sylvian fissure (hatched). Brodmann area numbers are indicated. Adapted from Braitenberg & Pulvermüller, 1992 with permission from the publisher.

We briefly summarize an explanatory-neuromechanistic approach to language, progressing from the levels of speech sounds and signs to those of meaning and constructions, and on to communicative actions and action sequences. We highlight some issues of current debate in which predictions immanent to the explanatory-neuromechanistic approach diverge from those of most established brain language models, and then close with a summary and outlook.

26.2 PHONEMES

Phonemes, the smallest units of speech that distinguish between meaningful spoken words, are a characteristic ingredient of spoken human languages. The world's languages include approximately 100 overall, and each language has approximately 50 of them. In comparison, apes only have a few oral gestures (Call & Tomasello, 2007). Why is this so? The normal learning of phonemes requires that speech sounds be produced, which babies start doing at approximately 6 months and throughout the so-called *babbling phase* until the end of their first year of life (Locke, 1993). Babbling consists of productions of meaningless syllable sequences. Brain mechanisms implicated by such activity includes nerve cell activity in motor regions, where the articulatory gestures are initiated and controlled, and activity in the auditory and somatosensory cortex, because the infants also perceive the tactile self-stimulations produced by articulating along with the self-produced

sounds. This means coactivation of nerve cells (or neurons) across a range of cortical areas close to the sylvian fissure (*perisylvian areas*: articulatory motor and somatosensory cortex, auditory cortex; see Figure 26.1D). If there were direct connections between the specific neurons involved in controlling articulatory movements and responding to sensory aspects of the sounds produced, then the neuroscience principle of correlation learning would imply that the distributed set of neurons strengthened these links (Fry, 1966). However, it seems that the frontotemporal connections available in the left hemisphere of humans do not strongly interlink these areas directly, but rather primarily connect areas *adjacent* to motor and auditory cortices—in inferior premotor and prefrontal areas and in superior and middle temporal cortex (Figure 26.1C; Braitenberg & Schüz, 1992). This means that the correlated neuronal activity in sensory and motor cortex can only be mapped indirectly, including neurons in “higher” zones adjacent to relevant primary areas (other hatched areas in Figure 26.1D). The connection structure of inferior-frontal and superior-temporal areas, sometimes called the *language areas of Broca and Wernicke*, is illustrated schematically in Figure 26.2A, where these larger areas are each further subdivided into premotor and prefrontal areas and auditory belt and parabelt areas, respectively. The corresponding connection diagram (Figure 26.2B) illustrates the available between-area connections, including long-distance connections through the arcuate fascicle, and points to the crucial role of the language areas as connection hubs

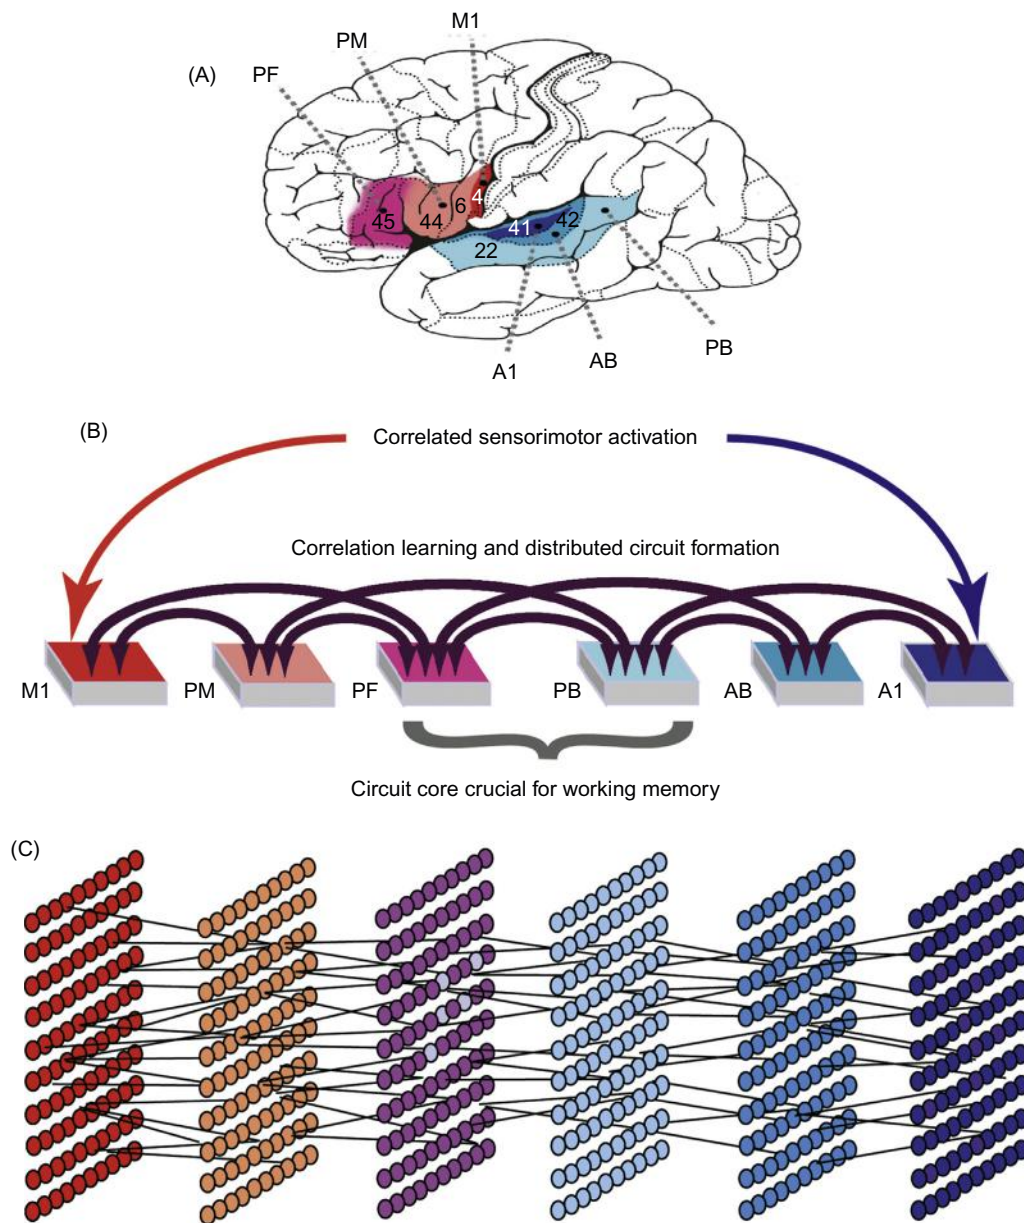

FIGURE 26.2 Formation of action perception circuits in the language network. (A) Neuroanatomical subdivision of inferior-frontal and superior-temporal cortex into six areas: M1, primary motor; PM, premotor; PF, prefrontal; A1, primary auditory; AB, auditory belt; and PB, auditory parabelt areas. (B) Schematic connection structure of the six areas highlighted. Correlated activation in M1 and A1 brought about by articulation leads to spreading activation in the network and distributed circuit formation for syllables and words. Their richer connectivity determines that PF and PB perisylvian hub areas develop circuit cores, where word form circuits link with each other in combinatorial learning. (C) Sketch of an *action perception circuit*, a distributed neuronal assembly driven by action perception correlation (indirect between-area connections are omitted; adapted from Garagnani & Pulvermüller, 2013; Pulvermüller, 2013).

within the language cortex (Garagnani & Pulvermüller, 2013; Garagnani, Wenekers, & Pulvermüller, 2008). Antonio Damasio called such hub areas *convergence zones* (Damasio, 1989).

Within this circuit structure, the arcuate fascicle may provide a prerequisite for building the more elaborate phoneme repertoire available to humans, but not to apes or monkeys. Together with the extreme capsule, which seems equally developed in apes and

humans, the arcuate provides a powerful connection between a range of inferior-frontal (including prefrontal and premotor) and superior-temporal (including auditory belt and parabelt) areas (Rilling, 2014). The availability of a powerful data highway between articulation and auditory perception and the resultant more elaborate repertoire of articulatory gestures may have constituted a significant selection advantage for humans in their phylogenetic development.

26.3 SIGNS

Much more than the slim repertoire of approximately 50 phonemes is the huge vocabulary of tens to hundreds of thousands of words as a hallmark of language. Steven Pinker estimates the size of the vocabulary of a typical language to be approximately 40,000 words (Pinker, 1994), and some dictionaries (e.g., of Chinese) even list up to one million word forms. In contrast, the number of gestures in the repertoire of great apes appears to be limited to between 40 and approximately 100, verbal gestures included (Call & Tomasello, 2007; Genty, Breuer, Hobaiter, & Byrne, 2009; Hobaiter & Byrne, 2011). This corresponds to the small size of the phoneme repertoire of humans, who apparently manage to combine their phonemes sequentially to yield an extraordinarily rich *vocabulary* of signs stored in a *lexicon*. How can this most dramatic increase be explained? It seems straightforward that rich connectivity is required for storing such an immense vocabulary. Phonemes or, perhaps more likely, context-sensitive phoneme variants depending on adjacent phonemes within a syllable and word need to be combined with each other. When learning and articulating novel spoken word forms, correlated motor and auditory information needs to be mapped to yield knowledge about the articulatory-phonological and acoustic-phonological aspects of phonemes, syllables, and whole spoken words and constructions. For such mapping of numerous forms, a powerful connection pathway may be required. Here, once again, the arcuate fascicle appears essential.

The formation of action perception circuits for words can be studied at the theoretical level using neurocomputational models that imitate aspects of the relevant cortical structures along with neurofunctional principles (Garagnani et al., 2008; Westermann & Reck Miranda, 2004). These simulations bolster, illustrate, and further elaborate the proposed explanation of the linkage of inferior-frontal and superior-temporal neuron populations underpinning spoken word and phoneme processing (Figure 26.2). When action perception circuits form, the neurons that become incorporated into them—which may have been either sensory or motor neurons, or may not have had any role in neither production nor perception—acquire a role in both production and recognition of one or more spoken word(s) and are active during both types of processes. Giacomo Rizzolatti and his team called neurons responding during execution and perception *mirror neurons* (Rizzolatti & Craighero, 2004; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). The activation of inferior-frontal areas homologue to macaque premotor area F5, where mirror neurons are present, is involved in speech processing (Fadiga, Craighero, Buccino, & Rizzolatti, 2002; Pulvermüller et al., 2006; Watkins,

Strafella, & Paus, 2003), and specific stimulation of motor representations of the articulators—for example, the tongue and lips—has a causal effect on the perceptual classification of speech sounds (D’Ausilio et al., 2009) and on the trajectories of articulatory movements (D’Ausilio et al., 2014). Thus, the perceptual language machinery of the human brain includes articulatory motor mechanisms as crucial elements connecting articulatory and acoustic aspects of phonemes and spoken word forms in the very same way as mirror neurons in monkeys’ motor systems map actions, visual perception of that action, and sometimes even the sound of that action (Kohler et al., 2002).

If vocabularies are built by action perception circuit formation, then this should be physiologically manifest. Vocabulary learning involving word articulations and repetitions—as it frequently happens in first language acquisition—leads to the formation of neuronal circuits integrating action and perception information and distributed over the frontal and temporal areas of the perisylvian language cortex. Because the frontotemporal connections of the arcuate fascicle are especially rich in the left hemisphere, left-laterality due to strong left-frontal involvement is predicted. But note that speech can also be picked up passively, for example, when the learner hears a foreign language but does not engage in speaking and communicating (Saffran, Aslin, & Newport, 1996). Such a situation is also enforced in patients with articulatory motor deficits (Bishop, Brown, & Robson, 1990). For such purely perceptual learning, no involvement of frontal or motor circuits would be predicted. A recent study compared the brain correlates induced by passive perceptual and active articulatory learning of novel syllable combinations (Pulvermüller, Kiff, & Shtyrov, 2012). The results showed that perceptual novel word learning led to an activation enhancement in bilateral superior-temporal areas, whereas the brain correlates of articulatory learning were left-lateralized and especially prominent in inferior prefrontal and premotor cortex (Figure 26.3). Because passive presentation of novel spoken words elicited these different activation patterns depending on learning type, they provide support for the action perception model of vocabulary formation.

26.4 MEANING

Especially exciting, interesting, and rich, but equally controversial, in the neuroscience of language is the brain basis of meaning. Already the best definition of what meaning might be is under hot dispute; when it comes to the cortical meaning locus, opinions diverge dramatically, unlike in any other area of the cognitive and brain sciences. One fraction of respectable researchers believes that a unitary meaning center, which Karalyn Patterson

FIGURE 26.3 Enhanced cortical activity (sources of event-related potentials) elicited by novel spoken word forms that had been learned in an articulatory condition, by hearing and repeating the novel items (A), or in a perceptual learning paradigm by listening to repeated presentations of the same novel spoken word forms (B). Enhanced bilaterally symmetric superior-temporal activity to learned novel items (orange ovals, relative to before learning) is seen independently of the learning method. However, additional enhanced, fast, automatic, left-lateralized premotor, inferior-frontal, and inferior-parietal activity to spoken novel words (yellow ovals) is present after articulatory, but not after perceptual, learning (*adapted from Pulvermüller, Kiff, et al., 2012*). These results suggest that language laterality is driven by auditory-motor information linking, possibly by way of the left-lateralized arcuate fascicle.

and her colleagues once dubbed the *semantic hub*, carries the main burden of meaning processing (Patterson, Nestor, & Rogers, 2007). Such a hub might serve the role of binding together different features that comprise a concept or meaning and, in addition, might bind symbolic semantics to symbol forms, for example, to spoken or written word forms. Unfortunately, opinions widely diverge regarding where such a hub might be located. Some theories saw a special role of the right hemisphere here (Paivio, 1991), whereas many cognitive neuroscientists consider specific left-hemispheric areas, in inferior-frontal (Bookheimer, 2002), inferior-parietal (Binder & Desai, 2011), posterior-middle-temporal (Hickok & Poeppel, 2007), or anterior-temporal regions (Patterson et al., 2007) as the main semantic hub and center for interfacing knowledge about signs with knowledge about their meaning. Because each of these positions receives support from experimental evidence that the respective area becomes strongly active during semantic processing and/or that a lesion or functional change in the respective site affects the performance on general semantic tasks but none of them can be considered a unique hub, it appears best to speak about a *hub territory* in the periphery of and surrounding the perisylvian language cortex (Figure 26.4A; Pulvermüller, 2013). The hub territory includes frontal, parietal, and temporal association (convergence) areas, which are heavily connected to several modality-preferential (e.g., visual, auditory, motor) areas. Therefore, they serve as hubs in a neuroanatomical sense

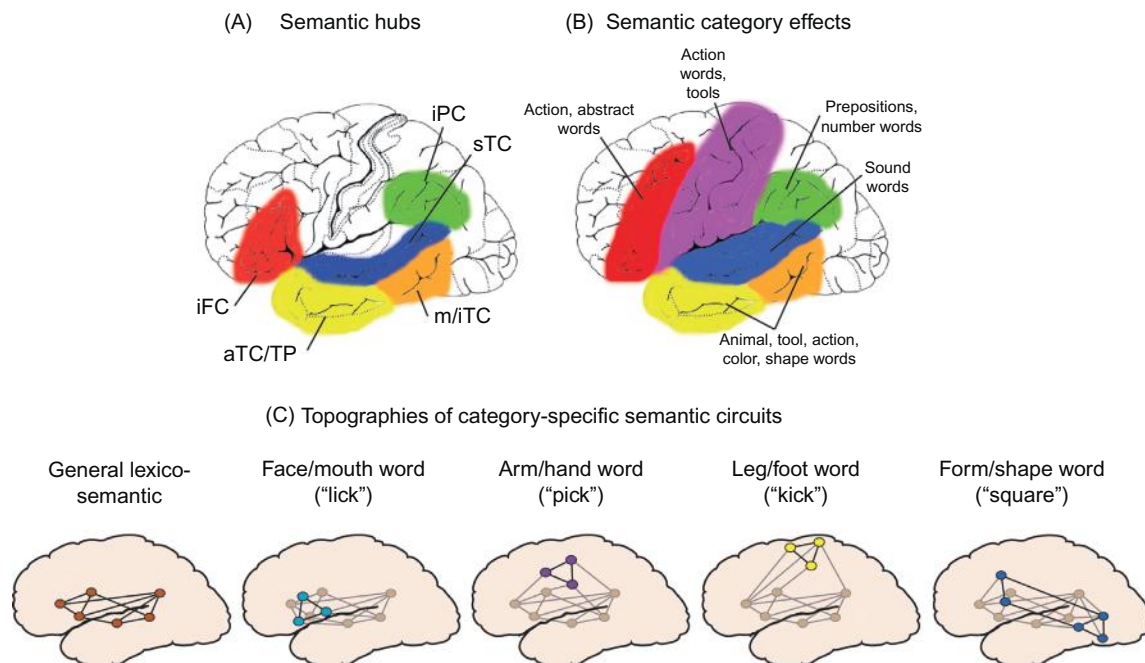

FIGURE 26.4 Cortical areas and circuits for semantics. (A) Proposed “semantic hubs” for general semantic processing. Abbreviations: iFC, inferior-frontal cortex; iPC, inferior-parietal cortex; sTC, superior-temporal cortex; m/iTC, middle/inferior-temporal cortex; aTC, anterior-temporal cortex; TP, temporal pole. (B) Cortical areas where semantic category-specific effects were reported in the literature. (C) Neuromechanistic model of action perception circuits for general lexicosemantic (leftmost graph) and category-specific referential-semantic information processing. Small circles represent local clusters of neurons and lines represent strong bidirectional connections between local clusters. *Adapted from Pulvermüller, 2013.*

(van den Heuvel & Sporns, 2013), which implies that they can also bridge between language areas and regions where modality-specific aspects of semantics are being processed.

Contrasting with the idea that there is one area—or entire widespread territory—that processes all meanings to the same degree, a different approach to meaning in the brain emphasizes the importance of *category-specific semantic mechanisms*. Interestingly, patients with focal cortical lesions frequently have deficits that primarily affect one or more semantic categories (e.g., animals or actions), and related neuroimaging studies show corresponding category-specific local brain activation. For example, the inferior-frontal cortex, including motor and premotor cortex, seems particularly important for processing action words and concepts (Pulvermüller, 2005), whereas part of the inferior-temporal lobe seems particularly relevant for animal words and concepts (Martin, 2007). Category-specific semantic deficits and brain activations are frequently present in and close to areas also carrying a role in action and perception, including fronto-central motor and premotor, superior-temporal auditory, inferior-temporal visual-object, and inferior-parietal visual-spatial processing areas, some of which are close to and overlap with the hub territory.

Why should specific brain parts contribute to meaning? Brain theory of meaning explains aspects of semantic mechanisms by neuroscience principles, including the correlation learning principle and specific features of between-area connectivity. When learning that a word such as “sun” relates to an object, the infant may experience such objects while the word is used at the same time. Therefore, neuronal populations for processing visual-object information and populations processing word forms coactivate and, according to the correlation learning rule, join together into a higher-order cell assembly linking the information about the word form with that of aspects of its meaning. Relevant areas where these semantic circuits are housed—or, more appropriately, *scattered*—include visual areas and visual-object processing areas in temporo-occipital and inferior-temporal cortex and language areas in perisylvian cortex (Farah & McClelland, 1991; McCarthy & Warrington, 1988; Pulvermüller, 1999). If words semantically relate to information from other modalities, for example, gustatory or auditory, then neuron population in the respective sensory areas plus interlinking connection hubs will come into play. For emotion words, motor circuits along with cortical and subcortical emotional-affective circuits of the limbic system seem relevant (Moseley, Carota, Hauk, Mohr, & Pulvermüller, 2012; Vigliocco et al., 2013). Words related to actions—for example “grasp”—may be heard when the learner performs related actions so

that, in this case, the correlation learning principle predicts distribution of semantic circuits over motor and language areas, in addition to interlinking areas. Note that, from the point of view of this cell assembly model of meaning, both the category-specific nature of semantic processes in modality-specific areas as well as the involvement of adjacent association cortices (convergence zones, connection hubs) are explained based on neuronal correlation and neuroanatomical connection structure (Pulvermüller, 2013).

A hot debate in the cognitive neuroscience of language still persists about the relevance of sensorimotor areas for meaning processing. Hub-centered models predict that meaning binding and integration are functions of the hub(s), with sensorimotor areas not essential or necessary for meaning (Bedny & Caramazza, 2011). Critical tests are sometimes difficult, not least because, first, hub areas and areas of category-specific semantic processing are, in several cases, located side-by-side, even with substantial overlap (Figure 26.4A and B), although there are clear dissociations. Second, the areas where category-specific brain activation was found, in many cases, were not exactly *in* those areas where critical sensory information was processed, but rather *adjacent* to them (e.g., Martin, Haxby, Lalonde, Wiggs, & Ungerleider, 1995). Third, many studies of category specificity are subject to confounds—for example, when action verbs and object nouns were compared and features different from semantics (word frequency, lexical status, combinatorial features, etc.) may have influenced the patterns of activation or deficits observed (Bird, Lambon-Ralph, Patterson, & Hodges, 2000). Therefore, more recent studies addressed the role of sensory and motor areas in semantic processing.

Key results supporting semantic category specificity came from investigations of action words typically used to speak about actions performed with different body parts, for example, “lick” (mouth/face), “pick” (hand/arm), and “kick” (foot/leg). Passive perception (listening, reading) of these words, as well as action-related phrases and sentences, led to activation of motor areas normally involved in performing (and/or perceiving) actions with the respective body parts (Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni, 2006; Hauk, Johnsrude, & Pulvermüller, 2004; Pulvermüller, Cook, & Hauk, 2012; Tettamanti et al., 2005). Task contexts influence these motor activations, although a degree of motor activation sometimes seems present when subjects are actively distracted from processing linguistic input (Pulvermüller, Shtyrov, & Ilmoniemi, 2005). The activations appear as early as the earliest brain indicators of meaning processing observed so far (Moseley, Pulvermüller, & Shtyrov, 2013). Furthermore, functional changes in motor systems, which can be induced by magnetic or electrical

stimulation or just behaviorally, led to differential causal influences on the processing of action word categories (Liuzzi et al., 2010; Pulvermüller, Hauk, Nikulin, & Ilmoniemi, 2005; Shebani & Pulvermüller, 2013; Willems, Labruna, D'Esposito, Ivry, & Casasanto, 2011). Lesions primarily affecting the motor system impair the processing of action meanings and action words (Bak, 2013; Kemmerer, Rudrauf, Manzel, & Tranel, 2012), although body part-specificity of functional degradation could so far be documented in healthy subjects (Shebani & Pulvermüller, 2013) but not in stroke patients (Arevalo, Baldo, & Dronkers, 2012). These results show that the motor system plays a causal and crucial role in semantic processing. Analogous data demonstrate the semantic relevance of sensory systems, including modality-specific areas for olfactory, gustatory, auditory, somatosensory, visual-object, and visual-spatial processing (Barrós-Loscertales et al., 2012; González et al., 2006; Kiefer, Sim, Herrnberger, Grothe, & Hoenig, 2008; Pulvermüller & Hauk, 2006; Simmons et al., 2007).

In essence, the seemingly diverging hub and category specificity positions can be integrated by viewing semantic processing as a function of neuronal circuits spread out over a range of areas whose formation and distribution are driven by neuronal correlation learning and neuroanatomical connectivity (Binder & Desai, 2011; Kiefer & Pulvermüller, 2012; Pulvermüller, 2013). Because semantic learning requires grounding and, thus, correlated information in the senses, category-specific semantic areas emerge in category-preferential areas, sometimes reaching out into sensorimotor cortex far away from core perisylvian language cortex. Because many of the connections bridging between modality-specific areas run through convergence zones in modality-unspecific association cortex, the hub territory in the periphery of and surrounding the perisylvian language cortex comes into play for all types of semantic processing.

26.5 COMBINATIONS AND CONSTRUCTIONS

Not all meaning is being picked up directly from perceptions and actions semantically related to signs. The meaning of most words is actually learned from context (Kintsch, 2008). After a stock of words has been semantically grounded in actions and perception knowledge, further semantic learning can be based on language contexts, where novel word forms can bind with semantic features of co-occurring familiar words. Note that in this case correlations are also essential, particularly the correlation structure of word forms

co-occurring with other word forms in constructions and larger pieces of discourse. The brain mechanism for such “parasitic” semantic learning, or “symbolic theft” (Cangelosi, Greco, & Harnad, 2002), may be correlated activity of already established semantic circuits and newly forming circuits for novel word forms. If word meaning can be picked up indirectly from other signs, then this implies that semantic learning is not bound to sensorimotor constellations available in the world; potentially, new combinations of semantic feature combinations and, hence, concepts can arise.

Abstract words, such as “freedom” or “beauty,” may be related to a range of variable contexts and equally variable constellations of actions, objects, and knowledge, so that it is more difficult to pick up their meaning from contextual or sensorimotor correlation. Because a sunset, face, flower, and piece of art may all be called “beautiful” based on sometimes radically different visual features and linguistic contexts in which they occur, the correlation learning principle does not predict massive strengthening of sensorimotor and linguistic circuit connections. Still, it is possible that, by way of convergence zones, weak links are being built between signs and the variable instantiations of their abstract meaning in sensorimotor systems (Pulvermüller, 2013). Neuroimaging evidence regarding the brain basis of abstract meaning is heterogeneous, but some studies indicate an involvement of association areas, for example, in dorsolateral prefrontal cortex (Binder, Westbury, McKiernan, Possing, & Medler, 2005).

Combinatorial semantic learning is particularly important when whole constructions acquire meanings unrelated to the semantics of their constituent words, for example, as in the case of idiomatic phrases such as “grasping ... ideas” or “kicking ... habits,” where the idiom may denote cognitive processes unrelated to the motor acts of grasping or kicking (Gibbs & O'Brien, 1990). In this case, over and above the single words included, the whole phrase or construction may acquire a meaning of its own, which may be of an abstract nature. Again, some sensorimotor and combinatorial information may be relevant for such abstract idiomatic meaning, although the relevant contexts, both in terms of actions and perceptions and in terms of context words and constructions, are quite variable. As a consequence, the abstract meaning of idioms (as that of abstract words) may be mapped in convergence hubs, including dorsolateral prefrontal cortex and anterior-inferior temporal cortex. Neuroimaging studies of abstract idiom processing indeed confirm these hub area activations to idioms but not to matched literal constructions (“Berta kicked the habit” vs. “... the ball”) (Boulenger, Hauk, & Pulvermüller, 2009; Lauro, Tettamanti, Cappa, & Papagno, 2008). Interestingly, motor systems activation reflecting the meaning of

action words included in the constructions was seen for both literal and idiomatic phrases at a point in time when sentence meaning was processed (Boulenger et al., 2009; Desai, Conant, Binder, Park, & Seidenberg, 2013). This can be interpreted as an indication that, in idiomatic construction understanding, semantic information regarding the whole construction and the constituent words (here: action words) is being retrieved and, potentially, integrated. A study of the time course of semantic processing using magnetoencephalography showed that brain indexes of abstract idiom-related information in hub areas were manifest immediately and simultaneously with those of action word-related semantic information processing in sensorimotor systems (Boulenger, Shtyrov, & Pulvermüller, 2012). These neurophysiological results are consistent with the view that compositional and whole-construction-related semantic information are being processed simultaneously and interactively in idiom comprehension.

Some combinatorial aspects of language are captured by syntax, which describes abstract combinatorial rules for conjoining the members of large vocabulary groups (lexical categories) into phrases and increasingly complex sentences. In contrast to views dominating linguistics for many years, according to which most syntactic knowledge is genetically predetermined and learning only plays a modulatory role in language acquisition (Chomsky, 1980), neurocomputational investigations indicate that much combinatorial knowledge relevant to syntax can be picked up from the correlation structure of words in constructions (Chater & Manning, 2006; Elman et al., 1996). A further belief dominating linguistics for decades has been called into question by recent evidence, the claim that syntax and semantics belong to different cognitive systems that are informationally encapsulated toward each other. In contrast to this claim, neurocomputational simulation of combinatorial learning of constructions shows that syntactic mappings are colored by meaning so that, for example, nouns and verbs are being subcategorized into semantic subtypes (Elman, 1990). This conforms with postulates immanent to cognitive linguistics and the construction grammar framework, where syntax and semantics are viewed as intrinsically linked to each other (Goldberg, 2006). One further claim held by linguists has inspired much recent neurocomputational research, the claim that combinatorial mechanisms are discrete, that is, that they exhibit an all-or-none character rather than being probabilistic in nature. Whereas some researchers have strongly argued against this position (Elman et al., 1996), recent neurophysiological work and neurocomputational work seem to support the discreteness position (Pulvermüller, Cappelle, & Shtyrov, 2013; Pulvermüller & Knoblauch, 2009).

A close functional link between linguistic combinatorial knowledge and general action knowledge receives

support from studies of patients with brain lesions usually causing grammar processing problems. These patients have been reported to exhibit difficulty in processing combinatorial information about general actions, further supporting the idea that language and action systems are tightly interwoven (Fazio et al., 2009). Although the grammar of sentences and that of complex human actions show structural similarities setting apart human combinatorial brain systems from those available to apes and monkeys (Pulvermüller & Fadiga, 2010), the discussion about precise analogies and differences between combinatorial systems of syntax and action is ongoing (Moro, 2014; Pulvermüller, 2014).

26.6 SPEECH ACTS AND SOCIAL-COMMUNICATIVE INTERACTION

Brain research on language so far has mostly dealt with linguistic structures, that is, words and sentences, without considering language use and communication as a social form of interaction. A word such as “apple” can be used as a tool to achieve different goals, for example, the goal to NAME an object in the context of a language exercise or, alternatively, the goal to REQUEST and obtain an apple. It is obvious that the same word or utterance can be a tool to reach different goals and that the utterance is therefore being linked with context-specific sets of assumptions and intentions (e.g., Alston, 1964 #11939; Fritz & Hundsnurscher, 1994 #396; Ehlich, 2007 #11562; Stalnaker, 2002 #12042) as follows: in the NAMING context with the expectation that the label can function as a tool to refer to the relevant object, but in the REQUEST context with a range of additional social-interactive expectations that the other party will hand over the object, that such an object is available to the other party, and that he or she is, in principle, willing to pass it. In close relationship to these different expectations, assumptions, intentions, and goals, the different speech acts in the present example NAMING and REQUEST are linked into different typical *action sequence schemas* (Figure 26.5A). When communicating successfully, interacting partners may have the same sequence schema representations active in their brains, together with the action perception circuits for the utterances with which the speech acts are performed. The context-dependent activation of different communicative sequence schemas by the same utterance has been shown to be manifest in brain activation. The action-heavy knowledge about the different sequences opened up by a REQUEST is manifest in activation of the motor and premotor cortex, whereas the emphasis of language-object links in NAMING draws on inferior-temporal areas. The different action sequence schemas characterizing specific social-communicative actions performed

FIGURE 26.5 Brain basis of social-communicative speech acts. Results of an EEG experiment on understanding of NAMING and REQUEST actions performed by use of the same words. Compared with NAMING (in blue), stronger brain activation was seen in the REQUEST context (in red) starting already at 100–150 ms after critical (written) word onset. Plotted is global field power (GFP) calculated from multiple electrodes. Sources of this enhanced activity to REQUESTs (L1 minimum norm current estimates, see inset) were primarily localized in left fronto-central and right parieto-temporal cortex (*adapted from Egorova et al., 2013 with permission from the publisher*). These additional activations may reflect the processing of knowledge about interaction sequences, intentions, and action goals relevant to understanding REQUESTs.

with the same linguistic structures therefore have a brain correlate in speech act–specific cortical activations. These emerge rapidly (100–200 ms), thus demonstrating an almost instantaneous access to linguistic-pragmatic knowledge (Egorova, Pulvermüller, & Shtyrov, 2014; Egorova, Shtyrov, & Pulvermüller, 2013).

26.7 OUTLOOK: KEY ISSUES IN BRAIN LANGUAGE RESEARCH

The new field of the cognitive neuroscience of language is rapidly advancing toward a better understanding of the brain basis of a most remarkable human faculty. We comment on key issues in this progress, and future research will be particularly important.

26.7.1 Modeling Real Circuits

During the decade of the brain (2000–2010), a main effort addressed the role of different cortical areas (and other brain parts) in cognitive processing, language processing included. As a result, the box and arrow diagrams were, in many cases, supplied with cortical area labels (e.g., Hickok & Poeppel, 2007). However, a main insight from computational neuroscience is that neuronal processes can be shared by distributed neuronal assemblies so that it would be inaccurate to label one area with one function—because the function is, in fact, distributed over many areas—and each area could, in principle, carry a multitude of neurons belonging to different neuronal circuits with different functions. Therefore, it appears more appropriate to consider *distributed neuronal assemblies* (DNAs) instead

of areas or whole systems as the carriers of functions, and thus to specify the *cortical topographies of functions*. The example of meaning not situated in one local hub but rather distributed over a set of areas that reflect relevant category-specific information has been discussed in detail. It seems an important step forward to replace the labeled box and arrow diagrams with brain topography maps of linguistic and cognitive functions and to make definite these topographic models in realistic neurocomputational simulations that mimic specific aspects of brain anatomy and physiology (Pulvermüller, Garagnani, & Wennekers, 2014).

26.7.2 Motor Involvement in Speech Perception and Comprehension

Some models consider primary and higher auditory cortices in superior-temporal cortex as the cortical locus of speech perception (Poeppel, Emmorey, Hickok, & Pylkkanen, 2012; Rauschecker & Scott, 2009). According to this perspective, frontal cortex, motor systems included, may play a role in predicting likely future perceptions in case of noisy environments or under high attentional demands. However, when speech is perceived passively, such models would not predict any inferior-frontal activation. Contrasting with this prediction, experimental neurophysiological studies showed that speech stimuli activate superior-temporal and inferior-frontal cortex activation in close temporal succession, even when subjects were actively distracted from language processing. Recent results suggest that motor system activation in speech processing and frontotemporal connectivity through the arcuate fascicle predict verbal short-term memory and

word learning performance (Lopez-Barroso et al., 2013; Szenkovits, Peelle, Norris, & Davis, 2012), thus pointing to further features of their functional relevance.

The causal influence of motor and inferior-frontal activation on speech perception is one more fact that makes it difficult to maintain the idea that, under normal conditions, temporal cortex processes speech without feedback from frontal areas. As mentioned, local stimulation of tongue and lip motor cortex biases perceptual classification of speech sounds (D'Ausilio et al., 2009; Möttönen, Dutton, & Watkins, 2013; Möttönen & Watkins, 2009). Although it has been argued that this behavioral change may be caused at the decision stage, leading to a decision bias rather than a perceptual change (Venezia, Saberi, Chubb, & Hickok, 2012), most recent evidence provides further support for a genuine causal effect of motor cortex activation on phoneme perception (Möttönen et al., 2013) and speech comprehension (Schomers et al., 2014). Data from patients still require further attention because some authors report phoneme classification deficits with inferior-frontal lesions (Caplan, Gow, & Makris, 1995), but others failed to replicate these (Rogalsky, Love, Driscoll, Anderson, & Hickok, 2011). A possible integration of these diverging results may draw on right inferior-frontal areas, which may contribute to different degrees, depending on the degree of laterality of the arcuate fascicle in specific individuals. Another most important issue is the involvement of inferior-frontal and motor systems in single word comprehension. Lesions in these key regions cause deficits in understanding single words under difficult perceptual conditions and, for clearly pronounced words, a significant processing delay has been documented (Mirman, Yee, Blumstein, & Magnuson, 2011; Moineau, Dronkers, & Bates, 2005). However, discussions are still ongoing about the status of these findings for brain language theory.

26.7.3 Localizing Semantics

As discussed in the semantics section, a broad area surrounding the sylvian fissure contributes to general semantic processing, and even more widely distributed networks are involved in category-specific semantics (Figure 26.4). Still, it may be asked whether the perisylvian cortex's *semantic rim* is indeed best conceived as a hub processing all semantics to the same degree and in a similar manner. Would these areas also show a degree of category specificity, as it has previously been shown for anterior-temporal, middle temporal, angular, and inferior-frontal cortex? Similar questions arise for areas contributing to category-specific semantics. Which are the specific facets of

semantic knowledge that get lost if motor and other modality-preferential areas are lesioned? For which semantic categories would motor systems be important? Apart from genuine action words, a recent suggestion is that they are also crucial for abstract emotion words, idioms, and other abstract language (Boulenger et al., 2012; Moseley et al., 2012). What about abstract words with variable use? To which degree is abstract meaning processing shared or divided between action and connection hub systems of the human brain? A set of exciting questions may spark further brain research in the semantic domain, some of which also relate to context-dependent neuro-pragmatic function. Another important issue addresses the time course of semantic processing. Whereas the classic neurophysiological indexes of semantics, such as the N400 brain potential, emerge at 300 to 500 ms and later (Kutas & Federmeier, 2011), early brain reflections of meaning have been reported with the first 100 to 200 ms (Pulvermüller, Shtyrov, & Hauk, 2009). As for the localization in space, the localization of semantic subfunctions in time appears as an eminently important future research target.

26.7.4 Task Modulation and Attention

The interplay between language and attention mechanisms is one of the most delicate facets to be addressed in the neuroscience of language. This does not only imply that brain activation patterns change if linguistic items are being processed in different tasks. Note that the latter is quite trivial, because common psycholinguistic tasks (for example, attentive reading, lexical decision, and semantic categorization) differ so fundamentally (for example, in the need for overt responses, decisions, or comparison between stimuli) that their brain manifestations cannot be the same. But language-related brain activation is also under the influence of fine-grained task features that direct attention to different aspects of linguistic stimuli (Garagnani, Shtyrov, & Pulvermüller, 2009; Hoenig, Sim, Bochev, Herrnberger, & Kiefer, 2008). Early models had suggested that processing in specific "modules" can be switched on and off by the level of processing imposed by specific tasks. In this view, a semantic task may switch on semantic processing, but a phonological task may suppress it. Contrasting with this view, much evidence supports automatic semantic access, which seems very difficult to suppress (Stroop, 1935). Still, task demand may modulate the degree to which neuronal circuits processing word forms or meanings become active. One proposal is that a complex system of area-specific feedback regulation loops controls attention and that the gain in these regulation loops implements the

level of attention to specific linguistic and cognitive aspects (Garagnani et al., 2008). Research about language attention interplay is still in its infancy. An avenue toward a better understanding may be opened up by conjoined performance of neurocomputational modeling and experimental neurophysiological research.

26.7.5 Neurocomputational Modeling and Temporal Dynamics

Using concrete neurobiologically grounded models—as illustrated in Figure 26.2, where specific connectivity features of perisylvian language cortex are implemented—it becomes possible to make predictions regarding brain physiology beyond the level previously possible. For example, the simulation of cell assemblies developing in perisylvian language cortex allows for testing their activation time course. When these distributed circuits become active, they follow a sequence of activation states that may be of interest for a better understanding of cognitive processing. The circuit is first stimulated from its sensory end. If this early stage of reception provides sufficient input activation, then it is followed by rapid spreading of activation throughout the circuit, a process called ignition. During ignition, most of the cell assembly neurons become active; however, because of biasing input, feedback regulation, and control mechanisms, the precise set of neurons partaking in the ignition may vary in a context-dependent and task-/attention-dependent manner. After ignition, activity declines because of inhibitory mechanisms set off by the strong excitation processes, but activation still survives and reverberates in those parts of the circuit that are most strongly connected. The different dynamic stages of the circuit activation process (stimulation, ignition, reverberation) can be related to different cognitive and linguistic processes (reception, word recognition, verbal working memory) and to different neurophysiological indexes (P50, N100/N160, N400 conjoined with high-frequency activity; Pulvermüller et al., 2014). Finding and refining the parallels between mechanistic-neurobiological, cognitive-linguistic, and neurophysiological mechanisms is one of the most exciting tasks for the future.

Acknowledgments

We wish to thank Malte Schomers, Rachel Moseley and Sabina Mollenhauer for discussion and help in preparing this ms. This work was supported by the Freie Universität Berlin, the Deutsche Forschungsgemeinschaft (Pu 97/15-1, Pu 97/16-1), and the Engineering and Physical Sciences Research Council and Behavioural and Brain Sciences Research Council (UK) (BABEL grant, EP/J004561/1). This work has been partially funded by Poeticon++ EU grant.

The Dual Loop Model in Language

*Cornelius Weiller, Tobias Bormann, Dorothee Kuemmerer,
Mariachristina Musso and Michel Rijntjes*

Department of Neurology and Clinical Neuroscience, University Hospital Freiburg, Freiburg, Germany

The idea of two parallel streams to process language seems almost ancient. For instance, Herder distinguished a more automatic production route from a close association of language with “self-consciousness” (Herder, 1772). The idea of conceptual representations independent of linguistic representations is commonly attributed to Lichtheim (1885), which may be due to his invention of the famous house diagram. Yet in his 1874 treatise Wernicke notes, “thinking and speaking are two independent processes, which even may inhibit each other” (Wernicke, 1874).

Based on the neuropsychological method, the distinction between phonological representations and nonlinguistic representations of conceptual knowledge has been incorporated in most modern (Dell, Martin, & Schwartz, 2007; Lambon Ralph, Graham, Ellis, & Hodges, 1998; Levelt, 1999; Morton, 1980) as well as historical (Freud, 1891; Goldstein, 1927; Kleist, 1905, see Weiller, Bormann, Saur, Musso, & Rijntjes, 2011) models of language processing. In all cognitive models of word processing, the mapping is achieved through different layers of representations, but all these models assume at least two parallel cognitive streams.

It was Carl Wernicke (at 26 years old) who, in his “physiological model on an anatomical basis,” developed a central and very modern idea of how language is processed in the brain (Wernicke, 1874). Wernicke assumed only two centers in the brain, “the center for images of movement for sound production in the first frontal convolution” (i.e., the inferior frontal gyrus [IFG], called Broca’s area) and “a sensory language center, containing the storage of sound images of speech in the first temporal convolution” (i.e., the superior temporal gyrus [STG], later called Wernicke’s area), and all language functions would be derived from the interaction between both centers.

This interaction is accomplished through two principal routes. The route for the “direct” interaction of Broca’s and Wernicke’s area would represent “sensorimotor mapping” and produce the so-called Wortbegriff (translated as “word-concept” or “word-form”) (DeWitt & Rauschecker, 2013) as an intrinsic integration of sensory and motor aspects of the word, learned during development in early age through imitation and that is later used to produce speech. In parallel, there are concepts associated with a word distributed over the entire cortex and connected to Wernicke’s and Broca’s areas through the “indirect” route for understanding (“semantic route”) and uttering thoughts. “Soon after we have learned to speak a word, we lose the intention only to reproduce sounds and plan to utter a meaning” (Wernicke, 1874). “We have to assume that (then) the majority of speech impulses reach the word concepts from the remaining cerebral cortex” (Wernicke, 1906). Here, we have the first description of a brain network with nodes and connections.

The ensuing confusion about the locations of association tracts for these two routes was partly due to the insistence by Wernicke that those tracts mediating the processing of the “Wortbegriff” (i.e., the “direct” route) should be located behind the insula, and conduction aphasia postulated as a consequence of an isolated damage of this direct route was not found in insular lesions (for more details see Weiller et al., 2011). Today, the function Wernicke ascribed to the direct route (e.g., sensorimotor mapping) is equivalent to what we today would ascribe to the dorsal route along the arcuate fascicle/superior longitudinal fascicle. Wernicke did not make any differentiation between dorsal and ventral tracts; however, he explicitly, clearly, and repeatedly mentioned the extreme capsule that is today seen as the major connection of the ventral stream. He referred to

the notion of his academic mentor Meynert, who was the first to ascribe a language function to a set of regions comprising the claustrum, the insula, as well as the ascending acoustic fibers in the external and extreme capsule (Meynert, 1866). Wernicke was aware of other association tracts (e.g., the arcuate fascicle [AF]) that he saw “not actually a special bundle, but a general system of association fibers, which must be considered in the anatomy of speech regions” (Wernicke, 1906). Later, under the influence of eminent researchers in Wernicke’s time (von Monakow, Charcot, Dejerine; see Weiller et al., 2011), the arcuate fascicle was established as the main or sometimes only connecting tract between Wernicke’s and Broca’s areas. Geschwind’s iconic diagram with an anterior “language center” in the inferior frontal region, commonly related to speech production, a posterior temporal region, related to speech comprehension connected through a single fiber system above the level of the ventricles, and the arcuate fascicle, along which language information is transferred, has been the blueprint that almost all textbooks refer to (Geschwind, 1972). Geschwind’s preference for the arcuate fascicle (see Weiller et al., 2011) may be due to the importance he gave to the angular gyrus as multimodal integration area for language: “the function of Wernicke’s area implies the existence of extensive connexions to the angular gyrus region” (Geschwind, 1965). Thus, the ventral pathway along the extreme capsule was out of sight until recently (Weiller et al., 2011).

Although the notion of a ventral pathway connecting temporal and frontal lobes for language processing got lost, the idea of a dual stream model emerged in the area of vision, assuming two parallel processes for perception of visual stimuli: “one ambient, determining space at large around the body, the other focal, which examines detail in small areas or space” (Trevarthen, 1968). This idea developed into the very well-known ventral “what” and dorsal “where/how” pathways (Kravitz, Saleem, Baker, & Mishkin, 2011; Milner & Goodale, 1995; Mishkin, Ungerleider, & Macko, 1983). The processing of a “where” and “what” of a visual stimulus take different courses, both starting in the primary visual cortex but with a subdivision in dorsal and ventral streams already present in extrastriate regions, extending toward the parietal and temporal lobe, respectively. Over the years, a subdivision of different processing streams was also proposed in the motor system (Rizzolatti & Matelli, 2003) or for visuospatial attention (Corbetta, Kincade, Lewis, Snyder, & Sapiro, 2005). Studies of comparative anatomy revealing two processing streams for the acoustic modalities (Romanski et al., 1999) and a larger number of imaging studies in humans led to a “new” hypothesis of dual stream processing for auditory language

system in the brain (Demonet, Thierry, & Cardebat, 2005; Hickok & Poeppel, 2004; Rauschecker, 1998; Scott, Blank, Rosen, & Wise, 2000; Wise, 2003): the dorsal stream is involved in mapping speech sound to articulation, whereas the ventral one would support speech to meaning correspondences. In these models, the frontal termination of the ventral stream has not exactly been determined and Broca’s area is sometimes described only in the context of the dorsal stream. Wise (2003), favoring the anterior temporal lobe (ATL) as decisive for language comprehension, pointed to the uncinat fascicle (UF) as a ventral connection, as has been supported by DTI studies (Friederici, Bahlmann, Heim, Schubotz, & Anwender, 2006; Parker et al., 2005). Coming from the gold standard, tracing experiments in monkeys, Pandya’s group suggested the extreme capsule as an important connecting pathway in language, and also in grammar, connecting the temporal lobe with what is seen as BA 45 in humans (Pandya & Yeterian, 1996; Petrides & Pandya, 1988, 2009; Petrides & Pandya, 2002, 2009; Schmahmann & Pandya, 2006).

This was the situation when we aimed to integrate functional connotations with tract morphology to test the anatomical basis of the “dual-stream model” as it was proposed by Hickok and Poeppel (2004) by combining fMRI with diffusion tensor imaging (DTI), assuming a distributed network comprising specialized brain areas (network nodes) and their interconnecting white matter fiber tracts (network connections) (Saur et al., 2008). The findings revealed that a sublexical, phonological speech task (pseudoword repetition) was sustained by a dorsal pathway connecting the superior temporal lobe and premotor cortices in the frontal lobe via superior longitudinal fascicles and the arcuate fascicle. In contrast, a higher-level language comprehension task was mediated by a ventral pathway connecting the middle temporal lobe and the ventrolateral prefrontal cortex via the extreme capsule. The finding of the extreme capsule as the place for connecting fibers within the ventral pathway was supported by similar publications on DTI trackings in humans (Croxson et al., 2005; Frey, Campbell, Pike, & Petrides, 2008; Friederici et al., 2006; Makris & Pandya, 2009; Parker et al., 2005).

Evidence from functional studies support the idea of the dual loop model; during presurgical assessment of epileptic patients, stereo-electroencephalographic recordings were performed and ERP signals were recorded during a phoneme task on a pair of pseudowords and a lexical-semantic task on adjective-nouns pairs. Phonological information processing predominantly occurred in the left supramarginal gyrus (SMG) (dorsal stream) and processing lexicosemantic information occurred in the anterior/middle temporal and

fusiform gyrus (ventral stream) (Trebuchon, Demonet, Chauvel, & Liégeois-Chauvel, 2013). Stimulating the dorsal pathway with electrostimulation leads to phonological paraphasias (Leclercq et al., 2010), whereas electrostimulation of the ventral EmC leads to semantic paraphasias (Duffau et al., 2005).

27.1 PATIENTS

Results from patients with acute aphasia support the claim that language is processed within a dual pathway network. Repetition impairments were mainly associated with posterior temporoparietal regions and damage of the AF/SLF, whereas comprehension impairments were associated with lesions more ventrally in temporoprefrontal regions projecting on the ventral EmC (Kuemmerer et al., 2013). Although this study complemented and supported the previous DTI study, patients commonly present with syndromes (i.e., a typical collection of symptoms). Ueno, Saito, Rogers, and Lambon Ralph (2011) implemented the dual pathway network in a computational model and could virtually relate symptoms like repetition and comprehension impairments and also syndromes like Wernicke's and Broca's aphasia to the expected lesion sites. Allocation of symptom collections to syndromes could also be related to lesions in acute aphasic patients (Kuemmerer et al., 2012). Lesions associated with Broca's aphasia were in the IFG, Insula, and SMG, whereas lesions correlating with Wernicke's aphasia were in the STG, postcentral gyrus, and Insula. Semantic paraphasias and comprehension impairments in Wernicke's aphasia may be due to temporal lesions and damage to the ventral pathway, whereas phonemic paraphasias may be related to damage to the dorsal pathway. Thus, Wernicke aphasia affects both the ventral and the dorsal pathway.

Another aphasia syndrome, conduction aphasia (Damasio & Damasio, 1980; Poncet, Habib, & Robillard, 1987), is characterized by fluent, meaningful spontaneous speech with preserved auditory comprehension but frequent phonemic paraphasias and repetition impairments (Bernal & Ardila, 2009; Damasio & Damasio, 1980; Hickok, 2012; Weiller et al., 2011). The original conception of conduction aphasia as a disconnection syndrome (Wernicke, 1874) through damage to the AF/SLF (Geschwind, 1965) is supported by several recent studies (Duffau, Peggy Gatignol, Mandonnet, Capelle, & Taillandier, 2008; Yamada et al., 2007). However, many other contemporary studies favor the idea that lesions to cortical gray matter in the left inferior parietal and superior temporal lobe (Anderson et al., 1999; Bartha & Benke, 2003;

Hickok, 2009, 2012; Quigg, Geldmacher, & Elias, 2006) or SMG (Axer, von Keyserlingk, Berks, & von Keyserlingk, 2001; Baldo & Dronkers, 2006; Baldo, Katseff, & Dronkers, 2012) lead to the syndrome of conduction aphasia. Tracts or cortical regions, both constellations, evidence the dorsal stream as responsible for conduction aphasia.

This consideration could also be taken into account when trying to understand symptoms in degenerative disease. The logopenic variant of primary progressive aphasia (PPA) has also similar symptoms as conduction aphasia and is characterized by intact word comprehension, but it has repetition and phonological impairments (Galantucci et al., 2011) and is associated with atrophy of temporoparietal regions. Impaired phonological processing can be explained by deficits in tasks that require phonological storage and the presence of phonological paraphasias (Gorno-Tempini et al., 2008). Results of studies using DTI, fractional anisotropy (FA), and volumetric studies (Galantucci et al., 2011; Gorno-Tempini et al., 2008; Hu et al., 2010) demonstrate the involvement of the dorsal pathway (phonological loop) and also gray matter atrophy in these patients, supporting the role of the dorsal stream in phonological processing.

Semantic dementia may also be seen in light of the dual loop model. This disorder is characterized by impaired comprehension and naming, but intact repetition (Jefferies, Patterson, Jones, & Lambon Ralph, 2009; Lambon Ralph et al., 1998; Mummery et al., 1999; Wilson et al., 2009). Atrophy in these patients is located in the ATL/temporal lobe/ventral semantic processing stream of the temporal lobe (Agosta et al., 2010; Galton et al., 2001; Hodges, Patterson, Oxbury, & Funnell, 1992). Within the computational model of Ueno et al. (2011), the specific symptom constellation in patients with semantic dementia could be elicited by virtual damage to the ATL and anterior STG, supporting the relevance of the ventral pathway in semantic dementia.

Taken together, damage within the dual pathway model has an effect on language impairments of patients with acute aphasia in stroke (Fridriksson et al., 2010; Hosomi et al., 2009; Kuemmerer et al., 2013), as well as on patients with chronic progressive language impairments, like semantic dementia or logopenic PPA (Schwindt et al., 2013). Within this model it is possible to relate different symptoms and syndromes to different lesion sites. However, most cognitive processes do naturally require an interaction of both pathways (Ueno et al., 2011; Weiller et al., 2011). Therefore, it is essential to further explore how different models of connectivity relate to language impairments to improve our understanding of the functional relevance of both pathways (Dick & Tremblay, 2012).

27.2 NEUROPSYCHOLOGY

We have seen that patient studies have played an important role in the development of early models of language processing in the brain. The approach of Wernicke, Lichtheim, and others, however, eventually grew out of fashion, partially because predictions about the localization of cognitive functions proved to be wrong (Head, 1926). In a revival of this type of approach beginning in the 1970s, cognitive neuropsychology has been most influential in developing cognitive models of language processing (Shallice, 1988; Rapp, 2001). Early research in acquired dyslexia has led to the proposal of a dual-route model of reading based on dissociations among dyslexic individuals (Coltheart, Patterson, & Marshall, 1980). One route, the lexical-semantic route, involved mapping of the visual word onto a semantic representation and subsequent access of the phonological word form in the mental lexicon. The other route, the so-called sublexical route, involved the mapping of graphemes onto their respective sounds without access to the word's representation in the mental lexicon. Evidence for this dual-route model came from patients with phonological dyslexia who were unable to use their sublexical route: They are unable to read nonwords but are able to read regular and exception words. Please note that the "dual-route" in reading may not be identical with the proposed anatomical dual-route system along the AF/SLF and extreme capsule tracts.

The mirror impairment, surface dyslexia, can be observed in patients with a semantic impairment and is characterized by a predominant reliance on the sublexical reading route. Comparable dissociations and "syndromes" have also been reported for repetition, suggesting the involvement of at least two routes in this task. McCarthy and Warrington (1984) reported three individuals, two with conduction aphasia and one with transcortical motor aphasia. The authors argued that two routes were involved in repetition and speech production: a fast, automatic phonological route and a slow semantic route. McCarthy and Warrington (2001) reported a patient with a severe semantic impairment due to semantic dementia. The patient had a severe naming impairment and was also considerably impaired in word comprehension tasks. However, his digit span was preserved. A different syndrome is deep dysphasia, which consists of a severe repetition deficit. Patients with deep dysphasia are rare but present with an impressive, counterintuitive pattern of strengths and weaknesses. They usually have a severely limited digit span, not exceeding a single digit. They are unable to repeat nonwords, and they produce semantic errors in repetition tasks. One

individual we worked with was asked to repeat the words "czar" and "raw" on two different occasions. She produced "castle" and "meat" instead. This syndrome suggests a severe impairment to the phonological loop and reliance on semantic information derived from the auditorily presented word. However, the semantic errors in repetition suggest the additional involvement of a mild semantic impairment in this syndrome besides the severe impairment in the non-lexical repetition route. A similar, yet milder, deficit is present in another syndrome, impaired phonological short-term memory (STM). This is sometimes also referred to as repetition conduction aphasia (Shallice & Warrington, 1977). These patients also suffer from reduced spans for digits and words and impaired repetition of long nonwords. Processing the meaning of stimuli presented for repetition is better preserved. In sentence repetition, STM patients appear to have the meaning of the sentence preserved, suggesting involvement of semantic processing in this task (Baldo, Klostermann, & Dronkers, 2008). It has been argued that deep dysphasia and STM deficit reflect the continuum of a deficit rather than two independent syndromes (Martin, Saffran, & Dell, 1996).

Cognitive neuropsychology has preferably used this type of dissociation among tasks to develop models of complex cognitive skills. More recently, however, associations of functional impairments have been used to develop models further. In a recent study, Dell, Schwartz, Nozari, Faseyitan, and Coslett (2013) have mapped the parameters of a dual-route model of naming and repetition onto neural regions. Their model is a dual-route interactive model, which has been implemented as a computer model. In this model, a representation of a phonological input is interactively linked to phonological output units, a lexical and a semantic layer. The connections between the input and the phonological output units represent the nonlexical, nonsemantic route. In contrast, during repetition of single words, lexical and semantic representations are activated in parallel, reflecting the contribution of a word's lexical status and its meaning. The model has been successfully "fitted" to large groups of aphasic individuals. With some exceptions, an aphasic person's pattern in naming and repetition can be simulated by changing parameters in the computer model (Dell et al., 2007). This means that the pattern of errors of an aphasic speaker can be simulated within that model, and each aphasic participant is represented by a specific combination of model parameters.

In their more recent study, Dell et al. (2013) mapped the individual patients' model parameters onto lesions. Artificial lesions to the lexical-semantic

connections in the computer model were correlated with neural lesions in anterior temporal areas, inferior temporal areas, IFG, and the SMG. These regions had been identified as substrates of various aspects of processing of meaning in the brain. In contrast, artificial lesions to the phonological output representations in the computer model mapped onto the SMG, postcentral gyrus, precentral gyrus, and insula what the authors suggest is the “anterior part of the dorsal stream.” The model’s connections between auditory input and output phonemes mapped onto “the STG, the posterior third of the planum temporale and cortex at the juncture of the parietal and temporal lobes (area Spt) as well as the SMG and postcentral gyrus” (Dell et al., 2013).

27.3 FUNCTIONS OF THE DUAL LOOP MODEL

There is no reason to suppose that the organization of the acoustic language system is different from other modalities. Thus, a dual loop system has been postulated in various domains (see Rijntjes, Weiller, Bormann, & Musso, 2012 for an overview of various studies showing an involvement of a dorsal and a ventral pathway). Thus, the function ascribed to dorsal or ventral pathways in each modality may differ, but only in their modality-specific aspect (Rijntjes et al., 2012). Discussions have taken place regarding how the common aspects of processing in the dorsal and ventral streams in different modalities might be described (Hickok & Poeppel, 2007; Rauschecker & Scott, 2009; Rijntjes et al., 2012; Weiller et al., 2011; Weiller, Musso, Rijntjes, & Saur, 2009).

We postulated that a dual loop system, comprising long association tracts connecting prerolandic and postrolandic parts of the brain with different computational abilities, provides a scaffolding system around which various functions may have been developed (Rijntjes et al., 2012; Weiller et al., 2011). It may be the synergy between time-sensitive analysis of sequences comparing the (correct) serial alignment of segments with acquired (e.g., phonological) representations as a possible function of the dorsal stream and identification of an invariant set of auditory (and probably also visual) hierarchical structural relationships between the elements (e.g., words), that is, time-independent, along the ventral stream, which makes language possible (Weiller et al., 2011).

The dorsal stream is not limited to “where” or “how” functions; rather, it analyzes the sequence of elements in time and in space, allowing for a fast online integration between sensory event information

and “internal models or emulators” (Rauschecker & Scott, 2009). Thus, the dorsal stream is responsible for the ordering of elements in a continuous string to assure a correct production of behavior (e.g., subsequent syllables, word order, movement trajectories, orienting to a visual stimulus, and updating the place value of an Arab digit), irrespective of whether this behavior has been executed before or has a meaning. Therefore, processing is “time-dependent.” In language, correct phonology may be learned through imitation and repetition, and the dorsal stream may serve as an automated correction mechanism for correct production of speech. This function is typically attributed to what is called the dorso-dorsal stream (along SLF II) (Binkofski & Buxbaum, 2013; Hoeren et al., 2014; Vry et al., 2012; Vry et al., 2014), which connects with dorsal premotor cortex. Through exercise and experience, the sequences can be converted into blueprints (e.g., one’s own signature; Rijntjes et al., 1999) that are stored in SMG and BA 44 in IFG (“canonical neurons”) and may relate to context and semantics, thus accessing areas in the inferior parietal cortex (IPC) and posterior temporal lobe, constituting what is called the dorsal-ventral stream (SLF III and arcuate fascicle) (Binkofski & Buxbaum, 2013; Hoeren et al., 2014; Vry et al., 2014). Recall and execution of stored blueprints might be possible rapidly and without the dorso-dorsal stream, and thus may substitute, in part, the work of the dorso-dorsal stream. Adaptations in the blueprints (e.g., changing to a new swing of a golf-pro) may require temporary relearning through the dorso-dorsal stream.

Most scientists would agree that the ventral stream is involved in meaning. We postulated that, in more general terms, the ventral pathway would be involved in the identification of the structural (hierarchical) relations of elements that may not be adjacent, and thus “time-independent,” independent of the sequence of occurrence (Weiller et al., 2011), as in grammar (Friederici et al., 2006; Rauschecker & Scott, 2009; Weiller et al., 2009), in tonal dependencies in music or in the categorical identification of the digits involved in difficult mental arithmetic (Klein, Korbinian, Glauche, Weiller, & Willmes, 2012) (Willmes, Korbinian, & Klein, 2014). Also in the visuospatial domain, relevance and meaning of stimuli require the ventral stream (Umarova et al., 2010) as well as imagery of movement (Vry et al., 2012) or pantomiming (Hoeren et al., 2014; Vry et al., 2014).

27.4 ANATOMY, HUBS, DIVISIONS

A clear distinction should be made between the terms “streams” and “tracts.” Processing “streams” address

the functions that are thought to be mediated by the ventral or dorsal pathways, which include tracts and the cortical regions connected by them. The term “tracts” should be reserved for the anatomical correlates (here, of long association tracts) connecting these cortical regions. Tracts themselves do not have functions; they only mediate between cortical areas, and the result of this interaction might lead to a constellation that we recognize as a “function” or, in the clinical setting, a symptom may be attributed to its disturbance. We know that inside one stream several tracts are known to connect different brain areas, and because we also know that certain types of functional processing take place in this stream, we may equate one cortico-cortical connection with one of these functions. But we have to be careful here. As stated elsewhere, “Interruption of the network has an impact on the remaining (“intact”) parts of the network. In other words, the functions of Broca’s or Wernicke’s area with an intact arcuate fascicle may not be the same as after that fascicle’s destruction.” And “. . . the destruction of the interconnection (of the arcuate fascicle) may not result in a solitary repetition failure, but in a complete new phenomenological constellation, as the tract lesion affects the function of the regions it connects, and other regions in the remaining network, including in the other hemisphere, may become operational” (Rijntjes et al., 2012). However, this does not contradict the assumption that a particular connection in a network on its own is necessary for a specific function (e.g., repetition), as was shown recently (Kuemmerer et al., 2013).

Anatomically, the segregation between dorsal and ventral systems is alluded to by the orientation—in humans superior or inferior—of the involved cortical regions (e.g., in the motor system) (Rizzolatti & Matelli, 2003) or in the visuospatial attention system (Corbetta et al., 2005). Here, we take a different approach by defining dorsal and ventral systems by the course of the long association tracts connecting postrolandic and prerolandic brain regions, either above (i.e., “dorsal”) or below (i.e., “ventral”) the sylvian fissure. Note that this may give different results because cortical areas may have dorsal as well as ventral connections, and thus may serve as integration hubs.

It is common ground that dorsal and ventral streams use various anatomical tracts. The dorsal stream uses the superior longitudinal fascicles (SLF II, III) for parieto-frontal connections and the arcuate fascicle (AF) for temporo-frontal connections. Depending on the frontal endings, an anatomical correlate to the functional division originating from studies in the motor system [i.e., dorso-dorsal to premotor cortex and dorso-ventral connections to prefrontal cortex (Binkofski & Buxbaum, 2013)] starts to emerge (Hoeren et al., 2013, 2014). The

ventral pathway comprises fibers running through the extreme capsule (Makris & Pandya, 2009) and the UF. Fibers in the ventral part of the external and extreme capsule have similar orientations and contribute to what in humans is called the IFOF (inferior frontal-occipital fasciculus) (Axer, Klingner, & Prescher, 2013; Fernández-Miranda, Rhoton, Kakizawa, Choi, & Alvarez-Linera, 2008; Gierhan, 2013). Thus, fibers from different cortical areas join and leave the IFOF, not only in the frontal or occipital lobes (as suggested by its name) but also in the temporal and parietal lobes (Umarova et al., 2010), which is not unlike entering and exiting a highway. The UF can be differentiated from the fibers of the extreme capsule and mainly connects medial and anterior temporal lobe regions with inferior frontal cortex. It is unclear whether there are direct ventral connections between inferior parietal lobule and prefrontal cortex, as suggested by human studies (Caspers et al., 2011; Catani, Howard, Pajevic, & Jones, 2002; Umarova et al., 2010; Vry et al., 2012) but without clear proof in primate studies (Schmahmann & Pandya, 2006). A connection between IPC and the temporal lobe was seen in primates studies; the middle longitudinal fascicle (mdIF) (Seltzer & Pandya, 1984) has been found in humans (Makris & Pandya, 2009; Saur et al., 2008; Wong, Chandrasekaran, Garibaldi, & Wong, 2011), but stimulation studies have not confirmed this connection so far (DeWitt Hamer, Morit-Gasser, Gatignol, & Duffau, 2011).

The exact anatomy of the fiber tracts and the cortical regions they connect, mainly based on tracing studies in nonhuman primates as well as a discussion on the pro and cons of human DTI-based fiber tracking in humans, are described elsewhere (Dick & Tremblay, 2012; Weiller et al., 2011) (Figure 27.1).

Conceptually, the dual loop model comprises at least three parallel layers. As the innermost layer, functionally close to the environmental end of the action–perception cycle, the dorsal streams use tracts to connect superior temporal lobe and IPC with premotor or posterior prefrontal cortex (BA 6,44, 45 B) (Bernal & Ardila, 2009; Parker et al., 2005; Saur et al., 2008, 2010). The next outer shell is provided by the ventral stream, which connects the middle and inferior temporal lobe with prefrontal cortices (BA 45A, 47) (Parker et al., 2005; Saur et al., 2008). Finally, prefrontal cortex (BA 47) and anterior temporal pole (ATL), functionally related to abstract and conceptual processing (Shallice & Cooper, 2013), are connected via the UF and may reflect the outermost layer. Also, in the parietal cortex, an onion bulb–like contribution to dorsal and ventral tracts has been suggested (Caspers et al., 2011) (Figures 27.2 and 27.3).

IFG is a region within the dual loop model that has direct ventral and dorsal connections with the two

FIGURE 27.1 A schematic drawing of streams and tracts in the dual loop model. Blue denotes participation in the dorsal pathway and red denotes participation in the ventral pathway. There are at least three components within the dorsal system: the most superior tract relates to the “dorso-dorsal-stream” for “sensorimotor mapping” and may be mediated in humans by SLF II. The “dorso-ventral-stream” connects IPC with IFG along the SLF III. These two stream connotations are derived from the motor system. The AF connects the temporal lobe with Pmd and IFG, probably contributing to dorso-dorsal and dorso-ventral streams. The ventral stream has at least two components, the UF connecting the anterior part of the temporal lobe with the most inferior part of the IFG (BA 47). Fibers that may be related to the IFOF run through the extreme capsule and connect the middle and posterior parts of the temporal lobe with inferior anterior IFG (BA 45, 47). In this diagram we give the mdLF, which connects the temporal lobe with IPC a green color, thus attributing it neither to the dorsal nor to the ventral stream exclusively. Note that there are other opinions. Parietotemporal connections have been attributed to (an indirect part of) the arcuate fascicle (Catani et al., 2005), and direct connections between IPC and prefrontal cortex have been postulated. Clearly, this diagram is not comprehensive for the tracts involved in language processing (e.g., tracts connecting to SMA or to visual association cortex as Wernicke’s perpendicular tract have been left out) but capitalizes on the dual loop system of long association tracts connecting prerolandic and postrolandic parts of the brain.

others lobes, temporal and parietal, which in turn might act in a kind of division of labor (Plaut et al., 1996) mediated by the mdLF, belonging to neither dorsal nor ventral streams, to master the extensive sensory processing (e.g., AG and pMTG may both play a role in “semantic control” (Noonan et al., 2013). IFG is also the only frontal area with connections to almost the entire rest of the prefrontal cortex, putting it in an ideal situation to integrate dorsal and ventral streams under frontal control. This was the reason we suggest that syntax, essentially to extract hierarchical relationships out of a sequence of elements, may rely on the

integration of dorsal and ventral processing streams within Broca’s area (Musso et al., 2003; Petrides & Pandya, 2002; Thompson-Schill, D’Esposito, Aguirre, & Farah, 1997; Weiller et al., 2009). There is a consensus that syntax, generally defined as a rule system capable of generating infinite sets of sequences, may not be processed by a single, monolithic cognitive computation, and thus may not be segregable in a single specific, isolated brain area, but rather it is processed in a widespread network. However, opinions are contrasting on how many and which pathways are involved in syntax processing, which tract is more relevant for language syntax, and what kind of functional processing may underlie syntactic-related pathways. There is an argument that the arcuate fascicle, especially the part connecting with BA 44, is essential or even specific for syntax (in the context of language) and decisive for child development and evolution of humans. We suggest that dorsal and ventral streams are both needed for syntax (Weiller et al., 2009). In a DTI study, Wilson et al. (2011) found reduced FA in patients with PPA in the AF as well as in the ventral tracts (UF and EmC). However, a correlation between severity of syntactic deficits and microstructural damage was related only with a decrease in FA in the arcuate within the AF/SLF tract, supporting the importance of the AF for syntax. These findings do not exclude the relevance of the ventral system for syntactic processing per se; instead, they show that interruption of AF fibers is critical in the breakdown of syntactic processing in this syndrome. Studies using healthy volunteers showed that syntax processing requires both ventral and dorsal tracts (Flöel, de Vries, Scholz, Breitenstein, & Johansen-Berg, 2009; Friederici et al., 2006; Lopez-Barroso et al., 2011). In the study by Friederici et al. (2006), processing of stimuli, generated by either a finite state or a phrase structure grammar (FSG versus PSG), was linked to the ventral route. Only stimuli generated by PSG were processed in the left pars opercularis of the IFG and thus belonged to the dorsal stream, which is in line, to some extent, with the Wilson et al. (2011) data. Thus, the studies of Wilson and Friederici appear to link the dorsal language route to syntactic complexity. Flöel et al. (2009) showed that FSG is also processed in the pars opercularis and the integrity of both ventral and dorsal tracts predicted high performance of grammar acquisition. In stroke patients, syntax was related to both the AF and the EmC systems (Griffiths, Marslen-Wilson, Stamatakis, & Tyler, 2012; Rolheiser, Stamatakis, & Tyler, 2011) and damage to the left ATL predicts impairment of complex syntax processing (Magnusdottir et al., 2013). Why should syntactic deficits in aphasia patients, but not in PPA patients, involve the ventral route? Etiology, disease course,

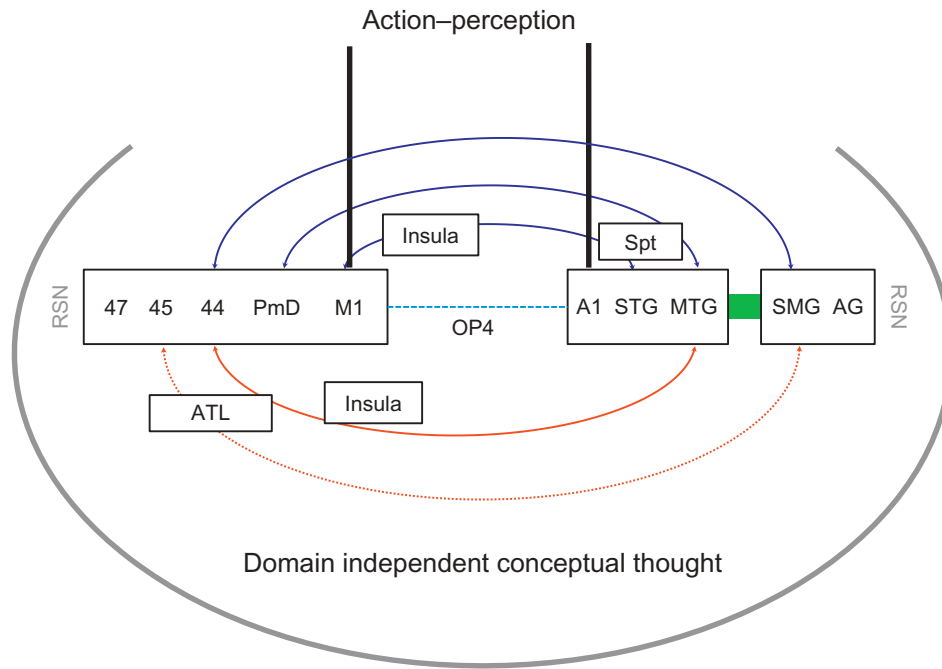

FIGURE 27.2 A diagram of connected regions of the dual loop model. Several dorsal (blue) tracts (see Figure 27.1) and ventral (red) tracts connect prerolandic (left) and postrolandic (right) brain regions. Most regions are connected by both dorsal and ventral tracts, resulting in a fully developed parallel dual loop system with reciprocal connections and equivalent pathways. Hierarchy is not determined by one specific pathway, although specific functions may primarily or crucially involve one or both, but rather by an extension of this system to regulatory, cytoarchitecturally more developed areas in prefrontal, temporal, and parietal neocortex in humans (Weiller et al., 2011). There are also regions that belong to either dorsal or ventral streams only (ATL). An onion-like structure is suggested by the different layers. For Op4, see Sepulcre (2013). RSN denotes resting-state network.

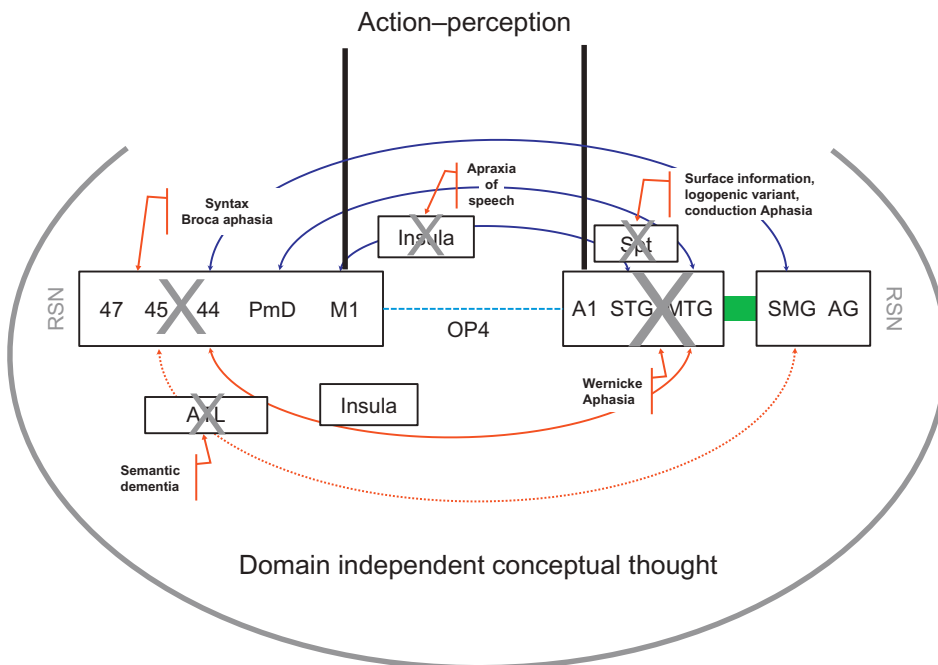

FIGURE 27.3 Hypothetical lesion sites of various forms of language disorders are put on the diagram in Figure 27.2, illustrating how symptoms or syndromes of patients might be fitted anatomically into the context of the dual loop model (“work in progress”).

and functional reorganization of these two pathologies (aphasia and PPA) are different (Saur et al., 2006; Wilson et al., 2010). In PPA patients, progressive brain degeneration correlates with decreasing and, to some extent, abnormal brain plasticity (Wilson et al., 2010). Aphasia is due to an acute event that is followed by brain reorganization. Here, brain reorganization correlates with progressive recovery of language impairments in the acute, subacute, and chronic states (Weiller et al., 1995; Saur et al., 2006). There are also methodological differences between the studies. The extreme capsule mask used for extraction of FA values and used in the more recent DTI studies (Griffiths et al., 2012; Rolheiser et al., 2011) was centered on the left IFG (BA 45), whereas Wilson et al. (2011) used a mask starting in the insula. Different attributions to ventral or dorsal streams may follow these differences.

There are also claims of fundamentally different computational capacities of the various dorsal tracts, with (within the language domain) a specific role for syntax for the tract to IFG and a clear differentiation for language production for the other stream (Friederici et al., 2012) or a differentiation in one for sensorimotor integration and one for phonological processing (Catani, Jones, & ffytche, 2005). In the context of this chapter, similar differentiations have been made in other domains, such as with a dorsal-dorsal (for correct movement execution) and a dorsal-ventral (for the use of blueprints) stream in the motor system (Hoeren et al., 2013, 2014). We advocate that both dorsal streams have the capacity for time-dependent analysis (Rauschecker & Scott, 2009), which may be used for various functions. Also, the role of working memory or the phonological loop commonly attributed to the dorsal stream (to BA 44) (Paulesu, Frith, & Frackowiak, 1993) in mastering complex grammar should be taken into account. Syntactic relations, whether adjacent or long-distance, require strategies that not only are dependent on the temporal or spatial sequence of elements but also are optimized to test a limited number of possible combinations to convey meaningful relations. We attribute the latter features of syntax to the ventral route. One aspect, however, seems clear when looking at the current literature: syntax is served by both dorsal and ventral long association routes, which work in concert, albeit with different functional specializations. A clear division of the dorsal and ventral processing stream is artificial, resulting from experimental situations that do not reflect processing within the natural environment. For most functions, both streams would not be mutually exclusive but instead work in parallel (Cloutman, 2013; Makris & Pandya, 2009; Rauschecker & Scott, 2009; Rolheiser et al., 2011),

constituting a loop (Weiller et al., 2011). Figure 27.3 potentially relates alterations of language to the dual loop model

27.5 DEVELOPMENT

A recent article shows that at birth, anterior and posterior language zones can be activated specifically but are not yet fully functionally connected (Perani et al., 2011), and that the interaction between the two regions becomes significantly synchronized at approximately 7 years of age (Friederici, Brauer, & Lohmann, 2011). This finding was considered in relation to the fact that, in contrast to the ventral pathway, the dorsal pathway has not yet fully matured (Brauer, Anwender, & Friederici, 2011; Brauer, Anwender, & Friederici, 2013) and that children up to the age of 7 are rather poor at comprehending syntactically complex sentences (Dittmar, Abbot-Smith, Lieven, & Tomasello, 2008; Dubois et al., 2008; Hahne, Eckstein, & Friederici, 2004).

Also, the full development of inner speech appears to occur around this age. According to Vygotsky, we do have conceptual awareness at birth, but no inner speech (Vygotsky, 1934). Young children approximately 4 years of age accompany their actions with speech in social situations. This speech is under the influence of continuous feedback from the environment and evolves from speech for others to overt speech for oneself, called “egocentric” or “private” speech that is still used in social situations, but its meaning is gradually directed at the child itself. During the process of a few years, until the age of approximately 7 years, egocentric speech is replaced by inner speech completely (Ehrich, 2006; Vygotsky, 1934).

It was suggested that it is only after the internalization of speech and after complete interaction of both pathways within the dual loop model that it is possible to *simultaneously* combine phonological and abstract thought proficiently (Figure 27.4). One assumption is that the development of inner speech is related to the mastering of complex grammar, which (until the age of 7) is something children fail in complex tasks because of metalinguistic demands. However, for both hypotheses the explanation could be that, for mastering these tasks, simultaneous analysis of both time-dependent and time-independent processing is required. Only then can we start using language as a tool to represent abstract concepts (Deutscher, 2005) and, as Jackendoff noted, use language as a “scaffolding that makes possible certain varieties of reasoning more complex than are available to nonlinguistic organisms”

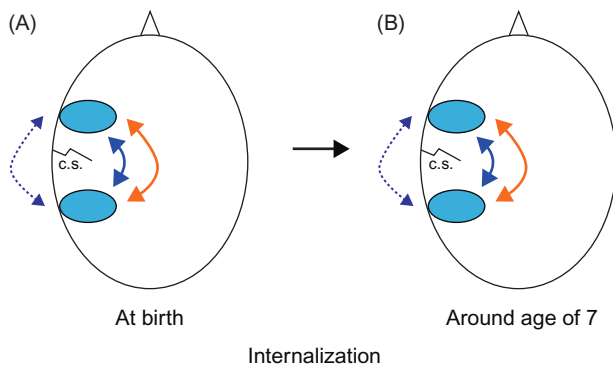

FIGURE 27.4 Heads seen from above with prerolandic and postrolandic areas around the central sulcus (c.s.). (A) At birth, dorsal anatomical connections (blue, dotted line) between prerolandic and postrolandic areas are present but immature. In the first years, influenced by the continuous percept and anticipation of the consequence of movement and speech via feedback (blue, continuous line), internal connections and representations synchronize and mature. (B) Over time, external behavior (blue, dotted line) is increasingly replaced by internal representations (blue, continuous line), whereas the interaction between dorsal (blue, continuous line) and ventral (red) pathways increases. For novel tasks, the external pathway can still be used (Rijntjes et al., 2012).

(Jackendoff, 1997), permitting self-description, reflection, self-questioning, and problem-solving (Barkley, 2001).

It is suggested that during this crucial age of 4–7 years in children, not only in language but also in all modalities, internalization takes place (Diaz & Berk, 1992; Vygotsky, 1978), “following the same general sequence of stages as the internalization of speech,” and outer-directed behavior becomes turned on the self as a means to control one’s own behavior (Barkley, 2001).

Of course, when encountering a new and difficult task, this process can be activated consciously, such as when reading a difficult text slowly and aloud to capture its meaning or when learning a new language and communicating with a teacher. In these cases, internalization will be a second step after externalization of the subject studied. It might be worthwhile to examine in patients with aphasia whether therapy should emphasize the externalization of language functions as a first step. Two new and promising therapies that were proven to be effective, CIAT (constraint-induced aphasia therapy) and PACE (promoting aphasics’ communicative effectiveness), seem to have their focus exactly there.

MUC (Memory, Unification, Control): A Model on the Neurobiology of Language Beyond Single Word Processing

Peter Hagoort

Donders Institute for Brain, Cognition and Behaviour, Max Planck Institute for Psycholinguistics,
Nijmegen, The Netherlands

28.1 INTRODUCTION

Until not too long ago, the neurobiological model that has dominated our view on the neural architecture of language was the Wernicke-Lichtheim-Geschwind model. In this classical model, the human language faculty was situated in the left perisylvian cortex, with a division of labor between the frontal and temporal regions. Wernicke's area in left temporal cortex was assumed to subserve the comprehension of speech, whereas Broca's area in left inferior frontal cortex (LIFC) was claimed to subserve language production. The arcuate fasciculus connected these two areas. This model was based on single word processing. Since then, researchers interested in brain and language have realized that language is more than the concatenation of single words. Research focusing on sentence processing has found that lesions in Broca's region and adjacent cortex impair not only language production but also language comprehension (Caramazza & Zurif, 1976), whereas lesions in Wernicke's region not only affect language comprehension but also language production. More recent neuroimaging studies provided further evidence that central aspects of language production and comprehension are subserved by shared neural circuitry (Menenti, Gierhan, Segaert, & Hagoort, 2011; Segaert, Menenti, Weber, Petersson, & Hagoort, 2012). Since the advent of a whole toolkit of neuroimaging techniques, new models of the neural architecture of human language skills have been proposed. Here, I focus mainly on the Memory-Unification-Control (MUC) model as a model that tries to integrate

knowledge about language processing beyond single words (Hagoort, 2005, 2013). After describing its three components, I discuss the evidence that has accumulated in support of the model.

28.2 MEMORY, UNIFICATION, AND CONTROL

The MUC model distinguishes three functional components of language processing: Memory, Unification, and Control. The Memory component refers to the linguistic knowledge that in the course of language acquisition gets consolidated in neocortical memory structures (see Davis & Gaskell, 2009, for the shift from medial temporal lobe to neocortical structures during consolidation). It is the only language-specific component of the model. The knowledge about the building blocks of language that is stored in memory (e.g., phonological, morphological, syntactic building blocks; jointly referred to as lexical items) is domain-specific and, hence, coded in a format that is different from, for example, color and visual object information.

However, language processing is more than memory retrieval and more than the simple concatenation of retrieved lexical items. The expressive power of human language derives from being able to combine elements from memory in novel ways. This process of deriving higher-level (i.e., sentence and beyond) meaning is referred to as Unification. Although as a result of the Chomskyan revolution in linguistics psycholinguistic studies of unification have mainly focused on

syntactic analysis, unification operations not only take place at the syntactic processing level but also are a hallmark of language across representational domains (Jackendoff, 2002). Thus, at the semantic and phonological levels, lexical elements are combined and integrated into larger structures. Hence, I distinguish between syntactic, semantic, and phonological unification (Hagoort, 2005).

Finally, the Control component relates language to joint action and social interaction, and it is invoked, for instance, when the contextually appropriate target language has to be selected, or for handling the joint action aspects of using language in conversational settings. Later, it is shown how languages have built-in linguistic devices that trigger the attentional control system into operation.

In the MUC model, the distribution of labor is as follows (Figure 28.1). Regions in the temporal cortex (in yellow) and the angular gyrus in parietal cortex subserve the knowledge representations that have been laid down in memory during acquisition. These regions store information, including phonological word forms, morphological information, word meanings, and the syntactic templates associated with noun, verbs, and adjectives (for details, see Hagoort, 2003, 2005, 2009). Dependent on knowledge type, different parts of temporal cortex are involved. Frontal regions (Broca's area and adjacent cortex; in blue) are crucial for unification operations. These operations generate larger structures from the building blocks that are

retrieved from memory. Within LIFC (Unification Space), there seems to be a certain spatial distribution of recruitment dependent on the type of information that gets unified. Semantic unification recruits BA 47 and BA 45; syntactic unification has its focus in BA 45 and BA 44; phonological processes recruit BA 44 and ventral parts of BA 6 (Hagoort & Indefrey, 2014). In addition, executive control needs to be exerted such that the correct target language is selected, turn-taking in conversation is orchestrated, attention is given to the most relevant information in the input, and so forth. Control regions involve dorsolateral prefrontal cortex (in pink) and midline structure, including the anterior cingulate cortex and the parts of parietal cortex that are involved in attention (not shown in Figure 28.1).

The distribution of labor in the MUC model is not absolute. Language functions do not reside in single brain regions. Instead, language is subserved by dynamic networks of brain regions, including the ones outlined here. Ultimately, the mapping of a given language function onto the neural architecture of the brain is in terms of a network of brain areas instantiating that particular language function (McIntosh, 2008; Mesulam, 1998; Sporns, 2011). This is what Fedorenko and Thompson-Schill (2014) refer to as Networks of Interest. Typically, each node in such a network will participate dynamically in other functional networks as well. Although one can claim a certain contribution of a specific region (e.g., part of Broca's area), it is crucial to realize that such a contribution depends on the interaction with other regions that are part of the network. In short, "the mapping between neurons and cognition relies less on what individual nodes can do and more on the topology of their connectivity" (Sporns, 2011, p. 184). Therefore, before discussing the empirical evidence for the distribution of labor within the MUC framework, I discuss the connectivity profile of the language networks in the brain.

FIGURE 28.1 The MUC model of language. The figure displays a lateral view of the left hemisphere. The numbers indicate Brodmann areas. These are areas with differences in the cytoarchitectonics (i.e., composition of cell types). The memory areas are in the temporal cortex (in yellow) including the angular gyrus in parietal cortex. Unification requires the contribution of Broca's area (Brodmann areas 44 and 45) and adjacent cortex (Brodmann areas 47 and 6) in the frontal lobe. Control operations recruit another part of the frontal lobe (in pink) and the anterior cingulate cortex, as well as areas involved in attention (not shown in the figure).

28.3 THE NETWORK TOPOLOGY OF THE LANGUAGE CORTEX

The classical model has given the arcuate fasciculus a central role in connecting the language-relevant parts of the brain. This was based on the idea that Broca's area and Wernicke's area were the two central nodes in the language network. The language network is much more extended than was assumed in the classical model and includes not only regions in the left hemisphere but also the right hemisphere areas. However, the evidence of additional activations in the right hemisphere and areas other than Broca's and Wernicke's does not take away the crucial role of left

FIGURE 28.2 The arcuate fasciculus in a human, chimpanzee, and macaque in a schematic lateral view of the left hemisphere. From *Rilling et al. (2008)*, courtesy of Nature Publishing Group.

perisylvian cortex. In a recent meta-analysis based on 128 neuroimaging studies, *Vigneau et al. (2010)* compared left and right hemisphere activations observed in relation to language processing. For phonological processing, lexico-semantic processing, and sentence or text processing, the number of activation peaks in the right hemisphere comprised less than one-third of the activation peaks in the left hemisphere. Moreover, in the majority of cases the right hemisphere activations were found in homotopic regions, suggesting a strong interhemispheric dependency. It is therefore justified to think that for the majority of the human population (e.g., with the exception of some portion of left-handers, cases of left hemispherectomy), the language-readiness of the human brain is strongly but not exclusively based on the organization of the left perisylvian cortex. This, however, does not deny the relevant contributions of the right hemisphere in, for instance, speech recognition (*Hickok & Poeppel, 2007*).

A recent technique for tracing fiber bundles in the living brain is diffusion tensor imaging (DTI). Using DTI, *Rilling et al. (2008)* tracked the arcuate fasciculus in humans, chimpanzees, and macaques. These authors found in humans a prominent temporal lobe projection of the arcuate fasciculus that is much smaller or absent in nonhuman primates (*Figure 28.2*). Moreover, connectivity with the middle temporal gyrus (MTG) was more widespread in the left than in the right hemisphere. This human specialization may be relevant for the evolution of language. *Catani et al. (2007)* found that the human arcuate fasciculus is strongly lateralized to the left, with quite some variation on the right. On the right, some people lack an arcuate fasciculus, in others it is smaller in size, and only in a minority of the population is this fiber bundle of equal size in both hemispheres. This pattern of lateralization was confirmed in a study involving 183 healthy right-handed volunteers in the age range between 5 and 30 years (*Lebel & Beaulieu, 2009*). The functionality of the arcuate fasciculus is not limited to single word processing. In a recent work, *Wilson, Galantucci, Tartaglia, and Gorno-Tempini (2012)* reported syntactic deficits in patients with primary

FIGURE 28.3 Simplified illustration of the anatomy and connectivity of the left hemisphere language network. Cortical areas are represented as red circles: pars orbitalis (or), pars triangularis (tr), and pars opercularis (op) of the LIFC, angular gyrus (ag), superior and middle temporal gyri (tg), fusiform gyrus (fg), and temporal pole (tp).

progressive aphasia after damage to the dorsal tracts but not after damage to the ventral tracts. This suggests that the dorsal tracts, including the arcuate fasciculus, are a key component in connecting frontal and temporal regions involved in syntactic processing. Again, exclusivity is difficult to establish. Part of these tracts might also subserve other aspects of language processing.

In addition to the arcuate fasciculus, other fiber bundles are important in connecting frontal with temporoparietal language regions (*Figure 28.3*). These include the superior longitudinal fasciculus (adjacent to the arcuate fasciculus) and the extreme capsule fasciculus, as well as the uncinate fasciculus, connecting Broca's area with superior and middle temporal cortex along a ventral path (*Anwander, Tittgemeyer, von Cramon, Friederici, & Knosche, 2007; Friederici, 2009; Kelly et al., 2010*). *Figure 28.3* provides a schematic overview of the more extended connectivity profile of the left perisylvian cortex.

FIGURE 28.4 The topographical connectivity pattern between frontal and temporal/parietal cortex in the perisylvian language networks. Connections to the left pars opercularis (oper), pars triangularis (tri), and pars orbitalis (orbi) are shown in black, dark grey, and white arrows, respectively. The solid arrows represent the main (most significant) correlations and the dashed arrows represent the extending (overlapping) connections. Brain areas assumed to be mainly involved in phonological, syntactic, and semantic processing are shown in black, dark grey, and light grey circles, respectively. P1, supramarginal gyrus; P3, angular gyrus (AG); P2, the area between SMG and AG in the superior/inferior parietal lobule; T1, posterior superior temporal gyrus; T2, posterior MTG; P3, posterior inferior temporal gyrus.

Using resting state fMRI, Xiang, Fonteijn, Norris, and Hagoort (2010) found a clear topographically organized connectivity pattern in the left inferior frontal, parietal, and temporal regions (Figure 28.4). In the left—but not in the right—perisylvian cortex, functional connectivity patterns obeyed the tripartite nature of language processing (phonology, syntax, and semantics). These results support the assumption of the functional division for phonology, syntax, and semantics of the LIFC, including Broca’s area, and revealed a topographical functional organization in the left perisylvian language network in which areas are most strongly connected according to information type (i.e., phonological, syntactic, and semantic). The dorsal pathways might be more relevant for phonological and syntactic processing, whereas the ventral pathways seem to be involved in connecting regions for semantic processing.

28.4 THE EMPIRICAL EVIDENCE FOR THE MUC MODEL

We have seen that there is a much more widespread connectivity profile in left perisylvian language cortex than was assumed in the classical model. The MUC model deviates from the classical model in the division

of labor between Broca’s area, Wernicke’s area, and adjacent regions. However, the proposed distribution of labor is not absolute, but rather embedded and situated in the network skeleton of the language system’s neural architecture.

What is the evidence for the relative division of labor proposed in the MUC model? Let us consider the syntactic network first. In comparison with phonological and semantic processing, which have compelling bilateral contributions, syntactic processing seems strongly lateralized to the left hemisphere perisylvian regions. Indirect support for a distinction between a memory component (i.e., the mental lexicon) and a unification component in syntactic processing comes from neuroimaging studies on syntactic processing. Two regions have been systematically reported in relation to syntactic processing (Hagoort & Indefrey, 2014): the left posterior superior/middle temporal gyrus (STG/MTG) and the LIFC. The left posterior temporal cortex is known to be involved in lexical processing (Hickok & Poeppel, 2004, 2007; Indefrey & Cutler, 2004; Lau, Stroud, Plesch, & Phillips, 2006). In connection to the MUC model, this part of the brain might be important for the retrieval of the syntactic frames that are stored in the lexicon. The idea of syntactic frames that specify the possible local syntactic environment of a given lexical item is in line with linguistic and computational approaches that assume syntactic knowledge to be lexically specified (Culicover & Jackendoff, 2006; Joshi & Schabes, 1997; Vosse & Kempen, 2000). The Unification Space, where individual frames are connected into a phrasal configuration for the whole utterance, might recruit the contribution of LIFC.

Direct empirical support for this distribution of labor between LIFC (Broca’s area) and temporal cortex was found in a study of Snijders et al. (2009). These authors performed an fMRI study in which participants read sentences and word sequences containing word-category (noun-verb) ambiguous words (e.g., “watch”) and the same materials with the unambiguous counterparts of the lexical-syntactic ambiguities. The ambiguous items were assumed to activate two independent syntactic frames, whereas the unambiguous counterparts result in the retrieval of only one syntactic frame. Solely based on a computational model of syntactic processing (Vosse & Kempen, 2000) and the hypothesized contribution of temporal and frontal cortex regions, it was predicted that the regions contributing to the syntactic unification process should show enhanced activation for sentences compared with words, and only within sentences should they display a larger signal for ambiguous than for unambiguous conditions. The posterior LIFC showed exactly this predicted pattern, confirming the hypothesis that

LIFC, particularly BA 44 and BA 45, contributes to syntactic unification. The left posterior MTG was activated more for ambiguous than unambiguous conditions, as predicted for regions subserving the retrieval of lexical-syntactic information from memory. It thus seems that the LIFC is crucial for syntactic processing in conjunction with the left posterior MTG, a finding supported by patient studies with lesions in these very same regions (Caplan & Waters, 1996; Rodd, Longe, Randall, & Tyler, 2010; Tyler et al., 2011). Presumably these regions are connected via the dorsal pathways.

In addition to syntactic unification, there is the need for semantic unification. One aspect of semantic unification is filling the slots in an abstract event schema. Semantic processing also recruits a left perisylvian network, albeit with a substantially weaker lateralization profile than syntactic processing. A series of fMRI studies aimed to identify the semantic processing network. These studies either compared sentences containing semantic/pragmatic anomalies with their correct counterparts (e.g., Friederici, Ruschemeyer, Hahne, & Fiebach, 2003; Hagoort, Hald, Bastiaansen, & Petersson, 2004; Kiehl, Laurens, & Liddle, 2002; Ruschemeyer, Zysset, & Friederici, 2006) or compared sentences with and without semantic ambiguities (Davis et al., 2007; Hoening & Scheef, 2005; Rodd, Davis, & Johnsrude, 2005). In the latter case, there are multiple word meanings for a given lexical item that will induce competition and selection in relation to filling a particular slot in the event schema. As with syntactic unification, the availability of multiple candidates for a slot will therefore increase the unification load. In the case of the lexical-semantic ambiguities, there is no syntactic competition. Increased processing is therefore attributable to unification of meaning instead of syntax. The most consistent finding across studies on semantic unification is the activation of the LIFC, particularly BA 47 and BA 45 (Hagoort & Indefrey, 2014).

A further indication for the contribution of LIFC in semantic unification comes from a few studies investigating semantic unification of multimodal information with language. Using fMRI, Willems, Özyürek, and Hagoort (2007) assessed the neural integration of semantic information from spoken words and from co-speech gestures into a preceding sentence context. Spoken sentences were presented in which a critical word was accompanied by a co-speech gesture. Either the word or the gesture could be semantically incongruous with respect to the previous sentence context. Both an incongruous word as well as an incongruous gesture led to increased activation in LIFC (BA 45/47) as compared with congruous words and gestures (for a similar finding with pictures of objects, see Willems, Özyürek, & Hagoort, 2008). This supports the claim

that LIFC is a key node in the semantic unification network, unifying semantic information from different modalities.

From these findings it seems that syntactic and semantic unification is realized in a dynamic interplay between LIFC as a multimodal unification site and also knowledge-specific regions. Again, it is important to stress that the interplay of these regions is crucial to realize the functional component of unification.

In other models, the anterior temporal lobe has been argued to be relevant for combinatorial operations (Hickok & Poeppel, 2007; Rogalsky et al., Chapter 47 of this volume). One possibility is that this is limited to conceptual combinations for which the mapping of grammatical roles (e.g., subject, object) onto thematic roles (e.g., agent, patient) is not required (Baron & Osherson, 2011). In the latter case, the contribution of Broca's region is presumably highly relevant.

28.5 A GENERAL ACCOUNT OF THE ROLE OF LIFC IN LANGUAGE PROCESSING

So far, we have seen that LIFC plays a central role in syntactic and semantic unification processes, albeit with different activation foci for these two types of unification. However, there is convincing evidence that LIFC also plays a role beneath the phrasal and sentence level. It is found to contribute to decomposition and unification at the word level. Words are not processed as unstructured, monolithic entities. Based on the morpho-phonological characteristics of a given word, a process of lexical decomposition takes place in which stems and affixes are separated. For spoken words, the trigger for decomposition can be something as simple as the inflectional rhyme pattern, which is a phonological pattern signaling the potential presence of an affix (Bozic, Tyler, Ives, Randall, & Marslen-Wilson, 2010). Decomposing lexical input appears to be a ubiquitous and mandatory perceptual strategy; that is, decompositional processes are triggered not only for words with obvious parts (e.g., work-ed) but also for semantically opaque words (e.g., bell-hop) and even nonwords with putative parts (e.g., blicket-s, blicket-ed). In a series of fMRI studies on the processing of inflectional morphology, Bozic et al. (2010) have found that LIFC, especially BA 45, subserves the process of morphological decomposition. Intracranial recordings in BA 45 from epileptic patients during pre-surgical preparation indicate that the same brain area is also involved in the generation of inflected forms during language production (Sahin, Pinker, Cash, Schomer, & Halgren, 2009; see also comments by Hagoort & Levelt, 2009).

The evidence for LIFC involvement at word- and sentence-level processing in both production and comprehension results in the question of how to account for its role more generally. This is still an open issue, but there is a possible answer. Notwithstanding the division of labor within LIFC, its overall contribution can be characterized in more general terms than hierarchical or even sentence-level processing. Instead, the LIFC is most likely involved in unification operations at the word and sentence level, in connection with temporal and parietal regions that are crucial for memory retrieval (Hagoort, 2005). Compositional and decompositional operations occur at multiple levels and at multiple time slices in the language processing system, but also outside the language system. Any time lexical and other building blocks enter into the process of utterance interpretation or construction, and any time the input string requires decomposition (presumably through analysis-by-synthesis) to contact the right lexical representations, LIFC is recruited.

This view is fully compatible with recent accounts in linguistics that view both morphology and syntax to involve the retrieval of pieces of stored structure with variables (Jackendoff, personal communication, 2014). Hence, no principled distinction is claimed between unification operations in syntax and morphology.

This account of LIFC's contribution is more general than is claimed in other models. For example, proposals have been made that LIFC (Broca's area) has a more specialized role in language processing, has more to do with linguistically motivated operations of syntactic movement (Grodzinsky & Santi, 2008), and is more involved in the processing of hierarchical structures (Friederici, Bahlmann, Heim, Schubotz, & Anwender, 2006). However, such proposals are difficult to reconcile with the LIFC contributions to morphological processes. Hence, the account specified here seems to have more empirical support.

28.6 THE DYNAMIC INTERPLAY BETWEEN MEMORY AND UNIFICATION

Although a connection is made between functional components of the cognitive architecture for language and specific brain regions, this is an idealization of the real neurophysiological dynamics of the perisylvian language network. Crucially, for language as for most other cognitive functions, the functional contribution of any area or region has to be characterized in the context of the network as a whole, where specialization of any given node is only relative and realized in a dynamic interaction with the other nodes in the network (Mesulam, 1990, 1998). How this can be viewed is specified in more detail for semantic

unification by way of illustrating the principle of dynamic interaction.

In posterior and inferior temporal and parietal (angular gyrus) regions, neuronal populations are activated that represent lexical information associated with the incoming word, including its semantic features. From here, neural signals can follow two routes. The first exploits local connectivity within these posterior regions, resulting in a graded activation of neighboring neuronal populations, coding for related lexical-semantic information. Such local spread of activation contributes to setting up a lexical-semantic context in temporo-parietal cortex (Figure 28.5, green circle). The second route is based on long-distance connections to LIFC, through direct white matter fibers, resulting in the selective activation of populations of frontal cortex neurons. These will respond with a self-sustaining firing pattern (see Durstewitz, Seamans, & Sejnowski, 2000 for a review). Efferent signals in this case can only take the long-range route back. The most parsimonious account here is that frontal neurons will send efferent signals back to the same regions in temporo-parietal cortex from where afferent signals were received. This produces another spread of activation to neighboring temporo-parietal regions, which implies that connections representing a given semantic

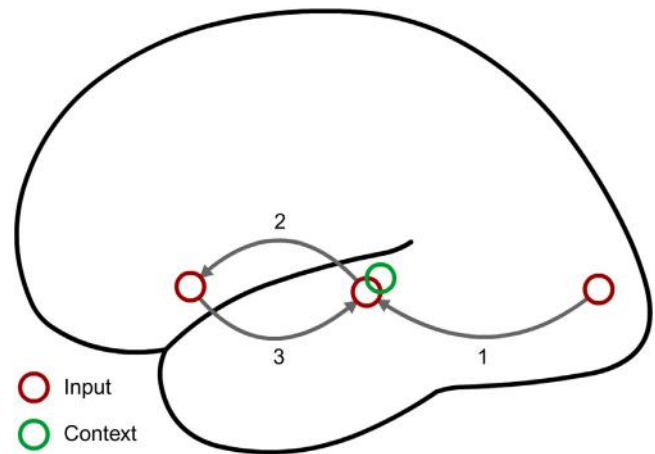

FIGURE 28.5 Processing cycle subserving semantic unification in the left hemisphere language network. Inputs are conveyed from sensory regions (here visual cortex) to the inferior, middle, and superior temporal gyri (1), where lexical information is activated. Signals are hence relayed to the inferior frontal gyrus (2), where neurons respond with a sustained firing pattern. Signals are then fed back into the same regions in temporal cortex from where they were received (3). A recurrent network is thus set-up, which allows information to be maintained online, a context (green circle) to be formed during subsequent processing cycles, and incoming words to be unified within the context. At each processing cycle a balance is achieved by letting input-driven activity find attractor states, that is, the maximum possible overlap with active populations in temporal cortex.

context will be strengthened. During each word processing cycle, the memory (temporo-parietal) and unification (inferior frontal) components interact by letting activation reverberate through the circuit in [Figure 28.5](#). Achieving the necessary outcomes for language comprehension may be more or less demanding, depending on how close the relation is between input and context.

28.7 ATTENTIONAL CONTROL

The third component in the MUC model is referred to as Control. One form of control is attentional control. In classical models of sentence comprehension—of either the syntactic-structure-driven variety ([Frazier, 1987](#)) or in a constraint-based framework ([Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995](#))—the implicit assumption is usually that a full phrasal configuration results and a complete interpretation of the input string is achieved. However, often the listener interprets the input on the basis of bits and pieces that are only partially analyzed. As a consequence, the listener might overhear semantic information (the Moses illusion; [Erickson & Mattson, 1981](#)) or syntactic information (the Chomsky illusion; [Wang, Bastiaansen, Yang, & Hagoort, 2012](#)). In the question “How many animals of each kind did Moses take on the ark?”, people often answer “two,” without noticing that it was Noah who was in command of the ark, not Moses. It was found that syntactic violations might not trigger a brain response if they are in a sentence constituent that provides no new information ([Wang et al., 2012](#)). [Ferreira, Bailey, and Ferraro \(2002\)](#) introduced the phrase “good-enough processing” to refer to the listeners’ and readers’ interpretation strategies. In a good-enough processing context, linguistic devices that highlight the most relevant parts of the input might help the listener/reader in allocating processing resources optimally. This aspect of linguistic meaning is known as “information structure” ([Buring, 2007](#); [Chafe, 1976](#); [Halliday, 1967](#); [Krifka, 2007](#)). The information structure of an utterance essentially focuses the listener’s attention on the crucial (new) information in it. In languages such as English and Dutch, prosody plays a crucial role in marking information structure. For instance, in question–answer pairs, the new or relevant information in the answer will typically be pitch accented. After a question like “What did Mary buy at the market?”, the answer might be “Mary bought VEGETABLES” (accented word in capitals). In this case, the word “vegetables” is the focus constituent, which corresponds to the information provided for the Wh-element in the question. In a recent fMRI study ([Kristensen, Wang, Petersson, & Hagoort, 2013](#)), we

tested the idea that pitch accent, which in Dutch is used to mark certain information as focus, recruits attentional networks in the service of more extended processing of the most relevant information. In our study, the attentional network was first localized in an auditory nonverbal attention task. This task activated, as expected, bilateral superior and inferior parietal cortex. In the language task, participants were listening to sentences with and sentences without semantic-pragmatic anomalies. In half of the cases these anomalies and their correct counterparts were marked as in focus by a pitch accent; in the other half of the cases they were not. The results showed an interaction in bilateral inferior parietal regions between prosody (pitch accent) and congruence; for incongruent sentences, but not for congruent ones, there was larger activation if the incongruent words carried a focus marker (i.e., the pitch accent).

Overall, the activation overlap in the attention networks between the localizer task and the sentence processing task indicated that marking of information structure modulated a domain-general attention network. Pitch accent signaled the saliency of the focused words and thereby recruited attentional resources for extended processing. This suggests that languages might have developed built-in linguistic devices (i.e., focus markers) that trigger the recruitment of attentional systems to safeguard against the possibility that in a good-enough processing system the most relevant information might go unnoticed. This provides one example of the interaction between a general demand/control system ([Fedorenko, Duncan, & Kanwisher, 2012](#)) and the core components of the language network.

28.8 BEYOND THE CLASSICAL MODEL

I have outlined the contours of a neurobiological model of language that is a substantial augmentation of the classical Wernicke-Lichtheim-Geschwind model, which was a model for single word processing mainly based on lesion and patient data.

Three major additions are worth highlighting. First, the connectivity of the language cortex in left perisylvian regions is much more extended than proposed in the classical model and is certainly not restricted to the arcuate fasciculus. Second, the distribution of labor between the core regions in left perisylvian cortex is not one in terms of production and comprehension. Shared circuitry has been established for core aspects of language production and comprehension. Both recruit temporal/parietal regions for retrieval of linguistic information that is laid down in memory during acquisition and LIFC for unification of building blocks into

utterances or interpretations that are constructed online. Unification “enables words to cooperate to form new meanings” (Nowak, 2011, p. 179). Third, the operation of language in its full glory requires a much more extended network than what the classical model contained, which was mainly based on evidence from single word processing. The basic principle of brain organization for higher cognitive functions is that these are based on the interaction between a number of neuronal circuits and brain regions that support the different contributing functional components. These circuits are not necessarily specialized for language; nevertheless, they need to be recruited for the sake of successful language processing. One example is the general attentional networks that might be triggered into operation by specific linguistic devices to safeguard against missing out on the most relevant (new, focused) information in the language input. Another example, not further discussed here, is the Theory of Mind network that seems crucial for designing our utterances with knowledge of the listener in mind or, as a listener, to make the step from coded meaning to speaker meaning (Bašnáková, Weber, Petersson, van Berkum, & Hagoort, 2013; Hagoort & Levinson, 2015).

Acknowledgments

I am grateful to my colleagues in the NBL department and to Greg Hickok for their helpful comments. This chapter is an adapted version of an earlier discussion of the MUC model (Hagoort, 2013).

The Neuroanatomical Pathway Model of Language: Syntactic and Semantic Networks

Angela D. Friederici

Department of Neuropsychology, Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

29.1 INTRODUCTION

Brain-related models of language have existed for more than 150 years, since [Wernicke \(1874\)](#) and [Lichtheim \(1884\)](#) published their models based on different aphasia syndromes. These models assumed separate centers for acoustic-sensory aspects supporting language comprehension and motor aspects supporting language production, as well as connections between them. It was assumed that if one of these centers or the connection between them was lesioned, then respective aphasic deficits would result, such as sensory aphasia, motor aphasia, or conduction aphasia. [Pick \(1909, 1913\)](#) was the first to incorporate syntactic and prosodic aspects in his model of language. However, the model remained vague with respect to the localization of these aspects, because it was again based on the analyses of language behavior in aphasic patients. In those days, the localization of the observed aphasia deficits had to wait until after the death of the patient, when the brain could be analyzed *ex vivo* ([Broca, 1861, 1865; Wernicke, 1874](#)).

Today, the existing brain imaging methodology allows us to localize different aspects of language in circumscribed brain regions and to specify their functional and structural connectivities *in vivo*. For the first time, this enables us to describe neural networks supporting semantic and syntactic processes in more detail and to formulate a functional neuroanatomical model of language.

Since the advent of functional magnetic resonance imaging (fMRI), a large number of studies have been conducted on word and sentence processing in different languages. These studies were able to localize different linguistic subfunctions such as phoneme discrimination, lexical retrieval, and syntactic phrase

structure building in different brain regions. However, from these studies it also became clear that semantic and syntactic processes effective during sentence comprehension cannot be localized to a single brain area, but instead must be localized in definable neural networks.

This chapter describes the syntactic and sentence-level semantic networks taking into consideration fMRI data and, moreover, recent findings from diffusion-weighted MRI (dMRI) studies that allow the identification of the white matter fiber bundles connecting those brain regions that support particular language functions. Here, we focus on sentence-level processes and leave aside the studies on single word processing that are well-described in recent reviews ([Binder, Desai, Graves, & Conant, 2009; Démonet, Thierry, & Cardebat, 2005; Price, 2000](#)). Semantic processes at the word level may differ from semantic processes at the sentence level, where the most relevant issue is the relationship between words, not only between two nouns (*cat–dog*) but also between verbs and their argument nouns (*X chases Y*). [Pick \(1913\)](#) had already noted that the understanding of sentences requires more than just the process of word perception, which could be described as a reactive emergence of word meaning from memory. For the understanding of sentences, it holds that the meaning of a sentence is more than the sum of the meaning of the individual words.

29.2 FROM DORSAL AND VENTRAL STREAMS TO FIBER TRACTS

The functional MRI studies on syntactic and semantic aspects of sentence processing conducted over the past decade have consistently revealed an involvement

of the inferior frontal cortex and the temporal cortex. Meta-analyses indicate that both semantic and syntactic processes recruit partly different regions in the inferior frontal gyrus (IFG) and the superior and middle temporal gyrus (STG/MTG) (Chapter 48; Price, 2010; Vigneau et al., 2006). These brain regions are connected to each other via different fiber bundles (see Catani & de Schotten, 2008) that are referred to as the dorsal and the ventral pathway (for a review see Friederici, 2009a; Weiller, Musso, Rijntjes, & Saur, 2009).

Without basing their model on dMRI evidence of the fiber tracts connecting the language-related brain regions, Hickok and Poeppel (2004) discussed a functional “dorsal stream” as being responsible for sensory-to-motor mapping in speech processing and a functional “ventral stream” as supporting sound-to-meaning mapping. The method of dMRI that allows a neuroanatomical specification of fiber tracts within the human brain *in vivo* only emerged at that time (Behrens et al., 2003; Catani, Jones, & Ffytche, 2005). It is yet unclear what the relation is between the *functional* dorsal and ventral streams as defined by Hickok and Poeppel (2004) and the *anatomical* dorsal and ventral pathways as identified using dMRI. The early dMRI studies were able to identify the neuroanatomical connections between predefined brain regions such as Broca’s area in the IFG and Wernicke’s area in the prefrontal cortex (Catani et al., 2005). But because dMRI analyses only provide structural information about the fiber bundles, the possible functions of these can only be assigned quite indirectly by identifying the function of the fibers’ termination regions (Friederici, 2009b).

A step toward a better description of the functions of fiber tracts was to use a combined fMRI–dMRI approach. In this approach, the specific function of particular brain regions is identified by an fMRI experiment. In a second step, these brain regions are used as seed regions from which the course of a fiber tract is calculated. The resulting fiber tract is interpreted to be relevant for the specific function processed in these brain regions. In principle, two methods of fiber tracking can be applied, probabilistic and deterministic fiber tracking. Probabilistic fiber tracking only takes one functionally defined region as the seed region and starting point of tractography, whereas deterministic fiber tracking takes two regions that are activated simultaneously by one function and calculates the fiber tract between the two.

A first study (Friederici, Bahlmann, Heim, Schubotz, & Anwander, 2006) using this combined fMRI–dMRI approach analyzed the dorsal and ventral fiber bundles connecting those prefrontal and temporal regions activated in response to a particular language function. The fMRI experiment applied an artificial grammar paradigm with rule-based syllable sequences after

either adjacent or hierarchical nonadjacent dependency rules. Although the former activated the left frontal operculum, the latter additionally activated the posterior portion of Broca’s area (BA 44). The dMRI data of probabilistic tracking from these two regions located in close vicinity revealed two distinct fiber tracts. First, a dorsal pathway connecting Broca’s area to the posterior STG/MTG was found when seeding in Broca’s area and, given this area’s activation in the processing of nonadjacent hierarchical dependencies, this pathway was interpreted to support the processing of complex syntactic structures. Second, fiber tracking with a seed in the frontal operculum that was activated for the processing of adjacent dependencies revealed a ventral pathway to the temporal cortex; therefore, this pathway was viewed to support the processing of adjacent dependencies. Subsequently, a second study (Saur et al., 2008) using a combined fMRI–dMRI approach in language investigated the comprehension of simple sentences (*The pilot is flying the plane*) and the repetition of single words and pseudowords. The functional data show activation in the premotor cortex (PMC) and in the temporal cortex for repetition, whereas comprehension activated regions in the anterior frontal and the temporal cortex. Using a deterministic tracking approach, a dorsal and a ventral connection were identified. The authors interpret their data to show that the dorsal pathway supports sensory-to-motor mapping necessary for sensorimotor integration during speech processing and the ventral pathway sound-to-meaning mapping necessary for comprehension.

This apparent contradiction between the two studies in their functional interpretation of the dorsal and ventral pathway, however, can be explained on the basis of novel dMRI that allow analyses of those fiber tracts that connect the frontal cortex and temporal cortex dorsally and ventrally. These analyses indicate that the dorsal stream can be subdivided into two pathways with different termination points. A recent review (Friederici, 2011) proposed that this is also the case for the ventral stream. The present review discusses the relevant functional language processing studies and the combined fMRI–dMRI reports published more recently. Based on these findings, the Neuroanatomical Pathway Model of Language was formulated.

29.3 THE NEUROANATOMICAL PATHWAY MODEL OF LANGUAGE

The current model assumes four neuroanatomically distinguishable pathways connecting the language-relevant regions in the frontal cortex and the temporal cortex, two pathways that run dorsally and two pathways that run ventrally (see Figure 29.1).

FIGURE 29.1 Language-relevant brain regions and schematic fiber tracts (displayed in the left hemisphere). Numbers represent cytoarchitecturally defined Brodmann areas (BAs). BA 44 and BA 45 together constitute Broca's area. BA 22 constitutes Wernicke's area. Different pathways are color-coded according to the color legend in the figure. Dorsal Pathway (D1) connects the PMC to the pSTG/MTG and involves the superior longitudinal fascicle (SLF). Dorsal Pathway (D2) connects BA 44 to the pSTG and involves the arcuate fascicle (AF). Ventral pathway (V1) connects BA 45/47 to the STG/MTG and involves the extreme capsule fiber system (ECFS)/longitudinal inferior-fronto-occipital fascicle (IFOF). Ventral pathway (V2) connects the frontal operculum to the aSTG and involves the uncinata fascicle (UF). PMC, premotor cortex; STG, superior temporal gyrus; pSTG, posterior superior temporal gyrus; aSTG, anterior superior temporal gyrus; MTG, middle temporal gyrus; pMTG, posterior middle temporal gyrus. *Adapted from Friederici and Gierhan (2013).*

29.3.1 Four Language-Related Pathways

Dorsally, one pathway (D1) connects the temporal cortex to the PMC and one pathway (D2) connects the temporal cortex to the posterior portion of Broca's area (BA 44). These two pathways can be distinguished neuroanatomically on the basis of their termination points, their relative location, and, moreover, they can be distinguished functionally. Neuroanatomically, the pathway from temporal cortex to PMC is located more dorsally and more laterally than the pathway to BA 44 (Perani et al., 2011). The pathway D1 that connects the STG and MTG with the PMC via the parietal cortex consists of fibers that are part of the SLF (Frey, Campbell, Pike, & Petrides, 2008; Saur et al., 2008). The SLF has been described as consisting of three different subparts (SLF I, II, III) (Makris et al., 2005). There is a fourth fiber bundle, the AF, that directly connects BA 44 in Broca's area with the posterior STG and MTG that constitute the pathway D2 (Frey et al., 2008; Friederici, Bahlmann, et al., 2006; Makris et al., 2005). Note that because this fascicle runs closely parallel with the SLF, some researchers label this connection AF/SLF.

Ventrally, one pathway (V1) connects the anterior portion of Broca's area (BA 45) and BA 47 to the STG via a fiber bundle called the extreme fiber capsule system (ECFS) and is sometimes labeled IFOF. The other ventral pathway (V2) that connects the most ventral

parts of the inferior frontal region including the frontal operculum to the temporal cortex via its anterior portion consists of the UF.

Only three of these four pathways are involved in sentence comprehension. The fourth pathway is the dorsal pathway (D1) that connects the temporal cortex to the PMC. In combined fMRI–dMRI studies, this pathway has clearly been shown to connect those brain regions that are involved in the repetition of speech (Gierhan, 2013; Saur et al., 2008). Thus, these findings are compatible with the model of Hickok and Poeppel (2004, 2007), which takes the dorsal pathway to support sensory-to-motor mapping. Furthermore, these authors proposed that this processing stream is most relevant during language acquisition (Hickok & Poeppel, 2007; but see Hickok, 2012; Hickok et al., 2011). Supporting evidence for this proposal, but at the same time evidence for a subdivision of the dorsal stream into two pathways, comes from a study comparing the fiber tracts in newborns and adults (Perani et al., 2011). Although the two dorsal pathways, the dorsal pathway (D1) connecting the temporal cortex to PMC and the dorsal pathway (D2) connecting the temporal cortex to posterior Broca's area, are present in adults, only the pathway (D1) to the PMC is present in newborns. Under the assumption that D1 supports sensory-to-motor mapping and that D2 supports the processing of complex hierarchical structures, it

appears useful that D1 is established early in life because it allows the infant to enter the stage of babbling, during which the infant's output is tuned toward its perceived language environment.

The dorsal pathway D2 and the two ventral pathways are involved in language comprehension as they transmit information necessary for sentence processing and understanding. This information transfer during online sentence processing must take place within milliseconds. How the information transfer during language comprehension throughout the stages of auditory perception, word recognition, phrase structure building, and, finally, comprehension can be conceived has recently been outlined elsewhere when taking stimulus-driven bottom-up and context-driven top-down processes into account (Friederici, 2012). Here, we focus on the description of the neural basis of syntactic and semantic processes during sentence comprehension.

29.3.2 Syntactic and Semantic Networks

The present model is a weak syntax-first model that assumes that the processing system initially builds up a local phrase structure on the basis of the available word category information (Friederici, 2002; Friederici, 2011). Semantic and higher-order syntactic relations are only processed after that, unless the context is syntactically and semantically highly predictive. Thus, the model assumes two different stages of syntactic processing (Friederici, 2002) that are taken to be represented in two different syntactic networks.

29.3.2.1 Syntactic Networks

This first processing step of local structure building is functionally based on the grammatical knowledge of the target language. This concerns the basic knowledge about the structure of adjacent dependencies, such as local phrases, and there are only a few in each language, such as the determiner phrase and prepositional phrase. This knowledge must be acquired during language learning and its use becomes automatic as learning proceeds. In the adult brain, this process is highly automatic and it involves the frontal operculum and the anterior STG (Friederici, Rüschemeyer, Hahne, & Fiebach, 2003). If the process is less automatized, as in second language processing (Rüschemeyer et al., 2005) and during development (Brauer & Friederici, 2007), then BA 44 is also recruited. This is interesting because these two regions located adjacent to each other differ in their phylogeny, with the frontal operculum being phylogenetically older than BA 44 (Amunts & Zilles, 2012; Sanides, 1962). Thus, it appears that the more simple processes of processing adjacent dependencies are dealt with by a phylogenetically older cortex than is the

more complex process of building structural hierarchies. The frontal operculum and the anterior STG are connected via the UF and comprise a network supporting local structure processing. The function of the respective regions could be defined as follows: in the adult brain, the anterior STG that receives its input from the auditory cortex represents templates of local phrases (determiner phrase, prepositional phrase), against which the incoming information is mapped. Thus, once the phrasal head (i.e., determiner, preposition) is encountered, the respective structure is made available in the anterior STG (Bornkessel & Schlesewsky, 2006). From here, the information is transferred via the UF to the frontal operculum, which in turn transmits this information to BA 44 for further processing. This ventral syntactic network is responsible for the most basic syntactic processes, that is, local syntactic computations.

A second syntactic network deals with more global computations. This refers to the processing of hierarchical dependencies as in syntactically complex sentences. The term complexity is used to cover different phenomena, including sentences with noncanonical word order (Friederici, Fiebach, Schlesewsky, Bornkessel, & von Cramon, 2006; Grewe et al., 2005; Meyer et al., 2012; Röder et al., 2002), sentences with varying degrees of embedding (Makuuchi et al., 2009), sentences with varying degrees of syntactically merged elements (Ohta et al., 2013), and the interplay of these sentence structures with working memory (see also Chapter 48). These studies indicate that across the different languages such as English, German, Hebrew, and Japanese, the factor of syntactic hierarchy operationalized as the reordering in noncanonical sentences or processing of embedded structures is localized in Broca's area, mostly in its posterior portion (BA 44). All these studies show that an increase in the level of hierarchy as defined in a syntactic tree leads to an increase in activation in BA 44.

A second region reported to be activated as a function of syntactic complexity and of verb-argument resolution is the posterior STG/STS (Ben-Shachar, Palti, & Grodzinsky, 2004; Friederici, Makuuchi, & Bahlmann, 2009; Kinno et al., 2008; Newman, Ikuta, & Burns, 2010; Santi & Grodzinsky, 2010). This region has also been activated when the semantic relation between a verb and its argument cannot be resolved (Friederici et al., 2003; Obleser & Kotz, 2010). Moreover, it was found that the factor of verb class and argument order interact in this region (Bornkessel, Zysset, Friederici, von Cramon, & Schlesewsky, 2005). Thus, it appears that the posterior STG/STS is a region in which syntactic information and semantic verb-argument information are integrated (Grodzinsky & Friederici, 2006). Posterior Broca's area (BA 44) together with the

posterior STG/STS constitute the second syntactic network, which is responsible for processing syntactically complex sentences. Within this dorsal syntactic network, BA 44 supports the build-up of hierarchical structures of nonadjacent elements, whereas the posterior STG/STS subserves the integration of semantic and syntactic information in complex sentences.

Thus, we have identified two syntactic networks, a ventral syntactic network and a dorsal syntactic network, each responsible for a different aspect of syntactic processing in the healthy adult brain. But the question arises whether there is further independent support for the view of two syntactic networks from either patient or developmental studies.

Unfortunately, patient studies do not allow us to distinguish between BA 44 and the frontal operculum, because both regions lie in the supply region of the middle artery. However, lesions in the IFG involving these two regions are reported to mostly result in syntactic processing deficits (for a review see Grodzinsky, 2000), although the diversity in group selection, design, and methodology leads to some diversity between the outcomes of different studies.

Recent fMRI and dMRI studies on patients revealed some interesting results concerning the dorsal and ventral syntactic network. A study by Griffiths, Marslen-Wilson, Stamatakis, and Tyler (2013) reported that patients with lesions in the left hemisphere involving either parts of the ventral network or the dorsal network showed some deficit in syntactic processing. Although this study does not systematically vary the complexity of the syntactic processes, the results generally support the idea that both networks are involved in syntactic processes. The study by Wilson et al. (2011) that investigated nonfluent progressive aphasics indicated that degeneration of the dorsal fiber tract connecting the temporal cortex (TC) and posterior Broca's area lead, in particular, to deficits in the processing of syntactically complex sentences. This finding is clearly in line with the current interpretation of D2.

Further support for the view that the pathway D2 subserves the processing of syntactically complex sentences stems from developmental studies on language that report that children, at an age when they are still deficient in processing noncanonical sentences, demonstrate a D2 that is not yet fully myelinated (Brauer, Anwender, & Friederici, 2011), and that the degree of myelination correlates with behavioral performance on processing noncanonical sentences (Skeide, 2012).

Concerning the ventral syntactic system, one must admit that reports on the relation between syntactic abilities and lesions in the temporal cortex are quite sparse because lesions in the temporal lobe are primarily related to semantic deficits. However, there is the interesting observation that only patients with

temporal lesions that extend and include the anterior portion show syntactic comprehension deficits (Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004). Additionally there is the report of a correlational analysis of the white matter integrity in stroke patients and their behavioral performance indicating that syntax is processed both dorsally and ventrally (Rolheiser, Stamatakis, & Tyler, 2011).

Thus, quite a number of studies are in line with the view that there are two syntactic networks, a dorsal one and a ventral one. Moreover, few studies specifically demonstrate that the dorsal syntactic system is necessary to process hierarchically structured sentences (Brauer et al., 2011; Wilson et al., 2011).

29.3.2.2 Semantic Networks

The ventral stream has long been taken to support semantic processes (Hickok & Poeppel, 2004; Saur et al., 2008). As discussed, the ventral stream can be divided into two pathways, one involves the UF and the other involves the ECFS or IFOF. The functional allocation of these pathways is still undergoing debate. Many researchers see the UF as being involved in language processes (Catani & Mesulam, 2008; Duffau, 2008; Friederici, Bahlmann, et al., 2006; Parker et al., 2005); however, its particular function is a matter of discussion. The fMRI study by Friederici, Bahlmann, et al. (2006) suggests that the UF supports the processing of adjacent dependencies during sentence perception. In a parent contrast, the interoperative brain stimulation study with glioma patients by Duffau, Gatignol, Moritz-Gasser, and Mandonnet (2009) reported that language production interrupts when stimulating the ECFS, but not when stimulating the UF, which led the authors to deny the involvement of UF in language. However, the tasks used in this stimulation study were counting and picture naming; the former task taps the automatic production of number words and the latter task requires the retrieval of words, which would certainly rely more on a semantic network than on a syntactic network. Thus, the view that the UF supports basic syntactic processes in language is not to be disregarded on the basis of the findings from the interoperative stimulation study.

The ECFS has been reported to support semantic processes in many fMRI–dMRI and dMRI behavior studies (Saur et al., 2008; Turken & Dronkers, 2011; Wilson et al., 2010, 2011). This fiber system is also referred to as IFOF, because it runs from the ventral portion of the IFG along the temporal cortex to the occipital cortex. This way, those inferior frontal brain areas that are reported to be involved in semantic processes such as BA 45 and BA 47 (Bookheimer, 2002) are connected to the temporal cortex, which is known

to support semantic processes including aspects of semantic memory (Patterson, Nestor, & Rogers, 2007).

BA 45/BA 47 as one of the regions in the semantic network is activated particularly when lexical semantic processes are under strategic control; that is when participants are required to perform some kind of semantic relatedness or plausibility judgement (Dapretto & Bookheimer, 1999; Fiez, 1997; Kuperberg et al., 2000; Newman et al., 2010; Thompson-Schill, D'Esposito, Aguirre, & Farah, 1997). The other region considered to be part of the semantic network is the anterior temporal lobe. Degeneration of this brain region leads to semantic deficits already at single-word level (Hodges, Patterson, Oxbury, & Funnell, 1992; Lambon Ralph & Patterson, 2008; Patterson et al., 2007).

Studies investigating sentence-level semantic processes are sparse. Different types of paradigms used to investigate sentence-level semantics revealed different findings. Studies that varied the semantic plausibility found activation in BA 45/47 in the IFG (Newman et al., 2010), whereas studies that investigated semantic predictability reported activation in the supramarginal and angular gyrus in the posterior temporo-parietal region (Obleser & Kotz, 2010).

At present, it is not entirely clear how to model these sentence-level semantic processes. What is clear, however, is that the anterior temporal lobe, the inferior frontal cortex, and the posterior temporo-parietal cortex are involved in sentence-level semantic processes, but that their interplay in the service of language understanding remains to be specified. The ventral pathway connecting the IFG and the STG/MTG plays a crucial part in semantic processes, but it is also conceived that the dorsal connection is involved whenever predictive processes are in dispute.

29.4 CONCLUSION

Sentence processing is based on three neuroanatomically defined networks: two syntactic networks and one semantic network. The semantic network involves the anterior temporal lobe, the anterior inferior frontal cortex, and the posterior temporo-parietal region. The former two regions are connected by a ventrally located pathway, the ECFS. Syntactic processes are based on two syntactic networks, a ventral and a dorsal network. The ventral network supporting the binding of adjacent dependencies, and thereby local syntactic building processes, involves the anterior STG and the frontal operculum connected via a ventrally located pathway (UF), whereas the dorsal network supporting the processing of syntactic hierarchies involves the posterior portion of Broca's area (BA 44) and the posterior STG connected via a dorsally located pathway (AF/SLF).

30.1 INTRODUCTION

The (extended) Argument Dependency Model (eADM) is somewhat of a newcomer to the scene of neurobiological models of language. It was originally formulated with the aim of accounting for cross-linguistic similarities and differences in the neurocognition of sentence processing (Bornkessel, 2002; Schlesewsky & Bornkessel, 2004) and has only recently aspired toward neurobiological grounding (Bornkessel-Schlesewsky & Schlesewsky, 2013b). In this way, the model's trajectory towards neurobiology has been somewhat unusual. However, this may be a strength rather than a weakness. In particular, the consideration of cross-linguistic diversity may provide some unique insights into the neurobiology of language. With approximately 7,000 living languages but only one human brain to process them, we argue that any biologically adequate model of language must be able to account for the striking differences in how individual languages are organized, and that an understanding of which patterns occur more frequently than others in the midst of this diversity can inform neurobiological models because these biases presumably reflect the organizational principles underlying the processing of language by the human brain. In this way, the current version of the eADM seeks to integrate neurobiological design principles with design principles gleaned from cross-linguistic considerations.

We first provide a very brief overview of the development of eADM and the changes that it has undergone (Section 30.2) before introducing the design principles—both language-based and neurobiological—underlying the current version of the model (Section 30.3). Section 30.4 then describes the current model architecture in more detail, followed by a discussion of the evidence supporting these architectural assumptions

(Section 30.5). In Section 30.6, we show how the model's architectural assumptions translate into predictions for electrophysiology. The chapter concludes with a brief outlook (Section 30.7).

30.2 A BRIEF HISTORY OF THE DEVELOPMENT OF eADM

As already noted, the Argument Dependency Model (ADM) was originally formulated as a neurocognitive model of sentence processing across languages (Bornkessel, 2002; Schlesewsky & Bornkessel, 2004). The first model version was primarily based on electrophysiological data from German focusing specifically on the processing demands imposed by verbal sentences. The model's name is derived from the proposal that interpretive dependencies (“who is acting on whom”) can be set up between sentence participants (“arguments”) even before the verb is encountered. In its original version, the ADM was an extension of Friederici's neurocognitive model of auditory language processing (Friederici, 1999, 2002) and therefore shared a number of assumptions with that model, perhaps most importantly the idea of different processing phases organized in a serial fashion.

On the basis of data from a range of languages, the ADM was expanded and modified to the extended Argument Dependency Model (eADM; Bornkessel & Schlesewsky, 2006; Bornkessel-Schlesewsky & Schlesewsky, 2008). As indicated by the modified name, the new model architecture incorporated some important changes, including the proposal of a cascaded rather than strictly serial organization. The eADM further posited that the processes underlying sentence comprehension are not

well-characterized by linguistic subdomains such as syntax and semantics. Finally, even more recent versions of the eADM have emphasized the importance of an “actor strategy” in sentence comprehension across languages, meaning that the language processing system endeavors to identify the participant primarily responsible for the state of affairs (the actor) as quickly and unambiguously as possible (Bornkessel-Schlesewsky & Schlesewsky, 2009, 2013a; for a computational formulation, see Alday, Schlesewsky, & Bornkessel-Schlesewsky, 2014).

All three assumptions—a cascaded architecture, no qualitative distinctions between syntactic and semantic cues, and the relevance of the actor strategy—play a central role in the current version of the eADM (Bornkessel-Schlesewsky & Schlesewsky, 2013b), which also introduced a number of neurobiological design principles. In the following sections, we first describe the language-based and neurobiological design principles underlying the current version of the eADM in more detail before introducing the latest version of the model architecture.

30.3 DESIGN PRINCIPLES

The design principles underlying the model are made explicit here. We begin by describing language-based design principles gleaned from cross-linguistic research (Section 30.3.1), and then discuss the relevant neurobiological design principles (Section 30.3.2).

30.3.1 Language-Based Design Principles

As described, one of the principal aims of the (e)ADM has always been to model cross-linguistic unity and diversity in the neurocognition of language. This goal is, in fact, inextricably intertwined with the goal of developing a neurobiologically plausible model of language processing, because any neurobiologically plausible model of language will need to ensure that linguistic diversity is adequately taken into account. Hence, the following design principles, all of which are motivated by cross-linguistic research, play an integral role in the current version of the eADM.

(L1) *Functional equivalence of syntactic and semantic cues*

The language processing literature often discusses the status of cues from different linguistic domains (e.g., syntax and semantics) in the comprehension architecture. However, since the seminal work conducted within the Competition Model (CM) framework from the late 1970s and early 1980s onward, systematic cross-linguistic comparisons have consistently provided evidence *against* a principled distinction between syntactic cues (e.g., word order, case marking, agreement) and semantic cues (e.g., animacy) in guiding comprehension (Bates, Devescovi, & Wulfeck, 2001; Bornkessel & Schlesewsky, 2006; MacWhinney & Bates, 1989; MacWhinney,

Bates, & Kliegl, 1984). More recent neurocognitive studies even suggest that cues from different domains are associated with qualitatively similar neural correlates (Bornkessel-Schlesewsky & Schlesewsky, 2009). On the basis of these observations, the eADM posits that the distinction between syntax and semantics is *not* an organizational principle underlying the language processing architecture.

In accordance with principle (L1), the architecture of the eADM does not posit a principled distinction between syntax and semantics (as assumed by Friederici, 2002, 2009, 2012) or between stored lexical representations and combinatory operations (Hagoort, 2005, 2013). Rather, knowledge that would traditionally be characterized as semantic, syntactic, lexical, or combinatory is processed in both the dorsal and ventral auditory streams and the division of labor between the streams is based on other distinctions (see Sections 30.3.2 and 30.4).

A further linguistic distinction that is often assumed by models of language processing concerns the difference between word categories (e.g., nouns and verbs). Like the distinction between syntactic and semantic information sources, the eADM assumes that a principled noun–verb distinction does not play a crucial role in the language processing architecture (design principle L2).

(L2) *Transcategoriality*

A recent review of neurolinguistic studies on different word categories concluded that nouns and verbs are not differentially represented by the brain at the single word level, with apparent category differences arising primarily from the distinction between objects and actions (Vigliocco, Vinson, Druks, Barber, & Cappa, 2011; see also Moseley & Pulvermüller, 2014). Differences do begin to emerge in sentence context, however. This result accords well with observations from linguistic typology, which suggest that not all languages code category distinctions at the single word level (“transcategoriality” or “precategoriality,” see Bisang, 2010) and that categories may differ between languages (Croft, 2001). In this way, findings from the neurocognition of language and linguistic typology converge in suggesting an “emergentist” view of categories, that is, a view in which word categories emerge from the interaction of form-based, meaning-based, and distributional properties.

Rather than assuming principled distinctions between purported linguistic modules such as syntax and semantics or categories such as nouns and verbs, the eADM posits that the combinatorial properties of higher-order language processing in the brain are based on a fundamental division of labor between two types of combinatory mechanisms, as described in (L3); see also Bornkessel-Schlesewsky, Schlesewsky, Small, & Rauschecker, in press.

(L3) *Sequence-based versus dependency-based combinatorics*

Although competing theories of grammar assume various different descriptive mechanisms for combining linguistic elements to form larger units, all existing theories (e.g., Bresnan, 2001; Chomsky, 2000; Goldberg, 2003; Van Valin, 2005)

assume two types of combinatory mechanisms in one form or another: (i) the combination of elements into sequences (i.e., combining elements A and B to form the sequence A-before-B); and (ii) the combination of elements to form dependencies, independent of sequential order. As an illustration, consider the phrase “the red boat” and its French counterpart “le bateau rouge” (literally, “the boat red”). In both cases, red describes a property of the boat (i.e., there is a dependency between boat and red), but the sequential order in which the two words are expressed differs between the two languages. While dependency formation correlates strongly with sequential information in some languages (e.g., English), most languages allow for a more flexible word order and, hence, a principled dissociation between sequence processing and dependency formation (e.g., German, Turkish, Hindi, Japanese, and Warlpiri, among many others).

Finally, it is important to note that the eADM rejects the notion that mechanisms particular to specific linguistic theories (e.g., merge, the notion of constructions) can be plausibly translated into neurobiologically valid constructs. It is well-known that competing theories of grammar are essentially equivalent in terms of their explanatory capacity, which can be demonstrated by expressing them in a single formalism (e.g., [Stabler, 2010](#)). In other words, competing theories overlap with regard to which sentences they classify as well-formed (part of a given language) or ill-formed (not part of a given language), but theories differ with respect to the descriptive computational mechanisms to which they attribute these differences in classification. Second, because no theory of grammar is currently constrained by knowledge regarding the structure/function of the human brain, it appears implausible to attempt to establish a neurobiological grounding for any of the computational operations specific to individual linguistic theories (for discussion, see [Schlesewsky & Bornkessel-Schlesewsky, 2012](#)). Hence, instead of drawing on mechanisms assumed in particular linguistic theories, the design principles L1–L3 are based primarily on the notion of cross-linguistic applicability.

30.3.2 Neurobiological Design Principles

The first neurobiological design principle underlying the eADM (NB1) concerns the existence of multiple streams of information processing. The assumption of a dorsal–ventral stream dissociation is shared with a wide range of other neurobiological models of speech and language processing ([Friederici, 2012](#); [Hagoort, 2013](#); [Hickok & Poeppel, 2007](#); [Rauschecker & Scott, 2009](#); [Saur et al., 2008](#); [Ueno, Saito, Rogers, & Lambon Ralph, 2011](#)). Principle NB2 (hierarchical organization), while also not particularly controversial in neurobiology more generally, has not been explored in detail with respect to its potential consequences for the neurobiology of higher-order language processing. Finally, principles NB3 and

NB4 are more controversial. NB3 posits a unified computational function for each stream (see [Friederici, 2011, 2012](#), for a different perspective), whereas NB4 assumes that the computations performed by each stream in higher-order language processing are grounded in the computations performed by that stream in nonhuman primate audition.

(NB1) *Multiple streams of information processing*

The perception–action cycle is implemented by multiple streams of information transfer in the human brain. As in the visual domain ([Goodale & Milner, 1992](#); [Ungerleider & Mishkin, 1982](#)), a dorsal and a ventral stream of audition can be distinguished ([Rauschecker, 1998](#)). The eADM posits that each stream can be associated with a distinguishable and internally unified function in information processing, irrespective of the fact that a stream comprises multiple fiber bundles. Furthermore, the computational properties of the dorsal and ventral streams are congruent with those of the dorsal and ventral streams in (human and nonhuman) primate audition ([Bornkessel-Schlesewsky, Schlesewsky, Small, & Rauschecker, in press](#); [Rauschecker, 2011](#); [Rauschecker & Scott, 2009](#)).

(NB2) *Hierarchical processing*

Following well-established findings in the visual ([Felleman & Van Essen, 1991](#)) and auditory ([Rauschecker & Tian, 2000](#)) domains (for an overarching synthesis concerning the relationship between perception and cognition, see [Mesulam, 1998](#)), the eADM assumes that the dorsal and ventral streams in language processing are organized in a hierarchical manner. Levels further downstream along a stream are sensitive to successively more intricate convergences of features (i.e., of features processed in levels further upstream). Hierarchical processing has been demonstrated convincingly for the ventral auditory stream using single unit recordings in monkeys ([Rauschecker & Tian, 2000](#)) and fMRI ([DeWitt & Rauschecker, 2012](#)). The eADM assumes that it also holds for the dorsal stream.

(NB3) *Computational functions of the dual streams*

In accordance with the classic assumption of a meaningful computational distinction between dorsal and ventral streams in both the visual and auditory domains ([Goodale & Milner, 1992](#); [Rauschecker, 1998](#); [Ungerleider & Mishkin, 1982](#)), the eADM assumes that the dorsal–ventral distinction in language amounts to a meaningful computational division of labor. Consequently, the dorsal and ventral streams have separable, but internally consistent, computational functions.

(NB4) *Computational grounding in primate audition*

The computations performed by the dorsal and ventral streams in higher-order language processing are grounded in the respective computational abilities of the two streams in primate audition.

Accordingly, the dorsal stream performs operations congruent with its role in auditory-motor mapping (such as the dense connectivity between auditory, parietal, and premotor regions in nonhuman primates, e.g., [Lewis & Van Essen, 2000](#); [Morecraft et al., 2012](#); [Ward, Peden, & Sugar, 1946](#); and evidence for auditory-motor interactions in

monkeys based on these structures, e.g., [Artchakov et al., 2012](#); [Kohler et al., 2002](#)) and as a “where” or “how” stream. Internal models, which serve to predict upcoming states of the world based on the current input and the properties of the model, have been proposed as a common denominator between the differing functions ([Rauschecker, 2011](#)). The ventral stream, by contrast, recognizes auditory objects. Like visual objects, auditory objects are identified as a coherent *gestalt* via certain grouping cues (e.g., in audition, harmonicity, coherent changes over time, and a common temporal onset; [Bizley & Cohen, 2013](#)). Studies in nonhuman primates have demonstrated a sensitivity for successively more complex auditory objects along the course of the ventral stream, ranging from elementary auditory features such as frequency-modulated (FM) sweeps or bandpass noise bursts to species-specific vocalizations ([Rauschecker, 2011](#); [Rauschecker & Scott, 2009](#); [Rauschecker & Tian, 2000](#)). Auditory object formation is a form of categorization in which spectro-temporal properties are grouped into perceptual ([Bizley & Cohen, 2013](#)) and, at higher hierarchical levels, conceptual units. It thus provides the computational basis for an elementary mapping from spectro-temporal patterns to concepts.

The final neurobiological design assumption (NB5) concerns the role of frontal cortex within the language processing architecture. In contrast to several other neurobiological models of language ([Friederici, 2012](#); [Hagoort, 2013](#)), the eADM does *not* assume that frontal regions—including IFG and vPMC—perform dedicated linguistic computations such as syntactic structuring or unification.

(NB5) *Control function of frontal cortex*

Frontal cortex, including vPMC and IFG, fulfill domain-general cognitive control functions in language processing ([Bornkessel-Schlesewsky, Grewe, & Schlesewsky, 2012](#); [January, Trueswell, & Thompson-Schill, 2009](#); [Novick, Trueswell, & Thompson-Schill, 2005](#); [Thompson-Schill, Bedny, & Goldberg, 2005](#); [Thompson-Schill, D’Esposito, Aguirre, & Farah, 1997](#)). Thus, they serve to select among multiple competing representations and provide a supervisory function that can shift the weighting attributed to the individual streams ([Miller & Cohen, 2001](#)). They are also crucial for the integration of information from the dorsal and ventral streams.

30.4 THE MODEL ARCHITECTURE

The basic model architecture of the eADM is shown in [Figure 30.1](#). In the following subsections, we explain the assumptions underlying this architecture in more detail. We begin by focusing on the assumed computational division of labor between the dorsal and ventral streams ([Section 30.4.1](#)) before turning to hierarchical processing as a common organizational principle of both streams ([Section 30.4.2](#)). [Sections 30.4.3 and 30.4.4](#) then discuss the assumed difference between the representation of actions in the two streams and cross-stream integration, respectively.

FIGURE 30.1 Schematic depiction of the eADM’s neuroanatomical assumptions (reproduced, with permission, from [Bornkessel-Schlesewsky et al., in press](#)). Both the ventral (green) and dorsal (red) streams are assumed to emanate from auditory cortex (AC) and to perform information processing in a hierarchically organized manner. Abbreviations: AC, auditory cortex; CS, central sulcus; IFG, inferior frontal cortex; IPL, inferior parietal lobule; PMc, premotor cortex; STS, superior temporal sulcus. Numbers denote Brodmann area.

30.4.1 The Computational Division of Labor Between the Dorsal and Ventral Streams

Building on the design principles that were discussed in the preceding section, the current version of the eADM posits the following fundamental computational distinction between the postero-dorsal and antero-ventral streams (see L3 and NB3): the dorsal stream processes sequential information, whereas the ventral stream computes dependencies independent of sequential order. Both types of computations are combinatorial in that they serve to construct larger units via the combination of smaller units. However, they differ with respect to the informativity of temporal ordering: for the combination of two elements A and B to form a larger unit C, if the order in which A and B are encountered is relevant, then the computation is one of sequencing; if the order of A and B is irrelevant, then it is one of dependency formation. In other words, time-independent computations are commutative (like addition or multiplication in arithmetic), whereas time-dependent computations are not (like subtraction or division).

In accordance with NB4, the computational mechanisms posited here for the dual streams are grounded in their respective computational functions in primate audition. For the dorsal stream, it has been proposed that its basic functions as a where or how stream can be

subsumed computationally under the construct of an internal model (Rauschecker, 2011; Rauschecker & Scott, 2009) that serves to predict the sensory consequences of actions (forward model) and to determine the necessary motor commands to produce a desired sensory outcome (inverse model). The eADM assumes that linguistic sequence processing within this stream can be understood using such internal model mechanisms. In particular, forward models provide the optimal means for predicting sequential information, as required at many different levels of language (see also Pickering & Garrod, 2007, 2013). The dorsal stream, which is generally viewed as the more “action-related” of the two auditory streams (Hickok & Poeppel, 2004, 2007; Saur et al., 2008; Ueno et al., 2011) and which shows considerable anatomical overlap with the “action observation network” (AON; Grafton, 2009), provides an ideal basis for this type of mechanism. In other words, because language and action share a number of constitutive characteristics (hierarchical organization, dynamic unfolding over time), neural architectures that are highly suited to implementing forward and inverse models of action should be able to serve a similar purpose with respect to the sequential properties of language.

In contrast to the sequence-based processing characteristics of the dorsal stream, the ventral stream processes feature structures (auditory objects) of increasing complexity. At the lower levels of the hierarchy (phoneme, syllable), we assume that these are represented as spectro-temporal patterns, similar to the monkey vocalizations discussed by Rauschecker and Tian (2000). On the basis of single unit recordings in macaques, these authors argued for a mechanism of spectral integration in which particular neurons show sensitivity to the combination of several spectral components comprised by a complex sound. They also proposed that similar mechanisms may be applicable in speech perception in humans, at least up to the level of the syllable. However, in accordance with the well-established idea that the ventral stream is somehow involved in mapping acoustic representations to semantic representations (e.g., Saur et al., 2008; Scott, Blank, Rosen, & Wise, 2000; Ueno et al., 2011; and, to a certain degree, Hickok & Poeppel, 2007), it appears clear that, at some level of the hierarchy, representations must begin to abstract from complex spectro-temporal acoustic patterns. The eADM posits that the level of the morpheme may be a promising candidate because there is general agreement in linguistics that morphemes are the smallest meaning-bearing units in language, and these are the smallest units that can plausibly be connected to an acoustically independent semantic representation.

The semantic representations assumed by the eADM are termed “actor event schemata” (AE schemata). They essentially reflect event scenarios comprising an event

instigator or causer (the actor) and the action undertaken, as well as optional additional components such as the entity acted on, the time, and location of the action. The centrality of the actor as opposed to other participants in the event scenario is motivated by cross-linguistic considerations (Bornkessel-Schlesewsky & Schlesewsky, 2009, 2013b, 2014). The various components of a schema are combined via dependency formation, which we view as an extension of the combination sensitivity that is already attested in basic auditory objects in nonhuman primates. Thus, in accordance with the abstraction from spectro-temporal to conceptual auditory objects described, dependency formation is a mechanism that groups linguistic units into conceptual schemata as opposed to acoustic features into more complex acoustic representations. Like auditory object formation in the acoustic domain, dependency formation draws on grouping cues. These can include the likelihood of certain words occurring in a particular semantic relation (e.g., given “apple” and “eat,” there is a high likelihood of the apple being interpreted as the thing eaten rather than the entity doing the eating) but also morphological cues such as case marking (such as the German noun phrase “den kleinen braunen Bären,” “the.ACC small.ACC brown.ACC bear.ACC” in which overlapping accusative case inflections serve to make clear the dependency between the various elements of the noun phrase). Importantly, as noted, dependency formation is independent of sequential order as demonstrated, for example, by the fact that the component parts of a noun phrase can be separated from one another in many languages of the world. The following examples from Ukrainian (Féry, Paslawaska, & Fanselow, 2007) illustrate this property. Note the accusative feminine marker that serves as a grouping cue to identify the dependency between “interesting” and “book.”

1. Dependency without sequential adjacency: split noun phrases in Ukrainian (Féry et al., 2007)
 - a. Marija pročytala cikavu knyžku
Mary has-read interesting-ACC.FEM book-ACC.FEM
“Mary has read an interesting book”
 - b. Cikavu Marija pročytala knyžku
interesting-ACC.FEM Mary has-read book-ACC.FEM
 - c. Knyžku Marija pročytala cikavu
book-ACC.FEM Mary has-read interesting-ACC.FEM

In a more general sense, AE schemata can be compared with the notion of scripts (i.e., knowledge structures that represent information about events) (Schank, 1999; Schank & Abelson, 1977). Neuroanatomically, the utilization of scripts has been tied to the anterior temporal lobe (Frith & Frith, 2003; Funnell, Corballis, & Gazzaniga, 2001), which is in accordance with the eADM’s notion of the antero-ventral stream. From a neurobiological

perspective, increasing detail at successive levels of the hierarchy (from the activation of individual AE schemata to their combination) will lead to the activation of an increasing number of neuronal populations activated in “synchrony” in accordance with the assumption of distributed semantic representations (e.g., [Martin, 2007](#); [Patterson, Nestor, & Rogers, 2007](#), for reviews).

30.4.2 Hierarchical Organization as a Common Principle

Despite the qualitatively different mechanisms of information processing that they implement, the dorsal and ventral streams have in common that processing is organized in a hierarchical manner (see NB2). This means that information integration increases successively the further downstream a region is within a stream (i.e., the further removed from auditory cortex). For example, if the first level of the hierarchy processes features at the level of, for example, phonemes (e.g., /b/, /p/, /a/), then the second level of the hierarchy will be sensitive to combinations of these features (e.g., distinguishing syllables such as /ba/ and /pa/). The assumption that the hierarchy is “built up” successively from auditory cortex, hence implying an asymmetry in the directionality of information flow within the two streams, is based on the idea that the streams serve to link perception (primary sensory regions) with action (frontal cortex). It thus adopts the perspective that the purpose of the human brain is to plan and execute movements, thereby allowing us to interact with our environment:

Movement is the only way we have of interacting with the world, whether foraging for food or attracting a waiter’s attention. Direct information transmission between people, through speech, arm gestures or facial expressions, is mediated through the motor system which provides a common code for communication. From

this viewpoint, the purpose of the human brain is to use sensory representations to determine future actions. [Wolpert, Doya, and Kawato \(2003, p. 593\)](#).

Building on this view, we propose that the goal of language comprehension is to translate linguistic input (i.e., a stream of phonetic, graphematic, or gestural input) into a representation of the action or event being expressed to allow for a suitable behavioral response. Note that “behavioral” is used in very general terms here, referring both to overt action and to more internal operations such as memory updating or consolidation. Nevertheless, connectivity within the streams is of course inherently bidirectional.

The nature of the hierarchy within a stream is in accordance with the information processing function of that stream. In the dorsal stream, we assume that the hierarchy is defined via temporal integration windows of successively increasing size: phoneme sequences, prosodic chunks, category sequences, action sequences, and discourse sequences. The ventral stream, by contrast, comprises a hierarchy of successively more complex (i.e., feature-rich) auditory objects.

Combining the assumed division of labor between the computations performed by the two streams with hierarchical processing as a key organizational principle yields the process models in [Figures 30.2 and 30.3](#) for the dorsal and ventral streams, respectively.

30.4.3 Representing Actions in the Dorsal and Ventral Streams

If, as suggested, the goal of (auditory) language comprehension is to translate an acoustic input into an action representation that can be used to guide future behavior, then this raises the question of how action representations differ between the dorsal and ventral streams. We

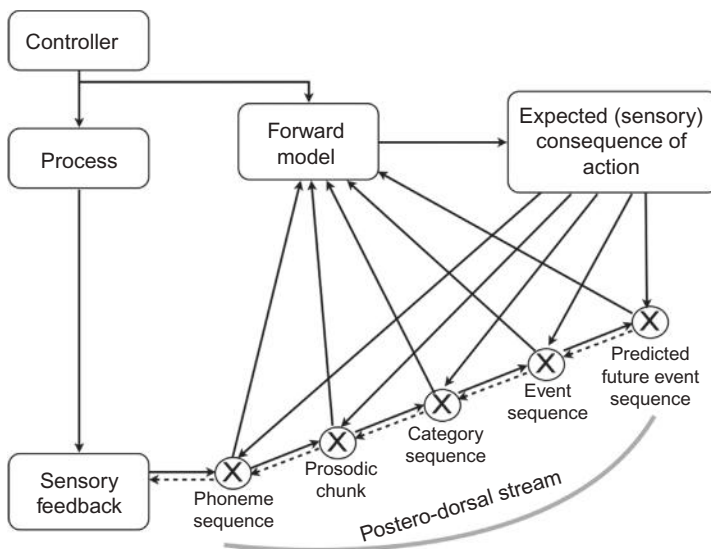

FIGURE 30.2 Functional organization of the postero-dorsal stream. Future input is predicted via a forward model and the expected consequences (sensory or more abstract) are compared with the actual input by a hierarchically organized series of comparators (designated by an X). Prediction errors arising in these comparisons are used to update the forward model.

propose that the crucial difference again lies in the dissociation between sequences and dependencies.

Let us consider the ventral stream first. Here, in accordance with the notion of AE schemata, we assume that action representations in the ventral stream are holistic in the sense that they encode the action and the participants involved in it, but not the precise manner in which the action unfolds in time.

The dorsal stream, by contrast, encodes an action in a sequence-based manner with the goal of predicting how the action/discourse event will continue to unfold over

time (sequentially). We posit that, to do this, the dorsal stream draws on a set of action-relevant linguistic entities that are particularly potent in their predictive capacity (Figure 30.4). Importantly, we suggest that the dorsal stream's action representation is centered on these action-relevant entities and their role in the sequential unfolding of an action and that the stream does not represent the overall action itself. This is the role of the ventral stream, as described. This assumption is in line with the proposal that the (visual) dorsal stream only has a very limited memory capacity such that actions are possible when an object (i.e., an action-relevant entity) is currently present, but not when reliance on stored object information is required (e.g., when grasping an object in the dark) (Grafton, 2010; Milner, Dijkerman, McIntosh, Rossetti, & Pisella, 2003). Under such circumstances the interaction with the ventral stream becomes crucially important (Cohen, Cross, Tunik, Grafton, & Culham, 2009).

As an example of an action-relevant entity in language, consider the actor role. The actor refers to the participant that is primarily responsible for the successful execution/completion of the event or state of affairs described (Bornkessel & Schlesewsky, 2006). Cross-linguistic evidence suggests that actor identification constitutes a central goal of sentence understanding in languages of very different types (Bornkessel-Schlesewsky & Schlesewsky, 2009) and, accordingly, that different participants (arguments) compete for the actor role (Bornkessel-Schlesewsky & Schlesewsky, 2013a, 2014). Competition is resolved via a set of cues (also termed prominence features), some of which appear

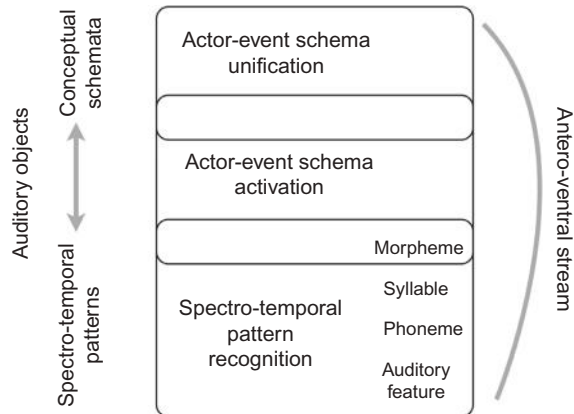

FIGURE 30.3 Functional organization of the antero-ventral stream that recognizes spectro-temporal patterns and maps these onto conceptual schemata (actor-event, AE schemata). AE schemata are combined to form more complex AE schemata via unification, a commutative combinatory operation. Adapted, with permission, from Bornkessel-Schlesewsky et al. (in press).

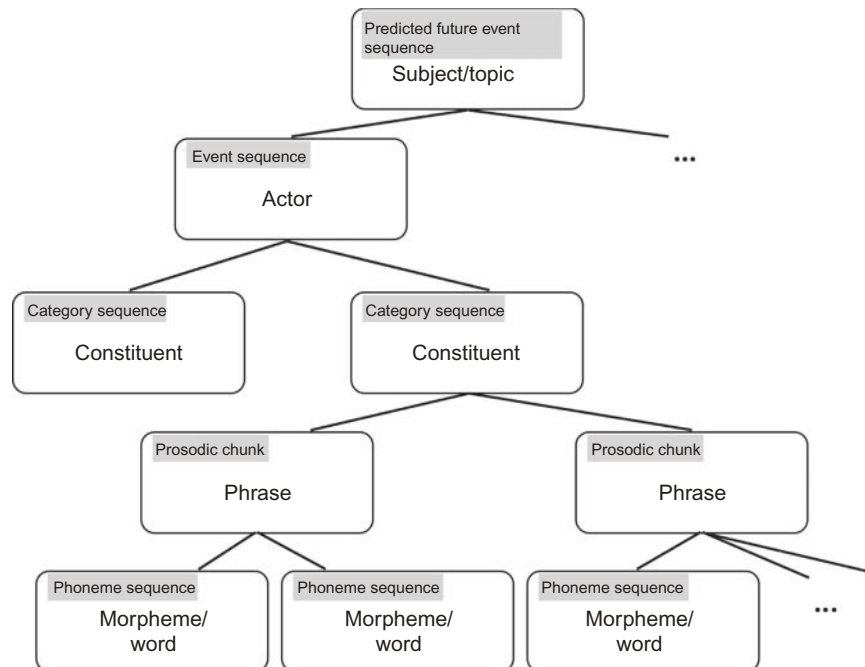

FIGURE 30.4 Hierarchical organization of the action-related entities in the dorsal stream.

to be universal (e.g., animacy, word order, first person), whereas others are language-specific (e.g., case marking, agreement). Individual cues are weighted differentially depending on the specific language being processed (Bates et al., 2001; Bates, McNew, MacWhinney, Devescovi, & Smith, 1982; Bornkessel & Schlesewsky, 2006; MacWhinney et al., 1984; MacWhinney & Bates, 1989). During language development, children learn which of the more abstract linguistic information sources (e.g., word order, case marking) correlate highly with actorhood in their native language—presumably based on more universal cues such as animacy or similarity to the first person (assuming that the self is used as a model for an optimal actor; Dahl, 2008; Haggard, 2008; Tomasello, 2003). Once the actor has been identified, it can be used to predict certain aspects of the event or state of affairs currently being described. For example, a human actor is likely to perform different types of actions—warranting different sets of linguistic descriptions—to an inanimate actor.

Predictions at a particular level of the hierarchy can also influence other levels (both higher and lower). For example, the anticipation of a particular action or set of possible actions depending on the actor can be used to constrain predictions with regard to the upcoming category sequence. Animate and particularly human actors are more likely than inanimate actors to perform goal-directed actions involving another person or object. Hence, in addition to a verb describing the action itself, the processing system may be more likely to anticipate an additional constituent describing an entity affected by the action (an undergoer), and the internal model will be modified to reflect this. At the same time, an actor participant is also very likely to be realized as the grammatical subject of a sentence. Following work in sentence production (see Myachykov, Thompson, Scheepers, & Garrod, 2011, for a review) and text analysis (Givón, 1983, 1994), the eADM assumes that a speaker codes an entity as the subject when he/she wishes to signal to the hearer that this entity will be particularly important in the upcoming discourse (Bornkessel-Schlesewsky & Schlesewsky, 2014). Hence, identifying the subject allows for predictions to be set up with regard to the next event to be described in the current discourse (i.e., a supra-sentential sequence prediction). Again, the internal model is dynamically modified in accordance with this prediction.

30.4.4 Integrating Information Between Streams

Finally, we turn to the interaction between the dorsal and ventral streams. Following Rauschecker and Scott (2009), the eADM posits that prefrontal cortex (specifically, the inferior frontal gyrus, IFG, and ventral premotor

cortex [vPMC]) serves as a point of integration between the two streams. It also serves a control function whenever mediation between conflicting representations is required (Bornkessel-Schlesewsky et al., 2012; Novick et al., 2005; Thompson-Schill et al., 1997; Thompson-Schill et al., 2005). In this way, the model assumes that prefrontal regions—and particularly the IFG—do not perform any language-specific computations such as syntactic structure building, but rather fulfill a more general supervisory function (Miller & Cohen, 2001).

The integration of information from the two streams in frontal cortex further allows for information from one stream to induce a top-down modulation of the other. For example, an event representation in the form of an AE schema from the ventral stream can, when translated into a dynamic sequence-based representation (possibly in the interaction between IFG and vPMC), modify the forward model being used to generate predictions about upcoming input in the dorsal stream. This may lead to more concrete predictions about category sequences and phoneme sequences (i.e., specific words and morphemes) than would be possible on the basis of the dorsal stream alone due to the more specific information about actors and events represented in the ventral stream. Conversely, sequence-based information from the dorsal stream can play an important role in modulating AE schema unification in the ventral stream. Because AE schemata conceptualize both actors and events and can therefore represent both “nouny” and “verby” constituents depending on the context in which they occur (for more detailed discussion, Bornkessel-Schlesewsky & Schlesewsky, 2013b), current sequence information can be used to determine whether a given AE schema refers to the actor or the event in the overarching action being described (i.e., for the schema “run(ner),” whether we are currently processing an event involving a runner, someone who is running, or both).

Beyond an interaction of the two streams at their “termination” points in frontal cortex, a more dynamic transfer of information at multiple points along each stream appears very likely, possibly supported by subcortical connectivity. Functionally, this could help to consolidate representations across streams. However, the anatomy of these putative connections remains to be determined in detail and, accordingly, the functional consequences of a more direct inter-stream interaction remain an important topic for future research.

30.5 EVIDENCE FOR THE MODEL

In the following, we briefly summarize the existing evidence for the architectural claims described. Note that this discussion is not exhaustive for reasons of space.

Let us first consider the dorsal stream, for which the model makes several claims that are not shared by other approaches. The notion of hierarchical organization is supported by a recent fMRI study (Lerner, Honey, Silbert, & Hasson, 2011) on temporal receptive windows in the dorsal auditory stream. Lerner and colleagues' participants listened to stories that were presented either normally or scrambled (i.e., cut into segments and reassembled randomly) at several different levels or time scales: single words, sentences, or paragraphs. Activation changes were observed along the dorsal stream, with areas successively further downstream from auditory cortex only showing activation increases in response to coherent information at successively higher levels (i.e., larger and longer linguistic units). Hence, Lerner et al. (2011) argue for a hierarchical organization of temporal receptive windows, with window size increasing from "low-level sensory to high-level perceptual and cognitive areas" (p. 2906). This result provides strong converging support for the eADM's proposal of a hierarchically organized dorsal auditory stream.

A second key claim with regard to the dorsal stream concerns sequential processing, an aspect of language comprehension that has been examined in a number of neuroimaging studies that aimed at investigating syntactic processing. Evidence for sequence processing in the dorsal stream stems from an fMRI study on constituent processing in French (Pallier, Devauchelle, & Dehaene, 2011) that undertook a parametric manipulation of constituent size (1–12 words) using both real French words and pseudowords. Activation in the pSTS increased parametrically with constituent size, irrespective of the word/pseudoword distinction, whereas a comparable activation increase in the anterior STS and temporal pole was only observed for constituents consisting of real words. This finding is consistent with the view that the posterior temporal lobe is important for the processing of category sequences, whereas combinatory effects in the anterior temporal lobe can be modeled as AE schema unification. Although it is conceivable that pseudowords activate AE schemata on the basis of their similarity to existing words, this activation should be considerably less pronounced than that for real words, therefore yielding a larger schema unification effect for real word constituents. Category sequences, by contrast, can be constructed just as successfully from pseudowords as long as these preserve grammatical information.

Further evidence for the assumption that syntactic processing relies on the dorsal stream is provided by patient studies. Wilson et al. (2011) studied patients with primary progressive aphasia (PPA) and observed that deficits in processing noncanonically ordered sentences in English (e.g., passives, object relative clauses) correlated with damage to dorsal fiber tracts (the superior longitudinal fasciculus and arcuate fasciculus), but not

ventral fiber tracts (the uncinate fasciculus and extreme capsule). An fMRI study using the same task that Wilson et al. (2010) used to assess patients' syntactic performance revealed activation in bilateral dorsal posterior IFG/IFS and anterior insulae, left mid-posterior STS and MTG, as well as left superior and medial (precuneus) parietal regions. Furthermore, in an additional study, Wilson et al. (2014) found that patients with semantic-type PPA and atrophy of the anterior temporal lobes showed statistically indistinguishable fMRI activation for noncanonical versus canonical sentences in comparison with healthy controls.

Coactivation of posterior superior temporal and posterior dorsal inferior frontal regions has also been reported in studies on word order variations (Bornkessel, Zysset, Friederici, von Cramon, & Schlesewsky, 2005; Röder, Stock, Neville, Bien, & Rösler, 2002) or for the contrast between locally (syntactically) ambiguous and unambiguous sentences (Snijders et al., 2009). Importantly, the eADM provides a principled explanation for the activation of both temporal and frontal regions, with temporal regions thought to perform the sequence processing necessary for recognizing syntactic structure and frontal regions providing the appropriate control mechanisms to supervise these processes. By contrast, models claiming that the left IFG is the core region for syntactic processing (Friederici, 2011) or linguistic combinatorics (Hagoort, 2013) do not straightforwardly account for the additional temporal activation in response to syntactic manipulations.

Turning now to the ventral stream, the claim that this stream processes auditory objects and provides a mapping from spectro-temporal patterns to conceptual schemata predicts that the anterior temporal lobe (aTL) should be sensitive to abstract semantic representations. There is evidence to suggest that auditory and visual processing converges in anterior temporal regions (e.g., Chan et al., 2011, for supramodal sensitivity to semantic categories in the aTL, as revealed by intracranial recordings) and that individual word meanings can be decoded from EEG and MEG recordings from anterior temporal cortex (Chan, Halgren, Marinkovic, & Cash, 2011). Dependency formation in the ventral stream is supported by combinatory effects in the aTL (i.e., increased activity in response to two-word sequences that yielded a meaningful modifier-head relation when combined, e.g., "red boat," in comparison with various controls) for both visual and auditory input (Bemis & Pylkkanen, 2013). The observation that semantic PPA patients with substantial atrophy of the aTL can process noncanonical word orders rather accurately and show similar dorsal stream activation to controls while doing so (Wilson et al., 2014) provides further converging evidence for the eADM's proposal that the combinatorics supported by the ventral stream are dependency-based (commutative) rather than sequence-based.

30.6 CONSEQUENCES FOR ELECTROPHYSIOLOGY

As noted in Section 30.1, the eADM was originally formulated on the basis of electrophysiological data. It therefore appears important to consider the consequences for electrophysiological measures of language processing arising from the architectural considerations outlined in the previous sections.

First, recall that the eADM posits no principled separation between syntax versus semantics, combinatorics versus lexicon, or linguistic rules versus representations. Hence, the model does not provide any basis for assuming a separation of ERP components based on such distinctions (e.g., the traditional assumption that N400 effects reflect semantic processing, whereas LAN and P600 effects reflect syntactic processing, e.g., Friederici, 2002; Hagoort, Brown, & Osterhout, 1999; Kutas, Van Petten, & Kluender, 2006; Osterhout & Nicol, 1999).

If linguistic subdomains are excluded, then what might be a plausible alternative for a functional classification of the ERP correlates of language processing? In this regard, let us first consider negative ERP deflections such as the left anterior negativity (LAN) and N400. Very broadly speaking, these are often regarded as reflecting mismatches with predicted information during language processing. From the perspective that forward models serve as a source of predictive processing within a dynamically unfolding linguistic input signal, it is apparent that prediction errors (i.e., mismatches between the predicted sensory consequences of an action and the sensory input that lead to an adjustment of the internal model) provide a unified mechanism for modeling prediction mismatches. The eADM thus proposes that endogenous language-related negativities can be subsumed under a unified mechanism: a prediction error during language processing. Rather than reflecting different linguistic domains, latency and topography of the negativity will vary depending on where in the underlying architecture the prediction error occurs (for a somewhat similar perspective, see Pulvermüller, Shtyrov, & Hauk, 2009). Note, however, that this does not mean that each component will be associated with a unique source. Rather, scalp ERP patterns likely reflect a mixing of a number of underlying sources and, hence, potentially, a range of prediction errors at multiple levels within the two streams.

With regard to positive ERP deflections, the eADM subscribes to the view that the P600 (and earlier language-related positivities) are instances of the domain-general P3 component (Coulson, King, & Kutas, 1998; Gunter, Stowe, & Mulder, 1997). A recent neurobiologically grounded model of the P3 proposes that this component reflects a systemic neuromodulatory response

to motivationally significant events stemming from the release of norepinephrine (NE) from the Locus Coeruleus (LC; a brain stem nucleus) (Nieuwenhuis, Aston-Jones, & Cohen, 2005). The NE release serves to increase neural responsivity (gain) to these motivationally significant stimuli, thereby sharpening the dichotomy between the response to target versus nontarget inputs and facilitating an appropriate behavioral response (“noradrenergic potentiation of information processing”; Nieuwenhuis et al., 2005, p. 510). Note that, as in Section 30.4, the notion of behavior used here is very general, including both overt responses and internal state changes such as memory updating. From this perspective, language-related endogenous positivity effects reflect a response to motivationally significant stimuli, rather than indexing a particular type of structural processing (such as syntactic processing or reanalysis). This idea is in line with the finding that positivity effects occur for both syntactically and semantically deviant materials (for semantic violations, see Faustmann, Murdoch, Finnigan, & Copland, 2007; Gunter, Jackson, & Mulder, 1992; Kolk, Chwilla, van Herten, & Oor, 2003; Kuperberg, Sitnikova, Caplan, & Holcomb, 2003; Lotze, Tune, Schlesewsky, & Bornkessel-Schlesewsky, 2011; Roehm, Bornkessel-Schlesewsky, Rösler, & Schlesewsky, 2007; Sanford, Leuthold, Bohan, & Sanford, 2011) and that they are considerably less pronounced or even absent without a task (Batterink & Neville, 2013; Hasting & Kotz, 2008). Further converging evidence stems from the recent observation that, like P3 effects, P600 effects in language comprehension are reaction-time aligned—a necessary prediction of subsuming the P600 under the LC/NE account of the P3 (Sassenhagen, Schlesewsky, & Bornkessel-Schlesewsky, 2014). This account also leads to a number of testable predictions, such as that P600 effects should covary with other physiological indicators of LC/NE activity, including heart rate, pupil dilation, and skin conductance.

30.7 OUTLOOK

The model architecture described here is intended as a first step toward a neurobiologically and cross-linguistically plausible model of human language processing. As is the case with every model, it can only provide an approximation of reality and it will likely continue to undergo an evolution over the coming years. Development presupposes falsifying assumptions of the current model version and modifying them in accordance with the data collected. Thus, an emphasis has been placed on clear design principles, many of which may ultimately prove too simple in their current form. For example, it may be the case that, although both

ventral and dorsal streams are organized hierarchically, the formulation of the hierarchy may need to be somewhat different in each case. To allow for the testing of such hypotheses, the current state of the model makes a range of testable and falsifiable predictions, some of which we have described in the present chapter.

Acknowledgments

Parts of the research reported here were supported by grants from the LOEWE program of the German state of Hesse (grant III L 4–518/70.004 to IBS) and the German Research Foundation (grants TRR 135/1 C05 to IBS and SCHL 544/6-1 to Ms). The authors thank Steve Small and Josef Rauschecker for many fruitful discussions related to this line of research, and Sarah Tune and Phillip Alday for helpful comments on a previous version of this manuscript.

Typically developing (TD) children will rapidly and comprehensively master at least one of the more than 6,000 languages that exist around the globe. The complexity of these language systems and the speed and apparent facility with which children master them have been the topic of philosophical and scientific speculation for millennia. In 397 AD, in reflecting on his own acquisition of language, St. Augustine wrote "... as I heard words repeatedly used in their proper places in various sentences, I gradually learnt to understand what objects they signified; and after I had trained my mouth to form these signs, I used them to express my own desires" (quoted in Wittgenstein, 1953/2001). St. Augustine's intuitions notwithstanding, more recent thinking and research on children's language acquisition suggest that the problem facing a child is much more intricate than simply remembering the association between a sound and an object and learning to reproduce the word's sound. The rich and multitiered nature of this problem—and the many and varied paths to its solution (Bates, Bretherton, & Snyder, 1988)—make the process of language acquisition a unique window into multiple low-level and high-level developmental processes.

Studies of language development have provided unparalleled views into broad neural and behavioral change in response to input and consolidation. In this chapter, we chart the multiple waves of change in language comprehension and production, beginning at birth with studies of speech perception, moving through babbling, phoneme, and word discrimination into the dawn of word comprehension and production, and the subsequent emergence of syntactic and pragmatic abilities. We also look at language's "fellow

travelers," skills such as social cognition, gestural communication, and environmental sound recognition that appear to presage or accompany linguistic milestones. We also consider the neural bases underlying early (mostly electrophysiological studies) and later language development (predominantly functional magnetic resonance imaging). In particular, recent neuroimaging literature increasingly demonstrates the importance of experience and learning in the development of neural correlates of language development, as well as the absence of any straightforward and task-independent language-specific neural substrates. We emphasize the impressive degree of individual differences in language learning—something that is of prime importance when evaluating language development in atypical populations (as discussed in other chapters in this volume). We also highlight the importance of the structure and statistics of the input to multiple levels of language learning. Finally, we close with an overview of some of the important studies contributing to our understanding of the development of the neurobiology of language.

31.1 PRECURSORS TO LANGUAGE

The onset of language development is not signaled by the child's first word. Rather, even before birth infants are adapting to their language environment, mastering the necessary prelinguistic building blocks that support later language learning. Infants seem to prefer human speech over a number of other auditory signals, such as filtered speech (Spence & DeCasper, 1987), warbled tones (Samples & Franklin, 1978), white

noise (Butterfield & Siperstein, 1970; Colombo & Bundy, 1981), and sine-wave analogues of speech (Vouloumanos & Werker, 2004, 2007). Three-month-old infants prefer listening to speech compared with other naturally occurring sounds in their environment, even other human sounds such as laughter and coughing (Shultz & Vouloumanos, 2010). As we see in this section, during the first year of life children make huge strides in constructing the social, perceptual, and attentional tools that language needs to get off the ground.

Even before and soon after birth it is possible to see the effects of experience-dependent speech discrimination. For instance, the heartbeat of term fetuses tends to increase in response to hearing their mother's voice (Kisilevsky et al., 2003). Infants as young as 4 days old can use rhythm to discriminate between familiar and unfamiliar languages (Nazzi, Bertoncini, & Mehler, 1998; similar skills have also been noted in Tamarin monkeys; Ramus, Hauser, Miller, Morris, & Mehler, 2000). Newborn infants also demonstrate some evidence of being able to discriminate between some of the vowels and consonants from human natural languages (Eimas, Siqueland, Jusczyk, & Vigorito, 1971; see Kuhl, 2004 for a review). Under certain testing conditions, infants, like adults, classify sounds into different categories. That is to say, as some physical characteristic of a phonetic contrast varies along a continuum (such as voice onset time), we do not hear gradual variation in the sounds, but instead a sharp change from one sound to another. This finding has been further elaborated by research illustrating that 3- to 6-month-old infants show graded, within-category perception of voice onset time (VOT) under appropriate testing conditions (McMurray & Aslin, 2005; Miller & Eimas, 1996), suggesting that although phonetic discrimination may be the most easily revealed, gradient perception is also possible. Again, this ability to categorically perceive speech sounds is not specific to humans, with monkeys (Kuhl & Miller, 1975) and chinchillas (Kuhl & Padden, 1983) demonstrating similar phonetic discrimination as do infants. One suggestion is that human phonetic categories have evolved around more general characteristics of mammalian sensory systems (Dick, Saygin, Moineau, Aydelott, & Bates, 2004; Kuhl, 1986; Smith & Lewicki, 2006, but also see Tomasello, 1999, for evidence of more human-specific abilities that may play a part in language development).

Infants younger than 6 months appear to discriminate a wide range of speech sound contrasts, including those that do not occur in their native language (see Saffran, Werker, & Werner, 2006 for a review). However, not all speech sound contrasts are equally discriminable. Sometimes this is because of

asymmetrical perception that results from the order in which speech sounds are presented, and sometimes this is the result of the salience of a contrast. Polka and Bohn (1996) found that an infant's perception of one vowel can shift their perception of a subsequent vowel. For example, if infants are first presented with one of point vowels (e.g., /i/) and then are presented with a more central vowel (e.g., /ɪ/), then the central vowel appears to be absorbed into the point vowel's auditory space, making it difficult for infants to discriminate between them (see Polka & Bohn, 2011 for a review). Kuhl (1991) found that the extreme productions of a vowel influence perception of a less extreme production of the same vowel. She argued that these more extreme tokens act as perceptual magnets attracting the less peripheral tokens into their categorical space. In the case of consonants, it has been shown that acoustic salience influences early speech sound discrimination. For example, Filipino and English infants 6 to 8 months old both have difficulty discriminating the alveolar /na/ versus the velar /ŋa/ nasal stop contrast in word initial position, even though the contrast exists in this position in Filipino and in syllable final positions in English. It is not until later in the development, approximately 10 months, that Filipino-learning infants discriminate this contrast, whereas English-learning infants at the same age still do not discriminate this contrast (Narayan, Werker, & Beddor, 2010), suggesting that perceptually difficult contrasts require more experience for infants to be able to discriminate between them.

Starting at approximately the half-year mark, infants' experience with their native language can be seen to influence their ability to distinguish between non-native speech sound contrasts, so that by approximately the first year infants form a strong bias towards *native language-specific phonetic perception*, beginning with vowels and subsequently extending to consonants (for a review see Werker & Desjardins, 1995). For instance, at 6 months an infant exposed to a Japanese-speaking environment can distinguish between the English /r/ and /l/ sounds, but by 12 months the same child discerns only a single phoneme, unlike an infant reared in an English speaking environment. Furthermore, children's abilities to make such phonetic classifications in their *native* language at 7 months *positively predict* language outcomes such as word production, mean length of utterance (MLU), and sentence complexity between 14 and 20 months, whereas ability regarding *non-native* phonetic contrasts is *inversely* related to later language measures (Kuhl, Conboy, Padden, Nelson, & Pruitt, 2005).

What underlies these developmental changes in infants' auditory discrimination? There is some evidence that in the first year of life, infants' phonetic

discriminations in their native language can, in part, rely on the stochastic *distributional information* available in natural speech. Although the actual examples of any given phoneme that an infant hears vary considerably along many acoustic dimensions, some tend to conform to general statistical distributions that the infant may be able to use to identify the most informative boundaries for distinguishing phonemes (Jusczyk, Luce, & Charles-Luce, 1994; Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Maye, Werker, & Gerken, 2002; Saffran & Thiessen, 2003). However, in many (if not most) cases, such statistical information may be insufficient for perceiving such distinctions (Feldman, Griffiths, Goldwater, & Morgan, 2013; Swingley, 2009). Other evidence suggests the visual and lexical information play an important role in speech sound discrimination. In illustration, if a unimodal distribution of a continuum between /ba/ and /da/ is presented simultaneously with synchronous visual articulations of a canonical /ba/ and /da/, infants 6 months of age discriminate the contrast; however, if the articulations are incorrect, then they no longer show discrimination (Teinonen, Aslin, Alku, & Csibra, 2008). Using visual objects, Yeung and Werker (2009) found that while English-learning infants no longer discriminate non-native contrasts, such as the Hindi dental/retroflex stop contrast (Werker & Tees, 1984), they can discriminate this difficult contrast at 9 months of age if each individual speech sound is paired with a specific object. This suggests that infants are using information gleaned from visual context to help detect contrasts. In addition, lexical influences are likely supporting speech sound discrimination. Feldman, Myers, White, Griffiths, and Morgan (2013) found that 8-month-olds could distinguish similar vowels only after hearing those vowels consistently in distinct word environments. Modeling work supports the usefulness of lexical knowledge in determining sound categories. Martin and colleagues argue that learners have access to proto-lexicon consisting of high-frequency units (n-grams), which can be used for learning their native language phonemes (Martin, Peperkamp, & Dupoux, 2013). Together these findings suggest that a number of factors, including distributional, visual, and lexical, contribute to whether infants can discriminate speech sounds.

Although infants do lose the ability to make discriminations for phonetic contrasts in all the world's languages at approximately the first birthday, this is *not* a straightforward example of a "critical" or "sensitive" period in brain maturation. An elegant combined behavioral and fMRI study by Pallier and colleagues demonstrated that Korean-speaking children who were adopted into French-speaking families between the ages of 3 and 8—importantly, with no further exposure to Korean—did not differ from children born

into French-speaking families when both were tested on phonetic contrasts in Korean and French as adults (Pallier et al., 2003).

In addition to learning to segment the speech stream into meaningful language, children are also faced with the task of producing meaningful speech themselves. Researchers interested in how sensorimotor factors might influence speech perception have examined the relationship between speech perception and production abilities. Using vocal motor schemes (VMS), which are defined as the consonants that are part of an infants' production inventory, DePaolis, Vihman, and Keren-Portnoy (2011) found that 10-month-olds who had multiple VMSs exhibited a novelty listening preference for passages whose nonwords contained consonants they did not consistently produce. Similar findings have been found for languages other than English, such as Italian (Majorano, Vihman, & DePaolis, 2013) and Welsh (DePaolis, Vihman, & Nakai, 2013). The link between perception and production has also been illustrated in studies exploring the patterns of neural activation in the temporal and frontal lobes of infants aged 6 and 12 months (Imada et al., 2006). The early *precursors of productive language* start with infants' preverbal vocalizations. From approximately 3 months, infants begin producing vowel sounds and appear to be able to imitate adult-modeled vowel sounds (Kuhl & Meltzoff, 1996). From 6 to 8 months, infants start *babbling*—making consonant vowel combinations (e.g., {ba}, {ata}). This early babbling is not obviously communicative, often occurring when the infant is on his/her own. As with phonetic perception, over the first year the sounds that an infant produces move from being "universal" (with respect to all of the world's languages) to increasingly resembling the sounds of the language(s) spoken around them. Infants produce native language-specific vowel and consonant sounds before they produce their first words, thus internalizing the acoustical or phonetic patterns of the language the child is exposed to (Boysson-Bardies, de, Halle, Sagart, & Durand, 1989; Boysson-Bardies & Vihman, 1991).

Although *social development* is not a direct precursor of word or syntax comprehension or production, it is entwined with language across early development. The early beneficial effects of social context on language learning are evident in infants' vocalizations and phonetic discriminations. For instance, Bloom, Russell, and Wassenberg (1987) showed that turn-taking can alter very young infants' vocalizations, and Goldstein, King, and West (2003) showed that parental feedback increases infant vocalizations. In addition, Kuhl, Tsao, and Liu (2003) found that North American infants learned non-native Mandarin phonemic contrasts in the presence of a Mandarin speaker but not from a video recording of the same information.

At approximately 3–6 months, social cognition in infants is perhaps most evident in *gaze following*, first directed at nearby targets (D'Entremont, Hains, & Muir, 1997) and expanding to further targets by approximately the first birthday (Corkum & Moore, 1995). As with other skills, this feature is not uniquely human and is present in at least several other nonhuman primate species (Tomasello, Carpenter, Call, Behne, & Moll, 2005). Starting at approximately 9 months, we also see a change from *diadic interactions* (i.e., the infant interacting with another object or another person) to *triadic interactions* (i.e., the infant and a caregiver jointly attending to each other and an object; Trevarthen & Hubley, 1978).

From the end of the first year and beyond, children become increasingly adept at understanding and directing other people's attention, using this information to make the task of language learning more tractable (Bates, 2004). In a longitudinal study of infants from 9 to 15 months, Carpenter, Nagell, and Tomasello (1998) showed a linked progression of gesture and *joint attention*, from infants initially sharing attention to subsequently following an adult's attention, to directing another's attention (for a detailed review see Tomasello et al., 2005). Slightly older infants use an adults' *communicative intent* to rapidly attach meaning to novel words (for a review see Tomasello, 2001). Given the prominence of joint attention and its relation to language development, it is not surprising that the quantity and type of joint attention between infant and caregiver predict children's early communicative abilities, with particular gains when the caregiver focuses on the object of the infant's attention (Carpenter et al., 1998; Tomasello & Todd, 1983).

31.2 FIRST WORDS

As the infant's native language discrimination improves, the child faces the simultaneous daunting task of using various cues in the speech input to *segment speech into words* and attach some meaning to them. Although adult listeners tend to perceive the speech stream as a series of discrete words presented one after another (at least in their native language), human speech actually affords no such luxury because there is generally no one-to-one mapping between pauses or silences and word boundaries. Despite this fact, by 7.5 months, infants can detect words they have been familiarized with from a stream of natural speech (Jusczyk & Aslin, 1995) and furthermore demonstrate longer-term memory for these words in speech (Jusczyk & Hohne, 1997). The speech stream contains a number of different clues regarding the location of word boundaries, such as *syllabic stress patterns* (Curtin,

Mintz, & Christiansen, 2005; Jusczyk, Houston, & Newsome, 1999), *transitional probabilities* (i.e., the likelihood that one phonetic segment follows another; Saffran, Aslin, & Newport, 1996), and *familiar words* (such as *mommy*), which can help infants find and segment adjacent word forms (Bortfeld, Rathbun, Morgan, & Golinkoff, 2005). Infants use a combination of these different cues to segment speech into words, with the relative weighting of cues varying over development (Johnson & Jusczyk, 2001; Thiessen & Saffran, 2003).

The purpose of this segmentation is, of course, to identify the chunks of speech (words) to which meaning can be attached and/or extracted. Evidence has emerged suggesting that infants recognize highly common words as young as 6 months of age (Bergelson & Swingley, 2012; Tincoff & Jusczyk, 1999). By 12 months, in an associative learning task, English-learning infants will appropriately map a novel word to a novel object that has the phonological form of a typical noun, but will reject: (i) forms with illegal sound sequences such as "ptak" (MacKenzie, Curtin, & Graham, 2012a); (ii) forms that are more function-word like such as "iv" (MacKenzie, Curtin, & Graham, 2012b); or (iii) sub-minimal forms (i.e., communicative sounds such as "ooh" and single phonemes such as "l"; MacKenzie, Graham, & Curtin, 2011). These results show that the phonological knowledge acquired over the first year of life influences word-object mapping. Infants become increasingly rapid and skillful at forming these word-to-meaning associations. By approximately 2 years (and possibly earlier), infants demonstrate "*fast mapping*" (Carey, 1978), whereby word-to-meaning mappings are learned after a single exposure. As with previous examples, this skill is neither specific to language (Markson & Bloom, 1997) nor specific to humans (Kaminski, Call, & Fischer, 2004).

As any proud (yet weary) parent will attest, young children are not just consumers of language, but they also use it increasingly productively to communicate their needs, desires, and interests with others. Whereas *word comprehension* typically starts at approximately 9–10 months, *word production* typically follows several weeks later (Fenson et al., 1994). In general, the size of a toddler's early receptive vocabulary maintains a healthy numerical superiority over his or her productive vocabulary, although there is considerable individual variability in the extent of this relationship (again see Fenson et al., 1994). Infants' early productive vocabulary is mostly composed of nominal labels for objects or people, although they also produce non-nominal words (for instance, the relational label "up"). However, straightforward classifications of infants' language in terms of adult linguistic categories such as verbs or nouns are probably inaccurate. Because infant speech is driven primarily by the desire to communicate, Tomasello argues that many of the early

one-word utterances are actually “holophrases”—expressing a holistic communicative function with a single label (Tomasello, 2006). For instance, an utterance such as “up” might serve as the infant’s shorthand for an adult phrase such as “pick it up.” Thus, the infant may be copying a part of the adult phrase as a way to express the communicative intent of the phrase as a whole.

31.3 INDIVIDUAL VARIABILITY, DEVELOPMENTAL TRAJECTORIES, AND THE VOCABULARY “BURST”

As noted in the introduction, to understand the mechanisms underlying both typical and atypical language development, it is vital to have an understanding of the trajectory of that development, both in the “average” child as well as in individual children. The MacArthur Bates Communicative Development Inventory (CDI) provides an excellent and carefully normed method of tracing an individual child’s linguistic developmental trajectory from the tentative start of meaningful communication around the first birthday (for the “average” child) through the advent of complex sentence production and comprehension. An instrument based on parental report (and validated through laboratory observation; Fenson et al., 2000), the CDI is extremely useful for comparing typical and atypical populations, and for assessing individual variation within a given sample.

One interesting finding of the initial MacArthur Bates CDI norming studies (Fenson et al., 1994, 2000) is that there is *little overall difference between girls and boys* in terms of the trajectory of language development. Girls are, on average, 1 month ahead of boys, but this difference accounts for only 2% of the variation within

and across age groups. Thus, these gender differences are relatively insignificant compared with the much greater variation between individuals. It is worth emphasizing how much *individual variation* there is between “typically” developing children—the idea of “typical” language development is something of a useful fiction. As an illustration of this, we have reprinted the cross-sectional growth curves from the Fenson et al. (1994) monograph showing the receptive and productive vocabulary size of children in the 10th, 25th, 50th, 75th, and 90th quartiles (Figures 31.1 and 31.2); we also show longitudinal growth curves for three different TD children for comparison (Figure 31.3).

The use of statistical averages to simplify complex and highly variable time series can sometimes mask more interesting phenomena. A case in point is the

FIGURE 31.1 Number of phrases on the Infant form of the MacArthur Bates CDI reported to be understood by children at each month. Median values and percentile ranks are shown. Reprinted from Fenson et al., 1994 with permission from the publisher.

FIGURE 31.2 Number of words on the Toddler form of the MacArthur Bates CDI reported to be produced by children at each month. Median values and percentile ranks are shown. Reprinted from Fenson et al., 1994 with permission from the publisher.

sudden acceleration at 16–20 months in a child’s vocabulary, the so-called “*vocabulary burst*” that follows a period of very gradual increases in vocabulary size after the first few words. This vocabulary acceleration involves not only an increase in the total number of words a child produces but also changes in the content of the words, with a shift to a greater proportion of adjectives and verbs (Bates et al., 1988; Fenson et al., 1994; Hampson & Nelson, 1993; Nelson, 1981; Tomasello, 2006). This sudden change in vocabulary size has often been considered an indicator of the onset of a new cognitive ability, such as developing a “naming insight” (Dore, 1974). However, this “average” picture masks the wide gamut of individual developmental trajectories observed with the CDI for so-called normal children (i.e., children without obvious language problems). There is wide individual variation in productive vocabulary size at the point when the “average” child launches his/her vocabulary burst. At this time in chronological development (~16 months), children in the highest 10th percentile produce approximately 180 words, whereas those in the lowest 10th percentile produce fewer than 10 words. It is very important to note that despite this early variation, most of these children—including those in the 10th percentile who are slow getting language off the ground—will go on to have similar language outcomes as adults as their initially more able peers. There is also massive variation in the shape of the growth curves for different individuals’ productive vocabulary with age. Some children show a recognizable burst, whereas others’ vocabulary appears to grow at a much steadier pace, with still others advancing in a series of small successive bursts. A strong possibility is that the *relationship between vocabulary size and age is inherently nonlinear*, rather than the

more frequently assumed form of one linear relationship giving way to another linear relationship with the onset of each new skill. The variability across individual’s vocabulary growth curves can be captured most parsimoniously using nonlinear models (Bates & Carnevale, 1993; see also Elman et al., 1996, for a more general discussion of nonlinearity in development). Irrespective of the cause, recognizing the tremendous individual variability is paramount when assessing atypical populations and in understanding in what ways these children differ from TD infants.

31.4 EARLY LANGUAGE AND ITS RELATIONSHIP TO NONLINGUISTIC ABILITIES

Meaningful language production and comprehension develop in tandem with a raft of nonlinguistic cognitive and motor abilities. The close developmental relationship between *gesture and language* (see Bates & Dick, 2002, for a review) appears to begin from around 6 months, with a correlation between the onset of babbling and the onset of rhythmic hand-banging. Toward the end of the first year, first word comprehension tends to co-occur with the start of deictic gestures (e.g., pointing and showing gestures) and gestural routines (e.g., waving goodbye; Bates, Benigni, Bretherton, Camaioni, & Volterra, 1977). In a similar vein, the later onset of productive vocabulary also co-occurs with—or is slightly preceded by—early recognitory gestures, such as putting a phone to the ear or a brush to hair (Volterra, Bates, Benigni, Bretherton, & Camaioni, 1979).

The ability to consistently imitate both behavioral and vocal cues does not seem to develop until

approximately 18 months (Jones, 2009). Interestingly, imitation in the form of repeating words emerges between 16 and 25 months and seems relatively stable despite language developing across this time (Bloom, Hood, & Lighbown, 1974). However, which words are imitated changes over time, with infants largely imitating words they do not know (i.e., would not produce spontaneously) and, then, once imitated enough, these words become part of spontaneous speech (Bloom et al., 1974). Motor skills are also related to some of the first forms of social communication, such as nonverbal requesting, initiating joint attention, and responding to joint attention. Impairment in any of these fundamental components could interfere with the foundations of interpersonal communication. Rhesus monkey infants who do not show imitative tongue protrusions are more likely to later develop stereotypes typical of those in human autism spectrum disorder (ASD) (Ferrari et al., 2009). Moreover, there is a negative correlation between the degree of tongue protrusion in infant imitation and language use in children with ASD (Gernsbacher, Sauer, Geye, Schweigert, & Goldsmith, 2008). Alcock and Krawczyk (2010) showed that oromotor control at 21 months is strongly associated with language production measures. The relationship between oromotor control and language production continues to be important through development. Using data from a large set of tasks tested on several samples of school-age children, Krishnan et al. (2013) found that oromotor praxis skills were the best predictor of nonword repetition skills, a key index of language proficiency.

Infants' word comprehension also shares a developmental trajectory similar to their understanding of familiar *environmental sounds* (i.e., meaningful, nonlinguistic sounds such as a cow mooing or a car starting). Cummings, Saygin, Bates, and Dick (2009) found that 15- to 25-month-old infants' accuracy in comprehending environmental sounds and spoken phrases was approximately equivalent (with a slight advantage for environmental sound recognition early in development). These results suggest that, in fact, speech does not appear to start out as being "privileged" as an acoustical transmitter of referential information.

During the course of development, the relationship between language, environmental sound comprehension, and gesture production changes as the infant gains more linguistic experience. Recognitory gesture is eclipsed by the exponential increase in a child's productive vocabulary as language "wins custody" over gesture as the prime means of expressive communication (Bates & Dick, 2002). Similarly, for environmental sound comprehension, infants with larger productive vocabularies show a significant accuracy advantage for comprehending spoken words over environmental sounds;

this advantage of words over environmental sounds is not revealed when infants are grouped by chronological age. Nonetheless, throughout the lifespan there remains a close relationship between language and gesture (Saygin, Dick, & Bates, 2005) and between language and environmental sound (Cummings, Ceponiene, Dick, Saygin, & Townsend; 2008; Cummings et al., 2006; Dick et al., 2007; Leech & Saygin, 2011; Saygin, Dick, Wilson, Dronkers, & Bates, 2003). In sum, language is not an isolated ability "fenced off" from the rest of cognition. Instead, language appears to emerge from the interactions of many domain-general cognitive processes, including memory, attention, object recognition and categorization, social and emotional abilities, as well as the nonlinguistic motor and acoustical abilities (Bates, Thal, Clancy, & Finlay, 2002). Language might best be described as a "*new machine constructed entirely out of old parts*" (Bates & MacWhinney, 1989).

31.5 RELATIONSHIP BETWEEN EARLY DEVELOPMENT AND LATER LANGUAGE ABILITIES

Development over the first 2 years of life has implications for later language abilities. For example, developmental changes in oro-facial movement speeds in infants between 9 and 21 months have been correlated with developmental advances in language and cognitive skill (Nip, Green, & Marx, 2011). Six-month-old infants' ability to discriminate two acoustically distinct vowels (/u/ and /y/) is correlated with language abilities at 13–24 months of age (Tsao, Liu, & Kuhl, 2004). Five-month-old infants who prefer listening to their native language stress pattern have larger vocabularies at 12 months (FERENCE & Curtin, 2013), and the amount of time 12-month-olds spend listening to speech is related to their vocabulary size at 18 months (Vouloumanos & Curtin, 2014). Speech segmentation abilities at 12 months correlate with expressive vocabulary at 24 months and language skills at 4–6 years (Newman, Ratner, Jusczyk, Jusczyk, & Dow, 2006). Ability to map minimally differing words in a word-object associative learning task (e.g., bih, dih; Stager & Werker, 1997) at 17 and 20 months is related to children's performance on standardized tests of language comprehension and production 2.5 years later (Bernhardt, Kemp, & Werker, 2007).

31.6 THE RELATIONSHIP BETWEEN VOCABULARY AND GRAMMAR

The sudden acceleration in vocabulary growth is accompanied or followed by the first two-word

FIGURE 31.4 Relationship between grammar and vocabulary size: variation within each vocabulary level. Reprinted from *Bates & Goodman, 1997* with permission from the publisher.

combinations at 18–20 months. Early word combinations mark the start of a second “burst” in the child’s abilities, this time in the realm of productive grammatical complexity.¹ As with previous language milestones, this rapid increase in syntactic sophistication does not occur in a vacuum. Rather, toddlers’ burgeoning syntactic abilities during the middle of the second year are closely yoked to their productive vocabularies—that is, *syntax is not independent from the lexicon* (Bates & Goodman, 1997).

Bates et al. (1988) found significant positive correlations between productive vocabulary size at 20–28 months and MLU² in the same period, with the strongest correlation between vocabulary at 20 months and MLU at 28 months—when the “average” child’s complex grammatical language is changing most rapidly. It is important to note that this tight synchronous and diachronous relationship between lexical size and grammatical complexity is not driven by a latent variable, like “maturation.” In this vein, Bates and Goodman (1997) used data from the large CDI norming study (Fenson et al., 1994) to demonstrate that total

vocabulary size correlated with grammatical complexity equally as strongly as grammatical complexity correlates with itself—and that this relationship held true when chronological age was partialled out. In fact, calculated over the entire CDI sample, hierarchical stepwise regressions revealed that age uniquely accounted for only 0.8% of the variance for grammatical complexity, whereas vocabulary size accounted for 32.3% of unique grammatical variance. These results suggest a law-like relationship whereby *total vocabulary size, irrespective of age, predicts grammatical complexity*. Furthermore, there is very little variability between individuals around this relationship—including in all but one clinical population where this question has been investigated (Figure 31.4).

Remarkably, the lawful relationship between grammar and the lexicon also appears to hold over languages, despite the fact that languages differ tremendously in terms of the morphosyntactic cues that provide “clues” to meaning. For example, in English the most reliable grammatical cue to agency (“who is doing what to whom”) is word order, whereas for

¹Note that in terms of comprehension, infants younger than 12 months old can discriminate patterns analogous to simple grammars (Gomez & Gerken, 1999).

²MLU is a frequently used measure of grammatical complexity calculated by taking the average number of morphemes (the smallest units of meaning) per phrase. MLU is a somewhat problematic measure for comparing children’s grammatical knowledge across ages and across languages (Bates et al., 1988). The CDI includes measures of grammatical complexity that have been normed across ages and languages, against benchmark laboratory studies, and so provide a more robust mechanism for investigating the grammar explosion seen in the third year.

some other languages (e.g., Italian), these sentential roles are often imparted through inflectional morphology. Prima facie, such languages show somewhat different grammatical developmental trajectories—for instance, in a highly inflected, regular, and transparent language like Turkish, the use of morphological particles is observed much earlier in development than in English (Slobin, 1985). However, this does not mean that the relation between the lexicon and syntax needs to be fundamentally different. The CDI has been used *cross-linguistically* to compare English and a language with rich inflectional morphology for tense, aspect, number, and gender—namely Italian. Despite the obvious differences in the languages, the same law-like predictive link between vocabulary size and grammatical complexity exists for Italian and English (Caselli, Casadio, & Bates, 1999), demonstrating the generality of this finding (Figure 31.2). The implication of this work is that grammar is not a completely separate process from word learning, nor does grammar simply require some word knowledge to get started. Instead, grammar and the lexicon are interwoven throughout early development.

31.7 THE NATURE OF CHILDREN'S EARLY GRAMMAR

One long-standing position in developmental psycholinguistics is that young children and adults fundamentally share the same syntactic “competence” (see Tomasello, 2000a for a detailed critical review). This “*continuity assumption*” is one offshoot of the theory that all human languages are built on a single innate universal grammar, with languages essentially differing only in the words they use (Pinker, 1989). An alternative developmental hypothesis postulates that children’s early syntax is item-based. That is, young children initially produce grammatical language not through the utilization of general and abstract linguistic structures (e.g., “subject,” “verb,” “noun”), but rather through reproduction and very conservative and gradual tweaking of individual and specific linguistic “constructions” that they have learned from others’ speech (Goldberg, 1995, 2006; Tomasello, 1992, 2000a, 2000b).

There is increasing evidence that at least some of *young children’s grammar is item-based*. A number of observational studies of children’s early language production (Pizutto & Caselli, 1992, 1994; Tomasello, 1992) have revealed that children’s early production of verbs does not reveal a systematic pattern of usage. Instead, young children produce many verbs in only a single form with no transfer of structure from verb to verb. For instance, for the verb “cut,” a child will only produce phrases of the form “cut__” (e.g., cut apple or cut bread).

This phenomenon, termed the “*verb island*” hypothesis (Tomasello, 1992), has been reported cross-linguistically (Pizutto & Caselli, 1992, 1994; Rubino & Pine, 1998).

Experimental studies have also investigated the item-based nature of early syntax by considering how well children produce novel verb constructions. In a series of studies, Tomasello and colleagues (see Tomasello, 2000a, 2000b for reviews) investigated what linguistic forms a 2- to 3-year-old child produces when given a novel verb to use in a variety of linguistic situations. For instance, if a novel verb like “tam” is only modeled for the child in intransitive form, will a child produce the transitive form of the verb given an appropriate context? These studies repeatedly demonstrate that before the age of approximately 3 years, children will generally base their verb productions on the input that they have heard. In other words, children will not transfer the transitive structure to a novel verb that they encountered in the intransitive form, even when explicitly asked to do so. Akhtar (1999) demonstrated an even more extreme example of how the *structure of the input* determines children’s linguistic productions. Exposing younger children (2- and 3-year-olds) to novel verbs in different word orders (i.e., subject verb object [SVO], SOV, and verb subject object [VSO]) led to framing the novel verb in ways that reflected the exposed verb order—even for non-canonical English word orders like SOV and VSO. In contrast, older children (at 4 years) generalized from their knowledge of SVO word order and used the novel verb only in a “canonical” English way, thus suggesting they were abstracting the verb away from its syntactic frame.

In general, these observational and experimental studies call into question the existence of abstract adult grammatical categories in children’s early syntactic development. These novel verb production studies also indicate that *early language is highly sensitive to statistical patterns in the ambient language* (e.g., the frequency of a word order, such as SVO, is a key determinant of its production by a child). Gradually, as the typical child develops, by 3–4 years of age that child will be increasingly able to generalize to novel verbs using existing templates such as the transitive SVO structure. However, it is important to note that these word-order preferences are not immutable; even college-age adults are exquisitely sensitive to changes in the relative frequency of word orders.

31.8 LANGUAGE DEVELOPMENT IN OLDER CHILDREN

Children by the age of 3–4 years are increasingly proficient language users with large productive

vocabularies, and they are able to fluently use and comprehend complex grammatical constructions (Bates & Goodman, 1997). However, this milestone does not mark the end of the development of language. Instead, *children's language abilities keep gradually improving into adolescence and beyond* (Nippold, 1998). One obvious area of improvement is vocabulary growth that continues throughout childhood, increasing by approximately 3,000 words per year (for a review see Graves, 1986). Similarly, auditory perception and speech perception continue to improve into adolescence (Ceponiene, Rinne, & Naatanen, 2002). Most surprisingly, perhaps, is that syntactic abilities also continue to develop into later life.

As with infants, school-age children remain sensitive to the frequency of syntactic constructions they hear. For instance, Huttenlocher, Vasilyeva, Cymerman, and Levine (2002) demonstrated that the proportion of complex syntactic constructions used by a child's primary school teacher predicts how well the child produces and understands difficult syntactic structures, over and above chronological age. Even approaching adolescence, children's syntactic comprehension can be demonstrated to vary from that of adults. Leech, Aydelott, Symons, Carnevale, and Dick (2007) explored children's (ages 5–17) and adults' (ages 18–51) comprehension of morphosyntactically diverse sentences under varying degrees of *attentional demands, auditory masking, and semantic interference*. The results indicated perceptual masking of the speech signal has an early and lasting impact on comprehension, particularly for more complex sentence structures, and that young children's syntactic comprehension is particularly vulnerable to disturbance. This study demonstrated not only that syntax follows an elongated developmental trajectory but also that other more general attentional and perceptual skills continue to play an important role in syntactic processing across the lifespan (see also Hayiou-Thomas, Bishop, & Plunkett, 2004).

31.9 NEURAL MEASURES OF LANGUAGE DEVELOPMENT

How is the child's brain reorganizing itself during this period of profound language development? A series of electrophysiological studies by Debra Mills and colleagues suggests that *"cerebral specialization for language emerges as a function of learning, and to some extent depends on the rate of learning"* (Sheehan & Mills, 2008). Mills and colleagues have shown that the relative lateralization of electrophysiological (EEG) components (P100, N200-400) during the first years of life is intimately related to language learning and expertise. In particular, the lateral distribution of the

N200-400 component for known versus unknown words is related to the overall size of the infant's vocabulary in a particular language. Conboy and Mills (2006) showed that in 20-month-old bilingual toddlers classified as having high or low total vocabulary sizes, the N200-400 difference between known versus unknown words was lateralized only in children with higher vocabularies, and only in their dominant language. Conversely, this known-versus-unknown word N200-400 difference was bilaterally distributed in the nondominant language and in the toddlers with lower total vocabulary. A similar finding was reported in a rapid-word-learning experiment by Mills, Plunkett, Prat, and Schafer (2005). Thus, changes in the large-scale topography of neural responses to words were driven by infants' expertise with words in general, as well as by their knowledge of specific word exemplars.

More generally, in their review of the infant and child EEG language literature, Sheehan and Mills (2008) point out that the relative *lateralization of EEG components changes dynamically over the lifespan*. As an example, they cite the case of the P1 component evoked in response to auditory stimuli, which shows an early left-lateralization from 3 months to 3 years, a symmetrical distribution from 6 to 12 years, and a right-lateralized distribution from 13 years into adulthood. The existence of such complex developmental trajectories demonstrates that any putative "early lateralization" for speech or language stimuli must be understood in the context of changes over the lifespan—a particularly important point for interpreting functional and structural magnetic resonance imaging (MRI) studies of language development.

Functional and structural MRI studies of language development are often directed at questions of relative lateralization (and regionalization) of function. In this vein, Perani et al. (2010, 2011) scanned newborn Italian infants (~2 days old) as speech and music stimuli were played to them. Among other results, the authors found that newborn infants showed a substantially *right-lateralized* response in primary and secondary auditory regions for naturally produced speech and music, whereas *altered* speech and music showed a bilateral or even slightly left-lateralized profile of activation. There is some indication that this early lateralization profile for passive language listening may vary in the first months of life. An fMRI study of 3-month-old infants listening to meaningful or reversed speech while asleep or awake reported more left-lateralized activity in the superior temporal and angular gyri (Dehaene-Lambertz, Dehaene, & Hertz-Pannier, 2002). In an fMRI study with 7-month-old infants, Blasi et al. (2011) showed that nonlinguistic vocalizations evoked greater bilateral but right-lateralized superior temporal gyrus and sulcus activation relative to nonvocal

environmental sounds. In terms of early underlying structural asymmetries related to language, O'Muircheartaigh et al. (2013) reported multiple age-contingent asymmetries in white matter myelination between ages 1 and 6 that were related to aspects of language proficiency as assessed by the Mullens Scales of Early Learning. In a study with early school-age children (ages 5–6), Brauer and Friederici (2007) showed that activation by passive sentence listening was somewhat less left-lateralized than for adults, but that children and adults were quite similar in their profile of perisylvian activation. Two early imaging studies of auditory language comprehension in young children also suggest that early language processing is predominantly bilateral, activating the inferior frontal gyrus (IFG) and the temporal cortices (Booth et al., 2000; Ulualp, Biswal, Yetkin, & Kidder, 1998).

Other developmental fMRI studies using language production have also focused on identifying patterns of language lateralization in individuals (Berl et al., 2014; Gaillard et al., 2004) over tasks (Bookheimer, Zeffiro, Blaxton, Gaillard, & Theodore, 2000; De Guibert et al., 2010; Lidzba, Schwilling, Grodd, Krägeloh-Mann, & Wilke, 2011) and over response modalities (Croft, Rankin, Liégeois, Banks, & Cross, 2013). By and large, developmental studies indicate that although most school-age children show left-lateralized responses, there are individual and task-dependent differences. Age-related changes in lateralization have also been described. For example, Szaflarski, Holland, Schmithorst, and Byars (2006) showed that neural activation for a covert verb generation task became increasingly left-lateralized between childhood and adolescence. In particular, age-related changes within so-called Broca's area have been a focus of many developmental language studies (reviewed in Berl et al., 2014). However, the conclusions that can be drawn appear to depend on the age range of the sample in question, as well as specific task demands. In general, studies that have used verbal fluency or categorization tasks tend to show age-related increases in activation over the left IFG (Holland et al., 2001), whereas studies using semantic association tasks tend to evoke differences over the right IFG (Booth et al., 2003; Chou et al., 2006). Yet other studies report that activation changes and increasing left-lateralization in the IFG are related to age (Berl et al., 2014) or performance (Bach et al., 2010; Blumenfeld, Booth, & Burman, 2006).

Much of what we know about the *neural development of language production* is based on a series of important developmental studies using well-characterized adult neuropsychological and/or fMRI language tasks. These include simple word repetition to an auditory cue (Church, Coalson, Lugar, Petersen, & Schlaggar,

2008), overt word reading (Church et al., 2008; Grande, Meffert, Huber, Amunts, & Heim, 2011; Heim et al., 2010; Schlaggar & McCandliss, 2007), word generation to a category (Gaillard et al., 2000, 2003) or more "metalinguistic" tasks such as verb, rhyme, or antonym generation to a read or heard cue word (Brown et al., 2005; Holland et al., 2001; Schapiro et al., 2004; Schlaggar et al., 2002; Szaflarski, Schmithorst, et al., 2006).

In a seminal study, Brown and colleagues (2005) studied a large group of children and adults performing overt word generation tasks (rhyme, verb, and opposite generation). By comparing adults and children with similar accuracy/reaction times on these tasks, they identified regions where age-related decreases (bilateral medial frontal, parietal, occipitotemporal, and cingulate cortex) and age-related increases in activity (left lateral and medial frontal regions) were observed. In contrast, by comparing adults and children whose performance differed, changes were noted over the right frontal cortex, medial parietal cortex, and posterior cingulate and occipital cortices bilaterally. These results were suggestive of increased activity in newly recruited regions such as frontal cortex over development and increased specialization of activity in earlier processing regions such as extrastriate cortex.

More recently, Krishnan, Leech, Mercure, Lloyd-Fox, and Dick (2014) used a picture naming fMRI paradigm with multiple levels of complexity to understand how school-age children (ages 7–12) and young adults responded to increasing processing demands. We found that neural organization for naming was largely similar in childhood and adulthood, where adults had greater activation in all naming conditions over inferior temporal gyri and superior temporal gyri/supramarginal gyri. However, naming complexity affected adults and children quite differently. Neural activation, especially over the dorsolateral prefrontal cortex but also in right posterior superior temporal sulcus (STS), showed complexity-dependent increases in adults but complexity-dependent *decreases* in children. These differences likely reflect adults' greater language repertoire, differential cognitive demands and strategies during word retrieval and production, as well as developmental changes in brain structure. It is clear that there must be considerable changes in the middle school and high school years in the neural organization for even fairly basic language production skills. In this vein, Ramsden et al. (2011) found that changes in individual subjects' verbal IQ between early and late adolescence were associated with changes in "gray matter density" in a left ventral somatomotor region where the same subjects also showed fMRI activation related to articulation.

Individual differences in language and grammatical ability have also been associated with activation for *comprehending* sentences. For instance, activation over the IFG for comprehending complex sentences correlates with individual differences in grammatical ability (Knoll, Obleser, Schipke, Friederici, & Brauer, 2012; Nuñez et al., 2011) and vocabulary knowledge (Yeatman, Ben-Shachar, Glover, & Feldman, 2010), rather than age.³ In a combined functional and structural MRI study with school-age children, adolescents, and adults, Richardson, Thomas, Filippi, Harth, and Price (2010) found that individual differences in vocabulary size were positively correlated with activation for auditory sentence comprehension in the left posterior STS and with “gray matter density” in the same region. These results suggest that the process of learning language significantly sculpts the networks underlying language processing, even quite late in development.

31.10 CONCLUSION

Language development is inherently a process of change. Exploring the multiple and varied trajectories of language can provide us with insights into the development of more general cognitive processes. Studies of language development have been particularly useful in helping us to understand the emergence of specialization of function and the scale and flexibility of cognitive processes during learning. Novel approaches and technologies for capturing the linguistic environment that the developing child grows up in (Greenwood, Thiemeann-Bourque, Walker, Buzhardt, & Gilkerson, 2011)—and for capturing what the child is saying (Oller et al., 2010)—should allow for more fleshed out theories and models of how language development actually works. Correspondingly, new tools for understanding brain structure (Dick et al., 2012; Glasser & Van Essen, 2011; Sereno, Lutti, Weiskopf, & Dick, 2013), development (Dosenbach et al., 2010), representation (Huth, Nishimoto, Vu, & Gallant, 2012) and learning (Wiestler & Diedrichsen, 2013) should allow us to make much finer-grained predictions about when, where, and how language development changes the brain.

Acknowledgments

The Neurobiology of Gesture and Its Development

Anthony Steven Dick and Iris Broce

Department of Psychology, Florida International University, Miami, FL, USA

The term gesture refers to the hand and arm movements that speakers routinely produce when they communicate, that occur naturally in face-to-face communication and that often accompany speech, and that play an important role in conveying a speaker's message (Goldin-Meadow, 2005; McNeill, 1992). The study of gesture has been important for understanding both thought and language, and the nature of the connection between them. The suggestion that symbolic gesture and spoken language are each pillars within a single semiotic system (Kelly, Ozyürek, & Maris, 2010; McNeill, 1992, 2005), that they develop together in children (Fenson et al., 1994), and that they share an overlapping neural substrate in the developing and adult brain (Bates & Dick, 2002) is supported by the research we review here. Moreover, the study of gesture and its development informs how we think about the neurobiology of language more generally.

32.1 EXPLORING GESTURE AND ITS DEVELOPMENT AT THE BEHAVIORAL LEVEL

To understand how the brain processes co-speech gesture, we must make distinctions among different types of gesture. There is a wealth of literature addressing these issues at the level of behavior, and this is expertly reviewed in a number of studies (Goldin-Meadow, 2005; Goldin-Meadow & Alibali, 2013; Kendon, 2004; McNeill, 1992, 2005). For our purposes, following the categorization outlined in McNeill (1992), we simply make some fundamental distinctions relevant to the neurobiology of gesture.

The first gesture types (at the “gesticulation” or “co-speech gesture” end of the continuum) are iconic and metaphoric gestures. Iconic gestures bear a formal relation to the content of speech, and they are most often understood only in the context of speech. For example, wiggling the fingers has a different meaning if it accompanies the sentence “She is quite the piano player” compared with “She tiptoed across the creaky floor.” These gestures can be complementary and reinforce the information in speech, as indicated in the example, or supplementary to add new information—“She is quite the musician” can be accompanied by the finger-tapping movement to indicate that the person plays the piano. In the second example, fully understanding the speaker's intended message requires the listener to integrate information from separate auditory (speech) and visual (gesture) modalities into a unitary, coherent semantic representation. Metaphoric gestures can similarly be integrated with speech but convey abstract rather than concrete objects or events.

Other gesture types contribute less in the way of semantic information. Beat (rhythmic) gestures most often indicate significance of an accompanying word or phrase. Deictic gestures are pointing gestures and serve as indicators for objects and events in the world. At the other end of the continuum are pantomimes and emblems, which rely less on speech (or sometimes not at all) to convey meaning and have more codified, socially regulated meanings. Pantomimes are sequences of movements or “mimes” conveying a narrative (e.g., moving the hand in front of the mouth in a particular manner to convey “brushing teeth”). Emblems are even more

standardized and have formalized meanings understood by viewers outside the context of speech (e.g., “Thumbs-up” for “It’s okay”). Signed language forms a third formalized category but is not discussed in this chapter because it represents a highly codified, autonomous system akin to spoken language.

Children and adults produce gestures and are able to glean meaning from gestures when other people produce them (Fenson et al., 1994; Goldin-Meadow & Alibali, 2013; Hostetter, 2011). However, there are also significant behavioral changes in gesture comprehension and production across childhood (Botting, Riches, Gaynor, & Morgan, 2010; Mohan & Helmer, 1988; Ozçalışkan & Goldin-Meadow, 2011; Stefanini, Bello, Caselli, Iverson, & Volterra, 2009). In fact, gesture development extends at least into later childhood and coincides with the development of language at multiple levels from earliest spoken word production to narrative comprehension.

Pointing and referential gestures are the first to appear, accompany, and often precede the emergence of spoken language, and they predict later spoken language ability (Acredolo & Goodwyn, 1988; Capirci, Iverson, Pizzuto, & Volterra, 1996; Iverson, Capirci, & Caselli, 1994; Morford & Goldin-Meadow, 1992; Rowe & Goldin-Meadow, 2009). During the preschool period, the ability to comprehend and produce symbolic or “representational” gestures (Göksun, Hirsh-Pasek, & Golinkoff, 2010; Kidd & Holler, 2009; Kumin & Lazar, 1974; McNeil, Alibali, & Evans, 2000; Mohan & Helmer, 1988) and pantomime (Boyatzis & Watson, 1993; Dick, Overton, & Kovacs, 2005; O’Reilly 1995; Overton & Jackson, 1973) emerges, and children begin to be able to use gestures to learn concepts (McGregor, Rohlfing, Bean, & Marschner, 2009). As children acquire more complex language abilities, gesture develops as well. During early and later childhood, children increasingly produce gestures to accompany narrative-level language (Colletta, Pellenq, & Guidetti, 2010; Demir, So, Ozyürek, & Goldin-Meadow, 2012; Riseborough 1982; So, Demir, & Goldin-Meadow, 2010) or to indicate knowledge (e.g., spatial knowledge; Sauter, Uttal, Alman, Goldin-Meadow, & Levine, 2012). Further, the ability to comprehend and take advantage of gestural information that accompanies spoken words (Thompson & Massaro, 1994), instructions (Church, Ayman-Nolley, & Mahootian, 2004; Goldin-Meadow, Kim, & Singer, 1999; Perry, Berch, & Singleton, 1995; Ping & Goldin-Meadow, 2008; Singer & Goldin-Meadow, 2005; Valenzeno, Alibali, & Klatzky, 2003), and narrative explanations (Kelly & Church, 1997, 1998) improves. Age-related changes in gesture are thus evidenced across childhood at multiple levels of language processing.

32.2 GESTURE AND ITS DEVELOPMENT IN THE CONTEXT OF A BROADER NEUROBIOLOGY OF LANGUAGE

The study of the neurobiology of gesture has been influenced by and has contributed to a revision of the classical model of the neurobiology of language (Poeppel, Emmorey, Hickok, & Pylkkänen, 2012). With the “shedding” of the classical model, a dual-stream “dorsal-ventral” model has emerged (Hickok & Poeppel, 2007; Rauschecker & Scott, 2009). Within the dorsal stream, fronto-temporo-parietal regions are proposed to be involved in mapping auditory speech sounds to articulatory (motor) representations (Hickok & Poeppel, 2007), or in processing complex syntax (Friederici & Gierhan, 2013). The major fiber pathway proposed to connect these regions is the superior longitudinal fasciculus/arcuate fasciculus. In contrast, the ventral stream is proposed to be involved in mapping auditory speech sounds to meaning (Hickok & Poeppel, 2007), or in processing less complex syntax (Friederici & Gierhan, 2013). A number of fiber pathways have been proposed to anchor the ventral stream, including the uncinate fasciculus, extreme capsule, middle longitudinal fasciculus, inferior occipitofrontal fasciculus, and inferior longitudinal fasciculus (Dick & Tremblay, 2012 for review). Co-speech gesture may recruit both streams to process semantic, phonological, or syntactic information in the accompanying speech. At the present time, the dorsal-ventral architecture is a promising framework in which to investigate how the adult and developing brain process gesture.

32.3 THE NEUROBIOLOGY OF GESTURE: ELECTROPHYSIOLOGY

Electrophysiological studies have contributed significantly to understanding how the brain processes gesture, with most of these studies investigating the N400 component when gesture and speech are presented together. This ERP response is thought to index semantic integration during language comprehension (Kutas & Federmeier, 2011). These studies manipulate the semantic relation between gesture and speech (e.g., present gestures that are semantically congruent or incongruent with speech) and have shown that the N400 is affected by these manipulations (Holle & Gunter, 2007; Kelly, Kravitz, & Hopkins, 2004; Kelly, Ward, Creigh, & Bartolotti, 2007; Özyürek, Willems, Kita, & Hagoort, 2007; Wang & Chu, 2013; Wu & Coulson, 2005, 2007a, 2007b). However, the source of the N400 in language and in gesture has been difficult

to determine, with some researchers emphasizing a left-lateralized temporo-parietal network (Friederici, Hahne, & von Cramon, 1998; Kwon et al., 2005; Simos, Basile, & Papanicolaou, 1997; Swaab, Brown, & Hagoort, 1997), and others suggesting a source in the inferior frontal gyrus (IFG) (Hagoort, Hald, Bastiaansen, & Petersson, 2004; Van Petten & Luka, 2006). Lau, Phillips, and Poeppel (2008) reviewed the literature on language without gesture and suggested that there is truth in both accounts. Specifically, they emphasized the contribution of the left IFG and left posterior middle temporal gyrus (MTGp) to processing semantic representations during language, with the left IFG proposed to be involved in semantic selection during retrieval, and the left MTGp proposed to be involved in lexical access/lexical storage. However, given the constraints on source localization, other functional imaging methods, such as magnetic resonance imaging (MRI), are necessary to characterize the brain regions that contribute to semantic processing during language comprehension.

32.4 THE NEUROBIOLOGY OF GESTURE: FUNCTIONAL IMAGING

32.4.1 Gesture Along the Ventral Stream

Within the broader dorsal-ventral model, the ventral stream is proposed to be involved in processing semantic information during language comprehension. Studies of gesture that have manipulated the semantic relation between co-speech gesture and speech have implicated the IFG (particularly the anterior *pars triangularis* but also more posterior *pars opercularis*; IFGTr and IFGOp), posterior superior temporal sulcus (STSp), and MTGp in gesture-speech integration at the semantic level (Dick, Goldin-Meadow, Hasson, Skipper, & Small, 2009; Dick, Goldin-Meadow, Solodkin, & Small, 2012; Dick, Mok, Beharelle, Goldin-Meadow, & Small, 2014; Green et al., 2009; Holle, Gunter, Rueschemeyer, Hennenlotter, & Iacoboni, 2008; Holle, Obleser, Rueschemeyer, & Gunter, 2010; Kircher et al., 2009; Skipper, Goldin-Meadow, Nusbaum, & Small, 2007, 2009; Straube, Green, Bromberger, & Kircher, 2011; Straube, Green, Jansen, Chatterjee, & Kircher, 2010; Straube, Green, Weis, Chatterjee, & Kircher, 2009; Straube, Green, Weis, & Kircher, 2012; Straube et al., 2013; Willems, Özyürek, & Hagoort, 2007, 2009; Wilson, Molnar-Szakacs, & Iacoboni, 2008).

These regions along the ventral stream, in particular left IFGTr and MTGp, are also implicated in semantic processing for receptive language that is not accompanied by gesture. Both regions are active when a

linguistic task requires activating and selecting among multiple potential meanings at the word (Hoening & Scheef, 2009) and sentence levels (Rodd, Davis, & Johnsrude, 2005; Zempleni, Renken, Hoeks, Hoogduin, & Stowe, 2007). The right hemisphere also makes contributions to language processing, particularly when demands on semantic selection are increased. For example, activity in the right IFGTr increases as a function of requirement for semantic selection among competing alternatives (Hein et al., 2007; Rodd et al., 2005), such as when the perceived spoken language requires considering multiple potential meanings (Lauro, Tettamanti, Cappa, & Papagno, 2008; Rodd et al., 2005; Stowe, Haverkort, & Zwarts, 2005; Zempleni et al., 2007).

Functional imaging studies in adults have also implicated these regions in processing the semantic relation between co-speech gestures and speech. For example, Willems et al. (2007) presented sentences accompanied by iconic gestures in which the gesture provided either congruent or incongruent information with speech (e.g., the verb “wrote” accompanied by a *hit* [incongruent] gesture or a *write* [congruent] gesture). Incongruent conditions elicited greater activity than the congruent conditions in the left inferior frontal gyrus (IFGTr). In a subsequent study, Willems et al. (2009) also showed that IFGTr responds more strongly to incongruent compared with congruent iconic gestures and pantomimes. Other studies report consistent results, suggesting the left IFG is recruited under conditions requiring additional semantic processing. For example, IFG responds more strongly to metaphoric gestures than to iconic gestures accompanying the same speech (Straube et al., 2011), and to iconic gestures that are unrelated to the accompanying speech (Green et al., 2009). Finally, Dick et al. (2014) found that the left IFGTr and IFGOp were more active when iconic gestures provided information supplementary compared with complementary to an accompanying narrative.

Sometimes the right IFG responds to manipulations of the semantic relation between gesture and speech (Dick et al., 2009; Straube et al., 2009, 2013). For example, Dick et al. (2009) presented spoken narratives accompanied by either meaningful iconic and metaphoric gestures or speech-unrelated self-adaptors (e.g., grooming movements such as pulling the shirt cuff). Although the left IFG was more active when hand movements accompanied speech compared to when it did not, this region did not respond differentially to meaningful iconic and metaphoric gestures compared with self-adaptors. In contrast, the right IFG responded more strongly when the hand movements were self-adaptors compared with gestures bearing a meaningful relation to speech. However, other

research failed to find any response of either left or right IFG. Holle et al. (2008) reported no differential response in IFG for gestures that supported the dominant versus the subordinate meaning of a homonym, nor did it show particular sensitivity to whether the hand movement was an iconic gesture or a grooming movement.

The posterior temporal cortex—namely the STSp and MTGp—also contributes to processing gesture. Holle et al. (2008, 2010) have suggested that STSp is responsive to semantic information in gestures; for example, this region was shown to respond more strongly to speech accompanied by meaningful gestures than to speech accompanied by nonmeaningful self-adaptive movements (Holle et al., 2008). Other studies have also reported sensitivity of STSp to semantic information in gestures, but in some cases it appears the activity is predominantly in the adjacent MTGp and extends into the STSp (Straube et al., 2011; Willems et al., 2009). In two studies, Dick et al. (2009) have directly addressed this issue using regions of interest (ROI) analysis defined according to the individual anatomy of participants. Examining the entire STSp (2009) and the upper and lower STSp banks separately (2014), Dick et al. showed that the bilateral STSp responds more strongly to speech with gestures than to speech alone, but it is not sensitive to the meaning relation between gesture and accompanying speech. They suggested that these findings are consistent with the region's putative involvement in processing biologically relevant motion (Beauchamp, Lee, Haxby, & Martin, 2003; Grossman et al., 2000) or with the lower-level integration of auditory and visual information during speech perception and comprehension.

The adjacent MTGp, however, does seem to be sensitive to semantic manipulations of the relation between gesture and speech. Straube et al. (2011) found that the MTGp extending into STSp responds to metaphoric and iconic gestures that are integrated with speech. Willems et al. (2009) reported that bilateral MTGp extending into STSp responded more to speech accompanied by incongruent pantomimes than to the same speech accompanied by congruent pantomimes, but they did not find that the region was sensitive to iconic gestures that were incongruent versus congruent with speech. They suggested that the MTGp/STSp is involved in mapping the information conveyed in gesture and speech onto a common object representation in long-term memory. That is, the MTGp is not involved in the construction of a novel representation as a result of combining information in the visual and auditory input streams. However, Dick et al. (2014) did find that blood oxygenation level-dependent (BOLD) signal amplitude in the MTGp is modulated by the semantic relation between

iconic gesture and speech. Like the left IFG, the left MTGp was more active for complementary compared with supplementary iconic gestures. The response of this region to gesture requires further investigation.

In summary, this brief review suggests that the IFG (especially the IFGTr) and MTGp have been the two regions most associated with semantic processing as part of the ventral stream in auditory language comprehension without gesture (Lau et al., 2008; Price, 2010; Vigneau et al., 2006 for review), and the same regions are implicated in gesture-speech integration. In Figure 32.1, we present a summary of these results focusing on activations in the inferior frontal and temporal lobes. Red and blue marked activation peaks represent a number of functional imaging studies that have manipulated semantic retrieval demands using similar paradigms used to assess N400 ERP responses during word, sentence, and narrative-level language comprehension (Bedny, McGill, & Thompson-Schill, 2008; Gennari, MacDonald, Postle, & Seidenberg, 2007; Giesbrecht, Camblin, & Swaab, 2004; Gold et al., 2006; Hoenig & Scheef, 2009; Kotz, Cappa, von Cramon, & Friederici, 2002; Matsumoto, Iidaka, Haneda, Okada, & Sadato, 2005; Rodd et al., 2005; Rossell, Price, & Nobre, 2003; Snijders et al., 2009; Wheatley, Weisberg, Beauchamp, & Martin, 2005; Whitney, Jefferies, & Kircher, 2011; Wible et al., 2006; Zempleni et al., 2007). For example, the typical study represented at the top of Figure 32.1 manipulated ambiguous versus unambiguous words or sentences, subordinate versus dominant concepts of homonyms, or high versus low demand for semantic retrieval.

Green marked activation peaks represent studies using similar manipulations for language produced with gesture. For example, the typical study represented manipulated whether gestures disambiguate the meaning of a homonym, whether they are semantically incongruent with or unrelated to the sentence context or a target word, or whether they supplemented versus complemented language in a narrative (Dick et al., 2009, 2012, 2014; Holle et al., 2008; Straube et al., 2011; Willems et al., 2007, 2009). The figure shows that the IFGTr and MTGp regions of the ventral language stream, particularly on the left but also on the right hemisphere, participate in processing semantic information from both gesture and speech and in the integration of the two modalities.

32.4.2 Gesture Along the Dorsal Stream

The notion that a perceiver's motor system is activated when watching another person performing actions—so-called observation-execution matching—is relatively uncontroversial. More controversial, though, is

Temporal and inferior frontal activation peaks
for semantic manipulations in speech and gesture

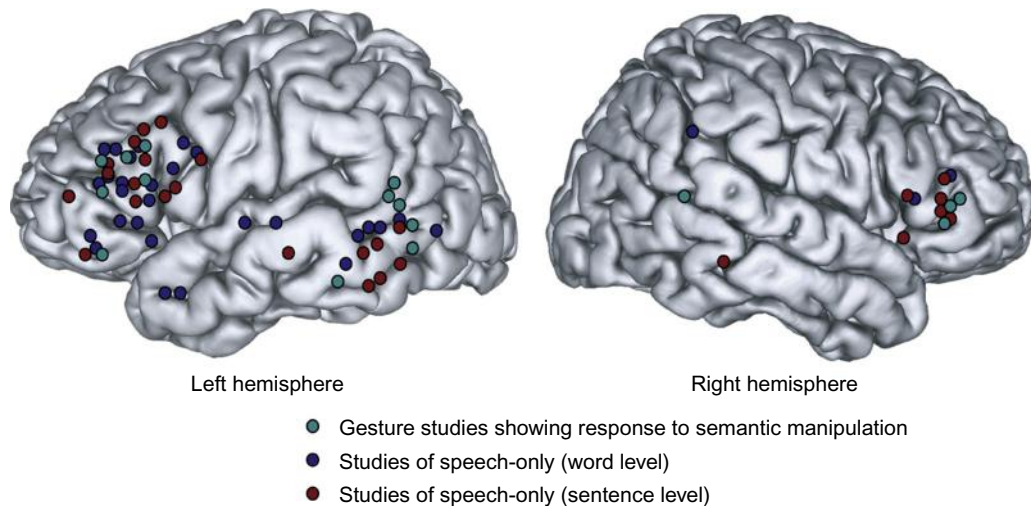

FIGURE 32.1 Temporal and inferior frontal activation peaks for semantic manipulations in speech and gesture. Red and blue marked activation peaks represent functional imaging studies that have manipulated semantic retrieval demands using similar paradigms used to assess N400 ERP responses during word-level and sentence-level language comprehension. Green marked activation peaks represent studies using similar manipulations for language produced with gesture. Only temporal and inferior frontal peaks are shown. Studies contributing to the figure are cited in the text.

the notion that understanding the meaning of actions is mediated, either in part or directly, through this motor system involvement (Kilner, 2011). Because gestures are observed actions, this controversy applies to gesture (Andric & Small, 2012; Willems & Hagoort, 2007).

Some behavioral evidence suggests that the motor system contributes to gesture understanding. For example, Ping, Goldin-Meadow, and Beilock (2013) found that moving the arms, but not the feet, interferes with gesture-speech integration, which implicates the motor system in understanding gesture at a semantic level. Behavioral literature suggesting that the motor system does *not* contribute to gesture understanding is more difficult to identify. The reason is that null findings in behavioral studies are difficult to publish (i.e., the “file-drawer problem”); consequently we were unable to find any that contributed to this side of the controversy. However, because null findings are published along with positive findings in neuroimaging, neuroimaging evidence provides one way to adjudicate this controversy.

Some studies have directly investigated this question (Holle et al., 2008; Skipper et al., 2007, 2009; Willems et al., 2007) with the expectation that premotor and inferior parietal regions along the dorsal stream, part of a putative “mirror neuron system” (Andric & Small, 2012; Kilner, 2011), would be sensitive to the semantic information contributed by gesture. For example, Skipper et al. (2009) reported that neural responses in premotor cortex and inferior

parietal cortex are “tuned” to the co-occurrence of meaningful gestures with speech, but not with non-meaningful gestures with speech. Holle et al. (2008) also showed that the premotor cortex and inferior parietal cortex fired more strongly when gestures were present compared with grooming movements. Similarly, Willems et al. (2007) showed that the bilateral premotor cortex was more active when iconic gestures were incongruent compared with congruent with an accompanying verb. Finally, Josse, Joseph, Bertasi, and Giraud (2012) found that the relation between gesture and speech modulated the BOLD response in the premotor cortex. The BOLD response was suppressed after repetition of a word accompanied by a congruent gesture (e.g., “grasp” + grasping gesture), but not when the same action word was accompanied by an incongruent gesture (e.g., “grasp” + sprinkle).

However, other studies have not found that the premotor cortex and/or inferior parietal cortices show sensitivity to gesture meaning. For example, several investigations (Dick et al., 2009, 2012, 2014; Green et al., 2009; Straube et al., 2011; Willems et al., 2009) failed to report significant age-related change or modulation of activity in response to gesture meaning in these premotor or inferior parietal cortices. In addition, in some cases the premotor and/or inferior parietal activity identified during gesture is also identified when the same participants view speech without gestures. For example, the age-related changes in the response of the premotor cortex to gesture that

Premotor and inferior parietal activation peaks
for observation of actions and gestures

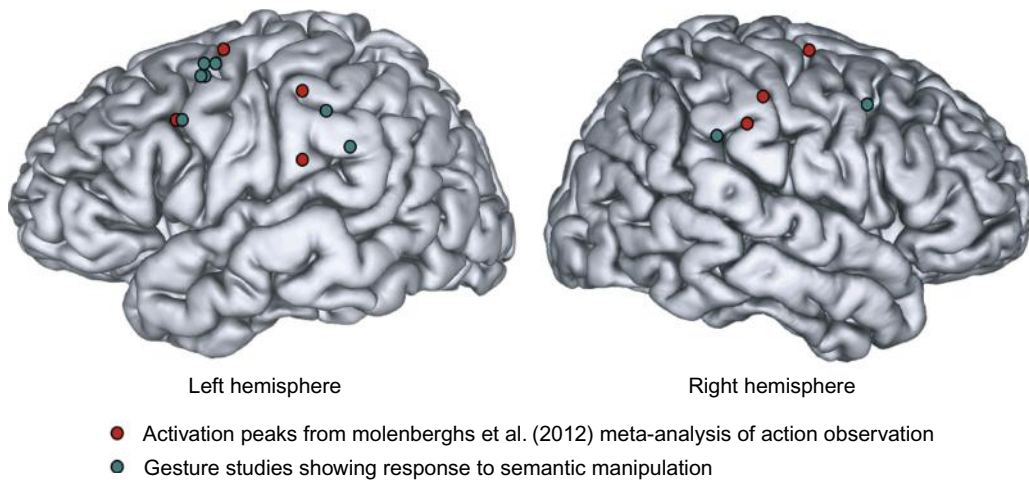

FIGURE 32.2 Premotor and inferior parietal activation peaks for studies of action observation and of gesture. Red marks show peaks identified by a meta-analysis of 125 studies of action observation (Molenberghs et al., 2012). Green marks show peaks of activation for studies in which premotor and inferior parietal regions indicated sensitivity to a semantic manipulation between gesture and speech. Studies contributing to the figure are cited in the text.

Wakefield, James, and James (2013) identified also occur for the speech-only condition without gestures, indicating that the response is not specific to processing gestures.

Other studies have suggested that the processing of motor and linguistic/semantic information in gesture can be dissociated in the brain. Thus, the evidence suggests that the motor system is recruited to process motor action information in gestures, but frontal and temporal regions contribute to processing linguistic/semantic aspects of gesture. Andric et al. (2013) investigated whether this is the case using fMRI while participants viewed two different kinds of hand actions—emblematic gestures (e.g., “thumbs-up!”) and grasping movements—or speech without gesture conveying the same meaning as the emblem (e.g., “It’s good!”). The results showed that when people observe emblems, regions of the brain involved in both observing grasping and listening to speech with the same meaning are active. Thus, lateral temporal (right MTGp and the anterior superior temporal gyrus) and inferior frontal (left IFGTr and IFGOp) were active in processing meaning, regardless of whether it was conveyed in gesture or speech (also see Xu, Gannon, Emmorey, Smith, & Braun, 2009). In contrast, premotor and inferior parietal regions were active in response to hand actions, regardless of whether the action was a grasping movement or an emblem. Thus, the motor system seems to contribute to processing gestures, but if it does contribute to processing meaning, then it does so in collaboration with brain regions also involved in processing linguistic aspects of gesture.

Studies of lesions provide further support for this notion. Mengotti et al. (2013) investigated the imitation of meaningful and meaningless gestures in people with left hemisphere stroke. They found that praxic performance and linguistic performance were associated when the gesture that needed to be imitated has meaning for the imitator, but they were dissociated when the gesture had no meaning. In other words, there is an overlap of brain regions underlying the linguistic abilities and the ability to imitate meaningful gestures (Andric et al., 2013). However, when the gestures are meaningless, they do not access the lexical semantic system; instead, they rely on visuo-motor processing. The authors suggested that this provides support for “two-pathway” models of processing gesture, and the recruitment of one or the other pathway may be determined by the specific kind of gesture and the context in which it occurs.

In summary, work continues to investigate whether and how the motor system contributes to understanding gesture at the semantic level. The answer to this question, as Mengotti et al. (2013) suggest, may depend on the specific kind of gesture, its relation to accompanying speech, and the context in which it is processed. In Figure 32.2, we summarize some of the relevant findings for premotor and inferior parietal regions. As Figure 32.2 shows, there is significant overlap for peaks of activity during observation of actions (as reviewed by Molenberghs, Cunnington, & Mattingley, 2012; red marks) and for manipulations of the semantic relationship between gesture and speech (green marks). Thus, premotor and parietal regions of

the dorsal stream appear to participate in processing gesture semantics in some situations.

32.5 THE NEUROBIOLOGY OF GESTURE DEVELOPMENT

To our knowledge, only one study has explored gesture development using electrophysiological measures. In this study, Sheehan, Namy, and Mills (2007) presented word-picture and gesture-picture pairs to 18-month-old and 26-month-old children while they conducted EEG recordings. For both word-picture and gesture-picture pairs, the 18-month-old children showed a larger N400 response if the word or gesture mismatched the picture compared with when it matched the picture. However, 26-month-old children showed the significant effect only for word-picture pairs, although the trend was in the same direction. Together, the evidence suggests that gestures affect semantic processing, at least in 18-month-old children. Whether this effect changes as children enter toddlerhood needs further investigation.

Only two studies have used functional imaging methods to study gesture in the developing brain. In the first study, Dick et al. (2012) investigated adults and 8-year-old to 11-year-old children in two conditions. In the first condition, participants watched a storyteller tell a story while making meaningful gestures; in the other condition, she told the story while making nonmeaningful self-adaptive movements. The same regions implicated in processing gestures with speech in adults—STSp, IFGTr, and MTGp—showed age-related differences in response to gestures. In the STSp, compared with children, adults showed a greater BOLD response for both the meaningful gesture and nonmeaningful adaptor condition—this region did not differentiate the meaning of the gesture but did activate more strongly for adults in response to hand movements. The right IFGTr and left MTGp, however, did show sensitivity to the manipulation of gesture meaning. In both regions, adults showed greater activity for nonmeaningful compared with meaningful gestures, whereas children showed the opposite pattern of activity. This difference in the pattern of activation may index developmental changes in how meaning from gesture is activated and selected within an accompanying linguistic context. Further, as in adults, the results implicate brain regions associated with the ventral stream for semantic processing during language comprehension.

In a second study of the neurobiology of gesture development, Wakefield et al. (2013) studied the comprehension of co-speech gestures in 5-year-olds, 7-year-olds, 10-year-olds, and adults. All participants

viewed a woman speaking a sentence with iconic content (e.g., the fingertips of right hand are placed together toward the mouth and spread apart as they are rotated away from mouth and outward, an action that accompanied the word “spoke”), speaking a sentence with iconic content and performing a corresponding iconic gesture, or performing a gesture in isolation. They showed that differences in activity in left MTGp between gesture and gesture and speech increased with age. Age-related differences were also detected in left precentral gyrus. This region was consistently recruited when adults viewed gestures, but it was not consistently recruited when children viewed gestures. The authors interpreted this finding to suggest that co-speech gesture production, which occurs with more frequency over the course of development and with which adults have more experience, contributes to the processing of co-speech gesture during perception. Notably, though, the same results were found for the speech-only condition without gesture; therefore, further research is needed to determine how motor regions contribute to gesture development.

In summary, although research on the neurobiology of gesture development is still emerging, there is the suggestion that the regions of both the ventral and dorsal streams involved in gesture processing in adults show age-related change. Further, there is the suggestion that the motor system contributes to the perception and understanding of gesture during development, but these findings need to be replicated in future studies.

32.6 CONCLUSION

The study of gesture and its development informs how we think about the neurobiology of language more broadly. Evidence from functional imaging in particular supports the dorsal-ventral model by showing that semantic processing of gestures influences activity in IFG and in MTGp regions of the ventral stream. Furthermore, in some situations the semantic contribution that gestures make influences activity in premotor and inferior parietal regions of the dorsal stream. This contributes to the emerging picture of how a broader language system processes communicative acts in multiple modalities.
