Names: Thorne, Kip S., author. | Blandford, Roger D., author.

Title: Modern classical physics : optics, fluids, plasmas, elasticity,
relativity, and statistical physics / Kip S. Thorne and Roger D. Blandford.

Description: Princeton : Princeton University Press, 2017. | Includes
bibliographical references and index.

Identifiers: LCCN 2014028150 | ISBN 9780691159027 (hardcover : alk. paper) |
ISBN 0691159025 (hardcover : alk. paper)

Subjects: LCSH: Physics.

Classification: LCC QC21.3 .T46 2015 | DDC 530—dc23

LC record available at <https://lccn.loc.gov/2014028150>

British Library Cataloging-in-Publication Data is available

This book has been composed in MinionPro, Whitney, and Ratio Modern using ZzT_EX by Windfall Software, Carlisle, Massachusetts

PART I FOUNDATIONS 1

1 Newtonian Physics: Geometric Viewpoint 5

1.1 Introduction 5

- 1.1.1 The Geometric Viewpoint on the Laws of Physics 5
- 1.1.2 Purposes of This Chapter 7
- 1.1.3 Overview of This Chapter 7

1.2 Foundational Concepts 8

1.3 Tensor Algebra without a Coordinate System 10

1.4 Particle Kinetics and Lorentz Force in Geometric Language 13

1.5 Component Representation of Tensor Algebra 16

- 1.5.1 Slot-Naming Index Notation 17
- 1.5.2 Particle Kinetics in Index Notation 19

1.6 Orthogonal Transformations of Bases 20

1.7 Differentiation of Scalars, Vectors, and Tensors; Cross Product and Curl 22

1.8 Volumes, Integration, and Integral Conservation Laws 26

- 1.8.1 Gauss's and Stokes' Theorems 27

1.9 The Stress Tensor and Momentum Conservation 29

- 1.9.1 Examples: Electromagnetic Field and Perfect Fluid 30
- 1.9.2 Conservation of Momentum 31

1.10 Geometrized Units and Relativistic Particles for Newtonian Readers 33

- 1.10.1 Geometrized Units 33
- 1.10.2 Energy and Momentum of a Moving Particle 34

Bibliographic Note 35

T2 Track Two; see page xxxiv
N Nonrelativistic (Newtonian) kinetic theory; see page 96
R Relativistic theory; see page 96

2	Special Relativity: Geometric Viewpoint	T2	37
2.1	Overview		37
2.2	Foundational Concepts		38
	2.2.1 Inertial Frames, Inertial Coordinates, Events, Vectors, and Spacetime Diagrams		38
	2.2.2 The Principle of Relativity and Constancy of Light Speed		42
	2.2.3 The Interval and Its Invariance		45
2.3	Tensor Algebra without a Coordinate System		48
2.4	Particle Kinetics and Lorentz Force without a Reference Frame		49
	2.4.1 Relativistic Particle Kinetics: World Lines, 4-Velocity, 4-Momentum and Its Conservation, 4-Force		49
	2.4.2 Geometric Derivation of the Lorentz Force Law		52
2.5	Component Representation of Tensor Algebra		54
	2.5.1 Lorentz Coordinates		54
	2.5.2 Index Gymnastics		54
	2.5.3 Slot-Naming Notation		56
2.6	Particle Kinetics in Index Notation and in a Lorentz Frame		57
2.7	Lorentz Transformations		63
2.8	Spacetime Diagrams for Boosts		65
2.9	Time Travel		67
	2.9.1 Measurement of Time; Twins Paradox		67
	2.9.2 Wormholes		68
	2.9.3 Wormhole as Time Machine		69
2.10	Directional Derivatives, Gradients, and the Levi-Civita Tensor		70
2.11	Nature of Electric and Magnetic Fields; Maxwell's Equations		71
2.12	Volumes, Integration, and Conservation Laws		75
	2.12.1 Spacetime Volumes and Integration		75
	2.12.2 Conservation of Charge in Spacetime		78
	2.12.3 Conservation of Particles, Baryon Number, and Rest Mass		79
2.13	Stress-Energy Tensor and Conservation of 4-Momentum		82
	2.13.1 Stress-Energy Tensor		82
	2.13.2 4-Momentum Conservation		84
	2.13.3 Stress-Energy Tensors for Perfect Fluids and Electromagnetic Fields		85
	Bibliographic Note		88

PART II STATISTICAL PHYSICS 91

3	Kinetic Theory	95
3.1	Overview	95
3.2	Phase Space and Distribution Function	97
	3.2.1 Newtonian Number Density in Phase Space, \mathcal{N}	97
	3.2.2 Relativistic Number Density in Phase Space, \mathcal{N}	99

3.2.3	Distribution Function $f(\mathbf{x}, \mathbf{v}, t)$ for Particles in a Plasma	105	N
3.2.4	Distribution Function I_ν/ν^3 for Photons	106	N R
3.2.5	Mean Occupation Number η	108	N R
3.3	Thermal-Equilibrium Distribution Functions	111	N R
3.4	Macroscopic Properties of Matter as Integrals over Momentum Space	117	
3.4.1	Particle Density n , Flux \mathbf{S} , and Stress Tensor \mathbf{T}	117	N
3.4.2	Relativistic Number-Flux 4-Vector \vec{S} and Stress-Energy Tensor \mathbf{T}	118	R T2
3.5	Isotropic Distribution Functions and Equations of State	120	
3.5.1	Newtonian Density, Pressure, Energy Density, and Equation of State	120	N
3.5.2	Equations of State for a Nonrelativistic Hydrogen Gas	122	N
3.5.3	Relativistic Density, Pressure, Energy Density, and Equation of State	125	R T2
3.5.4	Equation of State for a Relativistic Degenerate Hydrogen Gas	126	R T2
3.5.5	Equation of State for Radiation	128	N R
3.6	Evolution of the Distribution Function: Liouville's Theorem, the Collisionless Boltzmann Equation, and the Boltzmann Transport Equation	132	N R
3.7	Transport Coefficients	139	N
3.7.1	Diffusive Heat Conduction inside a Star	142	N
3.7.2	Order-of-Magnitude Analysis	143	N
3.7.3	Analysis Using the Boltzmann Transport Equation	144	N
	Bibliographic Note	153	
4	Statistical Mechanics	155	
4.1	Overview	155	
4.2	Systems, Ensembles, and Distribution Functions	157	
4.2.1	Systems	157	
4.2.2	Ensembles	160	
4.2.3	Distribution Function	161	
4.3	Liouville's Theorem and the Evolution of the Distribution Function	166	
4.4	Statistical Equilibrium	168	
4.4.1	Canonical Ensemble and Distribution	169	
4.4.2	General Equilibrium Ensemble and Distribution; Gibbs Ensemble; Grand Canonical Ensemble	172	
4.4.3	Fermi-Dirac and Bose-Einstein Distributions	174	
4.4.4	Equipartition Theorem for Quadratic, Classical Degrees of Freedom	177	
4.5	The Microcanonical Ensemble	178	
4.6	The Ergodic Hypothesis	180	
4.7	Entropy and Evolution toward Statistical Equilibrium	181	
4.7.1	Entropy and the Second Law of Thermodynamics	181	
4.7.2	What Causes the Entropy to Increase?	183	
4.8	Entropy per Particle	191	
4.9	Bose-Einstein Condensate	193	

4.10	Statistical Mechanics in the Presence of Gravity	201	T2
	4.10.1 Galaxies	201	T2
	4.10.2 Black Holes	204	T2
	4.10.3 The Universe	209	T2
	4.10.4 Structure Formation in the Expanding Universe: Violent Relaxation and Phase Mixing	210	T2
4.11	Entropy and Information	211	T2
	4.11.1 Information Gained When Measuring the State of a System in a Microcanonical Ensemble	211	T2
	4.11.2 Information in Communication Theory	212	T2
	4.11.3 Examples of Information Content	214	T2
	4.11.4 Some Properties of Information	216	T2
	4.11.5 Capacity of Communication Channels; Erasing Information from Computer Memories	216	T2
	Bibliographic Note	218	
5	Statistical Thermodynamics	219	
5.1	Overview	219	
5.2	Microcanonical Ensemble and the Energy Representation of Thermodynamics	221	
	5.2.1 Extensive and Intensive Variables; Fundamental Potential	221	
	5.2.2 Energy as a Fundamental Potential	222	
	5.2.3 Intensive Variables Identified Using Measuring Devices; First Law of Thermodynamics	223	
	5.2.4 Euler's Equation and Form of the Fundamental Potential	226	
	5.2.5 Everything Deducible from First Law; Maxwell Relations	227	
	5.2.6 Representations of Thermodynamics	228	
5.3	Grand Canonical Ensemble and the Grand-Potential Representation of Thermodynamics	229	
	5.3.1 The Grand-Potential Representation, and Computation of Thermodynamic Properties as a Grand Canonical Sum	229	
	5.3.2 Nonrelativistic van der Waals Gas	232	
5.4	Canonical Ensemble and the Physical-Free-Energy Representation of Thermodynamics	239	
	5.4.1 Experimental Meaning of Physical Free Energy	241	
	5.4.2 Ideal Gas with Internal Degrees of Freedom	242	
5.5	Gibbs Ensemble and Representation of Thermodynamics; Phase Transitions and Chemical Reactions	246	
	5.5.1 Out-of-Equilibrium Ensembles and Their Fundamental Thermodynamic Potentials and Minimum Principles	248	
	5.5.2 Phase Transitions	251	
	5.5.3 Chemical Reactions	256	
5.6	Fluctuations away from Statistical Equilibrium	260	

5.7	Van der Waals Gas: Volume Fluctuations and Gas-to-Liquid Phase Transition	266	
5.8	Magnetic Materials	270	T2
	5.8.1 Paramagnetism; The Curie Law	271	T2
	5.8.2 Ferromagnetism: The Ising Model	272	T2
	5.8.3 Renormalization Group Methods for the Ising Model	273	T2
	5.8.4 Monte Carlo Methods for the Ising Model	279	T2
	Bibliographic Note	282	
6	Random Processes	283	
6.1	Overview	283	
6.2	Fundamental Concepts	285	
	6.2.1 Random Variables and Random Processes	285	
	6.2.2 Probability Distributions	286	
	6.2.3 Ergodic Hypothesis	288	
6.3	Markov Processes and Gaussian Processes	289	
	6.3.1 Markov Processes; Random Walk	289	
	6.3.2 Gaussian Processes and the Central Limit Theorem; Random Walk	292	
	6.3.3 Doob's Theorem for Gaussian-Markov Processes, and Brownian Motion	295	
6.4	Correlation Functions and Spectral Densities	297	
	6.4.1 Correlation Functions; Proof of Doob's Theorem	297	
	6.4.2 Spectral Densities	299	
	6.4.3 Physical Meaning of Spectral Density, Light Spectra, and Noise in a Gravitational Wave Detector	301	
	6.4.4 The Wiener-Khintchine Theorem; Cosmological Density Fluctuations	303	
6.5	2-Dimensional Random Processes	306	T2
	6.5.1 Cross Correlation and Correlation Matrix	306	T2
	6.5.2 Spectral Densities and the Wiener-Khintchine Theorem	307	T2
6.6	Noise and Its Types of Spectra	308	
	6.6.1 Shot Noise, Flicker Noise, and Random-Walk Noise; Cesium Atomic Clock	308	
	6.6.2 Information Missing from Spectral Density	310	
6.7	Filtering Random Processes	311	
	6.7.1 Filters, Their Kernels, and the Filtered Spectral Density	311	
	6.7.2 Brownian Motion and Random Walks	313	
	6.7.3 Extracting a Weak Signal from Noise: Band-Pass Filter, Wiener's Optimal Filter, Signal-to-Noise Ratio, and Allan Variance of Clock Noise	315	
	6.7.4 Shot Noise	321	
6.8	Fluctuation-Dissipation Theorem	323	
	6.8.1 Elementary Version of the Fluctuation-Dissipation Theorem; Langevin Equation, Johnson Noise in a Resistor, and Relaxation Time for Brownian Motion	323	
	6.8.2 Generalized Fluctuation-Dissipation Theorem; Thermal Noise in a Laser Beam's Measurement of Mirror Motions; Standard Quantum Limit for Measurement Accuracy and How to Evade It	331	T2

- 6.9 Fokker-Planck Equation 335
 - 6.9.1 Fokker-Planck for a 1-Dimensional Markov Process 336
 - 6.9.2 Optical Molasses: Doppler Cooling of Atoms 340 T2
 - 6.9.3 Fokker-Planck for a Multidimensional Markov Process; Thermal Noise
in an Oscillator 343 T2
- Bibliographic Note 345

PART III OPTICS 347

- 7 Geometric Optics 351**
 - 7.1 Overview 351
 - 7.2 Waves in a Homogeneous Medium 352
 - 7.2.1 Monochromatic Plane Waves; Dispersion Relation 352
 - 7.2.2 Wave Packets 354
 - 7.3 Waves in an Inhomogeneous, Time-Varying Medium: The Eikonal Approximation and Geometric Optics 357
 - 7.3.1 Geometric Optics for a Prototypical Wave Equation 358
 - 7.3.2 Connection of Geometric Optics to Quantum Theory 362
 - 7.3.3 Geometric Optics for a General Wave 366
 - 7.3.4 Examples of Geometric-Optics Wave Propagation 368
 - 7.3.5 Relation to Wave Packets; Limitations of the Eikonal Approximation and Geometric Optics 369
 - 7.3.6 Fermat's Principle 371
 - 7.4 Paraxial Optics 375
 - 7.4.1 Axisymmetric, Paraxial Systems: Lenses, Mirrors, Telescopes, Microscopes, and Optical Cavities 377
 - 7.4.2 Converging Magnetic Lens for Charged Particle Beam 381
 - 7.5 Catastrophe Optics 384 T2
 - 7.5.1 Image Formation 384 T2
 - 7.5.2 Aberrations of Optical Instruments 395 T2
 - 7.6 Gravitational Lenses 396 T2
 - 7.6.1 Gravitational Deflection of Light 396 T2
 - 7.6.2 Optical Configuration 397 T2
 - 7.6.3 Microlensing 398 T2
 - 7.6.4 Lensing by Galaxies 401 T2
 - 7.7 Polarization 405
 - 7.7.1 Polarization Vector and Its Geometric-Optics Propagation Law 405
 - 7.7.2 Geometric Phase 406 T2
 - Bibliographic Note 409

8	Diffraction	411
8.1	Overview	411
8.2	Helmholtz-Kirchhoff Integral	413
	8.2.1 Diffraction by an Aperture	414
	8.2.2 Spreading of the Wavefront: Fresnel and Fraunhofer Regions	417
8.3	Fraunhofer Diffraction	420
	8.3.1 Diffraction Grating	422
	8.3.2 Airy Pattern of a Circular Aperture: Hubble Space Telescope	425
	8.3.3 Babinet's Principle	428
8.4	Fresnel Diffraction	429
	8.4.1 Rectangular Aperture, Fresnel Integrals, and the Cornu Spiral	430
	8.4.2 Unobscured Plane Wave	432
	8.4.3 Fresnel Diffraction by a Straight Edge: Lunar Occultation of a Radio Source	432
	8.4.4 Circular Apertures: Fresnel Zones and Zone Plates	434
8.5	Paraxial Fourier Optics	436
	8.5.1 Coherent Illumination	437
	8.5.2 Point-Spread Functions	438
	8.5.3 Abbé's Description of Image Formation by a Thin Lens	439
	8.5.4 Image Processing by a Spatial Filter in the Focal Plane of a Lens: High-Pass, Low-Pass, and Notch Filters; Phase-Contrast Microscopy	441
	8.5.5 Gaussian Beams: Optical Cavities and Interferometric Gravitational-Wave Detectors	445
8.6	Diffraction at a Caustic	451
	Bibliographic Note	454
9	Interference and Coherence	455
9.1	Overview	455
9.2	Coherence	456
	9.2.1 Young's Slits	456
	9.2.2 Interference with an Extended Source: Van Cittert-Zernike Theorem	459
	9.2.3 More General Formulation of Spatial Coherence; Lateral Coherence Length	462
	9.2.4 Generalization to 2 Dimensions	463
	9.2.5 Michelson Stellar Interferometer; Astronomical Seeing	464
	9.2.6 Temporal Coherence	472
	9.2.7 Michelson Interferometer and Fourier-Transform Spectroscopy	474
	9.2.8 Degree of Coherence; Relation to Theory of Random Processes	477
9.3	Radio Telescopes	479
	9.3.1 Two-Element Radio Interferometer	479
	9.3.2 Multiple-Element Radio Interferometers	480
	9.3.3 Closure Phase	481
	9.3.4 Angular Resolution	482

9.4	Etalons and Fabry-Perot Interferometers	483	
	9.4.1 Multiple-Beam Interferometry; Etalons	483	
	9.4.2 Fabry-Perot Interferometer and Modes of a Fabry-Perot Cavity with Spherical Mirrors	490	
	9.4.3 Fabry-Perot Applications: Spectrometer, Laser, Mode-Cleaning Cavity, Beam-Shaping Cavity, PDH Laser Stabilization, Optical Frequency Comb	496	T2
9.5	Laser Interferometer Gravitational-Wave Detectors	502	T2
9.6	Power Correlations and Photon Statistics: Hanbury Brown and Twiss Intensity Interferometer	509	
	Bibliographic Note	512	
10	Nonlinear Optics	513	
10.1	Overview	513	
10.2	Lasers	515	
	10.2.1 Basic Principles of the Laser	515	
	10.2.2 Types of Lasers and Their Performances and Applications	519	
	10.2.3 Ti:Sapphire Mode-Locked Laser	520	
	10.2.4 Free Electron Laser	521	
10.3	Holography	521	
	10.3.1 Recording a Hologram	522	
	10.3.2 Reconstructing the 3-Dimensional Image from a Hologram	525	
	10.3.3 Other Types of Holography; Applications	527	
10.4	Phase-Conjugate Optics	531	
10.5	Maxwell's Equations in a Nonlinear Medium; Nonlinear Dielectric Susceptibilities; Electro-Optic Effects	536	
10.6	Three-Wave Mixing in Nonlinear Crystals	540	
	10.6.1 Resonance Conditions for Three-Wave Mixing	540	
	10.6.2 Three-Wave-Mixing Evolution Equations in a Medium That Is Dispersion-Free and Isotropic at Linear Order	544	
	10.6.3 Three-Wave Mixing in a Birefringent Crystal: Phase Matching and Evolution Equations	546	T2
10.7	Applications of Three-Wave Mixing: Frequency Doubling, Optical Parametric Amplification, and Squeezed Light	553	
	10.7.1 Frequency Doubling	553	
	10.7.2 Optical Parametric Amplification	555	
	10.7.3 Degenerate Optical Parametric Amplification: Squeezed Light	556	
10.8	Four-Wave Mixing in Isotropic Media	558	
	10.8.1 Third-Order Susceptibilities and Field Strengths	558	
	10.8.2 Phase Conjugation via Four-Wave Mixing in CS ₂ Fluid	559	
	10.8.3 Optical Kerr Effect and Four-Wave Mixing in an Optical Fiber	562	
	Bibliographic Note	564	

11 Elastostatics 567

- 11.1 Overview 567
- 11.2 Displacement and Strain 570
 - 11.2.1 Displacement Vector and Its Gradient 570
 - 11.2.2 Expansion, Rotation, Shear, and Strain 571
- 11.3 Stress, Elastic Moduli, and Elastostatic Equilibrium 577
 - 11.3.1 Stress Tensor 577
 - 11.3.2 Realm of Validity for Hooke's Law 580
 - 11.3.3 Elastic Moduli and Elastostatic Stress Tensor 580
 - 11.3.4 Energy of Deformation 582
 - 11.3.5 Thermoelasticity 584
 - 11.3.6 Molecular Origin of Elastic Stress; Estimate of Moduli 585
 - 11.3.7 Elastostatic Equilibrium: Navier-Cauchy Equation 587
- 11.4 Young's Modulus and Poisson's Ratio for an Isotropic Material: A Simple Elastostatics Problem 589
- 11.5 Reducing the Elastostatic Equations to 1 Dimension for a Bent Beam: Cantilever Bridge, Foucault Pendulum, DNA Molecule, Elastica 592
- 11.6 Buckling and Bifurcation of Equilibria 602
 - 11.6.1 Elementary Theory of Buckling and Bifurcation 602
 - 11.6.2 Collapse of the World Trade Center Buildings 605
 - 11.6.3 Buckling with Lateral Force; Connection to Catastrophe Theory 606
 - 11.6.4 Other Bifurcations: Venus Fly Trap, Whirling Shaft, Triaxial Stars, and Onset of Turbulence 607
- 11.7 Reducing the Elastostatic Equations to 2 Dimensions for a Deformed Thin Plate: Stress Polishing a Telescope Mirror 609
- 11.8 Cylindrical and Spherical Coordinates: Connection Coefficients and Components of the Gradient of the Displacement Vector 614
- 11.9 Solving the 3-Dimensional Navier-Cauchy Equation in Cylindrical Coordinates 619
 - 11.9.1 Simple Methods: Pipe Fracture and Torsion Pendulum 619
 - 11.9.2 Separation of Variables and Green's Functions: Thermoelastic Noise in Mirrors 622
- Bibliographic Note 627

12 Elastodynamics 629

- 12.1 Overview 629
- 12.2 Basic Equations of Elastodynamics; Waves in a Homogeneous Medium 630
 - 12.2.1 Equation of Motion for a Strained Elastic Medium 630
 - 12.2.2 Elastodynamic Waves 636
 - 12.2.3 Longitudinal Sound Waves 637

	12.2.4 Transverse Shear Waves	638
	12.2.5 Energy of Elastodynamic Waves	640
12.3	Waves in Rods, Strings, and Beams	642
	12.3.1 Compression Waves in a Rod	643
	12.3.2 Torsion Waves in a Rod	643
	12.3.3 Waves on Strings	644
	12.3.4 Flexural Waves on a Beam	645
	12.3.5 Bifurcation of Equilibria and Buckling (Once More)	647
12.4	Body Waves and Surface Waves—Seismology and Ultrasound	648
	12.4.1 Body Waves	650
	12.4.2 Edge Waves	654
	12.4.3 Green’s Function for a Homogeneous Half-Space	658
	12.4.4 Free Oscillations of Solid Bodies	661
	12.4.5 Seismic Tomography	663
	12.4.6 Ultrasound; Shock Waves in Solids	663
12.5	The Relationship of Classical Waves to Quantum Mechanical Excitations	667
	Bibliographic Note	670

T2

PART V FLUID DYNAMICS 671

13	Foundations of Fluid Dynamics	675
13.1	Overview	675
13.2	The Macroscopic Nature of a Fluid: Density, Pressure, Flow Velocity; Liquids versus Gases	677
13.3	Hydrostatics	681
	13.3.1 Archimedes’ Law	684
	13.3.2 Nonrotating Stars and Planets	686
	13.3.3 Rotating Fluids	689
13.4	Conservation Laws	691
13.5	The Dynamics of an Ideal Fluid	695
	13.5.1 Mass Conservation	696
	13.5.2 Momentum Conservation	696
	13.5.3 Euler Equation	697
	13.5.4 Bernoulli’s Theorem	697
	13.5.5 Conservation of Energy	704
13.6	Incompressible Flows	709
13.7	Viscous Flows with Heat Conduction	710
	13.7.1 Decomposition of the Velocity Gradient into Expansion, Vorticity, and Shear	710
	13.7.2 Navier-Stokes Equation	711
	13.7.3 Molecular Origin of Viscosity	713
	13.7.4 Energy Conservation and Entropy Production	714

13.7.5	Reynolds Number	716	
13.7.6	Pipe Flow	716	
13.8	Relativistic Dynamics of a Perfect Fluid	719	T2
13.8.1	Stress-Energy Tensor and Equations of Relativistic Fluid Mechanics	719	T2
13.8.2	Relativistic Bernoulli Equation and Ultrarelativistic Astrophysical Jets	721	T2
13.8.3	Nonrelativistic Limit of the Stress-Energy Tensor	723	T2
	Bibliographic Note	726	
14	Vorticity	729	
14.1	Overview	729	
14.2	Vorticity, Circulation, and Their Evolution	731	
14.2.1	Vorticity Evolution	734	
14.2.2	Barotropic, Inviscid, Compressible Flows: Vortex Lines Frozen into Fluid	736	
14.2.3	Tornados	738	
14.2.4	Circulation and Kelvin's Theorem	739	
14.2.5	Diffusion of Vortex Lines	741	
14.2.6	Sources of Vorticity	744	
14.3	Low-Reynolds-Number Flow—Stokes Flow and Sedimentation	746	
14.3.1	Motivation: Climate Change	748	
14.3.2	Stokes Flow	749	
14.3.3	Sedimentation Rate	754	
14.4	High-Reynolds-Number Flow—Laminar Boundary Layers	757	
14.4.1	Blasius Velocity Profile Near a Flat Plate: Stream Function and Similarity Solution	758	
14.4.2	Blasius Vorticity Profile	763	
14.4.3	Viscous Drag Force on a Flat Plate	763	
14.4.4	Boundary Layer Near a Curved Surface: Separation	764	
14.5	Nearly Rigidly Rotating Flows—Earth's Atmosphere and Oceans	766	
14.5.1	Equations of Fluid Dynamics in a Rotating Reference Frame	767	
14.5.2	Geostrophic Flows	770	
14.5.3	Taylor-Proudman Theorem	771	
14.5.4	Ekman Boundary Layers	772	
14.6	Instabilities of Shear Flows—Billow Clouds and Turbulence in the Stratosphere	778	T2
14.6.1	Discontinuous Flow: Kelvin-Helmholtz Instability	778	T2

23 Nonlinear Dynamics of Plasmas 1111

- 23.1 Overview 1111
- 23.2 Quasilinear Theory in Classical Language 1113
 - 23.2.1 Classical Derivation of the Theory 1113
 - 23.2.2 Summary of Quasilinear Theory 1120
 - 23.2.3 Conservation Laws 1121
 - 23.2.4 Generalization to 3 Dimensions 1122
- 23.3 Quasilinear Theory in Quantum Mechanical Language 1123
 - 23.3.1 Plasmon Occupation Number η 1123
 - 23.3.2 Evolution of η for Plasmons via Interaction with Electrons 1124
 - 23.3.3 Evolution of f for Electrons via Interaction with Plasmons 1129
 - 23.3.4 Emission of Plasmons by Particles in the Presence of a Magnetic Field 1131
 - 23.3.5 Relationship between Classical and Quantum Mechanical Formalisms 1131
 - 23.3.6 Evolution of η via Three-Wave Mixing 1132
- 23.4 Quasilinear Evolution of Unstable Distribution Functions—A Bump in the Tail 1136
 - 23.4.1 Instability of Streaming Cosmic Rays 1138
- 23.5 Parametric Instabilities; Laser Fusion 1140
- 23.6 Solitons and Collisionless Shock Waves 1142
- Bibliographic Note 1149

PART VII GENERAL RELATIVITY 1151

24 From Special to General Relativity 1153

- 24.1 Overview 1153
- 24.2 Special Relativity Once Again 1153
 - 24.2.1 Geometric, Frame-Independent Formulation 1154
 - 24.2.2 Inertial Frames and Components of Vectors, Tensors, and Physical Laws 1156
 - 24.2.3 Light Speed, the Interval, and Spacetime Diagrams 1159
- 24.3 Differential Geometry in General Bases and in Curved Manifolds 1160
 - 24.3.1 Nonorthonormal Bases 1161

	24.3.2	Vectors as Directional Derivatives; Tangent Space; Commutators	1165
	24.3.3	Differentiation of Vectors and Tensors; Connection Coefficients	1169
	24.3.4	Integration	1174
24.4		The Stress-Energy Tensor Revisited	1176
24.5		The Proper Reference Frame of an Accelerated Observer	1180
	24.5.1	Relation to Inertial Coordinates; Metric in Proper Reference Frame; Transport Law for Rotating Vectors	1183
	24.5.2	Geodesic Equation for a Freely Falling Particle	1184
	24.5.3	Uniformly Accelerated Observer	1186
	24.5.4	Rindler Coordinates for Minkowski Spacetime	1187
		Bibliographic Note	1190

25 Fundamental Concepts of General Relativity 1191

25.1		History and Overview	1191
25.2		Local Lorentz Frames, the Principle of Relativity, and Einstein's Equivalence Principle	1195
25.3		The Spacetime Metric, and Gravity as a Curvature of Spacetime	1196
25.4		Free-Fall Motion and Geodesics of Spacetime	1200
25.5		Relative Acceleration, Tidal Gravity, and Spacetime Curvature	1206
	25.5.1	Newtonian Description of Tidal Gravity	1207
	25.5.2	Relativistic Description of Tidal Gravity	1208
	25.5.3	Comparison of Newtonian and Relativistic Descriptions	1210
25.6		Properties of the Riemann Curvature Tensor	1213
25.7		Delicacies in the Equivalence Principle, and Some Nongravitational Laws of Physics in Curved Spacetime	1217
	25.7.1	Curvature Coupling in the Nongravitational Laws	1218 T2
25.8		The Einstein Field Equation	1221
	25.8.1	Geometrized Units	1224
25.9		Weak Gravitational Fields	1224
	25.9.1	Newtonian Limit of General Relativity	1225
	25.9.2	Linearized Theory	1227
	25.9.3	Gravitational Field outside a Stationary, Linearized Source of Gravity	1231 T2
	25.9.4	Conservation Laws for Mass, Momentum, and Angular Momentum in Linearized Theory	1237 T2
	25.9.5	Conservation Laws for a Strong-Gravity Source	1238 T2

PREFACE

The study of physics (including astronomy) is one of the oldest academic enterprises. Remarkable surges in inquiry occurred in equally remarkable societies—in Greece and Egypt, in Mesopotamia, India and China—and especially in Western Europe from the late sixteenth century onward. Independent, rational inquiry flourished at the expense of ignorance, superstition, and obeisance to authority.

Physics is a constructive and progressive discipline, so these surges left behind layers of understanding derived from careful observation and experiment, organized by fundamental principles and laws that provide the foundation of the discipline today. Meanwhile the detritus of bad data and wrong ideas has washed away. The laws themselves were so general and reliable that they provided foundations for investigation far beyond the traditional frontiers of physics, and for the growth of technology.

The start of the twentieth century marked a watershed in the history of physics, when attention turned to the small and the fast. Although rightly associated with the names of Planck and Einstein, this turning point was only reached through the curiosity and industry of their many forerunners. The resulting quantum mechanics and relativity occupied physicists for much of the succeeding century and today are viewed very differently from each other. Quantum mechanics is perceived as an abrupt departure from the tacit assumptions of the past, while relativity—though no less radical conceptually—is seen as a logical continuation of the physics of Galileo, Newton, and Maxwell. There is no better illustration of this than Einstein’s growing special relativity into the general theory and his famous resistance to the quantum mechanics of the 1920s, which others were developing.

This is a book about classical physics—a name intended to capture the pre-quantum scientific ideas, augmented by general relativity. Operationally, it is physics in the limit that Planck’s constant $h \rightarrow 0$. Classical physics is sometimes used, pejoratively, to suggest that “classical” ideas were discarded and replaced by new principles and laws. Nothing could be further from the truth. The majority of applications of

physics today are still essentially classical. This does not imply that physicists or others working in these areas are ignorant or dismissive of quantum physics. It is simply that the issues with which they are confronted are mostly addressed classically. Furthermore, classical physics has not stood still while the quantum world was being explored. In scope and in practice, it has exploded on many fronts and would now be quite unrecognizable to a Helmholtz, a Rayleigh, or a Gibbs. In this book, we have tried to emphasize these contemporary developments and applications at the expense of historical choices, and this is the reason for our seemingly oxymoronic title, *Modern Classical Physics*.

This book is ambitious in scope, but to make it bindable and portable (and so the authors could spend some time with their families), we do not develop classical mechanics, electromagnetic theory, or elementary thermodynamics. We assume the reader has already learned these topics elsewhere, perhaps as part of an undergraduate curriculum. We also assume a normal undergraduate facility with applied mathematics. This allows us to focus on those topics that are less frequently taught in undergraduate and graduate courses.

Another important exclusion is numerical methods and simulation. High-performance computing has transformed modern research and enabled investigations that were formerly hamstrung by the limitations of special functions and artificially imposed symmetries. To do justice to the range of numerical techniques that have been developed—partial differential equation solvers, finite element methods, Monte Carlo approaches, graphics, and so on—would have more than doubled the scope and size of the book. Nonetheless, because numerical evaluations are crucial for physical insight, the book includes many applications and exercises in which user-friendly numerical packages (such as Maple, Mathematica, and Matlab) can be used to produce interesting numerical results without too much effort. We hope that, via this pathway from fundamental principle to computable outcome, our book will bring readers not only physical insight but also enthusiasm for computational physics.

Classical physics as we develop it emphasizes physical phenomena on macroscopic scales: scales where the particulate natures of matter and radiation are secondary to their behavior in bulk; scales where particles' statistical—as opposed to individual—properties are important, and where matter's inherent graininess can be smoothed over.

In this book, we take a journey through spacetime and phase space; through statistical and continuum mechanics (including solids, fluids, and plasmas); and through optics and relativity, both special and general. In our journey, we seek to comprehend the fundamental laws of classical physics in their own terms, and also in relation to quantum physics. And, using carefully chosen examples, we show how the classical laws are applied to important, contemporary, twenty-first-century problems and to everyday phenomena; and we also uncover some deep relationships among the various fundamental laws and connections among the practical techniques that are used in different subfields of physics.

Geometry is a deep theme throughout this book and a very important connector. We shall see how a few geometrical considerations dictate or strongly limit the basic principles of classical physics. Geometry illuminates the character of the classical principles and also helps relate them to the corresponding principles of quantum physics. Geometrical methods can also obviate lengthy analytical calculations. Despite this, long, routine algebraic manipulations are sometimes unavoidable; in such cases, we occasionally save space by invoking modern computational symbol manipulation programs, such as Maple, Mathematica, and Matlab.

This book is the outgrowth of courses that the authors have taught at Caltech and Stanford beginning 37 years ago. Our goal was then and remains now to fill what we saw as a large hole in the traditional physics curriculum, at least in the United States:

- We believe that every masters-level or PhD physicist should be familiar with the basic concepts of all the major branches of classical physics and should have had some experience in applying them to real-world phenomena; this book is designed to facilitate this goal.
- Many physics, astronomy, and engineering graduate students in the United States and around the world use classical physics extensively in their research, and even more of them go on to careers in which classical physics is an essential component; this book is designed to expedite their efforts.
- Many professional physicists and engineers discover, in mid-career, that they need an understanding of areas of classical physics that they had not previously mastered. This book is designed to help them fill in the gaps and see the relationship to already familiar topics.

In pursuit of this goal, we seek, in this book, to *give the reader a clear understanding of the basic concepts and principles of classical physics*. We present these principles in the language of modern physics (not nineteenth-century applied mathematics), and we present them primarily for physicists—though we have tried hard to make the content interesting, useful, and accessible to a much larger community including engineers, mathematicians, chemists, biologists, and so on. As far as possible, we emphasize theory that involves general principles which extend well beyond the particular topics we use to illustrate them.

In this book, we also seek to *teach the reader how to apply the ideas of classical physics*. We do so by presenting contemporary applications from a variety of fields, such as

- fundamental physics, experimental physics, and applied physics;
- astrophysics and cosmology;
- geophysics, oceanography, and meteorology;
- biophysics and chemical physics; and

- engineering, optical science and technology, radio science and technology, and information science and technology.

Why is the range of applications so wide? Because we believe that physicists should have enough understanding of general principles to attack problems that arise in unfamiliar environments. In the modern era, a large fraction of physics students will go on to careers outside the core of fundamental physics. For such students, a broad exposure to non-core applications can be of great value. For those who wind up in the core, such an exposure is of value culturally, and also because ideas from other fields often turn out to have impact back in the core of physics. Our examples illustrate how basic concepts and problem-solving techniques are freely interchanged across disciplines.

We strongly believe that classical physics should *not* be studied in isolation from quantum mechanics and its modern applications. Our reasons are simple:

- Quantum mechanics has primacy over classical physics. Classical physics is an approximation—often excellent, sometimes poor—to quantum mechanics.
- In recent decades, many concepts and mathematical techniques developed for quantum mechanics have been imported into classical physics and there used to enlarge our classical understanding and enhance our computational capability. An example that we shall study is nonlinearly interacting plasma waves, which are best treated as quanta (“plasmons”), despite their being solutions of classical field equations.
- Ideas developed initially for classical problems are frequently adapted for application to avowedly quantum mechanical subjects; examples (not discussed in this book) are found in supersymmetric string theory and in the liquid drop model of the atomic nucleus.

Because of these intimate connections between quantum and classical physics, quantum physics appears frequently in this book.

The amount and variety of material covered in this book may seem overwhelming. If so, keep in mind the key goals of the book: to teach the fundamental concepts, which are not so extensive that they should overwhelm, and to illustrate those concepts. Our goal is not to provide a mastery of the many illustrative applications contained in the book, but rather to convey the spirit of how to apply the basic concepts of classical physics. To help students and readers who feel overwhelmed, we have labeled as “Track Two” sections that can be skipped on a first reading, or skipped entirely—but are sufficiently interesting that many readers may choose to browse or study them. Track-Two sections are labeled by the symbol **T2**. To keep Track One manageable for a one-year course, the Track-One portion of each chapter is rarely longer than 40 pages (including many pages of exercises) and is often somewhat shorter. Track One is designed for a full-year course at the first-year graduate level; that is how we have

mostly used it. (Many final-year undergraduates have taken our course successfully, but rarely easily.)

The book is divided into seven parts:

- I. **Foundations**—which introduces our book’s powerful *geometric* point of view on the laws of physics and brings readers up to speed on some concepts and mathematical tools that we shall need. Many readers will already have mastered most or all of the material in Part I and might find that they can understand most of the rest of the book without adopting our avowedly geometric viewpoint. Nevertheless, we encourage such readers to browse Part I, at least briefly, before moving on, so as to become familiar with this viewpoint. We believe the investment will be repaid. Part I is split into two chapters, Chap. 1 on Newtonian physics and Chap. 2 on special relativity. Since nearly all of Parts II–VI is Newtonian, readers may choose to skip Chap. 2 and the occasional special relativity sections of subsequent chapters, until they are ready to launch into Part VII, General Relativity. Accordingly, Chap. 2 is labeled Track Two, though it becomes Track One when readers embark on Part VII.
- II. **Statistical Physics**—including kinetic theory, statistical mechanics, statistical thermodynamics, and the theory of random processes. These subjects underlie some portions of the rest of the book, especially plasma physics and fluid mechanics.
- III. **Optics**—by which we mean classical waves of all sorts: light waves, radio waves, sound waves, water waves, waves in plasmas, and gravitational waves. The major concepts we develop for dealing with all these waves include geometric optics, diffraction, interference, and nonlinear wave-wave mixing.
- IV. **Elasticity**—elastic deformations, both static and dynamic, of solids. Here we develop the use of tensors to describe continuum mechanics.
- V. **Fluid Dynamics**—with flows ranging from the traditional ones of air and water to more modern cosmic and biological environments. We introduce vorticity, viscosity, turbulence, boundary layers, heat transport, sound waves, shock waves, magnetohydrodynamics, and more.
- VI. **Plasma Physics**—including plasmas in Earth-bound laboratories and in technological (e.g., controlled-fusion) devices, Earth’s ionosphere, and cosmic environments. In addition to magnetohydrodynamics (treated in Part V), we develop two-fluid and kinetic approaches, and techniques of nonlinear plasma physics.
- VII. **General Relativity**—the physics of curved spacetime. Here we show how the physical laws that we have discussed in flat spacetime are modified to account for curvature. We also explain how energy and momentum

generate this curvature. These ideas are developed for their principal classical applications to neutron stars, black holes, gravitational radiation, and cosmology.

It should be possible to read and teach these parts independently, provided one is prepared to use the cross-references to access some concepts, tools, and results developed in earlier parts.

Five of the seven parts (II, III, V, VI, and VII) conclude with chapters that focus on applications where there is much current research activity and, consequently, there are many opportunities for physicists.

Exercises are a major component of this book. There are five types of exercises:

1. *Practice*. Exercises that provide practice at mathematical manipulations (e.g., of tensors).
2. *Derivation*. Exercises that fill in details of arguments skipped over in the text.
3. *Example*. Exercises that lead the reader step by step through the details of some important extension or application of the material in the text.
4. *Problem*. Exercises with few, if any, hints, in which the task of figuring out how to set up the calculation and get started on it often is as difficult as doing the calculation itself.
5. *Challenge*. Especially difficult exercises whose solution may require reading other books or articles as a foundation for getting started.

We urge readers to try working many of the exercises, especially the examples, which should be regarded as continuations of the text and which contain many of the most illuminating applications. Exercises that we regard as especially important are designated with **.

A few words on units and conventions. In this book we deal with practical matters and frequently need to have a quantitative understanding of the magnitudes of various physical quantities. This requires us to adopt a particular unit system. Physicists use both Gaussian and SI units; units that lie outside both formal systems are also commonly used in many subdisciplines. Both Gaussian and SI units provide a complete and internally consistent set for all of physics, and it is an often-debated issue as to which system is more convenient or aesthetically appealing. We will not enter this debate! One's choice of units should not matter, and a mature physicist should be able to change from one system to another with little thought. However, when learning new concepts, having to figure out "where the 2π s and 4π s go" is a genuine impediment to progress. Our solution to this problem is as follows. For each physics subfield that we study, we consistently use the set of units that seem most natural or that, we judge, constitute the majority usage by researchers in that subfield. We do not pedantically convert cm to m or vice versa at every juncture; we trust that the reader

can easily make whatever translation is necessary. However, where the equations are actually different—primarily in electromagnetic theory—we occasionally provide, in brackets or footnotes, the equivalent equations in the other unit system and enough information for the reader to proceed in his or her preferred scheme.

We encourage readers to consult this book's website, <http://press.princeton.edu/titles/MCP.html>, for information, errata, and various resources relevant to the book.

A large number of people have influenced this book and our viewpoint on the material in it. We list many of them and express our thanks in the Acknowledgments. Many misconceptions and errors have been caught and corrected. However, in a book of this size and scope, others will remain, and for these we take full responsibility. We would be delighted to learn of these from readers and will post corrections and explanations on this book's website when we judge them to be especially important and helpful.

Above all, we are grateful for the support of our wives, Carolee and Liz—and especially for their forbearance in epochs when our enterprise seemed like a mad and vain pursuit of an unreachable goal, a pursuit that we juggled with huge numbers of other obligations, while Liz and Carolee, in the midst of their own careers, gave us the love and encouragement that were crucial in keeping us going.

ACKNOWLEDGMENTS

This book evolved gradually from notes written in 1980–81, through improved notes, then sparse prose, and on into text that ultimately morphed into what you see today. Over these three decades and more, courses based on our evolving notes and text were taught by us and by many of our colleagues at Caltech, Stanford, and elsewhere. From those teachers and their students, and from readers who found our evolving text on the web and dove into it, we have received an extraordinary volume of feedback,¹ and also patient correction of errors and misconceptions as well as help with translating passages that were correct but impenetrable into more lucid and accessible treatments. For all this feedback and to all who gave it, we are extremely grateful. We wish that we had kept better records; the heartfelt thanks that we offer all these colleagues, students, and readers, named and unnamed, are deeply sincere.

Teachers who taught courses based on our evolving notes and text, and gave invaluable feedback, include Professors Richard Blade, Yanbei Chen, Michael Cross, Steven Frautschi, Peter Goldreich, Steve Koonin, Christian Ott, Sterl Phinney, David Politzer, John Preskill, John Schwarz, and David Stevenson at Caltech; Professors Tom Abel, Seb Doniach, Bob Wagoner, and Shoucheng Zhang at Stanford; and Professor Sandor Kovacs at Washington University in St. Louis.

Our teaching assistants, who gave us invaluable feedback on the text, improvements of exercises, and insights into the difficulty of the material for the students, include Jeffrey Atwell, Nate Bode, Yu Cao, Yi-Yuh Chen, Jane Dai, Alexei Dvoretzky, Fernando Echeverria, Jiyu Feng, Eanna Flanagan, Marc Goroff, Dan Grin, Arun Gupta, Alexandr Ikriannikov, Anton Kapustin, Kihong Kim, Hee-Won Lee, Geoffrey Lovelace, Miloje Makivic, Draza Markovic, Keith Matthews, Eric Moranson, Mike Morris, Chung-Yi Mou, Rob Owen, Yi Pan, Jaemo Park, Apoorva Patel, Alexander Putilin, Shuyan Qi, Soo Jong Rey, Fintan Ryan, Bonnie Shoemaker, Paul Simeon,

1. Specific applications that were originated by others, to the best of our memory, are acknowledged in the text.

Hidenori Sinoda, Matthew Stevenson, Wai Mo Suen, Marcus Teague, Guodang Wang, Xinkai Wu, Huan Yang, Jimmy Yee, Piljin Yi, Chen Zheng, and perhaps others of whom we have lost track!

Among the students and readers of our notes and text, who have corresponded with us, sending important suggestions and errata, are Bram Achterberg, Mustafa Amin, Richard Anantua, Alborz Bejnood, Edward Blandford, Jonathan Blandford, Dick Bond, Phil Bucksbaum, James Camparo, Conrado Cano, U Lei Chan, Vernon Chaplin, Mina Cho, Ann Marie Cody, Sandro Commandè, Kevin Fiedler, Krzysztof Findeisen, Jeff Graham, Casey Handmer, Ted Jacobson, Matt Kellner, Deepak Kumar, Andrew McClung, Yuki Moon, Evan O'Connor, Jeffrey Oishi, Keith Olive, Zhen Pan, Eric Peterson, Laurence Perreault Lévasseur, Vahbod Pourahmad, Andreas Reisenegger, David Reiss, Pavlin Savov, Janet Scheel, Yuki Takahashi, Fun Lim Yee, Yajie Yuan, and Aaron Zimmerman.

For computational advice or assistance, we thank Edward Campbell, Mark Scheel, Chris Mach, and Elizabeth Wood.

Academic support staff who were crucial to our work on this book include Christine Aguilar, JoAnn Boyd, Jennifer Formicelli, and Shirley Hampton.

The editorial and production professionals at Princeton University Press (Peter Dougherty, Karen Fortgang, Ingrid Gnerlich, Eric Henney, and Arthur Werneck) and at Princeton Editorial Associates (Peter Strupp and his freelance associates Paul Anagnostopoulos, Laurel Muller, MaryEllen Oliver, Joe Snowden, and Cyd Westmoreland) have been magnificent, helping us plan and design this book, and transforming our raw prose and primitive figures into a visually appealing volume, with sustained attention to detail, courtesy, and patience as we missed deadline after deadline.

Of course, we the authors take full responsibility for all the errors of judgment, bad choices, and mistakes that remain.

Roger Blandford thanks his many supportive colleagues at Caltech, Stanford University, and the Kavli Institute for Particle Astrophysics and Cosmology. He also acknowledges the Humboldt Foundation, the Miller Institute, the National Science Foundation, and the Simons Foundation for generous support during the completion of this book. And he also thanks the Berkeley Astronomy Department; Caltech; the Institute of Astronomy, Cambridge; and the Max Planck Institute for Astrophysics, Garching, for hospitality.

Kip Thorne is grateful to Caltech—the administration, faculty, students, and staff—for the supportive environment that made possible his work on this book, work that occupied a significant portion of his academic career.

FOUNDATIONS

In this book, a central theme will be a *Geometric Principle: The laws of physics must all be expressible as geometric (coordinate-independent and reference-frame-independent) relationships between geometric objects (scalars, vectors, tensors, . . .) that represent physical entities.*

There are three different conceptual frameworks for the classical laws of physics, and correspondingly, three different geometric arenas for the laws; see Fig. 1. General relativity is the most accurate classical framework; it formulates the laws as geometric relationships among geometric objects in the arena of curved 4-dimensional spacetime. Special relativity is the limit of general relativity in the complete absence of gravity; its arena is flat, 4-dimensional Minkowski spacetime.¹ Newtonian physics is the limit of general relativity when

- gravity is weak but not necessarily absent,
- relative speeds of particles and materials are small compared to the speed of light c , and
- all stresses (pressures) are small compared to the total density of mass-energy.

Its arena is flat, 3-dimensional Euclidean space with time separated off and made universal (by contrast with relativity's reference-frame-dependent time).

In Parts II–VI of this book (covering statistical physics, optics, elasticity, fluid mechanics, and plasma physics), we confine ourselves to the Newtonian formulations of the laws (plus special relativistic formulations in portions of Track Two), and accordingly, our arena will be flat Euclidean space (plus flat Minkowski spacetime in portions of Track Two). In Part VII, we extend many of the laws we have studied into the domain of strong gravity (general relativity)—the arena of curved spacetime.

1. This is so-called because Hermann Minkowski (1908) identified the special relativistic invariant interval as defining a metric in spacetime and elucidated the resulting geometry of flat spacetime.

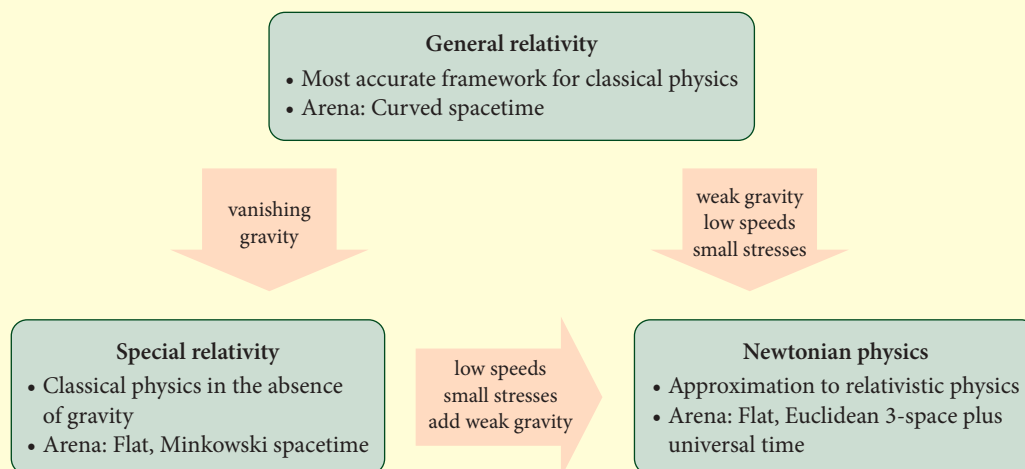

FIGURE 1 The three frameworks and arenas for the classical laws of physics and their relationship to one another.

In Parts II and III (on statistical physics and optics), in addition to confining ourselves to flat space (plus flat spacetime in Track Two), we avoid any sophisticated use of curvilinear coordinates. Correspondingly, when using coordinates in nontrivial ways, we confine ourselves to Cartesian coordinates in Euclidean space (and Lorentz coordinates in Minkowski spacetime).

Part I of this book contains just two chapters. Chapter 1 is an introduction to our geometric viewpoint on Newtonian physics and to all the geometric mathematical tools that we shall need in Parts II and III for Newtonian physics in its arena, 3-dimensional Euclidean space. Chapter 2 introduces our geometric viewpoint on special relativistic physics and extends our geometric tools into special relativity's arena, flat Minkowski spacetime. Readers whose focus is Newtonian physics will have no need for Chap. 2; and if they are already familiar with the material in Chap. 1 but not from our geometric viewpoint, they can successfully study Parts II–VI without reading Chap. 1. However, in doing so, they will miss some deep insights; so we recommend they at least browse Chap. 1 to get some sense of our viewpoint, then return to the chapter occasionally, as needed, when encountering an unfamiliar geometric argument.

In Parts IV, V, and VI, when studying elasticity, fluid dynamics, and plasma physics, we use curvilinear coordinates in nontrivial ways. As a foundation for this, at the beginning of Part IV, we extend our flat-space geometric tools to curvilinear coordinate systems (e.g., cylindrical and spherical coordinates). Finally, at the beginning of Part VII, we extend our geometric tools to the arena of curved spacetime.

Throughout this book, we pay close attention to the relationship between classical physics and quantum physics. Indeed, we often find it powerful to use quantum mechanical language or formalism when discussing and analyzing classical phenomena.

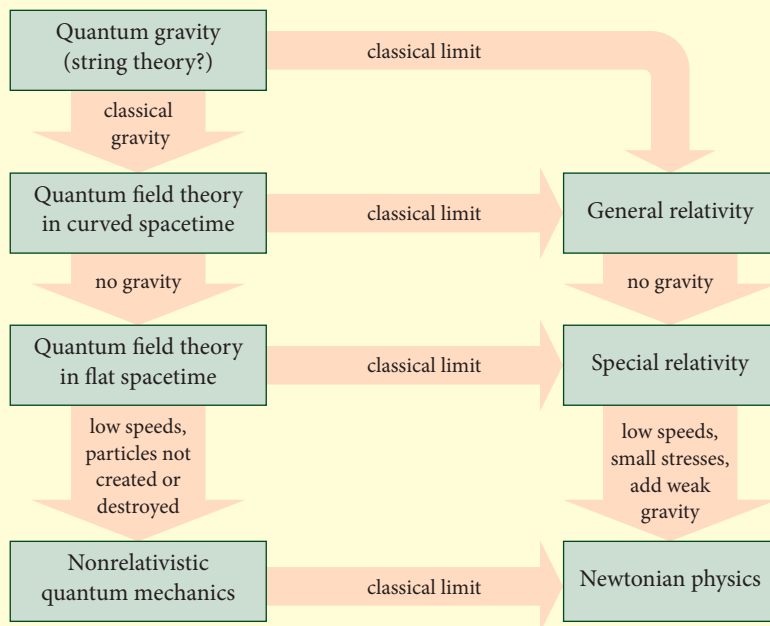

FIGURE 2 The relationship of the three frameworks for classical physics (on right) to four frameworks for quantum physics (on left). Each arrow indicates an approximation. All other frameworks are approximations to the ultimate laws of quantum gravity (whatever they may be—perhaps a variant of string theory).

This quantum power in classical domains arises because quantum physics is primary and classical physics is secondary. Today we see classical physics as arising from quantum physics, though historically the linkage was inverted. The relationship between quantum frameworks and arenas for the laws of physics, and classical frameworks, is sketched in Fig. 2.

Newtonian Physics: Geometric Viewpoint

Geometry postulates the solution of these problems from mechanics and teaches the use of the problems thus solved. And geometry can boast that with so few principles obtained from other fields, it can do so much.

ISAAC NEWTON, 1687

1.1 Introduction

1.1

1.1.1 The Geometric Viewpoint on the Laws of Physics

1.1.1

In this book, we adopt a different viewpoint on the laws of physics than that in many elementary and intermediate texts. In most textbooks, physical laws are expressed in terms of quantities (locations in space, momenta of particles, etc.) that are measured in some coordinate system. For example, Newtonian vectorial quantities are expressed as triplets of numbers [e.g., $\mathbf{p} = (p_x, p_y, p_z) = (1, 9, -4)$], representing the components of a particle's momentum on the axes of a Cartesian coordinate system; and tensors are expressed as arrays of numbers (e.g.,

$$\mathbf{I} = \begin{bmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{bmatrix} \quad (1.1)$$

for the moment of inertia tensor).

By contrast, in this book we express all physical quantities and laws in *geometric forms*, i.e., in forms that are *independent of any coordinate system or basis vectors*. For example, a particle's velocity \mathbf{v} and the electric and magnetic fields \mathbf{E} and \mathbf{B} that it encounters will be vectors described as arrows that live in the 3-dimensional, flat Euclidean space of everyday experience.¹ They require no coordinate system or basis vectors for their existence or description—though often coordinates will be useful. In other words, \mathbf{v} represents the vector itself and is not just shorthand for an ordered list of numbers.

1. This interpretation of a vector is close to the ideas of Newton and Faraday. Lagrange, Hamilton, Maxwell, and many others saw vectors in terms of Cartesian components. The vector notation was streamlined by Gibbs, Heaviside, and others, but the underlying coordinate system was still implicit, and \mathbf{v} was usually regarded as shorthand for (v_x, v_y, v_z) .

BOX 1.1. READERS' GUIDE

- This chapter is a foundation for almost all of this book.
- Many readers already know the material in this chapter, but from a viewpoint different from our *geometric* one. Such readers will be able to understand almost all of Parts II–VI of this book without learning our viewpoint. Nevertheless, that geometric viewpoint has such power that we encourage them to learn it by browsing this chapter and focusing especially on Secs. 1.1.1, 1.2, 1.3, 1.5, 1.7, and 1.8.
- The stress tensor, introduced and discussed in Sec. 1.9, plays an important role in kinetic theory (Chap. 3) and a crucial role in elasticity (Part IV), fluid dynamics (Part V), and plasma physics (Part VI).
- The integral and differential conservation laws derived and discussed in Secs. 1.8 and 1.9 play major roles throughout this book.
- The Box labeled **T2** is advanced material (Track Two) that can be skipped in a time-limited course or on a first reading of this book.

We insist that the Newtonian laws of physics all obey a *Geometric Principle*: they are all geometric relationships among geometric objects (primarily scalars, vectors, and tensors), expressible without the aid of any coordinates or bases. An example is the Lorentz force law $m d\mathbf{v}/dt = q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$ —a (coordinate-free) relationship between the geometric (coordinate-independent) vectors \mathbf{v} , \mathbf{E} , and \mathbf{B} and the particle's scalar mass m and charge q . As another example, a body's moment of inertia tensor \mathbf{I} can be viewed as a vector-valued linear function of vectors (a coordinate-independent, basis-independent geometric object). Insert into the tensor \mathbf{I} the body's angular velocity vector $\boldsymbol{\Omega}$, and you get out the body's angular momentum vector: $\mathbf{J} = \mathbf{I}(\boldsymbol{\Omega})$. No coordinates or basis vectors are needed for this law of physics, nor is any description of \mathbf{I} as a matrix-like entity with components I_{ij} required. Components are secondary; they only exist after one has chosen a set of basis vectors. Components (we claim) are an impediment to a clear and deep understanding of the laws of classical physics. The coordinate-free, component-free description is deeper, and—once one becomes accustomed to it—much more clear and understandable.²

2. This philosophy is also appropriate for quantum mechanics (see Box 1.2) and, especially, quantum field theory, where it is the invariance of the description under gauge and other symmetry operations that is the powerful principle. However, its implementation there is less direct, simply because the spaces in which these symmetries lie are more abstract and harder to conceptualize.

By adopting this geometric viewpoint, we gain great conceptual power and often also computational power. For example, when we ignore experiment and simply ask what forms the laws of physics can possibly take (what forms are allowed by the requirement that the laws be geometric), we shall find that there is remarkably little freedom. Coordinate independence and basis independence strongly constrain the laws of physics.³

This power, together with the elegance of the geometric formulation, suggests that in some deep sense, Nature's physical laws are geometric and have nothing whatsoever to do with coordinates or components or vector bases.

1.1.2 Purposes of This Chapter

1.1.2

The principal purpose of this foundational chapter is to teach the reader this geometric viewpoint.

The mathematical foundation for our geometric viewpoint is *differential geometry* (also called “tensor analysis” by physicists). Differential geometry can be thought of as an extension of the vector analysis with which all readers should be familiar. *A second purpose of this chapter is to develop key parts of differential geometry in a simple form well adapted to Newtonian physics.*

1.1.3 Overview of This Chapter

1.1.3

In this chapter, we lay the geometric foundations for the Newtonian laws of physics in flat Euclidean space. We begin in Sec. 1.2 by introducing some foundational geometric concepts: points, scalars, vectors, inner products of vectors, and the distance between points. Then in Sec. 1.3, we introduce the concept of a tensor as a linear function of vectors, and we develop a number of geometric tools: the tools of coordinate-free tensor algebra. In Sec. 1.4, we illustrate our tensor-algebra tools by using them to describe—without any coordinate system—the kinematics of a charged point particle that moves through Euclidean space, driven by electric and magnetic forces.

In Sec. 1.5, we introduce, for the first time, Cartesian coordinate systems and their basis vectors, and also the components of vectors and tensors on those basis vectors; and we explore how to express geometric relationships in the language of components. In Sec. 1.6, we deduce how the components of vectors and tensors transform when one rotates the chosen Cartesian coordinate axes. (These are the transformation laws that most physics textbooks use to define vectors and tensors.)

In Sec. 1.7, we introduce directional derivatives and gradients of vectors and tensors, thereby moving from tensor algebra to true differential geometry (in Euclidean space). We also introduce the Levi-Civita tensor and use it to define curls and cross

3. Examples are the equation of elastodynamics (12.4b) and the Navier-Stokes equation of fluid mechanics (13.69), which are both dictated by momentum conservation plus the form of the stress tensor [Eqs. (11.18), (13.43), and (13.68)]—forms that are dictated by the irreducible tensorial parts (Box 11.2) of the strain and rate of strain.

products, and we learn how to use *index gymnastics* to derive, quickly, formulas for multiple cross products. In Sec. 1.8, we use the Levi-Civita tensor to define vectorial areas, scalar volumes, and integration over surfaces. These concepts then enable us to formulate, in geometric, coordinate-free ways, integral and differential conservation laws. In Sec. 1.9, we discuss, in particular, the law of momentum conservation, formulating it in a geometric way with the aid of a geometric object called the *stress tensor*. As important examples, we use this geometric conservation law to derive and discuss the equations of Newtonian fluid dynamics, and the interaction between a charged medium and an electromagnetic field. We conclude in Sec. 1.10 with some concepts from special relativity that we shall need in our discussions of Newtonian physics.

1.2 Foundational Concepts

In this section, we sketch the foundational concepts of Newtonian physics without using any coordinate system or basis vectors. This is the geometric viewpoint that we advocate.

space and time

The arena for the Newtonian laws of physics is a spacetime composed of the familiar 3-dimensional Euclidean space of everyday experience (which we call *3-space*) and a universal time t . We denote points (locations) in 3-space by capital script letters, such as \mathcal{P} and \mathcal{Q} . These points and the 3-space in which they live require no coordinates for their definition.

scalar

A *scalar* is a single number. We are most interested in scalars that directly represent physical quantities (e.g., temperature T). As such, they are real numbers, and when they are functions of location \mathcal{P} in space [e.g., $T(\mathcal{P})$], we call them *scalar fields*. However, sometimes we will work with complex numbers—most importantly in quantum mechanics, but also in various Fourier representations of classical physics.

vector

A *vector* in Euclidean 3-space can be thought of as a straight arrow (or more formally a directed line segment) that reaches from one point, \mathcal{P} , to another, \mathcal{Q} (e.g., the arrow $\Delta\mathbf{x}$ in Fig. 1.1a). Equivalently, $\Delta\mathbf{x}$ can be thought of as a direction at \mathcal{P} and a number, the vector's length. Sometimes we shall select one point \mathcal{O} in 3-space as an “origin” and identify all other points, say, \mathcal{Q} and \mathcal{P} , by their vectorial separations $\mathbf{x}_{\mathcal{Q}}$ and $\mathbf{x}_{\mathcal{P}}$ from that origin.

distance and length

The Euclidean distance $\Delta\sigma$ between two points \mathcal{P} and \mathcal{Q} in 3-space can be measured with a ruler and so, of course, requires no coordinate system for its definition. (If one does have a Cartesian coordinate system, then $\Delta\sigma$ can be computed by the Pythagorean formula, a precursor to the invariant interval of flat spacetime; Sec. 2.2.3.) This distance $\Delta\sigma$ is also the *length* $|\Delta\mathbf{x}|$ of the vector $\Delta\mathbf{x}$ that reaches from \mathcal{P} to \mathcal{Q} , and the square of that length is denoted

$$|\Delta\mathbf{x}|^2 \equiv (\Delta\mathbf{x})^2 \equiv (\Delta\sigma)^2. \quad (1.2)$$

Of particular importance is the case when \mathcal{P} and \mathcal{Q} are neighboring points and $\Delta\mathbf{x}$ is a differential (infinitesimal) quantity $d\mathbf{x}$. This *infinitesimal displacement* is a more fundamental physical quantity than the finite $\Delta\mathbf{x}$. To create a finite vector out

FIGURE 1.1 (a) A Euclidean 3-space diagram depicting two points \mathcal{P} and \mathcal{Q} , their respective vectorial separations \mathbf{x}_P and \mathbf{x}_Q from the (arbitrarily chosen) origin \mathcal{O} , and the vector $\Delta \mathbf{x} = \mathbf{x}_Q - \mathbf{x}_P$ connecting them. (b) A curve $\mathcal{P}(\lambda)$ generated by laying out a sequence of infinitesimal vectors, tail-to-tip.

of infinitesimal vectors, one has to add several infinitesimal vectors head to tail, head to tail, and so on, and then take a limit. This involves *translating* a vector from one point to the next. There is no ambiguity about doing this in flat Euclidean space using the geometric notion of parallelism.⁴ This simple property of Euclidean space enables us to add (and subtract) vectors at a point. We attach the tail of a second vector to the head of the first vector and then construct the sum as the vector from the tail of the first to the head of the second, or vice versa, as should be quite familiar. The point is that we do not need to add the Cartesian components to sum vectors.

We can also rotate vectors about their tails by pointing them along a different direction in space. Such a rotation can be specified by two angles. The space that is defined by all possible changes of length and direction at a point is called that point's *tangent space*. Again, we generally view the rotation as being that of a physical vector in space, and not, as it is often useful to imagine, the rotation of some coordinate system's basis vectors, with the chosen vector itself kept fixed.

We can also construct a path through space by laying down a sequence of infinitesimal $d\mathbf{x}$ s, tail to head, one after another. The resulting path is a *curve* to which these $d\mathbf{x}$ s are tangent (Fig. 1.1b). The curve can be denoted $\mathcal{P}(\lambda)$, with λ a parameter along the curve and $\mathcal{P}(\lambda)$ the point on the curve whose parameter value is λ , or $\mathbf{x}(\lambda)$ where \mathbf{x} is the vector separation of \mathcal{P} from the arbitrary origin \mathcal{O} . The infinitesimal vectors that map the curve out are $d\mathbf{x} = (d\mathcal{P}/d\lambda) d\lambda = (d\mathbf{x}/d\lambda) d\lambda$, and $d\mathcal{P}/d\lambda = d\mathbf{x}/d\lambda$ is the tangent vector to the curve.

If the curve followed is that of a particle, and the parameter λ is time t , then we have defined the *velocity* $\mathbf{v} \equiv d\mathbf{x}/dt$. In effect we are multiplying the vector $d\mathbf{x}$ by the scalar $1/dt$ and taking the limit. Performing this operation at every point \mathcal{P} in the space occupied by a fluid defines the fluid's *velocity field* $\mathbf{v}(\mathbf{x})$. Multiplying a particle's velocity \mathbf{v} by its scalar mass gives its *momentum* $\mathbf{p} = m\mathbf{v}$. Similarly, the difference $d\mathbf{v}$

tangent space

curve

tangent vector

4. The statement that there is just one choice of line parallel to a given line, through a point not lying on the line, is the famous fifth axiom of Euclid.

of two velocity measurements during a time interval dt , multiplied by $1/dt$, generates the particle's *acceleration* $\mathbf{a} = d\mathbf{v}/dt$. Multiplying by the particle's mass gives the force $\mathbf{F} = m\mathbf{a}$ that produced the acceleration; dividing an electrically produced force by the particle's charge q gives the electric field $\mathbf{E} = \mathbf{F}/q$. And so on.

We can define inner products [see Eq. (1.4a) below] and cross products [Eq. (1.22a)] of pairs of vectors at the same point geometrically; then using those vectors we can define, for example, the rate that work is done by a force and a particle's angular momentum about a point.

These two products can be expressed geometrically as follows. If we allow the two vectors to define a parallelogram, then their cross product is the vector orthogonal to the parallelogram with length equal to the parallelogram's area. If we first rotate one vector through a right angle in a plane containing the other, and then define the parallelogram, its area is the vectors' inner product.

We can also define spatial derivatives. We associate the difference of a scalar between two points separated by $d\mathbf{x}$ at the same time with a *gradient* and, likewise, go on to define the scalar *divergence* and the vector *curl*. The freedom to translate vectors from one point to the next also underlies the association of a single vector (e.g., momentum) with a group of particles or an extended body. One simply adds all the individual momenta, taking a limit when necessary.

In this fashion (which should be familiar to the reader and will be elucidated, formalized, and generalized below), we can construct all the standard scalars and vectors of Newtonian physics. What is important is that *these physical quantities require no coordinate system for their definition*. They are geometric (coordinate-independent) objects residing in Euclidean 3-space at a particular time.

It is a fundamental (though often ignored) principle of physics that *the Newtonian physical laws are all expressible as geometric relationships among these types of geometric objects, and these relationships do not depend on any coordinate system or orientation of axes, nor on any reference frame* (i.e., on any purported velocity of the Euclidean space in which the measurements are made).⁵ We call this the *Geometric Principle* for the laws of physics, and we use it throughout this book. It is the Newtonian analog of Einstein's Principle of Relativity (Sec. 2.2.2).

derivatives of scalars and vectors

Geometric Principle

1.3 1.3 Tensor Algebra without a Coordinate System

In preparation for developing our geometric view of physical laws, we now introduce, in a coordinate-free way, some fundamental concepts of differential geometry: tensors, the inner product, the metric tensor, the tensor product, and contraction of tensors.

We have already defined a vector \mathbf{A} as a straight arrow from one point, say \mathcal{P} , in our space to another, say \mathcal{Q} . Because our space is flat, there is a unique and obvious way to

5. By changing the velocity of Euclidean space, one adds a constant velocity to all particles, but this leaves the laws (e.g., Newton's $\mathbf{F} = m\mathbf{a}$) unchanged.

FIGURE 1.2 A rank-3 tensor \mathbf{T} .

transport such an arrow from one location to another, keeping its length and direction unchanged.⁶ Accordingly, we shall regard vectors as unchanged by such transport. This enables us to ignore the issue of where in space a vector actually resides; it is completely determined by its direction and its length.

A *rank- n tensor* \mathbf{T} is, by definition, a real-valued linear function of n vectors.⁷ Pictorially we regard \mathbf{T} as a box (Fig. 1.2) with n slots in its top, into which are inserted n vectors, and one slot in its end, which prints out a single real number: the value that the tensor \mathbf{T} has when evaluated as a function of the n inserted vectors. Notationally we denote the tensor by a boldfaced sans-serif character \mathbf{T} :

$$\mathbf{T}(\underbrace{\quad, \quad, \quad, \quad}_{\swarrow \text{ } n \text{ slots in which to put the vectors.}}) \quad (1.3a)$$

This definition of a tensor is very different (and far simpler) than the one found in most standard physics textbooks (e.g., Marion and Thornton, 1995; Jackson, 1999; Griffiths, 1999). There, a tensor is an array of numbers that transform in a particular way under rotations. We shall learn the connection between these definitions in Sec. 1.6 below.

To illustrate this approach, if \mathbf{T} is a rank-3 tensor (has 3 slots) as in Fig. 1.2, then its value on the vectors \mathbf{A} , \mathbf{B} , \mathbf{C} is denoted $\mathbf{T}(\mathbf{A}, \mathbf{B}, \mathbf{C})$. Linearity of this function can be expressed as

$$\mathbf{T}(e\mathbf{E} + f\mathbf{F}, \mathbf{B}, \mathbf{C}) = e\mathbf{T}(\mathbf{E}, \mathbf{B}, \mathbf{C}) + f\mathbf{T}(\mathbf{F}, \mathbf{B}, \mathbf{C}), \quad (1.3b)$$

where e and f are real numbers, and similarly for the second and third slots.

We have already defined the squared length $(\mathbf{A})^2 \equiv \mathbf{A}^2$ of a vector \mathbf{A} as the squared distance between the points at its tail and its tip. The *inner product* (also called the dot product) $\mathbf{A} \cdot \mathbf{B}$ of two vectors is defined in terms of this squared length by

$$\mathbf{A} \cdot \mathbf{B} \equiv \frac{1}{4} \left[(\mathbf{A} + \mathbf{B})^2 - (\mathbf{A} - \mathbf{B})^2 \right]. \quad (1.4a)$$

In Euclidean space, this is the standard inner product, familiar from elementary geometry and discussed above in terms of the area of a parallelogram.

6. This is not so in curved spaces, as we shall see in Sec. 24.3.4.

7. This is a different use of the word *rank* than for a matrix, whose rank is its number of linearly independent rows or columns.

tensor

inner product

metric tensor

One can show that the inner product (1.4a) is a real-valued linear function of each of its vectors. Therefore, we can regard it as a tensor of rank 2. When so regarded, the inner product is denoted $\mathbf{g}(_, _)$ and is called the *metric tensor*. In other words, the metric tensor \mathbf{g} is that linear function of two vectors whose value is given by

$$\mathbf{g}(\mathbf{A}, \mathbf{B}) \equiv \mathbf{A} \cdot \mathbf{B}. \quad (1.4b)$$

Notice that, because $\mathbf{A} \cdot \mathbf{B} = \mathbf{B} \cdot \mathbf{A}$, the metric tensor is *symmetric* in its two slots—one gets the same real number independently of the order in which one inserts the two vectors into the slots:

$$\mathbf{g}(\mathbf{A}, \mathbf{B}) = \mathbf{g}(\mathbf{B}, \mathbf{A}). \quad (1.4c)$$

With the aid of the inner product, we can regard any vector \mathbf{A} as a tensor of rank one: the real number that is produced when an arbitrary vector \mathbf{C} is inserted into \mathbf{A} 's single slot is

$$\mathbf{A}(\mathbf{C}) \equiv \mathbf{A} \cdot \mathbf{C}. \quad (1.4d)$$

In Newtonian physics, we rarely meet tensors of rank higher than two. However, second-rank tensors appear frequently—often in roles where one sticks a single vector into the second slot and leaves the first slot empty, thereby producing a single-slotted entity, a vector. An example that we met in Sec. 1.1.1 is a rigid body's moment-of-inertia tensor $\mathbf{I}(_, _)$, which gives us the body's angular momentum $\mathbf{J}(_) = \mathbf{I}(_, \boldsymbol{\Omega})$ when its angular velocity $\boldsymbol{\Omega}$ is inserted into its second slot.⁸ Another example is the stress tensor of a solid, a fluid, a plasma, or a field (Sec. 1.9 below).

tensor product

From three vectors \mathbf{A} , \mathbf{B} , \mathbf{C} , we can construct a tensor, their *tensor product* (also called *outer product* in contradistinction to the inner product $\mathbf{A} \cdot \mathbf{B}$), defined as follows:

$$\mathbf{A} \otimes \mathbf{B} \otimes \mathbf{C}(\mathbf{E}, \mathbf{F}, \mathbf{G}) \equiv \mathbf{A}(\mathbf{E})\mathbf{B}(\mathbf{F})\mathbf{C}(\mathbf{G}) = (\mathbf{A} \cdot \mathbf{E})(\mathbf{B} \cdot \mathbf{F})(\mathbf{C} \cdot \mathbf{G}). \quad (1.5a)$$

Here the first expression is the notation for the value of the new tensor, $\mathbf{A} \otimes \mathbf{B} \otimes \mathbf{C}$ evaluated on the three vectors \mathbf{E} , \mathbf{F} , \mathbf{G} ; the middle expression is the ordinary product of three real numbers, the value of \mathbf{A} on \mathbf{E} , the value of \mathbf{B} on \mathbf{F} , and the value of \mathbf{C} on \mathbf{G} ; and the third expression is that same product with the three numbers rewritten as scalar products. Similar definitions can be given (and should be obvious) for the tensor product of any number of vectors, and of any two or more tensors of any rank; for example, if \mathbf{T} has rank 2 and \mathbf{S} has rank 3, then

$$\mathbf{T} \otimes \mathbf{S}(\mathbf{E}, \mathbf{F}, \mathbf{G}, \mathbf{H}, \mathbf{J}) \equiv \mathbf{T}(\mathbf{E}, \mathbf{F})\mathbf{S}(\mathbf{G}, \mathbf{H}, \mathbf{J}). \quad (1.5b)$$

contraction

One last geometric (i.e., frame-independent) concept we shall need is *contraction*. We illustrate this concept first by a simple example, then give the general definition.

8. Actually, it doesn't matter which slot, since \mathbf{I} is symmetric.

From two vectors \mathbf{A} and \mathbf{B} we can construct the tensor product $\mathbf{A} \otimes \mathbf{B}$ (a second-rank tensor), and we can also construct the scalar product $\mathbf{A} \cdot \mathbf{B}$ (a real number, i.e., a *scalar*, also known as a *rank-0 tensor*). The process of contraction is the construction of $\mathbf{A} \cdot \mathbf{B}$ from $\mathbf{A} \otimes \mathbf{B}$:

$$\boxed{\text{contraction}(\mathbf{A} \otimes \mathbf{B}) \equiv \mathbf{A} \cdot \mathbf{B}.} \quad (1.6a)$$

One can show fairly easily using component techniques (Sec. 1.5 below) that any second-rank tensor \mathbf{T} can be expressed as a sum of tensor products of vectors, $\mathbf{T} = \mathbf{A} \otimes \mathbf{B} + \mathbf{C} \otimes \mathbf{D} + \dots$. Correspondingly, it is natural to define the contraction of \mathbf{T} to be $\text{contraction}(\mathbf{T}) = \mathbf{A} \cdot \mathbf{B} + \mathbf{C} \cdot \mathbf{D} + \dots$. Note that this contraction process lowers the rank of the tensor by two, from 2 to 0. Similarly, for a tensor of rank n one can construct a tensor of rank $n - 2$ by contraction, but in this case one must specify which slots are to be contracted. For example, if \mathbf{T} is a third-rank tensor, expressible as $\mathbf{T} = \mathbf{A} \otimes \mathbf{B} \otimes \mathbf{C} + \mathbf{E} \otimes \mathbf{F} \otimes \mathbf{G} + \dots$, then the contraction of \mathbf{T} on its first and third slots is the rank-1 tensor (vector)

$$\&3\text{contraction}(\mathbf{A} \otimes \mathbf{B} \otimes \mathbf{C} + \mathbf{E} \otimes \mathbf{F} \otimes \mathbf{G} + \dots) \equiv (\mathbf{A} \cdot \mathbf{C})\mathbf{B} + (\mathbf{E} \cdot \mathbf{G})\mathbf{F} + \dots \quad (1.6b)$$

Unfortunately, there is no simple index-free notation for contraction in common use.

All the concepts developed in this section (vector, tensor, metric tensor, inner product, tensor product, and contraction of a tensor) can be carried over, with no change whatsoever, into any vector space⁹ that is endowed with a concept of squared length—for example, to the 4-dimensional spacetime of special relativity (next chapter).

1.4 Particle Kinetics and Lorentz Force in Geometric Language

1.4

In this section, we illustrate our geometric viewpoint by formulating Newton's laws of motion for particles.

In Newtonian physics, a classical particle moves through Euclidean 3-space as universal time t passes. At time t it is located at some point $\mathbf{x}(t)$ (its *position*). The function $\mathbf{x}(t)$ represents a curve in 3-space, the particle's *trajectory*. The particle's *velocity* $\mathbf{v}(t)$ is the time derivative of its position, its *momentum* $\mathbf{p}(t)$ is the product of its mass m and velocity, its *acceleration* $\mathbf{a}(t)$ is the time derivative of its velocity, and its *kinetic energy* $E(t)$ is half its mass times velocity squared:

trajectory, velocity, momentum, acceleration, and energy

$$\mathbf{v}(t) = \frac{d\mathbf{x}}{dt}, \quad \mathbf{p}(t) = m\mathbf{v}(t), \quad \mathbf{a}(t) = \frac{d\mathbf{v}}{dt} = \frac{d^2\mathbf{x}}{dt^2}, \quad E(t) = \frac{1}{2}m\mathbf{v}^2. \quad (1.7a)$$

9. Or, more precisely, any vector space over the real numbers. If the vector space's scalars are complex numbers, as in quantum mechanics, then slight changes are needed.

Since points in 3-space are geometric objects (defined independently of any coordinate system), so also are the trajectory $\mathbf{x}(t)$, the velocity, the momentum, the acceleration, and the energy. (Physically, of course, the velocity has an ambiguity; it depends on one's standard of rest.)

Newton's second law of motion states that the particle's momentum can change only if a force \mathbf{F} acts on it, and that its change is given by

$$d\mathbf{p}/dt = m\mathbf{a} = \mathbf{F}. \quad (1.7b)$$

If the force is produced by an electric field \mathbf{E} and magnetic field \mathbf{B} , then this law of motion in SI units takes the familiar Lorentz-force form

$$d\mathbf{p}/dt = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}). \quad (1.7c)$$

(Here we have used the vector cross product, with which the reader should be familiar, and which will be discussed formally in Sec. 1.7.)

laws of motion

The laws of motion (1.7) are geometric relationships among geometric objects. Let us illustrate this using something very familiar, planetary motion. Consider a light planet orbiting a heavy star. If there were no gravitational force, the planet would continue in a straight line with constant velocity \mathbf{v} and speed $v = |\mathbf{v}|$, sweeping out area A at a rate $dA/dt = rv_t/2$, where r is the radius, and v_t is the tangential speed. Elementary geometry equates this to the constant $vb/2$, where b is the impact parameter—the smallest separation from the star. Now add a gravitational force \mathbf{F} and let it cause a small radial impulse. A second application of geometry showed Newton that the product $rv_t/2$ is unchanged to first order in the impulse, and he recovered Kepler's second law ($dA/dt = \text{const}$) without introducing coordinates.¹⁰

Contrast this approach with one relying on coordinates. For example, one introduces an (r, ϕ) coordinate system, constructs a lagrangian and observes that the coordinate ϕ is ignorable; then the Euler-Lagrange equations immediately imply the conservation of angular momentum, which is equivalent to Kepler's second law. So, which of these two approaches is preferable? The answer is surely "both!" Newton wrote the *Principia* in the language of geometry at least partly for a reason that remains valid today: it brought him a quick understanding of fundamental laws of physics. Lagrange followed his coordinate-based path to the function that bears his name, because he wanted to solve problems in celestial mechanics that would not yield to

10. Continuing in this vein, when the force is inverse square, as it is for gravity and electrostatics, we can use Kepler's second law to argue that when the orbit turns through a succession of equal angles $d\theta$, its successive changes in velocity $d\mathbf{v} = \mathbf{a}dt$ (with \mathbf{a} the gravitational acceleration) all have the same magnitude $|d\mathbf{v}|$ and have the same angles $d\theta$ from one to another. So, if we trace the head of the velocity vector in velocity space, it follows a circle. The circle is not centered on zero velocity when the eccentricity is nonzero but there exists a reference frame in which the speed of the planet is constant. This graphical representation is known as a *hodograph*, and similar geometrical approaches are used in fluid mechanics. For Richard Feynman's masterful presentation of these ideas to first-year undergraduates, see Goodstein and Goodstein (1996).

Newton's approach. So it is today. Geometry and analysis are both indispensable. In the domain of classical physics, the geometry is of greater importance in deriving and understanding fundamental laws and has arguably been underappreciated; coordinates hold sway when we apply these laws to solve real problems. Today, both old and new laws of physics are commonly expressed geometrically, using lagrangians, hamiltonians, and actions, for example Hamilton's action principle $\delta \int L dt = 0$ where L is the coordinate-independent lagrangian. Indeed, being able to do this without introducing coordinates is a powerful guide to deriving these laws and a tool for comprehending their implications.

A comment is needed on the famous connection between *symmetry* and *conservation laws*. In our example above, angular momentum conservation followed from axial symmetry which was embodied in the lagrangian's independence of the angle ϕ ; but we also deduced it geometrically. This is usually the case in classical physics; typically, we do not need to introduce a specific coordinate system to understand symmetry and to express the associated conservation laws. However, symmetries are sometimes well hidden, for example with a nutating top, and coordinate transformations are then usually the best approach to uncover them.

Often in classical physics, real-world factors invalidate or complicate Lagrange's and Hamilton's coordinate-based analytical dynamics, and so one is driven to geometric considerations. As an example, consider a spherical marble rolling on a flat horizontal table. The analytical dynamics approach is to express the height of the marble's center of mass and the angle of its rotation as constraints and align the basis vectors so there is a single horizontal coordinate defined by the initial condition. It is then deduced that linear and angular momenta are conserved. Of course that result is trivial and just as easily gotten without this formalism. However, this model is also used for many idealized problems where the outcome is far from obvious and the approach is brilliantly effective. But consider the real world in which tables are warped and bumpy, marbles are ellipsoidal and scratched, air imposes a resistance, and wood and glass comprise polymers that attract one another. And so on. When one includes these factors, it is to geometry that one quickly turns to understand the real marble's actual dynamics. Even ignoring these effects and just asking what happens when the marble rolls off the edge of a table introduces a *nonholonomic* constraint, and figuring out where it lands and how fast it is spinning are best addressed not by the methods of Lagrange and Hamilton, but instead by considering the geometry of the gravitational and reaction forces. In the following chapters, we shall encounter many examples where we have to deal with messy complications like these.

symmetry and
conservation laws

Exercise 1.1 *Practice: Energy Change for Charged Particle*

Without introducing any coordinates or basis vectors, show that when a particle with charge q interacts with electric and magnetic fields, its kinetic energy changes at a rate

$$dE/dt = q \mathbf{v} \cdot \mathbf{E}. \quad (1.8)$$

EXERCISES

Exercise 1.2 Practice: Particle Moving in a Circular Orbit

Consider a particle moving in a circle with uniform speed $v = |\mathbf{v}|$ and uniform magnitude $a = |\mathbf{a}|$ of acceleration. Without introducing any coordinates or basis vectors, do the following.

- (a) At any moment of time, let $\mathbf{n} = \mathbf{v}/v$ be the unit vector pointing along the velocity, and let s denote distance that the particle travels in its orbit. By drawing a picture, show that $d\mathbf{n}/ds$ is a unit vector that points to the center of the particle's circular orbit, divided by the radius of the orbit.
- (b) Show that the vector (not unit vector) pointing from the particle's location to the center of its orbit is $(v/a)^2\mathbf{a}$.

1.5

1.5 Component Representation of Tensor Algebra

Cartesian coordinates and orthonormal basis vectors

In the Euclidean 3-space of Newtonian physics, there is a unique set of *orthonormal basis vectors* $\{\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z\} \equiv \{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ associated with any *Cartesian coordinate system* $\{x, y, z\} \equiv \{x^1, x^2, x^3\} \equiv \{x_1, x_2, x_3\}$. (In Cartesian coordinates in Euclidean space, we usually place indices down, but occasionally we place them up. It doesn't matter. By definition, in Cartesian coordinates a quantity is the same whether its index is down or up.) The basis vector \mathbf{e}_j points along the x_j coordinate direction, which is orthogonal to all the other coordinate directions, and it has unit length (Fig. 1.3), so

$$\mathbf{e}_j \cdot \mathbf{e}_k = \delta_{jk}, \tag{1.9a}$$

where δ_{jk} is the Kronecker delta.

Any vector \mathbf{A} in 3-space can be expanded in terms of this basis:

$$\mathbf{A} = A_j \mathbf{e}_j. \tag{1.9b}$$

Einstein summation convention

Cartesian components of a vector

Here and throughout this book, we adopt the *Einstein summation convention*: repeated indices (in this case j) are to be summed (in this 3-space case over $j = 1, 2, 3$), unless otherwise instructed. By virtue of the orthonormality of the basis, the components A_j of \mathbf{A} can be computed as the scalar product

$$A_j = \mathbf{A} \cdot \mathbf{e}_j. \tag{1.9c}$$

[The proof of this is straightforward: $\mathbf{A} \cdot \mathbf{e}_j = (A_k \mathbf{e}_k) \cdot \mathbf{e}_j = A_k (\mathbf{e}_k \cdot \mathbf{e}_j) = A_k \delta_{kj} = A_j$.]

Any tensor, say, the third-rank tensor $\mathbf{T}(_, _, _)$, can be expanded in terms of tensor products of the basis vectors:

$$\mathbf{T} = T_{ijk} \mathbf{e}_i \otimes \mathbf{e}_j \otimes \mathbf{e}_k. \tag{1.9d}$$

FIGURE 1.3 The orthonormal basis vectors \mathbf{e}_j associated with a Euclidean coordinate system in Euclidean 3-space.

The components T_{ijk} of \mathbf{T} can be computed from \mathbf{T} and the basis vectors by the generalization of Eq. (1.9c):

$$T_{ijk} = \mathbf{T}(\mathbf{e}_i, \mathbf{e}_j, \mathbf{e}_k). \quad (1.9e)$$

[This equation can be derived using the orthonormality of the basis in the same way as Eq. (1.9c) was derived.] As an important example, the components of the metric tensor are $g_{jk} = \mathbf{g}(\mathbf{e}_j, \mathbf{e}_k) = \mathbf{e}_j \cdot \mathbf{e}_k = \delta_{jk}$ [where the first equality is the method (1.9e) of computing tensor components, the second is the definition (1.4b) of the metric, and the third is the orthonormality relation (1.9a)]:

$$g_{jk} = \delta_{jk}. \quad (1.9f)$$

The components of a tensor product [e.g., $\mathbf{T}(_, _, _) \otimes \mathbf{S}(_, _)$] are easily deduced by inserting the basis vectors into the slots [Eq. (1.9e)]; they are $\mathbf{T}(\mathbf{e}_i, \mathbf{e}_j, \mathbf{e}_k) \otimes \mathbf{S}(\mathbf{e}_l, \mathbf{e}_m) = T_{ijk}S_{lm}$ [cf. Eq. (1.5a)]. In words, the components of a tensor product are equal to the ordinary arithmetic product of the components of the individual tensors.

In component notation, the inner product of two vectors and the value of a tensor when vectors are inserted into its slots are given by

$$\mathbf{A} \cdot \mathbf{B} = A_j B_j, \quad \mathbf{T}(\mathbf{A}, \mathbf{B}, \mathbf{C}) = T_{ijk} A_i B_j C_k, \quad (1.9g)$$

as one can easily show using previous equations. Finally, the contraction of a tensor [say, the fourth-rank tensor $\mathbf{R}(_, _, _, _)$] on two of its slots (say, the first and third) has components that are easily computed from the tensor's own components:

$$\text{components of [1\&3contraction of } \mathbf{R}] = R_{jik}. \quad (1.9h)$$

Note that R_{jik} is summed on the i index, so it has only two free indices, j and k , and thus is the component of a second-rank tensor, as it must be if it is to represent the contraction of a fourth-rank tensor.

1.5.1 Slot-Naming Index Notation

1.5.1

We now pause in our development of the component version of tensor algebra to introduce a very important new viewpoint.

BOX 1.2. VECTORS AND TENSORS IN QUANTUM THEORY T2

The laws of quantum theory, like all other laws of Nature, can be expressed as geometric relationships among geometric objects. Most of quantum theory's geometric objects, like those of classical theory, are vectors and tensors: the quantum state $|\psi\rangle$ of a physical system (e.g., a particle in a harmonic-oscillator potential) is a Hilbert-space vector—a generalization of a Euclidean-space vector \mathbf{A} . There is an inner product, denoted $\langle\phi|\psi\rangle$, between any two states $|\phi\rangle$ and $|\psi\rangle$, analogous to $\mathbf{B} \cdot \mathbf{A}$; but $\mathbf{B} \cdot \mathbf{A}$ is a real number, whereas $\langle\phi|\psi\rangle$ is a complex number (and we add and subtract quantum states with complex-number coefficients). The Hermitian operators that represent observables (e.g., the hamiltonian \hat{H} for the particle in the potential) are two-slotted (second-rank), complex-valued functions of vectors; $\langle\phi|\hat{H}|\psi\rangle$ is the complex number that one gets when one inserts ϕ and ψ into the first and second slots of \hat{H} . Just as, in Euclidean space, we get a new vector (first-rank tensor) $\mathbf{T}(_, \mathbf{A})$ when we insert the vector \mathbf{A} into the second slot of \mathbf{T} , so in quantum theory we get a new vector (physical state) $\hat{H}|\psi\rangle$ (the result of letting \hat{H} “act on” $|\psi\rangle$) when we insert $|\psi\rangle$ into the second slot of \hat{H} . In these senses, we can regard \mathbf{T} as a linear map of Euclidean vectors into Euclidean vectors and \hat{H} as a linear map of states (Hilbert-space vectors) into states.

For the electron in the hydrogen atom, we can introduce a set of orthonormal basis vectors $\{|1\rangle, |2\rangle, |3\rangle, \dots\}$, that is, the atom's energy eigenstates, with $\langle m|n\rangle = \delta_{mn}$. But by contrast with Newtonian physics, where we only need three basis vectors (because our Euclidean space is 3-dimensional), for the particle in a harmonic-oscillator potential, we need an infinite number of basis vectors (since the Hilbert space of all states is infinite-dimensional). In the particle's quantum-state basis, any observable (e.g., the particle's position \hat{x} or momentum \hat{p}) has components computed by inserting the basis vectors into its two slots: $x_{mn} = \langle m|\hat{x}|n\rangle$, and $p_{mn} = \langle m|\hat{p}|n\rangle$. In this basis, the operator $\hat{x}\hat{p}$ (which maps states into states) has components $x_{jk}p_{km}$ (a matrix product), and the noncommutation of position and momentum $[\hat{x}, \hat{p}] = i\hbar$ (an important physical law) is expressible in terms of components as $x_{jk}p_{km} - p_{jk}x_{km} = i\hbar\delta_{jm}$.

Consider the rank-2 tensor $\mathbf{F}(_, _)$. We can define a new tensor $\mathbf{G}(_, _)$ to be the same as \mathbf{F} , but with the slots interchanged: i.e., for any two vectors \mathbf{A} and \mathbf{B} , it is true that $\mathbf{G}(\mathbf{A}, \mathbf{B}) = \mathbf{F}(\mathbf{B}, \mathbf{A})$. We need a simple, compact way to indicate that \mathbf{F} and \mathbf{G} are equal except for an interchange of slots. The best way is to give the slots names, say a and b —i.e., to rewrite $\mathbf{F}(_, _)$ as $\mathbf{F}(_a, _b)$ or more conveniently as F_{ab} , and then to write the relationship between \mathbf{G} and \mathbf{F} as $G_{ab} = F_{ba}$. “NO!” some readers

might object. This notation is indistinguishable from our notation for components on a particular basis. “GOOD!” a more astute reader will exclaim. The relation $G_{ab} = F_{ba}$ in a particular basis is a true statement if and only if “ $\mathbf{G} = \mathbf{F}$ with slots interchanged” is true, so why not use the same notation to symbolize both? In fact, we shall do this. We ask our readers to look at any “index equation,” such as $G_{ab} = F_{ba}$, like they would look at an Escher drawing: momentarily think of it as a relationship between components of tensors in a specific basis; then do a quick mind-flip and regard it quite differently, as a relationship between geometric, basis-independent tensors with the indices playing the roles of slot names. This mind-flip approach to tensor algebra will pay substantial dividends.

As an example of the power of this *slot-naming index notation*, consider the contraction of the first and third slots of a third-rank tensor \mathbf{T} . In any basis the components of $1\&3\text{contraction}(\mathbf{T})$ are T_{aba} ; cf. Eq. (1.9h). Correspondingly, in slot-naming index notation we denote $1\&3\text{contraction}(\mathbf{T})$ by the simple expression T_{aba} . We can think of the first and third slots as annihilating each other by the contraction, leaving free only the second slot (named b) and therefore producing a rank-1 tensor (a vector).

We should caution that the phrase “slot-naming index notation” is unconventional. You are unlikely to find it in any other textbooks. However, we like it. It says precisely what we want it to say.

slot-naming index notation

1.5.2 Particle Kinetics in Index Notation

1.5.2

As an example of slot-naming index notation, we can rewrite the equations of particle kinetics (1.7) as follows:

$$v_i = \frac{dx_i}{dt}, \quad p_i = mv_i, \quad a_i = \frac{dv_i}{dt} = \frac{d^2x_i}{dt^2},$$

$$E = \frac{1}{2}mv_j v_j, \quad \frac{dp_i}{dt} = q(E_i + \epsilon_{ijk}v_j B_k). \quad (1.10)$$

(In the last equation ϵ_{ijk} is the so-called Levi-Civita tensor, which is used to produce the cross product; we shall learn about it in Sec. 1.7. And note that the scalar energy E must not be confused with the electric field vector E_i .)

Equations (1.10) can be viewed in either of two ways: (i) as the basis-independent geometric laws $\mathbf{v} = d\mathbf{x}/dt$, $\mathbf{p} = m\mathbf{v}$, $\mathbf{a} = d\mathbf{v}/dt = d^2\mathbf{x}/dt^2$, $E = \frac{1}{2}m\mathbf{v}^2$, and $d\mathbf{p}/dt = q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$ written in slot-naming index notation; or (ii) as equations for the components of \mathbf{v} , \mathbf{p} , \mathbf{a} , \mathbf{E} , and \mathbf{B} in some particular Cartesian coordinate system.

Exercise 1.3 Derivation: Component Manipulation Rules

EXERCISES

Derive the component manipulation rules (1.9g) and (1.9h).

Exercise 1.4 Example and Practice: Numerics of Component Manipulations

The third-rank tensor $\mathbf{S}(_, _, _)$ and vectors \mathbf{A} and \mathbf{B} have as their only nonzero components $S_{123} = S_{231} = S_{312} = +1$, $A_1 = 3$, $B_1 = 4$, $B_2 = 5$. What are the

components of the vector $\mathbf{C} = \mathbf{S}(\mathbf{A}, \mathbf{B}, \underline{\quad})$, the vector $\mathbf{D} = \mathbf{S}(\mathbf{A}, \underline{\quad}, \mathbf{B})$, and the tensor $\mathbf{W} = \mathbf{A} \otimes \mathbf{B}$?

[Partial solution: In component notation, $C_k = S_{ijk}A_iB_j$, where (of course) we sum over the repeated indices i and j . This tells us that $C_1 = S_{231}A_2B_3$, because S_{231} is the only component of \mathbf{S} whose last index is a 1; this in turn implies that $C_1 = 0$, since $A_2 = 0$. Similarly, $C_2 = S_{312}A_3B_1 = 0$ (because $A_3 = 0$). Finally, $C_3 = S_{123}A_1B_2 = +1 \times 3 \times 5 = 15$. Also, in component notation $W_{ij} = A_iB_j$, so $W_{11} = A_1 \times B_1 = 3 \times 4 = 12$, and $W_{12} = A_1 \times B_2 = 3 \times 5 = 15$. Here the \times stands for numerical multiplication, not the vector cross product.]

Exercise 1.5 Practice: Meaning of Slot-Naming Index Notation

- (a) The following expressions and equations are written in slot-naming index notation. Convert them to geometric, index-free notation: A_iB_{jk} , A_iB_{ji} , $S_{ijk} = S_{kji}$, $A_iB_i = A_iB_jg_{ij}$.
- (b) The following expressions are written in geometric, index-free notation. Convert them to slot-naming index notation: $\mathbf{T}(\underline{\quad}, \underline{\quad}, \mathbf{A})$, $\mathbf{T}(\underline{\quad}, \mathbf{S}(\mathbf{B}, \underline{\quad}), \underline{\quad})$.

1.6 Orthogonal Transformations of Bases

Consider two different Cartesian coordinate systems $\{x, y, z\} \equiv \{x_1, x_2, x_3\}$, and $\{\bar{x}, \bar{y}, \bar{z}\} \equiv \{\bar{x}_1, \bar{x}_2, \bar{x}_3\}$. Denote by $\{\mathbf{e}_i\}$ and $\{\mathbf{e}_{\bar{i}}\}$ the corresponding bases. It is possible to expand the basis vectors of one basis in terms of those of the other. We denote the expansion coefficients by the letter R and write

$$\mathbf{e}_i = \mathbf{e}_{\bar{i}}R_{\bar{i}i}, \quad \mathbf{e}_{\bar{i}} = \mathbf{e}_iR_{i\bar{i}}. \quad (1.11)$$

The quantities $R_{\bar{i}i}$ and $R_{i\bar{i}}$ are not the components of a tensor; rather, they are the elements of transformation matrices

$$[R_{\bar{i}i}] = \begin{bmatrix} R_{\bar{1}1} & R_{\bar{1}2} & R_{\bar{1}3} \\ R_{\bar{2}1} & R_{\bar{2}2} & R_{\bar{2}3} \\ R_{\bar{3}1} & R_{\bar{3}2} & R_{\bar{3}3} \end{bmatrix}, \quad [R_{i\bar{i}}] = \begin{bmatrix} R_{1\bar{1}} & R_{1\bar{2}} & R_{1\bar{3}} \\ R_{2\bar{1}} & R_{2\bar{2}} & R_{2\bar{3}} \\ R_{3\bar{1}} & R_{3\bar{2}} & R_{3\bar{3}} \end{bmatrix}. \quad (1.12a)$$

(Here and throughout this book we use square brackets to denote matrices.) These two matrices must be the inverse of each other, since one takes us from the barred basis to the unbarred, and the other in the reverse direction, from unbarred to barred:

$$R_{\bar{i}i}R_{i\bar{q}} = \delta_{\bar{i}q}, \quad R_{i\bar{i}}R_{\bar{j}i} = \delta_{ij}. \quad (1.12b)$$

The orthonormality requirement for the two bases implies that $\delta_{ij} = \mathbf{e}_i \cdot \mathbf{e}_j = (\mathbf{e}_{\bar{i}}R_{\bar{i}i}) \cdot (\mathbf{e}_{\bar{j}}R_{\bar{j}j}) = R_{\bar{i}i}R_{\bar{j}j}(\mathbf{e}_{\bar{i}} \cdot \mathbf{e}_{\bar{j}}) = R_{\bar{i}i}R_{\bar{j}j}\delta_{\bar{i}\bar{j}} = R_{\bar{i}i}R_{\bar{j}i}$. This says that the transpose of $[R_{\bar{i}i}]$ is its inverse—which we have already denoted by $[R_{i\bar{i}}]$:

$$[R_{i\bar{i}}] \equiv \text{inverse}([R_{\bar{i}i}]) = \text{transpose}([R_{\bar{i}i}]). \quad (1.12c)$$

This property implies that the transformation matrix is orthogonal, so the transformation is a reflection or a rotation (see, e.g., Goldstein, Poole, and Safko, 2002). Thus (as should be obvious and familiar), the bases associated with any two Euclidean coordinate systems are related by a reflection or rotation, and the matrices (1.12a) are called *rotation matrices*. Note that Eq. (1.12c) does not say that $[R_{i\bar{i}}]$ is a symmetric matrix. In fact, most rotation matrices are not symmetric [see, e.g., Eq. (1.14)].

The fact that a vector \mathbf{A} is a geometric, basis-independent object implies that $\mathbf{A} = A_i \mathbf{e}_i = A_i (\mathbf{e}_{\bar{i}} R_{\bar{i}i}) = (R_{\bar{i}i} A_i) \mathbf{e}_{\bar{i}} = A_{\bar{i}} \mathbf{e}_{\bar{i}}$:

$$A_{\bar{i}} = R_{\bar{i}i} A_i, \quad \text{and similarly,} \quad A_i = R_{i\bar{i}} A_{\bar{i}}; \quad (1.13a)$$

and correspondingly for the components of a tensor:

$$T_{\bar{p}\bar{q}\bar{r}} = R_{\bar{p}i} R_{\bar{q}j} R_{\bar{r}k} T_{ijk}, \quad T_{ijk} = R_{i\bar{p}} R_{j\bar{q}} R_{k\bar{r}} T_{\bar{p}\bar{q}\bar{r}}. \quad (1.13b)$$

It is instructive to compare the transformation law (1.13a) for the components of a vector with Eqs. (1.11) for the bases. To make these laws look natural, we have placed the transformation matrix on the left in the former and on the right in the latter. In Minkowski spacetime (Chap. 2), the placement of indices, up or down, will automatically tell us the order.

If we choose the origins of our two coordinate systems to coincide, then the vector \mathbf{x} reaching from the common origin to some point \mathcal{P} , whose coordinates are x_j and $x_{\bar{j}}$, has components equal to those coordinates; and as a result, the coordinates themselves obey the same transformation law as any other vector:

$$x_{\bar{j}} = R_{\bar{j}i} x_i, \quad x_i = R_{i\bar{j}} x_{\bar{j}}. \quad (1.13c)$$

The product of two rotation matrices $[R_{i\bar{i}} R_{\bar{i}\bar{s}}]$ is another rotation matrix $[R_{i\bar{s}}]$, which transforms the Cartesian bases $\mathbf{e}_{\bar{s}}$ to \mathbf{e}_i . Under this product rule, the rotation matrices form a mathematical *group*: the *rotation group*, whose *group representations* play an important role in quantum theory.

Exercise 1.6 ***Example and Practice: Rotation in x-y Plane*

Consider two Cartesian coordinate systems rotated with respect to each other in the x - y plane as shown in Fig. 1.4.

- (a) Show that the rotation matrix that takes the barred basis vectors to the unbarred basis vectors is

$$[R_{\bar{i}i}] = \begin{bmatrix} \cos \phi & \sin \phi & 0 \\ -\sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (1.14)$$

and show that the inverse of this rotation matrix is, indeed, its transpose, as it must be if this is to represent a rotation.

- (b) Verify that the two coordinate systems are related by Eq. (1.13c).

EXERCISES

FIGURE 1.4 Two Cartesian coordinate systems $\{x, y, z\}$ and $\{\bar{x}, \bar{y}, \bar{z}\}$ and their basis vectors in Euclidean space, rotated by an angle ϕ relative to each other in the x - y plane. The z - and \bar{z} -axes point out of the paper or screen and are not shown.

- (c) Let A_j be the components of the electromagnetic vector potential that lies in the x - y plane, so that $A_z = 0$. The two nonzero components A_x and A_y can be regarded as describing the two polarizations of an electromagnetic wave propagating in the z direction. Show that $A_{\bar{x}} + iA_{\bar{y}} = (A_x + iA_y)e^{-i\phi}$. One can show (cf. Sec. 27.3.3) that the factor $e^{-i\phi}$ implies that the quantum particle associated with the wave—the photon—has spin one [i.e., spin angular momentum $\hbar = (\text{Planck's constant})/2\pi$].
- (d) Let h_{jk} be the components of a symmetric tensor that is *trace-free* (its contraction h_{jj} vanishes) and is confined to the x - y plane (so $h_{zk} = h_{kz} = 0$ for all k). Then the only nonzero components of this tensor are $h_{xx} = -h_{yy}$ and $h_{xy} = h_{yx}$. As we shall see in Sec. 27.3.1, this tensor can be regarded as describing the two polarizations of a gravitational wave propagating in the z direction. Show that $h_{\bar{x}\bar{x}} + ih_{\bar{x}\bar{y}} = (h_{xx} + ih_{xy})e^{-2i\phi}$. The factor $e^{-2i\phi}$ implies that the quantum particle associated with the gravitational wave (the graviton) has spin two (spin angular momentum $2\hbar$); cf. Eq. (27.31) and Sec. 27.3.3.

1.7

1.7 Differentiation of Scalars, Vectors, and Tensors; Cross Product and Curl

directional derivative

Consider a tensor field $\mathbf{T}(\mathcal{P})$ in Euclidean 3-space and a vector \mathbf{A} . We define the *directional derivative* of \mathbf{T} along \mathbf{A} by the obvious limiting procedure

$$\nabla_{\mathbf{A}} \mathbf{T} \equiv \lim_{\epsilon \rightarrow 0} \frac{1}{\epsilon} [\mathbf{T}(\mathbf{x}_{\mathcal{P}} + \epsilon \mathbf{A}) - \mathbf{T}(\mathbf{x}_{\mathcal{P}})] \quad (1.15a)$$

and similarly for the directional derivative of a vector field $\mathbf{B}(\mathcal{P})$ and a scalar field $\psi(\mathcal{P})$. [Here we have denoted points, e.g., \mathcal{P} , by the vector $\mathbf{x}_{\mathcal{P}}$ that reaches from some

arbitrary origin to the point, and $\mathbf{T}(\mathbf{x}_p)$ denotes the field's dependence on location in space; \mathbf{T} 's slots and dependence on what goes into the slots are suppressed; and the units of ϵ are chosen to ensure that $\epsilon \mathbf{A}$ has the same units as \mathbf{x}_p . There is no other appearance of vectors in this chapter.] In definition (1.15a), the quantity in square brackets is simply the difference between two linear functions of vectors (two tensors), so the quantity on the left-hand side is also a tensor with the same rank as \mathbf{T} .

It should not be hard to convince oneself that this directional derivative $\nabla_{\mathbf{A}} \mathbf{T}$ of any tensor field \mathbf{T} is linear in the vector \mathbf{A} along which one differentiates. Correspondingly, if \mathbf{T} has rank n (n slots), then there is another tensor field, denoted $\nabla \mathbf{T}$, with rank $n + 1$, such that

$$\boxed{\nabla_{\mathbf{A}} \mathbf{T} = \nabla \mathbf{T}(_, _, _, \mathbf{A})}. \quad (1.15b)$$

Here on the right-hand side the first n slots (3 in the case shown) are left empty, and \mathbf{A} is put into the last slot (the “differentiation slot”). The quantity $\nabla \mathbf{T}$ is called the *gradient* of \mathbf{T} . In slot-naming index notation, it is conventional to denote this gradient by $T_{abc;d}$, where in general the number of indices preceding the semicolon is the rank of \mathbf{T} . Using this notation, the directional derivative of \mathbf{T} along \mathbf{A} reads [cf. Eq. (1.15b)] $T_{abc;j} A_j$.

It is not hard to show that in any Cartesian coordinate system, the components of the gradient are nothing but the partial derivatives of the components of the original tensor, which we denote by a comma:

$$\boxed{T_{abc;j} = \frac{\partial T_{abc}}{\partial x_j} \equiv T_{abc,j}}. \quad (1.15c)$$

In a non-Cartesian basis (e.g., the spherical and cylindrical bases often used in electromagnetic theory), the components of the gradient typically are not obtained by simple partial differentiation [Eq. (1.15c) fails] because of turning and/or length changes of the basis vectors as we go from one location to another. In Sec. 11.8, we shall learn how to deal with this by using objects called *connection coefficients*. Until then, we confine ourselves to Cartesian bases, so subscript semicolons and subscript commas (partial derivatives) can be used interchangeably.

Because the gradient and the directional derivative are defined by the same standard limiting process as one uses when defining elementary derivatives, they obey the standard (Leibniz) rule for differentiating products:

$$\begin{aligned} \nabla_{\mathbf{A}}(\mathbf{S} \otimes \mathbf{T}) &= (\nabla_{\mathbf{A}} \mathbf{S}) \otimes \mathbf{T} + \mathbf{S} \otimes \nabla_{\mathbf{A}} \mathbf{T}, \\ \text{or } (S_{ab} T_{cde})_{;j} A_j &= (S_{ab;j} A_j) T_{cde} + S_{ab} (T_{cde;j} A_j); \end{aligned} \quad (1.16a)$$

and

$$\nabla_{\mathbf{A}}(f \mathbf{T}) = (\nabla_{\mathbf{A}} f) \mathbf{T} + f \nabla_{\mathbf{A}} \mathbf{T}, \quad \text{or } (f T_{abc})_{;j} A_j = (f_{;j} A_j) T_{abc} + f T_{abc;j} A_j. \quad (1.16b)$$

gradient

In an orthonormal basis these relations should be obvious: they follow from the Leibniz rule for partial derivatives.

Because the components g_{ab} of the metric tensor are constant in any Cartesian coordinate system, Eq. (1.15c) (which is valid in such coordinates) guarantees that $g_{ab;j} = 0$; i.e., the metric has vanishing gradient:

$$\nabla \mathbf{g} = 0, \quad \text{or} \quad g_{ab;j} = 0. \quad (1.17)$$

From the gradient of any vector or tensor we can construct several other important derivatives by contracting on slots:

1. Since the gradient $\nabla \mathbf{A}$ of a vector field \mathbf{A} has two slots, $\nabla \mathbf{A}(_, _)$, we can contract its slots on each other to obtain a scalar field. That scalar field is the *divergence* of \mathbf{A} and is denoted

divergence

$$\nabla \cdot \mathbf{A} \equiv (\text{contraction of } \nabla \mathbf{A}) = A_{a;a}. \quad (1.18)$$

2. Similarly, if \mathbf{T} is a tensor field of rank 3, then $T_{abc;c}$ is its divergence on its third slot, and $T_{abc;b}$ is its divergence on its second slot.
3. By taking the double gradient and then contracting on the two gradient slots we obtain, from any tensor field \mathbf{T} , a new tensor field with the same rank,

laplacian

$$\nabla^2 \mathbf{T} \equiv (\nabla \cdot \nabla) \mathbf{T}, \quad \text{or} \quad T_{abc;jj}. \quad (1.19)$$

Here and henceforth, all indices following a semicolon (or comma) represent gradients (or partial derivatives): $T_{abc;jj} \equiv T_{abc;j;j}$, $T_{abc,jk} \equiv \partial^2 T_{abc} / \partial x_j \partial x_k$. The operator ∇^2 is called the *laplacian*.

The metric tensor is a fundamental property of the space in which it lives; it embodies the inner product and hence the space's notion of distance. In addition to the metric, there is one (and only one) other fundamental tensor that describes a piece of Euclidean space's geometry: the *Levi-Civita tensor* ϵ , which embodies the space's notion of volume.

Levi-Civita tensor

In a Euclidean space with dimension n , the Levi-Civita tensor ϵ is a completely antisymmetric tensor with rank n (with n slots). A parallelepiped whose edges are the n vectors $\mathbf{A}, \mathbf{B}, \dots, \mathbf{F}$ is said to have the *volume*

volume

$$\boxed{\text{volume} = \epsilon(\mathbf{A}, \mathbf{B}, \dots, \mathbf{F})}. \quad (1.20)$$

(We justify this definition in Sec. 1.8.) Notice that this volume can be positive or negative, and if we exchange the order of the parallelepiped's legs, the volume's sign changes: $\epsilon(\mathbf{B}, \mathbf{A}, \dots, \mathbf{F}) = -\epsilon(\mathbf{A}, \mathbf{B}, \dots, \mathbf{F})$ by antisymmetry of ϵ .

It is easy to see (Ex. 1.7) that (i) the volume vanishes unless the legs are all linearly independent, (ii) once the volume has been specified for one parallelepiped (one set of linearly independent legs), it is thereby determined for all parallelepipeds, and therefore, (iii) we require only one number plus antisymmetry to determine ϵ

fully. If the chosen parallelepiped has legs that are orthonormal (all are orthogonal to one another and all have unit length—properties determined by the metric \mathbf{g}), then it must have unit volume, or more precisely volume ± 1 . This is a compatibility relation between \mathbf{g} and ϵ . It is easy to see (Ex. 1.7) that (iv) ϵ is fully determined by its antisymmetry, compatibility with the metric, and a single sign: the choice of which parallelepipeds have positive volume and which have negative. It is conventional in Euclidean 3-space to give right-handed parallelepipeds positive volume and left-handed ones negative volume: $\epsilon(\mathbf{A}, \mathbf{B}, \mathbf{C})$ is positive if, when we place our right thumb along \mathbf{C} and the fingers of our right hand along \mathbf{A} , then bend our fingers, they sweep toward \mathbf{B} and not $-\mathbf{B}$.

These considerations dictate that in a right-handed orthonormal basis of Euclidean 3-space, the only nonzero components of ϵ are

$$\begin{aligned} \epsilon_{123} &= +1, \\ \epsilon_{abc} &= \begin{cases} +1 & \text{if } a, b, c \text{ is an even permutation of } 1, 2, 3 \\ -1 & \text{if } a, b, c \text{ is an odd permutation of } 1, 2, 3 \\ 0 & \text{if } a, b, c \text{ are not all different;} \end{cases} \end{aligned} \quad (1.21)$$

and in a left-handed orthonormal basis, the signs of these components are reversed.

The Levi-Civita tensor is used to define the cross product and the curl:

$$\mathbf{A} \times \mathbf{B} \equiv \epsilon(_, \mathbf{A}, \mathbf{B}); \quad \text{in slot-naming index notation, } \epsilon_{ijk} A_j B_k; \quad (1.22a)$$

$$\nabla \times \mathbf{A} \equiv (\text{the vector field whose slot-naming index form is } \epsilon_{ijk} A_{k;j}). \quad (1.22b)$$

[Equation (1.22b) is an example of an expression that is complicated if stated in index-free notation; it says that $\nabla \times \mathbf{A}$ is the double contraction of the rank-5 tensor $\epsilon \otimes \nabla \mathbf{A}$ on its second and fifth slots, and on its third and fourth slots.]

Although Eqs. (1.22a) and (1.22b) look like complicated ways to deal with concepts that most readers regard as familiar and elementary, they have great power. The power comes from the following property of the Levi-Civita tensor in Euclidean 3-space [readily derivable from its components (1.21)]:

$$\boxed{\epsilon_{ijm} \epsilon_{klm} = \delta_{kl}^{ij} \equiv \delta_k^i \delta_l^j - \delta_l^i \delta_k^j.} \quad (1.23)$$

Here δ_k^i is the Kronecker delta. Examine the 4-index delta function δ_{kl}^{ij} carefully; it says that either the indices above and below each other must be the same ($i = k$ and $j = l$) with a + sign, or the diagonally related indices must be the same ($i = l$ and $j = k$) with a – sign. [We have put the indices ij of δ_{kl}^{ij} up solely to facilitate remembering this rule. Recall (first paragraph of Sec. 1.5) that in Euclidean space and Cartesian coordinates, it does not matter whether indices are up or down.] With the aid of Eq. (1.23) and the index-notation expressions for the cross product and curl, one can quickly and easily derive a wide variety of useful vector identities; see the very important Ex. 1.8.

EXERCISES

Exercise 1.7 *Derivation: Properties of the Levi-Civita Tensor*

From its complete antisymmetry, derive the four properties of the Levi-Civita tensor, in n -dimensional Euclidean space, that are claimed in the text following Eq. (1.20).

Exercise 1.8 ***Example and Practice: Vectorial Identities for the Cross Product and Curl*

Here is an example of how to use index notation to derive a vector identity for the double cross product $\mathbf{A} \times (\mathbf{B} \times \mathbf{C})$: in index notation this quantity is $\epsilon_{ijk} A_j (\epsilon_{klm} B_l C_m)$. By permuting the indices on the second ϵ and then invoking Eq. (1.23), we can write this as $\epsilon_{ijk} \epsilon_{lmk} A_j B_l C_m = \delta_{ij}^{lm} A_j B_l C_m$. By then invoking the meaning of the 4-index delta function [Eq. (1.23)], we bring this into the form $A_j B_i C_j - A_j B_j C_i$, which is the slot-naming index-notation form of $(\mathbf{A} \cdot \mathbf{C})\mathbf{B} - (\mathbf{A} \cdot \mathbf{B})\mathbf{C}$. Thus, it must be that $\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = (\mathbf{A} \cdot \mathbf{C})\mathbf{B} - (\mathbf{A} \cdot \mathbf{B})\mathbf{C}$. Use similar techniques to evaluate the following quantities.

- (a) $\nabla \times (\nabla \times \mathbf{A})$.
- (b) $(\mathbf{A} \times \mathbf{B}) \cdot (\mathbf{C} \times \mathbf{D})$.
- (c) $(\mathbf{A} \times \mathbf{B}) \times (\mathbf{C} \times \mathbf{D})$.

Exercise 1.9 ***Example and Practice: Levi-Civita Tensor in 2-Dimensional Euclidean Space*

In Euclidean 2-space, let $\{\mathbf{e}_1, \mathbf{e}_2\}$ be an orthonormal basis with positive volume.

- (a) Show that the components of ϵ in this basis are

$$\epsilon_{12} = +1, \quad \epsilon_{21} = -1, \quad \epsilon_{11} = \epsilon_{22} = 0. \quad (1.24a)$$

- (b) Show that

$$\epsilon_{ik} \epsilon_{jk} = \delta_{ij}. \quad (1.24b)$$

1.8 1.8 Volumes, Integration, and Integral Conservation Laws

In Cartesian coordinates of 2-dimensional Euclidean space, the basis vectors are orthonormal, so (with a conventional choice of sign) the components of the Levi-Civita tensor are given by Eqs. (1.24a). Correspondingly, the area (i.e., 2-dimensional volume) of a parallelogram whose sides are \mathbf{A} and \mathbf{B} is

$$2\text{-volume} = \epsilon(\mathbf{A}, \mathbf{B}) = \epsilon_{ab} A_a B_b = A_1 B_2 - A_2 B_1 = \det \begin{bmatrix} A_1 & B_1 \\ A_2 & B_2 \end{bmatrix}, \quad (1.25)$$

a relation that should be familiar from elementary geometry. Equally familiar should be the following expression for the 3-dimensional volume of a parallelepiped with legs

\mathbf{A} , \mathbf{B} , and \mathbf{C} [which follows from the components (1.21) of the Levi-Civita tensor]:

$$3\text{-volume} = \epsilon(\mathbf{A}, \mathbf{B}, \mathbf{C}) = \epsilon_{ijk} A_i B_j C_k = \mathbf{A} \cdot (\mathbf{B} \times \mathbf{C}) = \det \begin{bmatrix} A_1 & B_1 & C_1 \\ A_2 & B_2 & C_2 \\ A_3 & B_3 & C_3 \end{bmatrix}. \quad (1.26)$$

3-volume

Our formal definition (1.20) of volume is justified because it gives rise to these familiar equations.

Equations (1.25) and (1.26) are foundations from which one can derive the usual formulas $dA = dx dy$ and $dV = dx dy dz$ for the area and volume of elementary surface and volume elements with Cartesian side lengths dx , dy , and dz (Ex. 1.10).

In Euclidean 3-space, we define the vectorial surface area of a 2-dimensional parallelogram with legs \mathbf{A} and \mathbf{B} to be

$$\boxed{\boldsymbol{\Sigma} = \mathbf{A} \times \mathbf{B} = \epsilon(_, \mathbf{A}, \mathbf{B})}. \quad (1.27)$$

This vectorial surface area has a magnitude equal to the area of the parallelogram and a direction perpendicular to it. Notice that this surface area $\epsilon(_, \mathbf{A}, \mathbf{B})$ can be thought of as an object that is waiting for us to insert a third leg, \mathbf{C} , so as to compute a 3-volume $\epsilon(\mathbf{C}, \mathbf{A}, \mathbf{B})$ —the volume of the parallelepiped with legs \mathbf{C} , \mathbf{A} , and \mathbf{B} .

vectorial surface area

A parallelogram's surface has two faces (two sides), called the *positive face* and the *negative face*. If the vector \mathbf{C} sticks out of the positive face, then $\boldsymbol{\Sigma}(\mathbf{C}) = \epsilon(\mathbf{C}, \mathbf{A}, \mathbf{B})$ is positive; if \mathbf{C} sticks out of the negative face, then $\boldsymbol{\Sigma}(\mathbf{C})$ is negative.

1.8.1 Gauss's and Stokes' Theorems

1.8.1

Such vectorial surface areas are the foundation for surface integrals in 3-dimensional space and for the familiar *Gauss's theorem*,

Gauss's and Stokes' theorems

$$\boxed{\int_{\mathcal{V}_3} (\nabla \cdot \mathbf{A}) dV = \int_{\partial\mathcal{V}_3} \mathbf{A} \cdot d\boldsymbol{\Sigma}} \quad (1.28a)$$

(where \mathcal{V}_3 is a compact 3-dimensional region, and $\partial\mathcal{V}_3$ is its closed 2-dimensional boundary) and *Stokes' theorem*,

$$\boxed{\int_{\mathcal{V}_2} \nabla \times \mathbf{A} \cdot d\boldsymbol{\Sigma} = \int_{\partial\mathcal{V}_2} \mathbf{A} \cdot d\mathbf{l}} \quad (1.28b)$$

(where \mathcal{V}_2 is a compact 2-dimensional region, $\partial\mathcal{V}_2$ is the 1-dimensional closed curve that bounds it, and the last integral is a line integral around that curve); see, e.g., Arfken, Weber, and Harris (2013).

This mathematics is illustrated by the integral and differential conservation laws for electric charge and for particles: The total charge and the total number of particles inside a 3-dimensional region of space \mathcal{V}_3 are $\int_{\mathcal{V}_3} \rho_e dV$ and $\int_{\mathcal{V}_3} n dV$, where ρ_e is the charge density and n the number density of particles. The rates that charge and particles flow out of \mathcal{V}_3 are the integrals of the current density \mathbf{j} and the particle flux

vector \mathbf{S} over its boundary $\partial\mathcal{V}_3$. Therefore, the *integral laws of charge conservation and particle conservation* are

integral conservation laws

$$\boxed{\frac{d}{dt} \int_{\mathcal{V}_3} \rho_e dV + \int_{\partial\mathcal{V}_3} \mathbf{j} \cdot d\boldsymbol{\Sigma} = 0}, \quad \boxed{\frac{d}{dt} \int_{\mathcal{V}_3} n dV + \int_{\partial\mathcal{V}_3} \mathbf{S} \cdot d\boldsymbol{\Sigma} = 0}. \quad (1.29)$$

Pull the time derivative inside each volume integral (where it becomes a partial derivative), and apply Gauss's law to each surface integral; the results are $\int_{\mathcal{V}_3} (\partial\rho_e/\partial t + \nabla \cdot \mathbf{j}) dV = 0$ and similarly for particles. The only way these equations can be true for all choices of \mathcal{V}_3 is for the integrands to vanish:

differential conservation laws

$$\boxed{\partial\rho_e/\partial t + \nabla \cdot \mathbf{j} = 0}, \quad \boxed{\partial n/\partial t + \nabla \cdot \mathbf{S} = 0}. \quad (1.30)$$

These are the *differential conservation laws for charge and for particles*. They have a standard, universal form: the time derivative of the density of a quantity plus the divergence of its flux vanishes.

Note that the integral conservation laws (1.29) and the differential conservation laws (1.30) require no coordinate system or basis for their description, and no coordinate system or basis was used in deriving the differential laws from the integral laws. This is an example of the fundamental principle that *the Newtonian physical laws are all expressible as geometric relationships among geometric objects*.

EXERCISES

Exercise 1.10 Derivation and Practice: Volume Elements in Cartesian Coordinates

Use Eqs. (1.25) and (1.26) to derive the usual formulas $dA = dx dy$ and $dV = dx dy dz$ for the 2-dimensional and 3-dimensional integration elements, respectively, in right-handed Cartesian coordinates. [Hint: Use as the edges of the integration volumes $dx \mathbf{e}_x$, $dy \mathbf{e}_y$, and $dz \mathbf{e}_z$.]

Exercise 1.11 Example and Practice: Integral of a Vector Field over a Sphere

Integrate the vector field $\mathbf{A} = z\mathbf{e}_z$ over a sphere with radius a , centered at the origin of the Cartesian coordinate system (i.e., compute $\int \mathbf{A} \cdot d\boldsymbol{\Sigma}$). Hints:

- (a) Introduce spherical polar coordinates on the sphere, and construct the vectorial integration element $d\boldsymbol{\Sigma}$ from the two legs $a d\theta \mathbf{e}_{\hat{\theta}}$ and $a \sin \theta d\phi \mathbf{e}_{\hat{\phi}}$. Here $\mathbf{e}_{\hat{\theta}}$ and $\mathbf{e}_{\hat{\phi}}$ are unit-length vectors along the θ and ϕ directions. (Here as in Sec. 1.6 and throughout this book, we use accents on indices to indicate which basis the index is associated with: hats here for the spherical orthonormal basis, bars in Sec. 1.6 for the barred Cartesian basis.) Explain the factors $a d\theta$ and $a \sin \theta d\phi$ in the definitions of the legs. Show that

$$d\boldsymbol{\Sigma} = \boldsymbol{\epsilon}(_, \mathbf{e}_{\hat{\theta}}, \mathbf{e}_{\hat{\phi}}) a^2 \sin \theta d\theta d\phi. \quad (1.31)$$

- (b) Using $z = a \cos \theta$ and $\mathbf{e}_z = \cos \theta \mathbf{e}_{\hat{r}} - \sin \theta \mathbf{e}_{\hat{\theta}}$ on the sphere (where $\mathbf{e}_{\hat{r}}$ is the unit vector pointing in the radial direction), show that

$$\mathbf{A} \cdot d\boldsymbol{\Sigma} = a \cos^2 \theta \boldsymbol{\epsilon}(\mathbf{e}_{\hat{r}}, \mathbf{e}_{\hat{\theta}}, \mathbf{e}_{\hat{\phi}}) a^2 \sin \theta d\theta d\phi.$$

- (c) Explain why $\epsilon(\mathbf{e}_{\hat{r}}, \mathbf{e}_{\hat{\theta}}, \mathbf{e}_{\hat{\phi}}) = 1$.
- (d) Perform the integral $\int \mathbf{A} \cdot d\boldsymbol{\Sigma}$ over the sphere's surface to obtain your final answer $(4\pi/3)a^3$. This, of course, is the volume of the sphere. Explain pictorially why this had to be the answer.

Exercise 1.12 *Example: Faraday's Law of Induction*

One of Maxwell's equations says that $\nabla \times \mathbf{E} = -\partial\mathbf{B}/\partial t$ (in SI units), where \mathbf{E} and \mathbf{B} are the electric and magnetic fields. This is a geometric relationship between geometric objects; it requires no coordinates or basis for its statement. By integrating this equation over a 2-dimensional surface \mathcal{V}_2 with boundary curve $\partial\mathcal{V}_2$ and applying Stokes' theorem, derive Faraday's law of induction—again, a geometric relationship between geometric objects.

1.9 The Stress Tensor and Momentum Conservation

Press your hands together in the y - z plane and feel the force that one hand exerts on the other across a tiny area A —say, one square millimeter of your hands' palms (Fig. 1.5). That force, of course, is a vector \mathbf{F} . It has a normal component (along the x direction). It also has a tangential component: if you try to slide your hands past each other, you feel a component of force along their surface, a “shear” force in the y and z directions. Not only is the force \mathbf{F} vectorial; so is the 2-surface across which it acts, $\boldsymbol{\Sigma} = A \mathbf{e}_x$. (Here \mathbf{e}_x is the unit vector orthogonal to the tiny area A , and we have chosen the negative side of the surface to be the $-x$ side and the positive side to be $+x$. With this choice, the force \mathbf{F} is that which the negative hand, on the $-x$ side, exerts on the positive hand.)

Now, it should be obvious that the force \mathbf{F} is a linear function of our chosen surface $\boldsymbol{\Sigma}$. Therefore, there must be a tensor, the *stress tensor*, that reports the force to us when we insert the surface into its second slot:

$$\mathbf{F}(_) = \mathbf{T}(_, \boldsymbol{\Sigma}), \quad \text{or} \quad F_i = T_{ij} \Sigma_j. \tag{1.32}$$

FIGURE 1.5 Hands, pressed together, exert a force on each other.

1.9

force vector

stress tensor

Newton's law of action and reaction tells us that the force that the positive hand exerts on the negative hand must be equal and opposite to that which the negative hand exerts on the positive. This shows up trivially in Eq. (1.32): by changing the sign of Σ , one reverses which hand is regarded as negative and which positive, and since \mathbf{T} is linear in Σ , one also reverses the sign of the force.

The definition (1.32) of the stress tensor gives rise to the following physical meaning of its components:

$$T_{jk} = \begin{pmatrix} j \text{ component of force per unit area} \\ \text{across a surface perpendicular to } \mathbf{e}_k \end{pmatrix} = \begin{pmatrix} j \text{ component of momentum that crosses a unit} \\ \text{area that is perpendicular to } \mathbf{e}_k, \text{ per unit time,} \\ \text{with the crossing being from } -x_k \text{ to } +x_k \end{pmatrix}. \quad (1.33)$$

meaning of components of stress tensor

The stresses inside a table with a heavy weight on it are described by the stress tensor \mathbf{T} , as are the stresses in a flowing fluid or plasma, in the electromagnetic field, and in any other physical medium. Accordingly, we shall use the stress tensor as an important mathematical tool in our study of force balance in kinetic theory (Chap. 3), elasticity (Part IV), fluid dynamics (Part V), and plasma physics (Part VI).

symmetry of stress tensor

It is not obvious from its definition, but the stress tensor \mathbf{T} is always symmetric in its two slots. To see this, consider a small cube with side L in any medium (or field) (Fig. 1.6). The medium outside the cube exerts forces, and hence also torques, on the cube's faces. The z -component of the torque is produced by the shear forces on the front and back faces and on the left and right. As shown in the figure, the shear forces on the front and back faces have magnitudes $T_{xy}L^2$ and point in opposite directions, so they exert identical torques on the cube, $N_z = T_{xy}L^2(L/2)$ (where $L/2$ is the distance of each face from the cube's center). Similarly, the shear forces on the left and right faces have magnitudes $T_{yx}L^2$ and point in opposite directions, thereby exerting identical torques on the cube, $N_z = -T_{yx}L^2(L/2)$. Adding the torques from all four faces and equating them to the rate of change of angular momentum, $\frac{1}{6}\rho L^5 d\Omega_z/dt$ (where ρ is the mass density, $\frac{1}{6}\rho L^5$ is the cube's moment of inertia, and Ω_z is the z component of its angular velocity), we obtain $(T_{xy} - T_{yx})L^3 = \frac{1}{6}\rho L^5 d\Omega_z/dt$. Now, let the cube's edge length become arbitrarily small, $L \rightarrow 0$. If $T_{xy} - T_{yx}$ does not vanish, then the cube will be set into rotation with an infinitely large angular acceleration, $d\Omega_z/dt \propto 1/L^2 \rightarrow \infty$ —an obviously unphysical behavior. Therefore, $T_{yx} = T_{xy}$, and similarly for all other components: *the stress tensor is always symmetric under interchange of its two slots.*

1.9.1

1.9.1 Examples: Electromagnetic Field and Perfect Fluid

Two examples will make the concept of the stress tensor more concrete.

- **Electromagnetic field:** See Ex. 1.14.
- **Perfect fluid:** A *perfect fluid* is a medium that can exert an isotropic pressure P but no shear stresses, so the only nonzero components of its stress tensor

perfect fluid

FIGURE 1.6 The shear forces exerted on the left, right, front, and back faces of a vanishingly small cube of side length L . The resulting torque about the z direction will set the cube into rotation with an arbitrarily large angular acceleration unless the stress tensor is symmetric.

in a Cartesian basis are $T_{xx} = T_{yy} = T_{zz} = P$. (Examples of nearly perfect fluids are air and water, but not molasses.) We can summarize this property by $T_{ij} = P\delta_{ij}$ or equivalently, since δ_{ij} are the components of the Euclidean metric, $T_{ij} = Pg_{ij}$. The frame-independent version of this is

$$\mathbf{T} = P\mathbf{g} \quad \text{or, in slot-naming index notation,} \quad T_{ij} = Pg_{ij}. \quad (1.34)$$

Note that, as always, the formula in slot-naming index notation looks identical to the formula $T_{ij} = Pg_{ij}$ for the components in our chosen Cartesian coordinate system. To check Eq. (1.34), consider a 2-surface $\Sigma = \mathbf{A}\mathbf{n}$ with area A oriented perpendicular to some arbitrary unit vector \mathbf{n} . The vectorial force that the fluid exerts across Σ is, in index notation, $F_j = T_{jk}\Sigma_k = Pg_{jk}An_k = PAn_j$ (i.e., it is a normal force with magnitude equal to the fluid pressure P times the surface area A). This is what it should be.

1.9.2 Conservation of Momentum

1.9.2

The stress tensor plays a central role in the Newtonian law of momentum conservation because (by definition) the force acting across a surface is the same as the rate of flow of momentum, per unit area, across the surface: *the stress tensor is the flux of momentum*.

Consider the 3-dimensional region of space \mathcal{V}_3 used above in formulating the integral laws of charge and particle conservation (1.29). The total momentum in \mathcal{V}_3 is $\int_{\mathcal{V}_3} \mathbf{G} dV$, where \mathbf{G} is the momentum density. This quantity changes as a result of momentum flowing into and out of \mathcal{V}_3 . The net rate at which momentum flows outward is the integral of the stress tensor over the surface $\partial\mathcal{V}_3$ of \mathcal{V}_3 . Therefore, by

analogy with charge and particle conservation (1.29), the *integral law of momentum conservation* says

integral conservation of momentum

$$\frac{d}{dt} \int_{\mathcal{V}_3} \mathbf{G} dV + \int_{\partial\mathcal{V}_3} \mathbf{T} \cdot d\boldsymbol{\Sigma} = 0. \quad (1.35)$$

By pulling the time derivative inside the volume integral (where it becomes a partial derivative) and applying the vectorial version of Gauss's law to the surface integral, we obtain $\int_{\mathcal{V}_3} (\partial\mathbf{G}/\partial t + \nabla \cdot \mathbf{T}) dV = 0$. This can be true for all choices of \mathcal{V}_3 only if the integrand vanishes:

differential conservation of momentum

$$\frac{\partial \mathbf{G}}{\partial t} + \nabla \cdot \mathbf{T} = 0, \quad \text{or} \quad \frac{\partial G_j}{\partial t} + T_{jk;k} = 0. \quad (1.36)$$

(Because \mathbf{T} is symmetric, it does not matter which of its slots the divergence acts on.) This is the *differential law of momentum conservation*. It has the standard form for any local conservation law: the time derivative of the density of some quantity (here momentum), plus the divergence of the flux of that quantity (here the momentum flux is the stress tensor), is zero. We shall make extensive use of this Newtonian law of momentum conservation in Part IV (elasticity), Part V (fluid dynamics), and Part VI (plasma physics).

EXERCISES

Exercise 1.13 ***Example: Equations of Motion for a Perfect Fluid*

- (a) Consider a perfect fluid with density ρ , pressure P , and velocity \mathbf{v} that vary in time and space. Explain why the fluid's momentum density is $\mathbf{G} = \rho\mathbf{v}$, and explain why its momentum flux (stress tensor) is

$$\mathbf{T} = P\mathbf{g} + \rho\mathbf{v} \otimes \mathbf{v}, \quad \text{or, in slot-naming index notation,} \quad T_{ij} = P g_{ij} + \rho v_i v_j. \quad (1.37a)$$

- (b) Explain why the law of mass conservation for this fluid is

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho\mathbf{v}) = 0. \quad (1.37b)$$

- (c) Explain why the derivative operator

$$\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \quad (1.37c)$$

describes the rate of change as measured by somebody who moves locally with the fluid (i.e., with velocity \mathbf{v}). This is sometimes called the fluid's *advective time derivative* or *convective time derivative* or *material derivative*.

(d) Show that the fluid's law of mass conservation (1.37b) can be rewritten as

$$\frac{1}{\rho} \frac{d\rho}{dt} = -\nabla \cdot \mathbf{v}, \quad (1.37d)$$

which says that the divergence of the fluid's velocity field is minus the fractional rate of change of its density, as measured in the fluid's local rest frame.

(e) Show that the differential law of momentum conservation (1.36) for the fluid can be written as

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P}{\rho}. \quad (1.37e)$$

This is called the fluid's *Euler equation*. Explain why this Euler equation is Newton's second law of motion, $\mathbf{F} = m\mathbf{a}$, written on a per unit mass basis.

In Part V of this book, we use Eqs. (1.37) to study the dynamical behaviors of fluids. For many applications, the Euler equation will need to be augmented by the force per unit mass exerted by the fluid's internal viscosity.

Exercise 1.14 ***Problem: Electromagnetic Stress Tensor*

(a) An electric field \mathbf{E} exerts (in SI units) a pressure $\epsilon_0 \mathbf{E}^2/2$ orthogonal to itself and a tension of this same magnitude along itself. Similarly, a magnetic field \mathbf{B} exerts a pressure $\mathbf{B}^2/2\mu_0 = \epsilon_0 c^2 \mathbf{B}^2/2$ orthogonal to itself and a tension of this same magnitude along itself. Verify that the following stress tensor embodies these stresses:

$$\mathbf{T} = \frac{\epsilon_0}{2} \left[(\mathbf{E}^2 + c^2 \mathbf{B}^2) \mathbf{g} - 2(\mathbf{E} \otimes \mathbf{E} + c^2 \mathbf{B} \otimes \mathbf{B}) \right]. \quad (1.38)$$

(b) Consider an electromagnetic field interacting with a material that has a charge density ρ_e and a current density \mathbf{j} . Compute the divergence of the electromagnetic stress tensor (1.38) and evaluate the derivatives using Maxwell's equations. Show that the result is the negative of the force density that the electromagnetic field exerts on the material. Use momentum conservation to explain why this has to be so.

1.10 Geometrized Units and Relativistic Particles for Newtonian Readers

1.10

Readers who are skipping the relativistic parts of this book will need to know two important pieces of relativity: (i) geometrized units and (ii) the relativistic energy and momentum of a moving particle.

1.10.1 Geometrized Units

1.10.1

The speed of light is independent of one's reference frame (i.e., independent of how fast one moves). This is a fundamental tenet of special relativity, and in the era before 1983, when the meter and the second were defined independently, it was tested and

confirmed experimentally with very high precision. By 1983, this constancy had become so universally accepted that it was used to redefine the meter (which is hard to measure precisely) in terms of the second (which is much easier to measure with modern technology).¹¹ The meter is now related to the second in such a way that the speed of light is precisely $c = 299,792,458 \text{ m s}^{-1}$ (i.e., 1 meter is the distance traveled by light in $1/299,792,458$ seconds). Because of this constancy of the light speed, it is permissible when studying special relativity to set c to unity. Doing so is equivalent to the relationship

$$c = 2.99792458 \times 10^8 \text{ m s}^{-1} = 1 \quad (1.39a)$$

between seconds and centimeters; i.e., equivalent to

$$1 \text{ s} = 2.99792458 \times 10^8 \text{ m}. \quad (1.39b)$$

geometrized units

We refer to units in which $c = 1$ as *geometrized units*, and we adopt them throughout this book when dealing with relativistic physics, since they make equations look much simpler. Occasionally it will be useful to restore the factors of c to an equation, thereby converting it to ordinary (SI or cgs) units. This restoration is achieved easily using dimensional considerations. For example, the equivalence of mass m and relativistic energy \mathcal{E} is written in geometrized units as $\mathcal{E} = m$. In SI units \mathcal{E} has dimensions of joule = $\text{kg m}^2 \text{ s}^{-2}$, while m has dimensions of kg, so to make $\mathcal{E} = m$ dimensionally correct we must multiply the right side by a power of c that has dimensions $\text{m}^2 \text{ s}^{-2}$ (i.e., by c^2); thereby we obtain $\mathcal{E} = mc^2$.

1.10.2

1.10.2 Energy and Momentum of a Moving Particle

relativistic energy and momentum

A particle with rest mass m , moving with velocity $\mathbf{v} = d\mathbf{x}/dt$ and speed $v = |\mathbf{v}|$, has a relativistic energy \mathcal{E} (including its rest mass), relativistic kinetic energy E (excluding its rest mass), and relativistic momentum \mathbf{p} given by

$$\mathcal{E} = \frac{m}{\sqrt{1-v^2}} \equiv \frac{m}{\sqrt{1-v^2/c^2}} \equiv E + m, \quad \mathbf{p} = \mathcal{E}\mathbf{v} = \frac{m\mathbf{v}}{\sqrt{1-v^2}}; \quad (1.40)$$

so $\mathcal{E} = \sqrt{m^2 + \mathbf{p}^2}$.

In the low-velocity (Newtonian) limit, the energy E with rest mass removed (kinetic energy) and the momentum \mathbf{p} take their familiar Newtonian forms:

$$\text{When } v \ll c \equiv 1, \quad E \rightarrow \frac{1}{2}mv^2 \quad \text{and } \mathbf{p} \rightarrow m\mathbf{v}. \quad (1.41)$$

11. The second is defined as the duration of 9,192,631,770 periods of the radiation produced by a certain hyperfine transition in the ground state of a ^{133}Cs atom that is at rest in empty space. Today (2016) all fundamental physical units except mass units (e.g., the kilogram) are defined similarly in terms of fundamental constants of Nature.

A particle with zero rest mass (a photon or a graviton)¹² always moves with the speed of light $v = c = 1$, and like other particles it has momentum $\mathbf{p} = \mathcal{E}\mathbf{v}$, so the magnitude of its momentum is equal to its energy: $|\mathbf{p}| = \mathcal{E}v = \mathcal{E}c = \mathcal{E}$.

When particles interact (e.g., in chemical reactions, nuclear reactions, and elementary-particle collisions) the sum of the particle energies \mathcal{E} is conserved, as is the sum of the particle momenta \mathbf{p} .

For further details and explanations, see Chap. 2.

EXERCISES

Exercise 1.15 Practice: Geometrized Units

Convert the following equations from the geometrized units in which they are written to SI units.

- The “Planck time” t_P expressed in terms of Newton’s gravitation constant G and Planck’s reduced constant \hbar , $t_P = \sqrt{G\hbar}$. What is the numerical value of t_P in seconds? in meters?
- The energy $\mathcal{E} = 2m$ obtained from the annihilation of an electron and a positron, each with rest mass m .
- The Lorentz force law $m d\mathbf{v}/dt = e(\mathbf{E} + \mathbf{v} \times \mathbf{B})$.
- The expression $\mathbf{p} = \hbar\omega\mathbf{n}$ for the momentum \mathbf{p} of a photon in terms of its angular frequency ω and direction \mathbf{n} of propagation.

How tall are you, in seconds? How old are you, in meters?

Bibliographic Note

Most of the concepts developed in this chapter are treated, though from rather different viewpoints, in intermediate and advanced textbooks on classical mechanics or electrodynamics, such as Marion and Thornton (1995); Jackson (1999); Griffiths (1999); Goldstein, Poole, and Safko (2002).

Landau and Lifshitz’s (1976) advanced text *Mechanics* is famous for its concise and precise formulations; it lays heavy emphasis on symmetry principles and their implications. A similar approach is followed in the next volume in their Course of Theoretical Physics series, *The Classical Theory of Fields* (Landau and Lifshitz, 1975), which is rooted in special relativity and goes on to cover general relativity. We refer to other volumes in this remarkable series in subsequent chapters.

The three-volume *Feynman Lectures on Physics* (Feynman, Leighton, and Sands, 2013) had a big influence on several generations of physicists, and even more so on their teachers. Both of us (Blandford and Thorne) are immensely indebted to Richard Feynman for shaping our own approaches to physics. His insights on the foundations

12. We do not know for sure that photons and gravitons are massless, but the laws of physics as currently understood require them to be massless, and there are tight experimental limits on their rest masses.

of classical physics and its relationship to quantum mechanics, and on calculational techniques, are as relevant today as in 1963, when his course was first delivered.

The geometric viewpoint on the laws of physics, which we present and advocate in this chapter, is not common (but it should be because of its great power). For example, the vast majority of mechanics and electrodynamics textbooks, including all those listed above, define a tensor as a matrix-like entity whose components transform under rotations in the manner described by Eq. (1.13b). This is a complicated definition that hides the great simplicity of a tensor as nothing more than a linear function of vectors; it obscures thinking about tensors geometrically, without the aid of any coordinate system or basis.

The geometric viewpoint comes to the physics community from mathematicians, largely by way of relativity theory. By now, most relativity textbooks espouse it. See the Bibliographic Note to Chap. 2. Fortunately, this viewpoint is gradually seeping into the nonrelativistic physics curriculum (e.g., Kleppner and Kolenkow, 2013). We hope this chapter will accelerate that seepage.

Special Relativity: Geometric Viewpoint T2

Henceforth space by itself, and time by itself, are doomed to fade away into mere shadows,
and only a kind of union of the two will preserve an independent reality.

HERMANN MINKOWSKI, 1908

2.1 Overview

2.1

This chapter is a fairly complete introduction to special relativity at an intermediate level. We extend the geometric viewpoint, developed in Chap. 1 for Newtonian physics, to the domain of special relativity; and we extend the tools of differential geometry, developed in Chap. 1 for the arena of Newtonian physics (3-dimensional Euclidean space) to that of special relativity (4-dimensional Minkowski spacetime).

We begin in Sec. 2.2 by defining inertial (Lorentz) reference frames and then introducing fundamental, geometric, reference-frame-independent concepts: events, 4-vectors, and the invariant interval between events. Then in Sec. 2.3, we develop the basic concepts of tensor algebra in Minkowski spacetime (tensors, the metric tensor, the inner product and tensor product, and contraction), patterning our development on the corresponding concepts in Euclidean space. In Sec. 2.4, we illustrate our tensor-algebra tools by using them to describe—without any coordinate system or reference frame—the kinematics (world lines, 4-velocities, 4-momenta) of point particles that move through Minkowski spacetime. The particles are allowed to collide with one another and be accelerated by an electromagnetic field. In Sec. 2.5, we introduce components of vectors and tensors in an inertial reference frame and rewrite our frame-independent equations in slot-naming index notation; then in Sec. 2.6, we use these extended tensorial tools to restudy the motions, collisions, and electromagnetic accelerations of particles. In Sec. 2.7, we discuss Lorentz transformations in Minkowski spacetime, and in Sec. 2.8, we develop spacetime diagrams and use them to study length contraction, time dilation, and simultaneity breakdown. In Sec. 2.9, we illustrate the tools we have developed by asking whether the laws of physics permit a highly advanced civilization to build time machines for traveling backward in time as well as forward. In Sec. 2.10, we introduce directional derivatives, gradients, and the Levi-Civita tensor in Minkowski spacetime, and in Sec. 2.11, we use these tools to discuss Maxwell's equations and the geometric nature of electric and magnetic fields.

BOX 2.1. READERS' GUIDE

- Parts II (Statistical Physics), III (Optics), IV (Elasticity), V (Fluid Dynamics), and VI (Plasma Physics) of this book deal almost entirely with Newtonian physics; only a few sections and exercises are relativistic. Readers who are inclined to skip those relativistic items (which are all labeled Track Two) can skip this chapter and then return to it just before embarking on Part VII (General Relativity). Accordingly, this chapter is Track Two for readers of Parts II–VI and Track One for readers of Part VII—and in this spirit we label it Track Two.
- More specifically, this chapter is a prerequisite for the following: sections on relativistic kinetic theory in Chap. 3, Sec. 13.8 on relativistic fluid dynamics, Ex. 17.9 on relativistic shocks in fluids, many comments in Parts II–VI about relativistic effects and connections between Newtonian physics and relativistic physics, and all of Part VII (General Relativity).
- We recommend that those readers for whom relativity is relevant—and who already have a strong understanding of special relativity—not skip this chapter entirely. Instead, we suggest they browse it, especially Secs. 2.2–2.4, 2.8, and 2.11–2.13, to make sure they understand this book's geometric viewpoint and to ensure their familiarity with such concepts as the stress-energy tensor that they might not have met previously.

In Sec. 2.12, we develop our final set of geometric tools: volume elements and the integration of tensors over spacetime; finally, in Sec. 2.13, we use these tools to define the stress-energy tensor and to formulate very general versions of the conservation of 4-momentum.

2.2 **2.2 Foundational Concepts**

2.2.1 Inertial Frames, Inertial Coordinates, Events, Vectors, and Spacetime Diagrams

Because the nature and geometry of Minkowski spacetime are far less obvious intuitively than those of Euclidean 3-space, we need a crutch in our development of the geometric viewpoint for physics in spacetime. That crutch will be inertial reference frames.

FIGURE 2.1 An inertial reference frame. From Taylor and Wheeler (1966). Used with permission of E. F. Taylor and the estate of J. A. Wheeler.

An inertial reference frame is a 3-dimensional latticework of measuring rods and clocks (Fig. 2.1) with the following properties:

- The latticework is purely conceptual and has arbitrarily small mass, so it does not gravitate.
- The latticework moves freely through spacetime (i.e., no forces act on it) and is attached to gyroscopes, so it is inertially nonrotating.
- The measuring rods form an orthogonal lattice, and the length intervals marked on them are uniform when compared to, for example, the wavelength of light emitted by some standard type of atom or molecule. Therefore, the rods form an orthonormal Cartesian coordinate system with the coordinate x measured along one axis, y along another, and z along the third.
- The clocks are densely packed throughout the latticework so that, ideally, there is a separate clock at every lattice point.
- The clocks tick uniformly when compared to the period of the light emitted by some standard type of atom or molecule (i.e., they are *ideal clocks*).
- The clocks are synchronized by the Einstein synchronization process: if a pulse of light, emitted by one of the clocks, bounces off a mirror attached to another and then returns, the time of bounce t_b , as measured by the clock that does the bouncing, is the average of the times of emission and reception, as measured by the emitting and receiving clock: $t_b = \frac{1}{2}(t_e + t_r)$.¹

1. For a deeper discussion of the nature of ideal clocks and ideal measuring rods see, for example, Misner, Thorne, and Wheeler (1973, pp. 23–29 and 395–399).

inertial reference frame

ideal clocks and their synchronization

(That inertial frames with these properties can exist, when gravity is unimportant, is an empirical fact; it tells us that, in the absence of gravity, spacetime is truly Minkowski.)

event

Our first fundamental, frame-independent relativistic concept is the *event*. An event is a precise location in space at a precise moment of time—a precise location (or *point*) in 4-dimensional spacetime. We sometimes denote events by capital script letters, such as \mathcal{P} and \mathcal{Q} —the same notation used for points in Euclidean 3-space.

4-vector

A *4-vector* (also often referred to as a *vector in spacetime* or just a *vector*) is a straight² arrow $\Delta\vec{x}$ reaching from one event \mathcal{P} to another, \mathcal{Q} . We often deal with 4-vectors and ordinary (3-space) vectors simultaneously, so we shall use different notations for them: boldface Roman font for 3-vectors, $\Delta\mathbf{x}$, and arrowed italic font for 4-vectors, $\Delta\vec{x}$. Sometimes we identify an event \mathcal{P} in spacetime by its vectorial separation $\vec{x}_{\mathcal{P}}$ from some arbitrarily chosen event in spacetime, the origin \mathcal{O} .

An inertial reference frame provides us with a coordinate system for spacetime. The coordinates $(x^0, x^1, x^2, x^3) = (t, x, y, z)$ that it associates with an event \mathcal{P} are \mathcal{P} 's location (x, y, z) in the frame's latticework of measuring rods and the time t of \mathcal{P} as measured by the clock that sits in the lattice at the event's location. (Many apparent paradoxes in special relativity result from failing to remember that the time t of an event is always measured by a clock that resides at the event—never by clocks that reside elsewhere in spacetime.)

spacetime diagrams

It is useful to depict events on *spacetime diagrams*, in which the time coordinate $t = x^0$ of some inertial frame is plotted upward; two of the frame's three spatial coordinates, $x = x^1$ and $y = x^2$, are plotted horizontally; and the third coordinate $z = x^3$ is omitted. Figure 2.2 is an example. Two events \mathcal{P} and \mathcal{Q} are shown there, along with their vectorial separations $\vec{x}_{\mathcal{P}}$ and $\vec{x}_{\mathcal{Q}}$ from the origin and the vector $\Delta\vec{x} = \vec{x}_{\mathcal{Q}} - \vec{x}_{\mathcal{P}}$ that separates them from each other. The coordinates of \mathcal{P} and \mathcal{Q} , which are the same as the components of $\vec{x}_{\mathcal{P}}$ and $\vec{x}_{\mathcal{Q}}$ in this coordinate system, are $(t_{\mathcal{P}}, x_{\mathcal{P}}, y_{\mathcal{P}}, z_{\mathcal{P}})$ and $(t_{\mathcal{Q}}, x_{\mathcal{Q}}, y_{\mathcal{Q}}, z_{\mathcal{Q}})$. Correspondingly, the components of $\Delta\vec{x}$ are

$$\begin{aligned}\Delta x^0 &= \Delta t = t_{\mathcal{Q}} - t_{\mathcal{P}}, & \Delta x^1 &= \Delta x = x_{\mathcal{Q}} - x_{\mathcal{P}}, \\ \Delta x^2 &= \Delta y = y_{\mathcal{Q}} - y_{\mathcal{P}}, & \Delta x^3 &= \Delta z = z_{\mathcal{Q}} - z_{\mathcal{P}}.\end{aligned}\tag{2.1}$$

We denote these components of $\Delta\vec{x}$ more compactly by Δx^α , where the index α and all other lowercased Greek indices range from 0 (for t) to 3 (for z).

When the physics or geometry of a situation being studied suggests some preferred inertial frame (e.g., the frame in which some piece of experimental apparatus is at rest), then we typically use as axes for our spacetime diagrams the coordinates of that preferred frame. By contrast, when our situation provides no preferred inertial frame, or when we wish to emphasize a frame-independent viewpoint, we use as axes

2. By “straight” we mean that in any inertial reference frame, the coordinates along $\Delta\vec{x}$ are linear functions of one another.

FIGURE 2.2 A spacetime diagram depicting two events \mathcal{P} and \mathcal{Q} , their vectorial separations $\vec{x}_{\mathcal{P}}$ and $\vec{x}_{\mathcal{Q}}$ from an (arbitrarily chosen) origin \mathcal{O} , and the vector $\Delta\vec{x} = \vec{x}_{\mathcal{Q}} - \vec{x}_{\mathcal{P}}$ connecting them. The laws of physics cannot involve the arbitrary origin; we introduce it only as a conceptual aid.

the coordinates of a completely arbitrary inertial frame and think of the diagram as depicting spacetime in a coordinate-independent, frame-independent way.

We use the terms *inertial coordinate system* and *Lorentz coordinate system* interchangeably³ to mean the coordinate system (t, x, y, z) provided by an inertial frame; we also use the term *Lorentz frame* interchangeably with *inertial frame*. A physicist or other intelligent being who resides in a Lorentz frame and makes measurements using its latticework of rods and clocks will be called an *observer*.

Although events are often described by their coordinates in a Lorentz reference frame, and 4-vectors by their components (coordinate differences), it should be obvious that the concepts of an event and a 4-vector need not rely on any coordinate system whatsoever for their definitions. For example, the event \mathcal{P} of the birth of Isaac Newton and the event \mathcal{Q} of the birth of Albert Einstein are readily identified without coordinates. They can be regarded as points in spacetime, and their separation vector is the straight arrow reaching through spacetime from \mathcal{P} to \mathcal{Q} . Different observers in different inertial frames will attribute different coordinates to each birth and different components to the births' vectorial separation, but all observers can agree that they are talking about the same events \mathcal{P} and \mathcal{Q} in spacetime and the same separation vector $\Delta\vec{x}$. In this sense, \mathcal{P} , \mathcal{Q} , and $\Delta\vec{x}$ are *frame-independent, geometric objects* (points and arrows) that reside in spacetime.

inertial coordinates

observer

3. It was Lorentz (1904) who first wrote down the relationship of one such coordinate system to another: the Lorentz transformation.

2.2.2 The Principle of Relativity and Constancy of Light Speed

Einstein's Principle of Relativity, stated in modern form, says that *Every (special relativistic) law of physics must be expressible as a geometric, frame-independent relationship among geometric, frame-independent objects* (i.e., such objects as points in spacetime and 4-vectors and tensors, which represent physical quantities, such as events, particle momenta, and the electromagnetic field). This is nothing but our Geometric Principle for physical laws (Chap. 1), lifted from the Euclidean-space arena of Newtonian physics to the Minkowski-spacetime arena of special relativity.

Since the laws are all geometric (i.e., unrelated to any reference frame or coordinate system), they can't distinguish one inertial reference frame from any other. This leads to an alternative form of the Principle of Relativity (one commonly used in elementary textbooks and equivalent to the above): *All the (special relativistic) laws of physics are the same in every inertial reference frame everywhere in spacetime*. This, in fact, is Einstein's own version of his Principle of Relativity; only in the sixty years since his death have we physicists reexpressed it in geometric language.

Because inertial reference frames are related to one another by Lorentz transformations (Sec. 2.7), we can restate Einstein's version of this Principle as *All the (special relativistic) laws of physics are Lorentz invariant*.

A more operational version of this Principle is: Give identical instructions for a specific physics experiment to two different observers in two different inertial reference frames at the same or different locations in Minkowski (i.e., gravity-free) spacetime. The experiment must be self-contained; that is, it must not involve observations of the external universe's properties (the "environment"). For example, an unacceptable experiment would be a measurement of the anisotropy of the universe's cosmic microwave radiation and a computation therefrom of the observer's velocity relative to the radiation's mean rest frame; such an experiment studies the universal environment, not the fundamental laws of physics. An acceptable experiment would be a measurement of the speed of light using the rods and clocks of the observer's own frame, or a measurement of cross sections for elementary particle reactions using particles moving in the reference frame's laboratory. The Principle of Relativity says that in these or any other similarly self-contained experiments, the two observers in their two different inertial frames must obtain identical experimental results—to within the accuracy of their experimental techniques. Since the experimental results are governed by the (nongravitational) laws of physics, this is equivalent to the statement that all physical laws are the same in the two inertial frames.

Perhaps the most central of special relativistic laws is the one stating that *The speed of light c in vacuum is frame independent*; that is, it is a constant, independent of the inertial reference frame in which it is measured. In other words, there is no "aether" that supports light's vibrations and in the process influences its speed—a remarkable fact that came as a great experimental surprise to physicists at the end of the nineteenth century.

The constancy of the speed of light, in fact, is built into Maxwell's equations. For these equations to be frame independent, the speed of light, which appears in them, must be frame independent. In this sense, the constancy of the speed of light follows from the Principle of Relativity; it is not an independent postulate. This is illustrated in Box 2.2.

BOX 2.2. MEASURING THE SPEED OF LIGHT WITHOUT LIGHT

In some inertial reference frame, we perform two thought experiments using two particles, one with a large charge Q ; the other, a test particle, with a much smaller charge q and mass μ . In the first experiment, we place the two particles at rest, separated by a distance $|\Delta x| \equiv r$, and measure the electrical repulsive acceleration a_e of q (panel a in the diagram). In Gaussian units (where the speed of light shows up explicitly instead of via $\epsilon_0 \mu_0 = 1/c^2$), the acceleration is $a_e = qQ/r^2\mu$. In the second experiment, we connect Q to ground by a long wire, and we place q at the distance $|\Delta x| = r$ from the wire and set it moving at speed v parallel to the wire. The charge Q flows down the wire with an e -folding time τ , so the current is $I = dQ/d\tau = (Q/\tau)e^{-t/\tau}$. At early times $0 < t \ll \tau$, this current $I = Q/\tau$ produces a solenoidal magnetic field at q with field strength $B = (2/cr)(Q/\tau)$, and this field exerts a magnetic force on q , giving it an acceleration $a_m = q(v/c)B/\mu = 2vqQ/c^2\tau r\mu$. The ratio of the electric acceleration in the first experiment to the magnetic acceleration in the second experiment is $a_e/a_m = c^2\tau/2rv$. Therefore, we can measure the speed of light c in our chosen inertial frame by performing this pair of experiments; carefully measuring the separation r , speed v , current Q/τ , and accelerations; and then simply computing $c = \sqrt{(2rv/\tau)(a_e/a_m)}$. The Principle of Relativity insists that the result of this pair of experiments should be independent of the inertial frame in which they are performed. Therefore, the speed of light c that appears in Maxwell's equations must be frame independent. In this sense, the constancy of the speed of light follows from the Principle of Relativity as applied to Maxwell's equations.

What makes light so special? What about the propagation speeds of other types of waves? Are they or should they be the same as light's speed? For a digression on this topic, see Box 2.3.

The constancy of the speed of light underlies our ability to use the geometrized units introduced in Sec. 1.10. Any reader who has not studied that section should do so now. We use geometrized units throughout this chapter (and also throughout this book) when working with relativistic physics.

BOX 2.3. PROPAGATION SPEEDS OF OTHER WAVES

Electromagnetic radiation is not the only type of wave in Nature. In this book, we encounter dispersive media, such as optical fibers and plasmas, where electromagnetic signals travel slower than c . We also analyze sound waves and seismic waves, whose governing laws do not involve electromagnetism at all. How do these fit into our special relativistic framework? The answer is simple. Each of these waves involves an underlying medium that is at rest in one particular frame (not necessarily inertial), and the velocity at which the wave's information propagates (the group velocity) is most simply calculated in this frame *from the wave's and medium's fundamental laws*. We can then use the kinematic rules of Lorentz transformations to compute the velocity in another frame. However, if we had chosen to compute the wave speed in the second frame directly, using the same fundamental laws, we would have gotten the same answer, albeit perhaps with greater effort. All waves are in full compliance with the Principle of Relativity. What is special about vacuum electromagnetic waves and, by extension, photons, is that no medium (or "aether," as it used to be called) is needed for them to propagate. Their speed is therefore the same in all frames. (Although some physicists regard the cosmological constant, discussed in Chap. 28, as a modern aether, we must emphasize that, unlike its nineteenth-century antecedent, its presence does not alter the propagation of photons through Lorentz frames.)

This raises an interesting question. What about other waves that do not require an underlying medium? What about electron de Broglie waves? Here the fundamental wave equation, Schrödinger's or Dirac's, is mathematically different from Maxwell's and contains an important parameter, the electron rest mass. This rest mass allows the fundamental laws of relativistic quantum mechanics to be written in a form that is the same in all inertial reference frames and at the same time allows an electron, considered as either a wave or a particle, to travel at a different speed when measured in a different frame.

(continued)

BOX 2.3. (continued)

Some particles that have been postulated (such as gravitons, the quanta of gravitational waves; Chap. 27) are believed to exist without a rest mass (or an aether!), just like photons. Must these travel at the same speed as photons? The answer, according to the Principle of Relativity, is “yes.” Why? Suppose there were two such waves or particles whose governing laws led to different speeds, c and $c' < c$, with each speed claimed to be the same in all reference frames. Such a claim produces insurmountable conundrums. For example, if we move with speed c' in the direction of propagation of the second wave, we will bring it to rest, in conflict with our hypothesis that its speed is frame independent. Therefore, all signals whose governing laws require them to travel with a speed that has no governing parameters (no rest mass and no underlying physical medium) must travel with a unique speed, which we call c . The speed of light is more fundamental to relativity than light itself!

2.2.3 The Interval and Its Invariance

Next we turn to another fundamental concept, the *interval* $(\Delta s)^2$ between the two events \mathcal{P} and \mathcal{Q} whose separation vector is $\Delta\vec{x}$. In a specific but arbitrary inertial reference frame and in geometrized units, $(\Delta s)^2$ is given by

$$(\Delta s)^2 \equiv -(\Delta t)^2 + (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2 = -(\Delta t)^2 + \sum_{i,j} \delta_{ij} \Delta x^i \Delta x^j;$$

(2.2a)

cf. Eq. (2.1). If $(\Delta s)^2 > 0$, the events \mathcal{P} and \mathcal{Q} are said to have a *spacelike* separation; if $(\Delta s)^2 = 0$, their separation is *null* or *lightlike*; and if $(\Delta s)^2 < 0$, their separation is *timelike*. For timelike separations, $(\Delta s)^2 < 0$ implies that Δs is imaginary; to avoid dealing with imaginary numbers, we describe timelike intervals by

$$(\Delta\tau)^2 \equiv -(\Delta s)^2,$$

(2.2b)

whose square root $\Delta\tau$ is real.

The coordinate separation between \mathcal{P} and \mathcal{Q} depends on one's reference frame: if $\Delta x^{\alpha'}$ and Δx^α are the coordinate separations in two different frames, then $\Delta x^{\alpha'} \neq$

2.2.3

the interval

spacelike, timelike, and null

Δx^α . Despite this frame dependence, the Principle of Relativity forces the interval $(\Delta s)^2$ to be the same in all frames:

$$\begin{aligned}(\Delta s)^2 &= -(\Delta t)^2 + (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2 \\ &= -(\Delta t')^2 + (\Delta x')^2 + (\Delta y')^2 + (\Delta z')^2.\end{aligned}\quad (2.3)$$

In Box 2.4, we sketch a proof for the case of two events \mathcal{P} and \mathcal{Q} whose separation is timelike.

Because of its frame invariance, the interval $(\Delta s)^2$ can be regarded as a geometric property of the vector $\Delta \vec{x}$ that reaches from \mathcal{P} to \mathcal{Q} ; we call it the *squared length* $(\Delta \vec{x})^2$ of $\Delta \vec{x}$:

$$(\Delta \vec{x})^2 \equiv (\Delta s)^2. \quad (2.4)$$

BOX 2.4. PROOF OF INVARIANCE OF THE INTERVAL FOR A TIMELIKE SEPARATION

A simple demonstration that the interval is invariant is provided by a thought experiment in which a photon is emitted at event \mathcal{P} , reflects off a mirror, and is then detected at event \mathcal{Q} . We consider the interval between these events in two reference frames, primed and unprimed, that move with respect to each other. Choose the spatial coordinate systems of the two frames in such a way that (i) their relative motion (with speed β , which will not enter into our analysis) is along the x and x' directions, (ii) event \mathcal{P} lies on the x and x' axes, and (iii) event \mathcal{Q} lies in the x - y and x' - y' planes, as depicted below. Then evaluate the interval between \mathcal{P} and \mathcal{Q} in the unprimed frame by the following construction: Place the mirror parallel to the x - z plane at precisely the height h that permits a photon, emitted from \mathcal{P} , to travel along the dashed line to the mirror, then reflect off the mirror and continue along the dashed path, arriving at event \mathcal{Q} . If the mirror were placed lower, the photon would arrive at the spatial location of \mathcal{Q} sooner than the time of \mathcal{Q} ; if placed higher, it would arrive later. Then the distance the photon travels (the length of the two-segment dashed line) is equal to $c\Delta t = \Delta t$, where Δt is the time between events \mathcal{P} and \mathcal{Q} as measured in the unprimed frame. If the mirror had not been present, the photon would have arrived at event \mathcal{R} after time Δt , so $c\Delta t$ is the distance between \mathcal{P} and \mathcal{R} . From the diagram, it is easy to see that the height of \mathcal{R} above the x -axis is $2h - \Delta y$, and the Pythagorean theorem then implies that

$$(\Delta s)^2 = -(\Delta t)^2 + (\Delta x)^2 + (\Delta y)^2 = -(2h - \Delta y)^2 + (\Delta y)^2. \quad (1a)$$

The same construction in the primed frame must give the same formula, but with primes:

$$(\Delta s')^2 = -(\Delta t')^2 + (\Delta x')^2 + (\Delta y')^2 = -(2h' - \Delta y')^2 + (\Delta y')^2. \quad (1b)$$

(continued)

BOX 2.4. (continued)

The proof that $(\Delta s')^2 = (\Delta s)^2$ then reduces to showing that the Principle of Relativity requires that distances perpendicular to the direction of relative motion be the same as measured in the two frames: $h' = h$, $\Delta y' = \Delta y$. We leave it to the reader to develop a careful argument for this (Ex. 2.2).

Note that this squared length, despite its name, can be negative (for timelike $\Delta\vec{x}$) or zero (for null $\Delta\vec{x}$) as well as positive (for spacelike $\Delta\vec{x}$).

The invariant interval $(\Delta s)^2$ between two events is as fundamental to Minkowski spacetime as the Euclidean distance between two points is to flat 3-space. Just as the Euclidean distance gives rise to the geometry of 3-space (as embodied, e.g., in Euclid's axioms), so the interval gives rise to the geometry of spacetime, which we shall be exploring. If this spacetime geometry were as intuitively obvious to humans as is Euclidean geometry, we would not need the crutch of inertial reference frames to arrive at it. Nature (presumably) has no need for such a crutch. To Nature (it seems evident), the geometry of Minkowski spacetime, as embodied in the invariant interval, is among the most fundamental aspects of physical law.

Exercise 2.1 *Practice: Geometrized Units*

Do Ex. 1.15 in Chap. 1.

EXERCISES
Exercise 2.2 *Derivation and Example: Invariance of the Interval*

Complete the derivation of the invariance of the interval given in Box 2.4, using the

Principle of Relativity in the form that the laws of physics must be the same in the primed and unprimed frames. Hints (if you need them):

- (a) Having carried out the construction in the unprimed frame, depicted at the bottom left of Box 2.4, use the same mirror and photons for the analogous construction in the primed frame. Argue that, independently of the frame in which the mirror is at rest (unprimed or primed), the fact that the reflected photon has (angle of reflection) = (angle of incidence) in its rest frame implies that this is also true for the same photon in the other frame. Thereby conclude that the construction leads to Eq. (1b) in Box 2.4, as well as to Eq. (1a).
- (b) Then argue that the perpendicular distance of an event from the common x - and x' -axes must be the same in the two reference frames, so $h' = h$ and $\Delta y' = \Delta y$; whence Eqs. (1b) and (1a) in Box 2.4 imply the invariance of the interval. [Note: For a leisurely version of this argument, see Taylor and Wheeler (1992, Secs. 3.6 and 3.7).]

2.3 Tensor Algebra without a Coordinate System

Having introduced points in spacetime (interpreted physically as events), the invariant interval $(\Delta s)^2$ between two events, 4-vectors (as arrows between two events), and the squared length of a vector (as the invariant interval between the vector's tail and tip), we can now introduce the remaining tools of tensor algebra for Minkowski spacetime in precisely the same way as we did for the Euclidean 3-space of Newtonian physics (Sec. 1.3), with the invariant interval between events playing the same role as the squared length between Euclidean points.

tensor

In particular: a *tensor* $\mathcal{T}(_, _, _)$ is a real-valued linear function of vectors in Minkowski spacetime. (We use slanted letters \mathcal{T} for tensors in spacetime and unslanted letters \mathbf{T} in Euclidean space.) A tensor's *rank* is equal to its number of slots. The *inner product* (also called the dot product) of two 4-vectors is

inner product

$$\vec{A} \cdot \vec{B} \equiv \frac{1}{4} \left[(\vec{A} + \vec{B})^2 - (\vec{A} - \vec{B})^2 \right], \quad (2.5)$$

where $(\vec{A} + \vec{B})^2$ is the squared length of this vector (i.e., the invariant interval between its tail and its tip). The *metric tensor* of spacetime is that linear function of 4-vectors whose value is the inner product of the vectors:

metric tensor

$$\mathbf{g}(\vec{A}, \vec{B}) \equiv \vec{A} \cdot \vec{B}. \quad (2.6)$$

Using the inner product, we can regard any vector \vec{A} as a rank-1 tensor: $\vec{A}(\vec{C}) \equiv \vec{A} \cdot \vec{C}$.

tensor product

Similarly, the *tensor product* \otimes is defined precisely as in the Euclidean domain, Eqs. (1.5), as is the *contraction* of two slots of a tensor against each other, Eqs. (1.6), which lowers the tensor's rank by two.

contraction

2.4 Particle Kinetics and Lorentz Force without a Reference Frame

2.4

T2

2.4.1 Relativistic Particle Kinetics: World Lines, 4-Velocity, 4-Momentum and Its Conservation, 4-Force

2.4.1

In this section, we illustrate our geometric viewpoint by formulating the special relativistic laws of motion for particles.

An accelerated particle moving through spacetime carries an *ideal clock*. By “ideal” we mean that the clock is unaffected by accelerations: it ticks at a uniform rate when compared to unaccelerated atomic oscillators that are momentarily at rest beside the clock and are well protected from their environments. The builders of inertial guidance systems for airplanes and missiles try to make their clocks as ideal as possible in just this sense. We denote by τ the time ticked by the particle’s ideal clock, and we call it the particle’s *proper time*.

ideal clock

The particle moves through spacetime along a curve, called its *world line*, which we can denote equally well by $\mathcal{P}(\tau)$ (the particle’s spacetime location \mathcal{P} at proper time τ), or by $\vec{x}(\tau)$ (the particle’s vector separation from some arbitrarily chosen origin at proper time τ).⁴

proper time

world line

We refer to the inertial frame in which the particle is momentarily at rest as its *momentarily comoving inertial frame* or *momentary rest frame*. Now, the particle’s clock (which measures τ) is ideal, and so are the inertial frame’s clocks (which measure coordinate time t). Therefore, a tiny interval $\Delta\tau$ of the particle’s proper time is equal to the lapse of coordinate time in the particle’s momentary rest frame $\Delta\tau = \Delta t$. Moreover, since the two events $\vec{x}(\tau)$ and $\vec{x}(\tau + \Delta\tau)$ on the clock’s world line occur at the same spatial location in its momentary rest frame ($\Delta x^i = 0$, where $i = 1, 2, 3$) to first order in $\Delta\tau$, the invariant interval between those events is $(\Delta s)^2 = -(\Delta t)^2 + \sum_{i,j} \Delta x^i \Delta x^j \delta_{ij} = -(\Delta t)^2 = -(\Delta\tau)^2$. Thus, *the particle’s proper time τ is equal to the square root of the negative of the invariant interval, $\tau = \sqrt{-s^2}$, along its world line.*

momentary rest frame

Figure 2.3 shows the world line of the accelerated particle in a spacetime diagram where the axes are coordinates of an arbitrary Lorentz frame. This diagram is intended to emphasize the world line as a frame-independent, geometric object. Also shown in the figure is the particle’s *4-velocity* \vec{u} , which (by analogy with velocity in 3-space) is the time derivative of its position

4-velocity

$$\vec{u} \equiv d\mathcal{P}/d\tau = d\vec{x}/d\tau \quad (2.7)$$

and is the tangent vector to the world line. The derivative is defined by the usual limiting process

$$\frac{d\mathcal{P}}{d\tau} = \frac{d\vec{x}}{d\tau} \equiv \lim_{\Delta\tau \rightarrow 0} \frac{\mathcal{P}(\tau + \Delta\tau) - \mathcal{P}(\tau)}{\Delta\tau} = \lim_{\Delta\tau \rightarrow 0} \frac{\vec{x}(\tau + \Delta\tau) - \vec{x}(\tau)}{\Delta\tau}. \quad (2.8)$$

4. One of the basic ideas in string theory is that an elementary particle is described as a 1-dimensional loop in space rather than a 0-dimensional point. This means that it becomes a cylinder-like surface in spacetime—a world tube.

FIGURE 2.3 Spacetime diagram showing the world line $\vec{x}(\tau)$ and 4-velocity \vec{u} of an accelerated particle. Note that the 4-velocity is tangent to the world line.

Here $\mathcal{P}(\tau + \Delta\tau) - \mathcal{P}(\tau)$ and $\vec{x}(\tau + \Delta\tau) - \vec{x}(\tau)$ are just two different ways to denote the same vector that reaches from one point on the world line to another.

The squared length of the particle's 4-velocity is easily seen to be -1 :

$$\vec{u}^2 \equiv \mathbf{g}(\vec{u}, \vec{u}) = \frac{d\vec{x}}{d\tau} \cdot \frac{d\vec{x}}{d\tau} = \frac{d\vec{x} \cdot d\vec{x}}{(d\tau)^2} = -1. \quad (2.9)$$

The last equality follows from the fact that $d\vec{x} \cdot d\vec{x}$ is the squared length of $d\vec{x}$, which equals the invariant interval $(\Delta s)^2$ along it, and $(d\tau)^2$ is the negative of that invariant interval.

4-momentum

The particle's *4-momentum* is the product of its 4-velocity and rest mass:

$$\vec{p} \equiv m\vec{u} = m d\vec{x}/d\tau \equiv d\vec{x}/d\zeta. \quad (2.10)$$

Here the parameter ζ is a renormalized version of proper time,

$$\zeta \equiv \tau/m. \quad (2.11)$$

affine parameter

This ζ and any other renormalized version of proper time with a position-independent renormalization factor are called *affine parameters* for the particle's world line. Expression (2.10), together with $\vec{u}^2 = -1$, implies that the squared length of the 4-momentum is

$$\vec{p}^2 = -m^2. \quad (2.12)$$

In quantum theory, a particle is described by a relativistic wave function, which, in the geometric optics limit (Chap. 7), has a wave vector \vec{k} that is related to the classical particle's 4-momentum by

$$\vec{k} = \vec{p}/\hbar. \quad (2.13)$$

The above formalism is valid only for particles with nonzero rest mass, $m \neq 0$. The corresponding formalism for a *particle with zero rest mass* (e.g., a photon or a graviton) can be obtained from the above by taking the limit as $m \rightarrow 0$ and $d\tau \rightarrow 0$ with the quotient $d\zeta = d\tau/m$ held finite. More specifically, the 4-momentum of a zero-rest-mass particle is well defined (and participates in the conservation law to be discussed below), and it is expressible in terms of the particle's affine parameter ζ by Eq. (2.10):

$$\vec{p} = d\vec{x}/d\zeta. \quad (2.14)$$

By contrast, the particle's 4-velocity $\vec{u} = \vec{p}/m$ is infinite and thus undefined, and proper time $\tau = m\zeta$ ticks vanishingly slowly along its world line and thus is undefined. Because proper time is the square root of the invariant interval along the world line, the interval between two neighboring points on the world line vanishes. Therefore, *the world line of a zero-rest-mass particle is null*. (By contrast, since $d\tau^2 > 0$ and $ds^2 < 0$ along the world line of a particle with finite rest mass, *the world line of a finite-rest-mass particle is timelike*.)

The 4-momenta of particles are important because of the *law of conservation of 4-momentum* (which, as we shall see in Sec. 2.6, is equivalent to the conservation laws for energy and ordinary momentum): If a number of “initial” particles, named $A = 1, 2, 3, \dots$, enter a restricted region of spacetime \mathcal{V} and there interact strongly to produce a new set of “final” particles, named $\bar{A} = \bar{1}, \bar{2}, \bar{3}, \dots$ (Fig. 2.4), then the total 4-momentum of the final particles must be the same as the total 4-momentum of the initial ones:

$$\boxed{\sum_{\bar{A}} \vec{p}_{\bar{A}} = \sum_A \vec{p}_A.} \quad (2.15)$$

Note that this law of 4-momentum conservation is expressed in frame-independent, geometric language—in accord with Einstein's insistence that all the laws of physics should be so expressible. As we shall see in Part VII, 4-momentum conservation is a consequence of the translation symmetry of flat, 4-dimensional spacetime. In general relativity's curved spacetime, where that translation symmetry is lost, we lose 4-momentum conservation except under special circumstances; see Eq. (25.56) and associated discussion.

If a particle moves freely (no external forces and no collisions with other particles), then its 4-momentum \vec{p} will be conserved along its world line, $d\vec{p}/d\zeta = 0$. Since \vec{p} is tangent to the world line, this conservation means that the direction of the world line in spacetime never changes: the free particle moves along a straight line through spacetime. To change the particle's 4-momentum, one must act on it with a *4-force* \vec{F} ,

$$d\vec{p}/d\tau = \vec{F}. \quad (2.16)$$

conservation of
4-momentum

4-force

FIGURE 2.4 Spacetime diagram depicting the law of 4-momentum conservation for a situation where two particles, numbered 1 and 2, enter an interaction region \mathcal{V} in spacetime, and there interact strongly and produce two new particles, numbered $\bar{1}$ and $\bar{2}$. The sum of the final 4-momenta, $\vec{p}_{\bar{1}} + \vec{p}_{\bar{2}}$, must be equal to the sum of the initial 4-momenta, $\vec{p}_1 + \vec{p}_2$.

If the particle is a fundamental one (e.g., photon, electron, proton), then the 4-force must leave its rest mass unchanged,

$$0 = dm^2/d\tau = -d\vec{p}^2/d\tau = -2\vec{p} \cdot d\vec{p}/d\tau = -2\vec{p} \cdot \vec{F}; \quad (2.17)$$

that is, the 4-force must be orthogonal to the 4-momentum in the 4-dimensional sense that their inner product vanishes.

2.4.2

2.4.2 Geometric Derivation of the Lorentz Force Law

As an illustration of these physical concepts and mathematical tools, we use them to deduce the relativistic version of the Lorentz force law. From the outset, in accord with the Principle of Relativity, we insist that the law we seek be expressible in geometric, frame-independent language, that is, in terms of vectors and tensors.

Consider a particle with charge q and rest mass $m \neq 0$ interacting with an electromagnetic field. It experiences an electromagnetic 4-force whose mathematical form we seek. The Newtonian version of the electromagnetic force $\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$ is proportional to q and contains one piece (electric) that is independent of velocity \mathbf{v} and a second piece (magnetic) that is linear in \mathbf{v} . It is reasonable to expect that, to produce this Newtonian limit, the relativistic 4-force \vec{F} will be proportional to q and will be linear in the 4-velocity \vec{u} . Linearity means there must exist some second-rank tensor $\mathbf{F}(_, _)$, the *electromagnetic field tensor*, such that

$$d\vec{p}/d\tau = \vec{F}(_) = q\mathbf{F}(_, \vec{u}). \quad (2.18)$$

Because the 4-force \vec{F} must be orthogonal to the particle's 4-momentum and thence also to its 4-velocity, $\vec{F} \cdot \vec{u} \equiv \vec{F}(\vec{u}) = 0$, expression (2.18) must vanish when \vec{u} is inserted into its empty slot. In other words, for all timelike unit-length vectors \vec{u} ,

$$\mathbf{F}(\vec{u}, \vec{u}) = 0. \quad (2.19)$$

It is an instructive exercise (Ex. 2.3) to show that this is possible only if \mathbf{F} is *antisymmetric*, so the electromagnetic 4-force is

$$d\vec{p}/d\tau = q\mathbf{F}(_, \vec{u}), \quad \text{where} \quad \mathbf{F}(\vec{A}, \vec{B}) = -\mathbf{F}(\vec{B}, \vec{A}) \quad \text{for all } \vec{A} \text{ and } \vec{B}. \quad (2.20)$$

electromagnetic 4-force

Equation (2.20) must be the relativistic form of the Lorentz force law. In Sec. 2.11 we deduce the relationship of the electromagnetic field tensor \mathbf{F} to the more familiar electric and magnetic fields, and the relationship of this relativistic Lorentz force to its Newtonian form (1.7c).

The discussion of particle kinematics and the electromagnetic force in this Sec. 2.4 is elegant but perhaps unfamiliar. In Secs. 2.6 and 2.11, we shall see that it is equivalent to the more elementary (but more complex) formalism based on components of vectors in Euclidean 3-space.

EXERCISES

Exercise 2.3 *Derivation and Example: Antisymmetry of Electromagnetic Field Tensor*

Show that Eq. (2.19) can be true for all timelike, unit-length vectors \vec{u} if and only if \mathbf{F} is antisymmetric. [Hints: (i) Show that the most general second-rank tensor \mathbf{F} can be written as the sum of a symmetric tensor \mathbf{S} and an antisymmetric tensor \mathbf{A} , and that the antisymmetric piece contributes nothing to Eq. (2.19), so $\mathbf{S}(\vec{u}, \vec{u})$ must vanish for every timelike \vec{u} . (ii) Let \vec{a} be a timelike vector, let \vec{b} be an arbitrary vector (timelike, null, or spacelike), and let ϵ be a number small enough that $\vec{A}_\pm \equiv \vec{a} \pm \epsilon\vec{b}$ are both timelike. From the fact that $\mathbf{S}(\vec{A}_+, \vec{A}_+)$, $\mathbf{S}(\vec{A}_-, \vec{A}_-)$, and $\mathbf{S}(\vec{a}, \vec{a})$ all vanish, deduce that $\mathbf{S}(\vec{b}, \vec{b}) = 0$ for the arbitrary vector \vec{b} . (iii) From this, deduce that \mathbf{S} vanishes (i.e., it gives zero when any two vectors are inserted into its slots).]

Exercise 2.4 *Problem: Relativistic Gravitational Force Law*

In Newtonian theory, the gravitational potential Φ exerts a force $\mathbf{F} = d\mathbf{p}/dt = -m\nabla\Phi$ on a particle with mass m and momentum \mathbf{p} . Before Einstein formulated general relativity, some physicists constructed relativistic theories of gravity in which a Newtonian-like scalar gravitational field Φ exerted a 4-force $\vec{F} = d\vec{p}/d\tau$ on any particle with rest mass m , 4-velocity \vec{u} , and 4-momentum $\vec{p} = m\vec{u}$. What must that force law have been for it to (i) obey the Principle of Relativity, (ii) reduce to Newton's law in the nonrelativistic limit, and (iii) preserve the particle's rest mass as time passes?

In Minkowski spacetime, associated with any inertial reference frame (Fig. 2.1 and Sec. 2.2.1), there is a Lorentz coordinate system $\{t, x, y, z\} = \{x^0, x^1, x^2, x^3\}$ generated by the frame's rods and clocks. (Note the use of superscripts.) And associated with these coordinates is a set of *Lorentz basis vectors* $\{\vec{e}_t, \vec{e}_x, \vec{e}_y, \vec{e}_z\} = \{\vec{e}_0, \vec{e}_1, \vec{e}_2, \vec{e}_3\}$. (Note the use of subscripts. The reason for this convention will become clear below.) The basis vector \vec{e}_α points along the x^α coordinate direction, which is orthogonal to all the other coordinate directions, and it has squared length -1 for $\alpha = 0$ (vector pointing in a timelike direction) and $+1$ for $\alpha = 1, 2, 3$ (spacelike):

$$\vec{e}_\alpha \cdot \vec{e}_\beta = \eta_{\alpha\beta}. \quad (2.21)$$

Here $\eta_{\alpha\beta}$ (a spacetime analog of the Kronecker delta) are defined by

$$\eta_{00} \equiv -1, \quad \eta_{11} \equiv \eta_{22} \equiv \eta_{33} \equiv 1, \quad \eta_{\alpha\beta} \equiv 0 \text{ if } \alpha \neq \beta. \quad (2.22)$$

Any basis in which $\vec{e}_\alpha \cdot \vec{e}_\beta = \eta_{\alpha\beta}$ is said to be *orthonormal* (by analogy with the Euclidean notion of orthonormality, $\mathbf{e}_j \cdot \mathbf{e}_k = \delta_{jk}$).

Because $\vec{e}_\alpha \cdot \vec{e}_\beta \neq \delta_{\alpha\beta}$, many of the Euclidean-space component-manipulation formulas (1.9b)–(1.9h) do not hold in Minkowski spacetime. There are two approaches to recovering these formulas. One approach, used in many older textbooks (including the first and second editions of Goldstein's *Classical Mechanics* and Jackson's *Classical Electrodynamics*), is to set $x^0 = it$, where $i = \sqrt{-1}$ and correspondingly make the time basis vector be imaginary, so that $\vec{e}_\alpha \cdot \vec{e}_\beta = \delta_{\alpha\beta}$. When this approach is adopted, the resulting formalism does not depend on whether indices are placed up or down; one can place them wherever one's stomach or liver dictates without asking one's brain. However, this $x^0 = it$ approach has severe disadvantages: (i) it hides the true physical geometry of Minkowski spacetime, (ii) it cannot be extended in any reasonable manner to nonorthonormal bases in flat spacetime, and (iii) it cannot be extended in any reasonable manner to the curvilinear coordinates that must be used in general relativity. For these reasons, most modern texts (including the third editions of Goldstein and Jackson) take an alternative approach, one always used in general relativity. This alternative, which we shall adopt, requires introducing two different types of components for vectors (and analogously for tensors): *contravariant components* denoted by superscripts (e.g., $T^{\alpha\beta\gamma}$) and *covariant components* denoted by subscripts (e.g., $T_{\alpha\beta\gamma}$). In Parts I–VI of this book, we introduce these components only for orthonormal bases; in Part VII, we develop a more sophisticated version of them, valid for nonorthonormal bases.

A vector's or tensor's contravariant components are defined as its expansion coefficients in the chosen basis [analog of Eqs. (1.9b) and (1.9d) in Euclidean 3-space]:

$$\vec{A} \equiv A^\alpha \vec{e}_\alpha, \quad \mathbf{T} \equiv T^{\alpha\beta\gamma} \vec{e}_\alpha \otimes \vec{e}_\beta \otimes \vec{e}_\gamma. \quad (2.23a)$$

Here and throughout this book, *Greek (spacetime) indices are to be summed when they are repeated with one up and the other down*; this is called the Einstein summation convention.

The covariant components are defined as the numbers produced by evaluating the vector or tensor on its basis vectors [analog of Eq. (1.9e) in Euclidean 3-space]:

$$A_\alpha \equiv \vec{A}(\vec{e}_\alpha) = \vec{A} \cdot \vec{e}_\alpha, \quad T_{\alpha\beta\gamma} \equiv \mathbf{T}(\vec{e}_\alpha, \vec{e}_\beta, \vec{e}_\gamma). \quad (2.23b)$$

(Just as there are contravariant and covariant components A^α and A_α , so also there is a second set of basis vectors \vec{e}^α dual to the set \vec{e}_α . However, for economy of notation we delay introducing them until Part VII.)

These definitions have a number of important consequences. We derive them one after another and then summarize them succinctly with equation numbers:

- (i) The covariant components of the metric tensor are $g_{\alpha\beta} = \mathbf{g}(\vec{e}_\alpha, \vec{e}_\beta) = \vec{e}_\alpha \cdot \vec{e}_\beta = \eta_{\alpha\beta}$. Here the first equality is the definition (2.23b) of the covariant components, the second equality is the definition (2.6) of the metric tensor, and the third equality is the orthonormality relation (2.21) for the basis vectors.
- (ii) The covariant components of any tensor can be computed from the contravariant components by

$$\begin{aligned} T_{\lambda\mu\nu} &= \mathbf{T}(\vec{e}_\lambda, \vec{e}_\mu, \vec{e}_\nu) = T^{\alpha\beta\gamma} \vec{e}_\alpha \otimes \vec{e}_\beta \otimes \vec{e}_\gamma(\vec{e}_\lambda, \vec{e}_\mu, \vec{e}_\nu) \\ &= T^{\alpha\beta\gamma} (\vec{e}_\alpha \cdot \vec{e}_\lambda)(\vec{e}_\beta \cdot \vec{e}_\mu)(\vec{e}_\gamma \cdot \vec{e}_\nu) = T^{\alpha\beta\gamma} g_{\alpha\lambda} g_{\beta\mu} g_{\gamma\nu}. \end{aligned}$$

The first equality is the definition (2.23b) of the covariant components, the second is the expansion (2.23a) of \mathbf{T} on the chosen basis, the third is the definition (1.5a) of the tensor product, and the fourth is one version of our result (i) for the covariant components of the metric.

- (iii) This result, $T_{\lambda\mu\nu} = T^{\alpha\beta\gamma} g_{\alpha\lambda} g_{\beta\mu} g_{\gamma\nu}$, together with the numerical values (i) of $g_{\alpha\beta}$, implies that when one lowers a spatial index there is no change in the numerical value of a component, and when one lowers a temporal index, the sign changes: $T_{ijk} = T^{ijk}$, $T_{0jk} = -T^{0jk}$, $T_{0j0} = +T^{0j0}$, $T_{000} = -T^{000}$. We call this the “sign-flip-if-temporal” rule. As a special case, $-1 = g_{00} = g^{00}$, $0 = g_{0j} = -g^{0j}$, $\delta_{jk} = g_{jk} = g^{jk}$ —that is, the metric’s covariant and contravariant components are numerically identical; they are both equal to the orthonormality values $\eta_{\alpha\beta}$.
- (iv) It is easy to see that this sign-flip-if-temporal rule for lowering indices implies the same sign-flip-if-temporal rule for raising them, which in turn can be written in terms of metric components as $T^{\alpha\beta\gamma} = T_{\lambda\mu\nu} g^{\lambda\alpha} g^{\mu\beta} g^{\nu\gamma}$.
- (v) It is convenient to define *mixed components* of a tensor, components with some indices up and others down, as having numerical values obtained

covariant components

raising and lowering indices: sign flip if temporal

components of metric tensor

mixed components

by raising or lowering some but not all of its indices using the metric, for example, $T^\alpha_{\mu\nu} = T^{\alpha\beta\gamma} g_{\beta\mu} g_{\gamma\nu} = T_{\lambda\mu\nu} g^{\lambda\alpha}$. Numerically, this continues to follow the sign-flip-if-temporal rule: $T^0_{0k} = -T^{00k}$, $T^0_{jk} = T^{0jk}$, and it implies, in particular, that the mixed components of the metric are $g^\alpha_\beta = \delta_{\alpha\beta}$ (the Kronecker-delta values; +1 if $\alpha = \beta$ and 0 otherwise).

These important results can be summarized as follows. *The numerical values of the components of the metric in Minkowski spacetime are expressed in terms of the matrices $[\delta_{\alpha\beta}]$ and $[\eta_{\alpha\beta}]$ as*

$$g_{\alpha\beta} = \eta_{\alpha\beta}, \quad g^\alpha_\beta = \delta_{\alpha\beta}, \quad g_\alpha^\beta = \delta_{\alpha\beta}, \quad g^{\alpha\beta} = \eta_{\alpha\beta}; \quad (2.23c)$$

indices on all vectors and tensors can be raised and lowered using these components of the metric:

$$A_\alpha = g_{\alpha\beta} A^\beta, \quad A^\alpha = g^{\alpha\beta} A_\beta, \quad T^\alpha_{\mu\nu} \equiv g_{\mu\beta} g_{\nu\gamma} T^{\alpha\beta\gamma}, \quad T^{\alpha\beta\gamma} \equiv g^{\beta\mu} g^{\gamma\nu} T^\alpha_{\mu\nu}, \quad (2.23d)$$

which is equivalent to the sign-flip-if-temporal rule.

This index notation gives rise to formulas for tensor products, inner products, values of tensors on vectors, and tensor contractions that are obvious analogs of those in Euclidean space:

$$[\text{Contravariant components of } \mathbf{T}(_, _, _) \otimes \mathbf{S}(_, _)] = T^{\alpha\beta\gamma} S^{\delta\epsilon}, \quad (2.23e)$$

$$\vec{A} \cdot \vec{B} = A^\alpha B_\alpha = A_\alpha B^\alpha, \quad \mathbf{T}(\mathbf{A}, \mathbf{B}, \mathbf{C}) = T_{\alpha\beta\gamma} A^\alpha B^\beta C^\gamma = T^{\alpha\beta\gamma} A_\alpha B_\beta C_\gamma, \quad (2.23f)$$

$$\text{Covariant components of [1\&3contraction of } \mathbf{R}] = R^\mu_{\alpha\mu\beta},$$

$$\text{Contravariant components of [1\&3contraction of } \mathbf{R}] = R^{\mu\alpha}_{\mu\beta}. \quad (2.23g)$$

Notice the very simple pattern in Eqs. (2.23b) and (2.23d), which universally permeates the rules of index gymnastics, a pattern that permits one to reconstruct the rules without any memorization: *Free indices (indices not summed over) must agree in position (up versus down) on the two sides of each equation.* In keeping with this pattern, one can regard the two indices in a pair that is summed as “annihilating each other by contraction,” and one speaks of “lining up the indices” on the two sides of an equation to get them to agree. These rules provide helpful checks when performing calculations.

In Part VII, when we use nonorthonormal bases, all these index-notation equations (2.23) will remain valid except for the numerical values [Eq. (2.23c)] of the metric components and the sign-flip-if-temporal rule.

2.5.3 Slot-Naming Notation

In Minkowski spacetime, as in Euclidean space, we can (and often do) use slot-naming index notation to represent frame-independent geometric objects and equations and

physical laws. (Readers who have not studied Sec. 1.5.1 on slot-naming index notation should do so now.)

For example, we often write the frame-independent Lorentz force law $d\vec{p}/d\tau = q\mathbf{F}(_, \vec{u})$ [Eq. (2.20)] as $dp_\mu/d\tau = qF_{\mu\nu}u^\nu$.

Notice that, because the components of the metric in any Lorentz basis are $g_{\alpha\beta} = \eta_{\alpha\beta}$, we can write the invariant interval between two events x^α and $x^\alpha + dx^\alpha$ as

$$ds^2 = g_{\alpha\beta}dx^\alpha dx^\beta = -dt^2 + dx^2 + dy^2 + dz^2. \quad (2.24)$$

This is called the special relativistic *line element*.

line element

EXERCISES

Exercise 2.5 Derivation: Component Manipulation Rules

Derive the relativistic component manipulation rules (2.23e)–(2.23g).

Exercise 2.6 Practice: Numerics of Component Manipulations

In some inertial reference frame, the vector \vec{A} and second-rank tensor \mathbf{T} have as their only nonzero components $A^0 = 1$, $A^1 = 2$; $T^{00} = 3$, $T^{01} = T^{10} = 2$, $T^{11} = -1$. Evaluate $\mathbf{T}(\vec{A}, \vec{A})$ and the components of $\mathbf{T}(\vec{A}, _)$ and $\vec{A} \otimes \mathbf{T}$.

Exercise 2.7 Practice: Meaning of Slot-Naming Index Notation

- (a) Convert the following expressions and equations into geometric, index-free notation: $A^\alpha B_{\gamma\delta}$; $A_\alpha B_\gamma{}^\delta$; $S_\alpha{}^{\beta\gamma} = S^{\gamma\beta}{}_\alpha$; $A^\alpha B_\alpha = A_\alpha B^\beta g^\alpha{}_\beta$.
- (b) Convert $\mathbf{T}(_, \mathbf{S}(\mathbf{R}(\vec{C}, _), _), _)$ into slot-naming index notation.

Exercise 2.8 Practice: Index Gymnastics

- (a) Simplify the following expression so the metric does not appear in it:

$$A^{\alpha\beta\gamma} g_{\beta\rho} S_{\gamma\lambda} g^{\rho\delta} g^\lambda{}_\alpha.$$

- (b) The quantity $g_{\alpha\beta} g^{\alpha\beta}$ is a scalar since it has no free indices. What is its numerical value?
- (c) What is wrong with the following expression and equation?

$$A_\alpha{}^{\beta\gamma} S_{\alpha\gamma}; \quad A_\alpha{}^{\beta\gamma} S_\beta T_\gamma = R_{\alpha\beta\delta} S^\beta.$$

2.6 Particle Kinetics in Index Notation and in a Lorentz Frame

2.6

As an illustration of the component representation of tensor algebra, let us return to the relativistic, accelerated particle of Fig. 2.3 and, from the frame-independent equations for the particle's 4-velocity \vec{u} and 4-momentum \vec{p} (Sec. 2.4), derive the component description given in elementary textbooks.

We introduce a specific inertial reference frame and associated Lorentz coordinates x^α and basis vectors $\{\vec{e}_\alpha\}$. In this Lorentz frame, the particle's world line

$\vec{x}(\tau)$ is represented by its coordinate location $x^\alpha(\tau)$ as a function of its proper time τ . The contravariant components of the separation vector $d\vec{x}$ between two neighboring events along the particle's world line are the events' coordinate separations dx^α [Eq. (2.1)]; and correspondingly, the components of the particle's 4-velocity $\vec{u} = d\vec{x}/d\tau$ are

$$u^\alpha = dx^\alpha/d\tau \quad (2.25a)$$

(the time derivatives of the particle's spacetime coordinates). Note that Eq. (2.25a) implies

$$v^j \equiv \frac{dx^j}{dt} = \frac{dx^j/d\tau}{dt/d\tau} = \frac{u^j}{u^0}. \quad (2.25b)$$

This relation, together with $-1 = \vec{u}^2 = g_{\alpha\beta}u^\alpha u^\beta = -(u^0)^2 + \delta_{ij}u^i u^j = -(u^0)^2(1 - \delta_{ij}v^i v^j)$, implies that the components of the 4-velocity have the forms familiar from elementary textbooks:

$$u^0 = \gamma, \quad u^j = \gamma v^j, \quad \text{where} \quad \gamma = \frac{1}{(1 - \delta_{ij}v^i v^j)^{\frac{1}{2}}}. \quad (2.25c)$$

ordinary velocity

slice of simultaneity

It is useful to think of v^j as the components of a 3-dimensional vector \mathbf{v} , the *ordinary velocity*, that lives in the 3-dimensional Euclidean space $t = \text{const}$ of the chosen Lorentz frame (the green plane in Fig. 2.5). This 3-space is sometimes called the frame's *slice of simultaneity* or *3-space of simultaneity*, because all events lying in it are simultaneous, as measured by the frame's observers. This 3-space is not well defined until a Lorentz frame has been chosen, and correspondingly, \mathbf{v} relies for its existence on a specific choice of frame. However, once the frame has been chosen, \mathbf{v} can be regarded as a coordinate-independent, basis-independent 3-vector lying in the frame's slice of simultaneity. Similarly, the spatial part of the 4-velocity \vec{u} (the part with components u^j in our chosen frame) can be regarded as a 3-vector \mathbf{u} lying in the frame's 3-space; and Eqs. (2.25c) become the component versions of the coordinate-independent, basis-independent 3-space relations

$$\mathbf{u} = \gamma \mathbf{v}, \quad \gamma = \frac{1}{\sqrt{1 - \mathbf{v}^2}}, \quad (2.25d)$$

where $\mathbf{v}^2 = \mathbf{v} \cdot \mathbf{v}$. This γ is called the "Lorentz factor."

The components of the particle's 4-momentum \vec{p} in our chosen Lorentz frame have special names and special physical significances: The time component of the 4-momentum is the particle's (relativistic) *energy* \mathcal{E} as measured in that frame:

relativistic energy

$$\begin{aligned} \mathcal{E} \equiv p^0 &= mu^0 = m\gamma = \frac{m}{\sqrt{1 - \mathbf{v}^2}} = (\text{the particle's energy}) \\ &\simeq m + \frac{1}{2}m\mathbf{v}^2 \quad \text{for } |\mathbf{v}| \ll 1. \end{aligned} \quad (2.26a)$$

FIGURE 2.5 Spacetime diagram in a specific Lorentz frame, showing the frame's 3-space $t = 0$ (green region), the world line of a particle, the 4-velocity \vec{u} of the particle as it passes through the 3-space, and two 3-dimensional vectors that lie in the 3-space: the spatial part \mathbf{u} of the particle's 4-velocity and the particle's ordinary velocity \mathbf{v} .

Note that this energy is the sum of the particle's *rest mass-energy* $m = mc^2$ and its *kinetic energy*

rest mass-energy

$$E \equiv \mathcal{E} - m = m \left(\frac{1}{\sqrt{1 - \mathbf{v}^2}} - 1 \right) \simeq \frac{1}{2} m \mathbf{v}^2 \quad \text{for } |\mathbf{v}| \ll 1. \quad (2.26b)$$

kinetic energy

The spatial components of the 4-momentum, when regarded from the viewpoint of 3-dimensional physics, are the same as the components of the *momentum*, a 3-vector residing in the chosen Lorentz frame's 3-space:

momentum

$$p^j = m u^j = m \gamma v^j = \frac{m v^j}{\sqrt{1 - \mathbf{v}^2}} = \mathcal{E} v_j = (j \text{ component of particle's momentum}); \quad (2.26c)$$

or, in basis-independent, 3-dimensional vector notation,

$$\mathbf{p} = m \mathbf{u} = m \gamma \mathbf{v} = \frac{m \mathbf{v}}{\sqrt{1 - \mathbf{v}^2}} = \mathcal{E} \mathbf{v} = (\text{particle's momentum}). \quad (2.26d)$$

For a zero-rest-mass particle, as for one with finite rest mass, we identify the time component of the 4-momentum, in a chosen Lorentz frame, as the particle's energy,

and the spatial part as its momentum. Moreover, if—appealing to quantum theory—we regard a zero-rest-mass particle as a quantum associated with a monochromatic wave, then quantum theory tells us that the wave’s angular frequency ω as measured in a chosen Lorentz frame is related to its energy by

$$\mathcal{E} \equiv p^0 = \hbar\omega = (\text{particle's energy}); \quad (2.27a)$$

and, since the particle has $\vec{p}^2 = -(p^0)^2 + \mathbf{p}^2 = -m^2 = 0$ (in accord with the lightlike nature of its world line), its momentum as measured in the chosen Lorentz frame is

$$\mathbf{p} = \mathcal{E}\mathbf{n} = \hbar\omega\mathbf{n}. \quad (2.27b)$$

Here \mathbf{n} is the unit 3-vector that points in the direction of the particle’s travel, as measured in the chosen frame; that is (since the particle moves at the speed of light $v = 1$), \mathbf{n} is the particle’s ordinary velocity. Eqs. (2.27a) and (2.27b) are respectively the temporal and spatial components of the geometric, frame-independent relation $\vec{p} = \hbar\vec{k}$ [Eq. (2.13), which is valid for zero-rest-mass particles as well as finite-mass ones].

3+1 split of spacetime into space plus time

The introduction of a specific Lorentz frame into spacetime can be said to produce a 3+1 split of every 4-vector into a 3-dimensional vector plus a scalar (a real number). The 3+1 split of a particle’s 4-momentum \vec{p} produces its momentum \mathbf{p} plus its energy $\mathcal{E} = p^0$. Correspondingly, the 3+1 split of the law of 4-momentum conservation (2.15) produces a law of conservation of momentum plus a law of conservation of energy:

$$\sum_{\bar{A}} \mathbf{p}_{\bar{A}} = \sum_A \mathbf{p}_A, \quad \sum_{\bar{A}} \mathcal{E}_{\bar{A}} = \sum_A \mathcal{E}_A. \quad (2.28)$$

The unbarred quantities in Eqs. (2.28) are momenta and energies of the particles entering the interaction region, and the barred quantities are those of the particles leaving (see Fig. 2.4).

Because the concept of energy does not even exist until one has chosen a Lorentz frame—and neither does that of momentum—the laws of energy conservation and momentum conservation separately are frame-dependent laws. In this sense, they are far less fundamental than their combination, the frame-independent law of 4-momentum conservation.

By learning to think about the 3+1 split in a geometric, frame-independent way, one can gain conceptual and computational power. As an example, consider a particle with 4-momentum \vec{p} , being studied by an observer with 4-velocity \vec{U} . In the observer’s own Lorentz reference frame, her 4-velocity has components $U^0 = 1$ and $U^j = 0$, and therefore, her 4-velocity is $\vec{U} = U^\alpha \vec{e}_\alpha = \vec{e}_0$; that is, it is identically equal to the time basis vector of her Lorentz frame. Thus the particle energy that she measures is $\mathcal{E} = p^0 = -p_0 = -\vec{p} \cdot \vec{e}_0 = -\vec{p} \cdot \vec{U}$. This equation, derived in the observer’s Lorentz frame, is actually a geometric, frame-independent relation: the inner product of two 4-vectors. It says that *when an observer with 4-velocity \vec{U} measures the energy of a*

particle with 4-momentum \vec{p} , the result she gets (the time part of the 3+1 split of \vec{p} as seen by her) is

$$\mathcal{E} = -\vec{p} \cdot \vec{U}. \quad (2.29)$$

We shall use this equation in later chapters. In Exs. 2.9 and 2.10, the reader can gain experience deriving and interpreting other frame-independent equations for 3+1 splits. Exercise 2.11 exhibits the power of this geometric way of thinking by using it to derive the Doppler shift of a photon.

EXERCISES

Exercise 2.9 ***Practice: Frame-Independent Expressions for Energy, Momentum, and Velocity*

An observer with 4-velocity \vec{U} measures the properties of a particle with 4-momentum \vec{p} . The energy she measures is $\mathcal{E} = -\vec{p} \cdot \vec{U}$ [Eq. (2.29)].

(a) Show that the particle's rest mass can be expressed in terms of \vec{p} as

$$m^2 = -\vec{p}^2. \quad (2.30a)$$

(b) Show that the momentum the observer measures has the magnitude

$$|\mathbf{p}| = [(\vec{p} \cdot \vec{U})^2 + \vec{p} \cdot \vec{p}]^{\frac{1}{2}}. \quad (2.30b)$$

(c) Show that the ordinary velocity the observer measures has the magnitude

$$|\mathbf{v}| = \frac{|\mathbf{p}|}{\mathcal{E}}, \quad (2.30c)$$

where $|\mathbf{p}|$ and \mathcal{E} are given by the above frame-independent expressions.

(d) Show that the ordinary velocity \mathbf{v} , thought of as a 4-vector that happens to lie in the observer's slice of simultaneity, is given by

$$\vec{v} = \frac{\vec{p} + (\vec{p} \cdot \vec{U})\vec{U}}{-\vec{p} \cdot \vec{U}}. \quad (2.30d)$$

Exercise 2.10 ***Example: 3-Metric as a Projection Tensor*

Consider, as in Ex. 2.9, an observer with 4-velocity \vec{U} who measures the properties of a particle with 4-momentum \vec{p} .

(a) Show that the Euclidean metric of the observer's 3-space, when thought of as a tensor in 4-dimensional spacetime, has the form

$$\mathbf{P} \equiv \mathbf{g} + \vec{U} \otimes \vec{U}. \quad (2.31a)$$

Show, further, that if \vec{A} is an arbitrary vector in spacetime, then $-\vec{A} \cdot \vec{U}$ is the component of \vec{A} along the observer's 4-velocity \vec{U} , and

$$\mathbf{P}(_, \vec{A}) = \vec{A} + (\vec{A} \cdot \vec{U})\vec{U} \quad (2.31b)$$

is the projection of \vec{A} into the observer's 3-space (i.e., it is the spatial part of \vec{A} as seen by the observer). For this reason, \mathbf{P} is called a *projection tensor*. In quantum mechanics, the concept of a *projection operator* \hat{P} is introduced as one that satisfies the equation $\hat{P}^2 = \hat{P}$. Show that the projection tensor \mathbf{P} is a projection operator in the same sense:

$$P_{\alpha\mu} P^{\mu}_{\beta} = P_{\alpha\beta}. \quad (2.31c)$$

- (b) Show that Eq. (2.30d) for the particle's ordinary velocity, thought of as a 4-vector, can be rewritten as

$$\vec{v} = \frac{\mathbf{P}(\underline{\quad}, \vec{p})}{-\vec{p} \cdot \vec{U}}. \quad (2.32)$$

Exercise 2.11 ***Example: Doppler Shift Derived without Lorentz Transformations*

- (a) An observer at rest in some inertial frame receives a photon that was emitted in direction \mathbf{n} by an atom moving with ordinary velocity \mathbf{v} (Fig. 2.6). The photon frequency and energy as measured by the emitting atom are ν_{em} and \mathcal{E}_{em} ; those measured by the receiving observer are ν_{rec} and \mathcal{E}_{rec} . By a calculation carried out solely in the receiver's inertial frame (the frame of Fig. 2.6), and without the aid of any Lorentz transformation, derive the standard formula for the photon's Doppler shift:

$$\frac{\nu_{\text{rec}}}{\nu_{\text{em}}} = \frac{\sqrt{1 - v^2}}{1 - \mathbf{v} \cdot \mathbf{n}}. \quad (2.33)$$

[Hint: Use Eq. (2.29) to evaluate \mathcal{E}_{em} using receiver-frame expressions for the emitting atom's 4-velocity \vec{U} and the photon's 4-momentum \vec{p} .]

- (b) Suppose that instead of emitting a photon, the emitter produces a particle with finite rest mass m . Using the same method as in part (a), derive an expression for the ratio of received energy to emitted energy, $\mathcal{E}_{\text{rec}}/\mathcal{E}_{\text{em}}$, expressed in terms of the emitter's ordinary velocity \mathbf{v} and the particle's ordinary velocity \mathbf{V} (both as measured in the receiver's frame).

FIGURE 2.6 Geometry for Doppler shift, drawn in a slice of simultaneity of the receiver's inertial frame.

2.7 Lorentz Transformations

2.7

T2

Consider two different inertial reference frames in Minkowski spacetime. Denote their Lorentz coordinates by $\{x^\alpha\}$ and $\{x^{\bar{\mu}}\}$ and their bases by $\{\mathbf{e}_\alpha\}$ and $\{\mathbf{e}_{\bar{\mu}}\}$, respectively, and write the transformation from one basis to the other as

$$\vec{e}_\alpha = \vec{e}_{\bar{\mu}} L^{\bar{\mu}}{}_\alpha, \quad \vec{e}_{\bar{\mu}} = \vec{e}_\alpha L^\alpha{}_{\bar{\mu}}. \quad (2.34)$$

As in Euclidean 3-space (the rotation matrices of Sec 1.6), $L^{\bar{\mu}}{}_\alpha$ and $L^\alpha{}_{\bar{\mu}}$ are elements of two different transformation matrices, and since these matrices operate in opposite directions, they must be the inverse of each other:

$$L^{\bar{\mu}}{}_\alpha L^\alpha{}_{\bar{\nu}} = \delta^{\bar{\mu}}{}_{\bar{\nu}}, \quad L^\alpha{}_{\bar{\mu}} L^{\bar{\mu}}{}_\beta = \delta^\alpha{}_\beta. \quad (2.35a)$$

Notice the up/down placement of indices on the elements of the transformation matrices: the first index is always up, and the second is always down. This is just a convenient convention, which helps systematize the index shuffling rules in a way that can easily be remembered. Our rules about summing on the same index when up and down, and matching unsummed indices on the two sides of an equation automatically dictate the matrix to use in each of the transformations (2.34); and similarly for all other equations in this section.

In Euclidean 3-space the orthonormality of the two bases dictates that the transformations must be orthogonal (i.e., must be reflections or rotations). In Minkowski spacetime, orthonormality implies $g_{\alpha\beta} = \vec{e}_\alpha \cdot \vec{e}_\beta = (\vec{e}_{\bar{\mu}} L^{\bar{\mu}}{}_\alpha) \cdot (\vec{e}_{\bar{\nu}} L^{\bar{\nu}}{}_\beta) = L^{\bar{\mu}}{}_\alpha L^{\bar{\nu}}{}_\beta g_{\bar{\mu}\bar{\nu}}$; that is,

$$g_{\bar{\mu}\bar{\nu}} L^{\bar{\mu}}{}_\alpha L^{\bar{\nu}}{}_\beta = g_{\alpha\beta}, \quad \text{and similarly,} \quad g_{\alpha\beta} L^\alpha{}_{\bar{\mu}} L^\beta{}_{\bar{\nu}} = g_{\bar{\mu}\bar{\nu}}. \quad (2.35b)$$

Any matrix whose elements satisfy these equations is a *Lorentz transformation*.

From the fact that vectors and tensors are geometric, frame-independent objects, one can derive the Minkowski-space analogs of the Euclidean transformation laws for components (1.13a) and (1.13b):

$$A^{\bar{\mu}} = L^{\bar{\mu}}{}_\alpha A^\alpha, \quad T^{\bar{\mu}\bar{\nu}\bar{\rho}} = L^{\bar{\mu}}{}_\alpha L^{\bar{\nu}}{}_\beta L^{\bar{\rho}}{}_\gamma T^{\alpha\beta\gamma}, \quad (2.36a)$$

and similarly in the opposite direction. Notice that here, as elsewhere, these equations can be constructed by lining up indices in accord with our standard rules.

If (as is conventional) we choose the spacetime origins of the two Lorentz coordinate systems to coincide, then the vector \vec{x} extending from the origin to some event \mathcal{P} , whose coordinates are x^α and $x^{\bar{\alpha}}$, has components equal to those coordinates. As a result, the transformation law for the coordinates takes the same form as Eq. (2.36a) for the components of a vector:

$$x^\alpha = L^\alpha{}_{\bar{\mu}} x^{\bar{\mu}}, \quad x^{\bar{\mu}} = L^{\bar{\mu}}{}_\alpha x^\alpha. \quad (2.36b)$$

transformation matrix

Lorentz transformation

The product $L^\alpha_{\bar{\mu}} L^{\bar{\mu}}_{\bar{\rho}}$ of two Lorentz transformation matrices is a Lorentz transformation matrix. Under this product rule, the Lorentz transformations form a mathematical group, the *Lorentz group*, whose representations play an important role in quantum field theory (cf. the rotation group in Sec. 1.6).

An important specific example of a Lorentz transformation is:

$$\left[L^\alpha_{\bar{\mu}} \right] = \begin{bmatrix} \gamma & \beta\gamma & 0 & 0 \\ \beta\gamma & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad \left[L^{\bar{\mu}}_{\alpha} \right] = \begin{bmatrix} \gamma & -\beta\gamma & 0 & 0 \\ -\beta\gamma & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad (2.37a)$$

where β and γ are related by

$$|\beta| < 1, \quad \gamma \equiv (1 - \beta^2)^{-\frac{1}{2}}. \quad (2.37b)$$

[Notice that γ is the Lorentz factor associated with β ; cf. Eq. (2.25d).]

One can readily verify (Ex. 2.12) that these matrices are the inverses of each other and that they satisfy the Lorentz-transformation relation (2.35b). These transformation matrices produce the following change of coordinates [Eq. (2.36b)]:

$$\begin{aligned} t &= \gamma(\bar{t} + \beta\bar{x}), & x &= \gamma(\bar{x} + \beta\bar{t}), & y &= \bar{y}, & z &= \bar{z}, \\ \bar{t} &= \gamma(t - \beta x), & \bar{x} &= \gamma(x - \beta t), & \bar{y} &= y, & \bar{z} &= z. \end{aligned} \quad (2.37c)$$

These expressions reveal that any particle at rest in the unbarred frame (a particle with fixed, time-independent x, y, z) is seen in the barred frame to move along the world line $\bar{x} = \text{const} - \beta\bar{t}, \bar{y} = \text{const}, \bar{z} = \text{const}$. In other words, the unbarred frame is seen by observers at rest in the barred frame to move with uniform velocity $\mathbf{v} = -\beta\mathbf{e}_{\bar{x}}$, and correspondingly the barred frame is seen by observers at rest in the unbarred frame to move with the opposite uniform velocity $\mathbf{v} = +\beta\mathbf{e}_x$. This special Lorentz transformation is called a *pure boost* along the x direction.

EXERCISES

Exercise 2.12 Derivation: Lorentz Boosts

Show that the matrices (2.37a), with β and γ satisfying Eq. (2.37b), are the inverses of each other, and that they obey the condition (2.35b) for a Lorentz transformation.

Exercise 2.13 Example: General Boosts and Rotations

(a) Show that, if n^j is a 3-dimensional unit vector and β and γ are defined as in Eq. (2.37b), then the following is a Lorentz transformation [i.e., it satisfies Eq. (2.35b)]:

$$L^0_{\bar{0}} = \gamma, \quad L^0_{\bar{j}} = L^j_{\bar{0}} = \beta\gamma n^j, \quad L^j_{\bar{k}} = L^k_{\bar{j}} = (\gamma - 1)n^j n^k + \delta^{jk}. \quad (2.38)$$

Show, further, that this transformation is a pure boost along the direction \mathbf{n} with speed β , and show that the inverse matrix $L^{\bar{\mu}}_{\alpha}$ for this boost is the same as $L^\alpha_{\bar{\mu}}$, but with β changed to $-\beta$.

(b) Show that the following is also a Lorentz transformation:

$$[L^{\alpha}_{\bar{\mu}}] = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & & & \\ 0 & [R_{i\bar{j}}] & & \\ 0 & & & \end{bmatrix}, \quad (2.39)$$

where $[R_{i\bar{j}}]$ is a 3-dimensional rotation matrix for Euclidean 3-space. Show, further, that this Lorentz transformation rotates the inertial frame's spatial axes (its latticework of measuring rods) while leaving the frame's velocity unchanged (i.e., the new frame is at rest with respect to the old).

One can show (not surprisingly) that the general Lorentz transformation [i.e., the general solution of Eqs. (2.35b)] can be expressed as a sequence of pure boosts, pure rotations, and pure inversions (in which one or more of the coordinate axes are reflected through the origin, so $x^{\alpha} = -x^{\bar{\alpha}}$).

2.8 Spacetime Diagrams for Boosts

2.8

Figure 2.7 illustrates the pure boost (2.37c). Panel a in that figure is a 2-dimensional spacetime diagram, with the y - and z -coordinates suppressed, showing the \bar{t} - and \bar{x} -axes of the boosted Lorentz frame $\bar{\mathcal{F}}$ in the t, x Lorentz coordinate system of the unboosted frame \mathcal{F} . That the barred axes make angles $\tan^{-1} \beta$ with the unbarred axes, as shown, can be inferred from the Lorentz transformation (2.37c). Note that the orthogonality of the \bar{t} - and \bar{x} -axes to each other ($\vec{e}_{\bar{t}} \cdot \vec{e}_{\bar{x}} = 0$) shows up as the two axes making the same angle $\pi/2 - \beta$ with the null line $x = t$. The invariance of the interval guarantees that, as shown for $a = 1$ or 2 in Fig. 2.7a, the event $\bar{x} = a$ on the \bar{x} -axis lies at the intersection of that axis with the dashed hyperbola $x^2 - t^2 = a^2$; and similarly, the event $\bar{t} = a$ on the \bar{t} -axis lies at the intersection of that axis with the dashed hyperbola $t^2 - x^2 = a^2$.

FIGURE 2.7 Spacetime diagrams illustrating the pure boost (2.37c) from one Lorentz reference frame to another.

As shown in Fig. 2.7b, the barred coordinates $\{\bar{t}, \bar{x}\}$ of an event \mathcal{P} can be inferred by projecting from \mathcal{P} onto the \bar{t} - and \bar{x} -axes, with the projection parallel to the \bar{x} - and \bar{t} -axes, respectively. Figure 2.7c shows the 4-velocity \vec{u} of an observer at rest in frame \mathcal{F} and that, $\vec{\bar{u}}$, of an observer at rest in frame $\bar{\mathcal{F}}$. The events that observer \mathcal{F} regards as all simultaneous, with time $t = 0$, lie in a 3-space that is orthogonal to \vec{u} and includes the x -axis. This is a slice of simultaneity of reference frame \mathcal{F} . Similarly, the events that observer $\bar{\mathcal{F}}$ regards as all simultaneous, with $\bar{t} = 0$, live in the 3-space that is orthogonal to $\vec{\bar{u}}$ and includes the \bar{x} -axis (i.e., in a slice of simultaneity of frame $\bar{\mathcal{F}}$).

Exercise 2.14 uses spacetime diagrams similar to those in Fig. 2.7 to deduce a number of important relativistic phenomena, including the contraction of the length of a moving object (length contraction), the breakdown of simultaneity as a universally agreed-on concept, and the dilation of the ticking rate of a moving clock (time dilation). This exercise is extremely important; every reader who is not already familiar with it should study it.

EXERCISES

Exercise 2.14 ***Example: Spacetime Diagrams*

Use spacetime diagrams to prove the following:

- Two events that are simultaneous in one inertial frame are not necessarily simultaneous in another. More specifically, if frame $\bar{\mathcal{F}}$ moves with velocity $\vec{v} = \beta\vec{e}_x$ as seen in frame \mathcal{F} , where $\beta > 0$, then of two events that are simultaneous in $\bar{\mathcal{F}}$ the one farther “back” (with the more negative value of \bar{x}) will occur in \mathcal{F} before the one farther “forward.”
- Two events that occur at the same spatial location in one inertial frame do not necessarily occur at the same spatial location in another.
- If \mathcal{P}_1 and \mathcal{P}_2 are two events with a timelike separation, then there exists an inertial reference frame in which they occur at the same spatial location, and in that frame the time lapse between them is equal to the square root of the negative of their invariant interval, $\Delta t = \Delta\tau \equiv \sqrt{-(\Delta s)^2}$.
- If \mathcal{P}_1 and \mathcal{P}_2 are two events with a spacelike separation, then there exists an inertial reference frame in which they are simultaneous, and in that frame the spatial distance between them is equal to the square root of their invariant interval, $\sqrt{g_{ij}\Delta x^i\Delta x^j} = \Delta s \equiv \sqrt{(\Delta s)^2}$.
- If the inertial frame $\bar{\mathcal{F}}$ moves with speed β relative to the frame \mathcal{F} , then a clock at rest in $\bar{\mathcal{F}}$ ticks more slowly as viewed from \mathcal{F} than as viewed from $\bar{\mathcal{F}}$ —more slowly by a factor $\gamma^{-1} = (1 - \beta^2)^{\frac{1}{2}}$. This is called *relativistic time dilation*. As one consequence, the lifetimes of unstable particles moving with speed β are increased by the Lorentz factor γ .
- If the inertial frame $\bar{\mathcal{F}}$ moves with velocity $\vec{v} = \beta\vec{e}_x$ relative to the frame \mathcal{F} , then an object at rest in $\bar{\mathcal{F}}$ as studied in \mathcal{F} appears shortened by a factor $\gamma^{-1} = (1 - \beta^2)^{\frac{1}{2}}$ along the x direction, but its length along the y and z directions

is unchanged. This is called *Lorentz contraction*. As one consequence, heavy ions moving at high speeds in a particle accelerator appear to act like pancakes, squashed along their directions of motion.

Exercise 2.15 *Problem: Allowed and Forbidden Electron-Photon Reactions*

Show, using spacetime diagrams and also using frame-independent calculations, that the law of conservation of 4-momentum forbids a photon to be absorbed by an electron, $e + \gamma \rightarrow e$, and also forbids an electron and a positron to annihilate and produce a single photon, $e^+ + e^- \rightarrow \gamma$ (in the absence of any other particles to take up some of the 4-momentum); but the annihilation to form two photons, $e^+ + e^- \rightarrow 2\gamma$, is permitted.

2.9 Time Travel

2.9

2.9.1 Measurement of Time; Twins Paradox

2.9.1

Time dilation is one facet of a more general phenomenon: time, as measured by ideal clocks, is a personal thing, different for different observers who move through spacetime on different world lines. This is well illustrated by the infamous “twins paradox,” in which one twin, Methuselah, remains forever at rest in an inertial frame and the other, Florence, makes a spacecraft journey at high speed and then returns to rest beside Methuselah.

twins paradox

The twins’ world lines are depicted in Fig. 2.8a, a spacetime diagram whose axes are those of Methuselah’s inertial frame. The time measured by an ideal clock that Methuselah carries is the coordinate time t of his inertial frame; and its total time lapse, from Florence’s departure to her return, is $t_{\text{return}} - t_{\text{departure}} \equiv T_{\text{Methuselah}}$. By contrast, the time measured by an ideal clock that Florence carries is her proper time τ (i.e., the square root of the invariant interval (2.4) along her world line). Thus her total time lapse from departure to return is

$$T_{\text{Florence}} = \int d\tau = \int \sqrt{dt^2 - \delta_{ij} dx^i dx^j} = \int_0^{T_{\text{Methuselah}}} \sqrt{1 - v^2} dt. \quad (2.40)$$

Here (t, x^i) are the time and space coordinates of Methuselah’s inertial frame, and v is Florence’s ordinary speed, $v = \sqrt{\delta_{ij} (dx^i/dt)(dx^j/dt)}$, as measured in Methuselah’s frame. Obviously, Eq. (2.40) predicts that T_{Florence} is less than $T_{\text{Methuselah}}$. In fact (Ex. 2.16), even if Florence’s acceleration is kept no larger than one Earth gravity throughout her trip, and her trip lasts only $T_{\text{Florence}} =$ (a few tens of years), $T_{\text{Methuselah}}$ can be hundreds or thousands or millions or billions of years.

Does this mean that Methuselah actually “experiences” a far longer time lapse, and actually ages far more than Florence? Yes! The time experienced by humans and the aging of the human body are governed by chemical processes, which in turn are governed by the natural oscillation rates of molecules, rates that are constant to high accuracy when measured in terms of ideal time (or, equivalently, proper time τ).

FIGURE 2.8 (a) Spacetime diagram depicting the so-called “twins paradox.” Marked along the two world lines are intervals of proper time as measured by the two twins. (b) Spacetime diagram depicting the motions of the two mouths of a wormhole. Marked along the mouths’ world tubes are intervals of proper time τ_c as measured by the single clock that sits in the common mouths.

Therefore, a human’s experiential time and aging time are the same as the human’s proper time—so long as the human is not subjected to such high accelerations as to damage her body.

In effect, then, Florence’s spacecraft has functioned as a time machine to carry her far into Methuselah’s future, with only a modest lapse of her own proper time (i.e., ideal, experiential, or aging time). This may be a “paradox” in the sense that it is surprising. However, it is in no sense a contradiction. This type of time dilation is routinely measured in high-energy physics storage rings.

2.9.2

2.9.2 Wormholes

Is it also possible, at least in principle, for Florence to construct a time machine that carries her into Methuselah’s past—and also her own past? At first sight, the answer would seem to be “yes.” Figure 2.8b shows one possible method, using a *wormhole*. [See Frolov and Novikov (1990), Friedman and Higuchi (2006), Everett and Roman (2011) for other approaches.]

Wormholes are hypothetical handles in the topology of space. A simple model of a wormhole can be obtained by taking a flat 3-dimensional space, removing from it the interiors of two identical spheres, and identifying the spheres’ surfaces so that if one enters the surface of one of the spheres, one immediately finds oneself exiting through the surface of the other. When this is done, there is a bit of strongly localized spatial curvature at the spheres’ common surface, so to analyze such a wormhole properly, one must use general relativity rather than special relativity. In particular, it is the laws of general relativity, combined with the laws of quantum field theory, that tell

wormhole

one how to construct such a wormhole and what kinds of materials are required to hold it open, so things can pass through it. Unfortunately, despite considerable effort, theoretical physicists have not yet deduced definitively whether those laws permit such wormholes to exist and stay open, though indications are pessimistic (Everett and Roman, 2011; Friedman and Higuchi, 2006). However, assuming such wormholes *can* exist, the following special relativistic analysis (Morris et al., 1988) shows how one might be used to construct a machine for backward time travel.

2.9.3 Wormhole as Time Machine

2.9.3

The two identified spherical surfaces are called the wormhole's mouths. Ask Methuselah to keep one mouth with him, forever at rest in his inertial frame, and ask Florence to take the other mouth with her on her high-speed journey. The two mouths' *world tubes* (analogous of world lines for a 3-dimensional object) then have the forms shown in Fig. 2.8b. Suppose that a single ideal clock sits in the wormhole's identified mouths, so that from the external universe one sees it both in Methuselah's wormhole mouth and in Florence's. As seen in Methuselah's mouth, the clock measures his proper time, which is equal to the coordinate time t (see tick marks along the left world tube in Fig. 2.8b). As seen in Florence's mouth, the clock measures her proper time, Eq. (2.40) (see tick marks along the right world tube in Fig. 2.8b). The result should be obvious, if surprising: When Florence returns to rest beside Methuselah, the wormhole has become a time machine. If she travels through the wormhole when the clock reads $\tau_c = 7$, she goes backward in time as seen in Methuselah's (or anyone else's) inertial frame; and then, in fact, traveling along the everywhere timelike world line (dashed in Fig. 2.8b), she is able to meet her younger self before she entered the wormhole.

world tube

This scenario is profoundly disturbing to most physicists because of the dangers of science-fiction-type paradoxes (e.g., the older Florence might kill her younger self, thereby preventing herself from making the trip through the wormhole and killing herself). Fortunately perhaps, it seems likely (though far from certain) that vacuum fluctuations of quantum fields will destroy the wormhole at the moment its mouths' motion first makes backward time travel possible. It may be that this mechanism will always prevent the construction of backward-travel time machines, no matter what tools one uses for their construction (Kay et al., 1997; Kim and Thorne, 1991); but see also contrary indications in research reviewed by Everett and Roman (2011) and Friedman and Higuchi (2006). Whether this is so we likely will not know until the laws of quantum gravity have been mastered.

chronology protection

Exercise 2.16 Example: Twins Paradox

- (a) The 4-acceleration of a particle or other object is defined by $\vec{a} \equiv d\vec{u}/d\tau$, where \vec{u} is its 4-velocity and τ is proper time along its world line. Show that, if an observer carries an accelerometer, the magnitude $|\mathbf{a}|$ of the 3-dimensional acceleration \mathbf{a} measured by the accelerometer will always be equal to the magnitude of the observer's 4-acceleration, $|\mathbf{a}| = |\vec{a}| \equiv \sqrt{\vec{a} \cdot \vec{a}}$.

EXERCISES

- (b) In the twins paradox of Fig. 2.8a, suppose that Florence begins at rest beside Methuselah, then accelerates in Methuselah's x -direction with an acceleration a equal to one Earth gravity, g , for a time $T_{\text{Florence}}/4$ as measured by her, then accelerates in the $-x$ -direction at g for a time $T_{\text{Florence}}/2$, thereby reversing her motion; then she accelerates in the $+x$ -direction at g for a time $T_{\text{Florence}}/4$, thereby returning to rest beside Methuselah. (This is the type of motion shown in the figure.) Show that the total time lapse as measured by Methuselah is

$$T_{\text{Methuselah}} = \frac{4}{g} \sinh \left(\frac{g T_{\text{Florence}}}{4} \right). \quad (2.41)$$

- (c) Show that in the geometrized units used here, Florence's acceleration (equal to acceleration of gravity at the surface of Earth) is $g = 1.033/\text{yr}$. Plot $T_{\text{Methuselah}}$ as a function of T_{Florence} , and from your plot estimate T_{Florence} if $T_{\text{Methuselah}}$ is the age of the Universe, 14 billion years.

Exercise 2.17 *Challenge: Around the World on TWA*

In a long-ago era when an airline named Trans World Airlines (TWA) flew around the world, Josef Hafele and Richard Keating (1972a) carried out a real live twins paradox experiment: They synchronized two atomic clocks and then flew one around the world eastward on TWA, and on a separate trip, around the world westward, while the other clock remained at home at the Naval Research Laboratory near Washington, D.C. When the clocks were compared after each trip, they were found to have aged differently. Making reasonable estimates for the airplane routing and speeds, compute the difference in aging, and compare your result with the experimental data in Hafele and Keating (1972b). [Note: The rotation of Earth is important, as is the general relativistic gravitational redshift associated with the clocks' altitudes; but the gravitational redshift drops out of the difference in aging, if the time spent at high altitude is the same eastward as westward.]

2.10

2.10 Directional Derivatives, Gradients, and the Levi-Civita Tensor

Derivatives of vectors and tensors in Minkowski spacetime are defined in precisely the same way as in Euclidean space; see Sec. 1.7. Any reader who has not studied that section should do so now. In particular (in extreme brevity, as the explanations and justifications are the same as in Euclidean space):

directional derivative

gradient

The directional derivative of a tensor \mathbf{T} along a vector \vec{A} is $\nabla_{\vec{A}}\mathbf{T} \equiv \lim_{\epsilon \rightarrow 0} (1/\epsilon) [\mathbf{T}(\vec{x}_{\mathcal{P}} + \epsilon \vec{A}) - \mathbf{T}(\vec{x}_{\mathcal{P}})]$; the gradient $\vec{\nabla}\mathbf{T}$ is the tensor that produces the directional derivative when one inserts \vec{A} into its last slot: $\nabla_{\vec{A}}\mathbf{T} = \vec{\nabla}\mathbf{T}(_, _, _, \vec{A})$. In slot-naming index notation (or in components on a basis), the gradient is denoted $T_{\alpha\beta\gamma;\mu}$. In a Lorentz basis (the basis vectors associated with an inertial reference frame), the components of the gradient are simply the partial derivatives of the tensor,

$T_{\alpha\beta\gamma;\mu} = \partial T_{\alpha\beta\gamma} / \partial x^\mu \equiv T_{\alpha\beta\gamma,\mu}$. (The comma means partial derivative in a Lorentz basis, as in a Cartesian basis.)

The gradient and the directional derivative obey all the familiar rules for differentiation of products, for example, $\nabla_{\vec{A}}(\mathbf{S} \otimes \mathbf{T}) = (\nabla_{\vec{A}}\mathbf{S}) \otimes \mathbf{T} + \mathbf{S} \otimes \nabla_{\vec{A}}\mathbf{T}$. The gradient of the metric vanishes, $\mathbf{g}_{\alpha\beta;\mu} = 0$. The divergence of a vector is the contraction of its gradient, $\vec{\nabla} \cdot \vec{A} = A_{\alpha;\beta} \mathbf{g}^{\alpha\beta} = A^\alpha{}_{;\alpha}$.

Recall that the divergence of the gradient of a tensor in Euclidean space is the Laplacian: $T_{abc;jk} \mathbf{g}_{jk} = T_{abc,jk} \delta_{jk} = \partial^2 T_{abc} \partial x^j \partial x^j$. By contrast, in Minkowski spacetime, because $\mathbf{g}^{00} = -1$ and $\mathbf{g}^{jk} = \delta^{jk}$ in a Lorentz frame, the divergence of the gradient is the wave operator (also called the d'Alembertian):

$$T_{\alpha\beta\gamma;\mu\nu} \mathbf{g}^{\mu\nu} = T_{\alpha\beta\gamma,\mu\nu} \mathbf{g}^{\mu\nu} = -\frac{\partial^2 T_{\alpha\beta\gamma}}{\partial t^2} + \frac{\partial^2 T_{\alpha\beta\gamma}}{\partial x^j \partial x^k} \delta^{jk} = \square T_{\alpha\beta\gamma}. \quad (2.42)$$

When one sets this to zero, one gets the wave equation.

As in Euclidean space, so also in Minkowski spacetime, there are two tensors that embody the space's geometry: the metric tensor \mathbf{g} and the Levi-Civita tensor ϵ . The Levi-Civita tensor in Minkowski spacetime is the tensor that is completely antisymmetric in all its slots and has value $\epsilon(\vec{A}, \vec{B}, \vec{C}, \vec{D}) = +1$ when evaluated on any *right-handed set of orthonormal 4-vectors*—that is, by definition, any orthonormal set for which \vec{A} is timelike and future directed, and $\{\vec{B}, \vec{C}, \vec{D}\}$ are spatial and right-handed. This means that in any right-handed Lorentz basis, the only nonzero components of ϵ are

$$\begin{aligned} \epsilon_{\alpha\beta\gamma\delta} &= +1 \text{ if } \alpha, \beta, \gamma, \delta \text{ is an even permutation of } 0, 1, 2, 3; \\ &= -1 \text{ if } \alpha, \beta, \gamma, \delta \text{ is an odd permutation of } 0, 1, 2, 3; \\ &= 0 \text{ if } \alpha, \beta, \gamma, \delta \text{ are not all different.} \end{aligned} \quad (2.43)$$

By the sign-flip-if-temporal rule, $\epsilon_{0123} = +1$ implies that $\epsilon^{0123} = -1$.

2.11 Nature of Electric and Magnetic Fields; Maxwell's Equations

2.11

Now that we have introduced the gradient and the Levi-Civita tensor, we can study the relationship of the relativistic version of electrodynamics to the nonrelativistic (Newtonian) version. In doing so, we use Gaussian units (with the speed of light set to 1), as is conventional among relativity theorists, and as does Jackson (1998) in his classic textbook, switching from SI to Gaussian when he moves into the relativistic domain.

Consider a particle with charge q , rest mass m , and 4-velocity \vec{u} interacting with an electromagnetic field $\mathbf{F}(_, _)$. In index notation, the electromagnetic 4-force acting on the particle [Eq. (2.20)] is

$$dp^\alpha / d\tau = q F^{\alpha\beta} u_\beta. \quad (2.44)$$

d'Alembertian

Levi-Civita tensor

Let us examine this 4-force in some arbitrary inertial reference frame in which the particle's ordinary-velocity components are $v^j = v_j$ and its 4-velocity components are $u^0 = \gamma$, $u^j = \gamma v^j$ [Eqs. (2.25c)]. Anticipating the connection with the nonrelativistic viewpoint, we introduce the following notation for the contravariant components of the antisymmetric electromagnetic field tensor:

$$F^{0j} = -F^{j0} = +F_{j0} = -F_{0j} = E_j, \quad F^{ij} = F_{ij} = \epsilon_{ijk} B_k. \quad (2.45)$$

Inserting these components of \mathbf{F} and \vec{u} into Eq. (2.44) and using the relationship $dt/d\tau = u^0 = \gamma$ between t and τ derivatives, we obtain for the components of the 4-force $dp_j/d\tau = \gamma dp_j/dt = q(F_{j0}u^0 + F_{jk}u^k) = qu^0(F_{j0} + F_{jk}v^k) = q\gamma(E_j + \epsilon_{jki}v_k B_i)$ and $dp^0/d\tau = \gamma dp^0/dt = qF^{0j}u_j = q\gamma E_j v_j$. Dividing by γ , converting into 3-space index notation, and denoting the particle's energy by $\mathcal{E} = p^0$, we bring these into the familiar Lorentz-force form

Lorentz force

$$d\mathbf{p}/dt = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}), \quad d\mathcal{E}/dt = q\mathbf{v} \cdot \mathbf{E}. \quad (2.46)$$

Evidently, \mathbf{E} is the electric field and \mathbf{B} the magnetic field as measured in our chosen Lorentz frame.

This may be familiar from standard electrodynamics textbooks (e.g., Jackson, 1999). Not so familiar, but very important, is the following geometric interpretation of \mathbf{E} and \mathbf{B} .

The electric and magnetic fields \mathbf{E} and \mathbf{B} are spatial vectors as measured in the chosen inertial frame. We can also regard them as 4-vectors that lie in a 3-surface of simultaneity $t = \text{const}$ of the chosen frame, i.e., that are orthogonal to the 4-velocity (denote it \vec{w}) of the frame's observers (cf. Figs. 2.5 and 2.9). We shall denote this 4-vector version of \mathbf{E} and \mathbf{B} by $\vec{E}_{\vec{w}}$ and $\vec{B}_{\vec{w}}$, where the subscript \vec{w} identifies the 4-velocity of the observer who measures these fields. These fields are depicted in Fig. 2.9.

In the rest frame of the observer \vec{w} , the components of $\vec{E}_{\vec{w}}$ are $E_{\vec{w}}^0 = 0$, $E_{\vec{w}}^j = E_j = F_{j0}$ [the E_j appearing in Eqs. (2.45)], and similarly for $\vec{B}_{\vec{w}}$; the components of \vec{w} are $w^0 = 1$, $w^j = 0$. Therefore, in this frame Eqs. (2.45) can be rewritten as

electric and magnetic fields measured by an observer

$$\boxed{E_{\vec{w}}^\alpha = F^{\alpha\beta} w_\beta, \quad B_{\vec{w}}^\beta = \frac{1}{2} \epsilon^{\alpha\beta\gamma\delta} F_{\gamma\delta} w_\alpha.} \quad (2.47a)$$

[To verify this, insert the above components of \mathbf{F} and \vec{w} into these equations and, after some algebra, recover Eqs. (2.45) along with $E_{\vec{w}}^0 = B_{\vec{w}}^0 = 0$.] Equations (2.47a) say that in one special reference frame, that of the observer \vec{w} , the components of the 4-vectors on the left and on the right are equal. This implies that in every Lorentz frame the components of these 4-vectors will be equal; that is, Eqs. (2.47a) are true when one regards them as geometric, frame-independent equations written in slot-naming index notation. *These equations enable one to compute the electric and magnetic fields measured by an observer (viewed as 4-vectors in the observer's 3-surface of simultaneity)*

FIGURE 2.9 The electric and magnetic fields measured by an observer with 4-velocity \vec{w} , shown as 4-vectors $\vec{E}_{\vec{w}}$ and $\vec{B}_{\vec{w}}$ that lie in the observer's 3-surface of simultaneity (green 3-surface orthogonal to \vec{w}).

from the observer's 4-velocity and the electromagnetic field tensor, without the aid of any basis or reference frame.

Equations (2.47a) embody explicitly the following important fact. Although the electromagnetic field tensor \mathbf{F} is a geometric, frame-independent quantity, the electric and magnetic fields $\vec{E}_{\vec{w}}$ and $\vec{B}_{\vec{w}}$ individually depend for their existence on a specific choice of observer (with 4-velocity \vec{w}), that is, a specific choice of inertial reference frame, or in other words, a specific choice of the split of spacetime into a 3-space (the 3-surface of simultaneity orthogonal to the observer's 4-velocity \vec{w}) and corresponding time (the Lorentz time of the observer's reference frame). *Only after making such an observer-dependent 3+1 split of spacetime into space plus time do the electric field and the magnetic field come into existence as separate entities.* Different observers with different 4-velocities \vec{w} make this spacetime split in different ways, thereby resolving the frame-independent \mathbf{F} into different electric and magnetic fields $\vec{E}_{\vec{w}}$ and $\vec{B}_{\vec{w}}$.

By the same procedure as we used to derive Eqs. (2.47a), one can derive the inverse relationship, the following expression for the electromagnetic field tensor in terms of the (4-vector) electric and magnetic fields measured by some observer:

$$F^{\alpha\beta} = w^\alpha E_{\vec{w}}^\beta - E_{\vec{w}}^\alpha w^\beta + \epsilon^{\alpha\beta}{}_{\gamma\delta} w^\gamma B_{\vec{w}}^\delta. \quad (2.47b)$$

Maxwell's equations in geometric, frame-independent form are (in Gaussian units)⁵

$$\begin{aligned} F^{\alpha\beta}{}_{;\beta} &= 4\pi J^\alpha, \\ \epsilon^{\alpha\beta\gamma\delta} F_{\gamma\delta;\beta} &= 0; \quad \text{i.e.,} \quad F_{\alpha\beta;\gamma} + F_{\beta\gamma;\alpha} + F_{\gamma\alpha;\beta} = 0. \end{aligned} \quad (2.48)$$

Maxwell's equations

5. In SI units the 4π gets replaced by $\mu_0 = 1/\epsilon_0$, corresponding to the different units for the charge-current 4-vector.

Here \vec{J} is the charge-current 4-vector, which in any inertial frame has components

$$J^0 = \rho_e = (\text{charge density}), \quad J^i = j_i = (\text{current density}). \quad (2.49)$$

Exercise 2.19 describes how to think about this charge density and current density as geometric objects determined by the observer's 4-velocity or 3+1 split of spacetime into space plus time. Exercise 2.20 shows how the frame-independent Maxwell's equations (2.48) reduce to the more familiar ones in terms of \mathbf{E} and \mathbf{B} . Exercise 2.21 explores potentials for the electromagnetic field in geometric, frame-independent language and the 3+1 split.

EXERCISES

Exercise 2.18 *Derivation and Practice: Reconstruction of \mathbf{F}*

Derive Eq. (2.47b) by the same method as was used to derive Eq. (2.47a). Then show, by a geometric, frame-independent calculation, that Eq. (2.47b) implies Eq. (2.47a).

Exercise 2.19 *Problem: 3+1 Split of Charge-Current 4-Vector*

Just as the electric and magnetic fields measured by some observer can be regarded as 4-vectors $\vec{E}_{\vec{w}}$ and $\vec{B}_{\vec{w}}$ that live in the observer's 3-space of simultaneity, so also the charge density and current density that the observer measures can be regarded as a scalar $\rho_{\vec{w}}$ and 4-vector $\vec{j}_{\vec{w}}$ that live in the 3-space of simultaneity. Derive geometric, frame-independent equations for $\rho_{\vec{w}}$ and $\vec{j}_{\vec{w}}$ in terms of the charge-current 4-vector \vec{J} and the observer's 4-velocity \vec{w} , and derive a geometric expression for \vec{J} in terms of $\rho_{\vec{w}}$, $\vec{j}_{\vec{w}}$, and \vec{w} .

Exercise 2.20 *Problem: Frame-Dependent Version of Maxwell's Equations*

By performing a 3+1 split on the geometric version of Maxwell's equations (2.48), derive the elementary, frame-dependent version

$$\begin{aligned} \nabla \cdot \mathbf{E} &= 4\pi\rho_e, & \nabla \times \mathbf{B} - \frac{\partial \mathbf{E}}{\partial t} &= 4\pi\mathbf{j}, \\ \nabla \cdot \mathbf{B} &= 0, & \nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} &= 0. \end{aligned} \quad (2.50)$$

3+1 split of Maxwell's equations

Exercise 2.21 *Problem: Potentials for the Electromagnetic Field*

(a) Express the electromagnetic field tensor as an antisymmetrized gradient of a 4-vector potential: in slot-naming index notation

$$F_{\alpha\beta} = A_{\beta;\alpha} - A_{\alpha;\beta}. \quad (2.51a)$$

Show that, whatever may be the 4-vector potential \vec{A} , the second of Maxwell's equations (2.48) is automatically satisfied. Show further that the electromagnetic field tensor is unaffected by a gauge change of the form

$$\vec{A}_{\text{new}} = \vec{A}_{\text{old}} + \vec{\nabla}\psi, \quad (2.51b)$$

where ψ is a scalar field (the generator of the gauge change). Show, finally, that it is possible to find a gauge-change generator that enforces *Lorenz gauge*

$$\vec{\nabla} \cdot \vec{A} = 0 \quad (2.51c)$$

on the new 4-vector potential, and show that in this gauge, the first of Maxwell's equations (2.48) becomes (in Gaussian units)

$$\square \vec{A} = -4\pi \vec{J}; \quad \text{i.e., } A^{\alpha;\mu}{}_{\mu} = -4\pi J^{\alpha}. \quad (2.51d)$$

- (b) Introduce an inertial reference frame, and in that frame split \mathbf{F} into the electric and magnetic fields \mathbf{E} and \mathbf{B} , split \vec{J} into the charge and current densities ρ_e and \mathbf{j} , and split the vector potential into a scalar potential and a 3-vector potential

$$\phi \equiv A_0, \quad \mathbf{A} = \text{spatial part of } \vec{A}. \quad (2.51e)$$

Deduce the 3+1 splits of Eqs. (2.51a)–(2.51d), and show that they take the form given in standard textbooks on electromagnetism.

2.12 Volumes, Integration, and Conservation Laws

2.12

2.12.1 Spacetime Volumes and Integration

2.12.1

In Minkowski spacetime as in Euclidean 3-space (Sec. 1.8), the Levi-Civita tensor is the tool by which one constructs volumes. The 4-dimensional parallelepiped whose legs are the four vectors \vec{A} , \vec{B} , \vec{C} , \vec{D} has a 4-dimensional volume given by the analog of Eqs. (1.25) and (1.26):

$$4\text{-volume} = \epsilon_{\alpha\beta\gamma\delta} A^{\alpha} B^{\beta} C^{\gamma} D^{\delta} = \epsilon(\vec{A}, \vec{B}, \vec{C}, \vec{D}) = \det \begin{bmatrix} A^0 & B^0 & C^0 & D^0 \\ A^1 & B^1 & C^1 & D^1 \\ A^2 & B^2 & C^2 & D^2 \\ A^3 & B^3 & C^3 & D^3 \end{bmatrix}. \quad (2.52)$$

4-volume

Note that this 4-volume is positive if the set of vectors $\{\vec{A}, \vec{B}, \vec{C}, \vec{D}\}$ is right-handed and negative if left-handed [cf. Eq. (2.43)].

Equation (2.52) provides us a way to perform volume integrals over 4-dimensional Minkowski spacetime. To integrate a smooth tensor field \mathbf{T} over some 4-dimensional region \mathcal{V} of spacetime, we need only divide \mathcal{V} up into tiny parallelepipeds, multiply the 4-volume $d\Sigma$ of each parallelepiped by the value of \mathbf{T} at its center, add, and take the limit. In any right-handed Lorentz coordinate system, the 4-volume of a tiny parallelepiped whose edges are dx^{α} along the four orthogonal coordinate axes is $d\Sigma = \epsilon(dt \vec{e}_0, dx \vec{e}_x, dy \vec{e}_y, dz \vec{e}_z) = \epsilon_{0123} dt dx dy dz = dt dx dy dz$ (the analog of $dV = dx dy dz$). Correspondingly, the integral of \mathbf{T} over \mathcal{V} can be expressed as

$$\int_{\mathcal{V}} T^{\alpha\beta\gamma} d\Sigma = \int_{\mathcal{V}} T^{\alpha\beta\gamma} dt dx dy dz. \quad (2.53)$$

By analogy with the vectorial area (1.27) of a parallelogram in 3-space, any 3-dimensional parallelepiped in spacetime with legs \vec{A} , \vec{B} , \vec{C} has a vectorial 3-volume $\vec{\Sigma}$ (not to be confused with the scalar 4-volume Σ) defined by

vectorial 3-volume

$$\vec{\Sigma}(_) = \epsilon(_, \vec{A}, \vec{B}, \vec{C}); \quad \Sigma_\mu = \epsilon_{\mu\alpha\beta\gamma} A^\alpha B^\beta C^\gamma. \quad (2.54)$$

Here we have written the 3-volume vector both in abstract notation and in slot-naming index notation. This 3-volume vector has one empty slot, ready and waiting for a fourth vector (“leg”) to be inserted, so as to compute the 4-volume Σ of a 4-dimensional parallelepiped.

Notice that the 3-volume vector $\vec{\Sigma}$ is orthogonal to each of its three legs (because of the antisymmetry of ϵ), and thus (unless it is null) it can be written as $\vec{\Sigma} = V\vec{n}$, where V is the magnitude of the 3-volume, and \vec{n} is the unit normal to the three legs.

Interchanging any two legs of the parallelepiped reverses the 3-volume’s sign. Consequently, the 3-volume is characterized not only by its legs but also by the order of its legs, or equally well, in two other ways: (i) by the direction of the vector $\vec{\Sigma}$ (reverse the order of the legs, and the direction of $\vec{\Sigma}$ will reverse); and (ii) by the *sense* of the 3-volume, defined as follows. Just as a 2-volume (i.e., a segment of a plane) in 3-dimensional space has two sides, so a 3-volume in 4-dimensional spacetime has two sides (Fig. 2.10). Every vector \vec{D} for which $\vec{\Sigma} \cdot \vec{D} > 0$ points out the *positive side* of the 3-volume $\vec{\Sigma}$. Vectors \vec{D} with $\vec{\Sigma} \cdot \vec{D} < 0$ point out its *negative side*. When something moves through, reaches through, or points through the 3-volume from its negative side to its positive side, we say that this thing is moving or reaching or pointing in the “positive sense;” similarly for “negative sense.” The examples shown in Fig. 2.10 should make this more clear.

positive and negative sides, and sense of 3-volume

Figure 2.10a shows two of the three legs of the volume vector $\vec{\Sigma} = \epsilon(_, \Delta x \vec{e}_x, \Delta y \vec{e}_y, \Delta z \vec{e}_z)$, where $\{t, x, y, z\}$ are the coordinates, and $\{\vec{e}_\alpha\}$ is the corresponding right-handed basis of a specific Lorentz frame. It is easy to show that this $\vec{\Sigma}$ can also be written as $\vec{\Sigma} = -\Delta V \vec{e}_0$, where ΔV is the ordinary volume of the parallelepiped as measured by an observer in the chosen Lorentz frame, $\Delta V = \Delta x \Delta y \Delta z$. Thus, the direction of the vector $\vec{\Sigma}$ is toward the past (direction of decreasing Lorentz time t). From this, and the fact that timelike vectors have negative squared length, it is easy to infer that $\vec{\Sigma} \cdot \vec{D} > 0$ if and only if the vector \vec{D} points out of the “future” side of the 3-volume (the side of increasing Lorentz time t); therefore, the positive side of $\vec{\Sigma}$ is the future side. It follows that the vector $\vec{\Sigma}$ points in the negative sense of its own 3-volume.

Figure 2.10b shows two of the three legs of the volume vector $\vec{\Sigma} = \epsilon(_, \Delta t \vec{e}_t, \Delta y \vec{e}_y, \Delta z \vec{e}_z) = -\Delta t \Delta A \vec{e}_x$ (with $\Delta A = \Delta y \Delta z$). In this case, $\vec{\Sigma}$ points in its own positive sense.

This peculiar behavior is completely general. When the normal to a 3-volume is timelike, its volume vector $\vec{\Sigma}$ points in the negative sense; when the normal is spacelike, $\vec{\Sigma}$ points in the positive sense. And as it turns out, when the normal is null, $\vec{\Sigma}$

FIGURE 2.10 Spacetime diagrams depicting 3-volumes in 4-dimensional spacetime, with one spatial dimension (that along the z direction) suppressed.

lies in the 3-volume (parallel to its one null leg) and thus points neither in the positive sense nor the negative.⁶

Note the physical interpretations of the 3-volumes of Fig. 2.10. Figure 2.10a shows an instantaneous snapshot of an ordinary, spatial parallelepiped, whereas Fig. 2.10b shows the 3-dimensional region in spacetime swept out during time Δt by the parallelogram with legs $\Delta y\vec{e}_y$, $\Delta z\vec{e}_z$ and with area $\Delta A = \Delta y\Delta z$.

Vectorial 3-volume elements can be used to construct integrals over 3-dimensional volumes (also called 3-dimensional surfaces) in spacetime, for example, $\int_{\mathcal{V}_3} \vec{A} \cdot d\vec{\Sigma}$. More specifically, let (a, b, c) be (possibly curvilinear) coordinates in the 3-surface (3-volume) \mathcal{V}_3 , and denote by $\vec{x}(a, b, c)$ the spacetime point \mathcal{P} on \mathcal{V}_3 whose coordinate values are (a, b, c) . Then $(\partial\vec{x}/\partial a)da$, $(\partial\vec{x}/\partial b)db$, $(\partial\vec{x}/\partial c)dc$ are the vectorial legs of the elementary parallelepiped whose corners are at (a, b, c) , $(a + da, b, c)$, $(a, b + db, c)$, and so forth; and the spacetime components of these vectorial legs are $(\partial x^\alpha/\partial a)da$, $(\partial x^\alpha/\partial b)db$, $(\partial x^\alpha/\partial c)dc$. The 3-volume of this elementary parallelepiped is $d\vec{\Sigma} = \epsilon(_, (\partial\vec{x}/\partial a)da, (\partial\vec{x}/\partial b)db, (\partial\vec{x}/\partial c)dc)$, which has spacetime components

$$d\Sigma_\mu = \epsilon_{\mu\alpha\beta\gamma} \frac{\partial x^\alpha}{\partial a} \frac{\partial x^\beta}{\partial b} \frac{\partial x^\gamma}{\partial c} dadbdc. \quad (2.55)$$

This is the integration element to be used when evaluating

$$\int_{\mathcal{V}_3} \vec{A} \cdot d\vec{\Sigma} = \int_{\mathcal{V}_3} A^\mu d\Sigma_\mu. \quad (2.56)$$

See Ex. 2.22 for an example.

6. This peculiar behavior gets replaced by a simpler description if one uses one-forms rather than vectors to describe 3-volumes; see, for example, Misner, Thorne, and Wheeler (1973, Box 5.2).

Just as there are Gauss's and Stokes' theorems (1.28a) and (1.28b) for integrals in Euclidean 3-space, so also there are Gauss's and Stokes' theorems in spacetime. Gauss's theorem has the obvious form

Gauss's theorem

$$\int_{\mathcal{V}_4} (\vec{\nabla} \cdot \vec{A}) d\Sigma = \int_{\partial\mathcal{V}_4} \vec{A} \cdot d\vec{\Sigma}, \quad (2.57)$$

where the first integral is over a 4-dimensional region \mathcal{V}_4 in spacetime, and the second is over the 3-dimensional boundary $\partial\mathcal{V}_4$ of \mathcal{V}_4 , with the boundary's positive sense pointing outward, away from \mathcal{V}_4 (just as in the 3-dimensional case). We shall not write down the 4-dimensional Stokes' theorem, because it is complicated to formulate with the tools we have developed thus far; easy formulation requires *differential forms* (e.g., Flanders, 1989), which we shall not introduce in this book.

2.12.2

2.12.2 Conservation of Charge in Spacetime

In this section, we use integration over a 3-dimensional region in 4-dimensional spacetime to construct an elegant, frame-independent formulation of the law of conservation of electric charge.

We begin by examining the geometric meaning of the charge-current 4-vector \vec{J} . We defined \vec{J} in Eq. (2.49) in terms of its components. The spatial component $J^x = J_x = J(\vec{e}_x)$ is equal to the x component of current density j_x : it is the amount Q of charge that flows across a unit surface area lying in the y - z plane in a unit time (i.e., the charge that flows across the unit 3-surface $\vec{\Sigma} = \vec{e}_x$). In other words, $\vec{J}(\vec{\Sigma}) = J(\vec{e}_x)$ is the total charge Q that flows across $\vec{\Sigma} = \vec{e}_x$ in $\vec{\Sigma}$'s positive sense and similarly for the other spatial directions. The temporal component $J^0 = -J_0 = \vec{J}(-\vec{e}_0)$ is the charge density ρ_e : it is the total charge Q in a unit spatial volume. This charge is carried by particles that are traveling through spacetime from past to future and pass through the unit 3-surface (3-volume) $\vec{\Sigma} = -\vec{e}_0$. Therefore, $\vec{J}(\vec{\Sigma}) = \vec{J}(-\vec{e}_0)$ is the total charge Q that flows through $\vec{\Sigma} = -\vec{e}_0$ in its positive sense. This interpretation is the same one we deduced for the spatial components of \vec{J} .

charge-current 4-vector

This makes it plausible, and indeed one can show, that for any small 3-surface $\vec{\Sigma}$, $\vec{J}(\vec{\Sigma}) \equiv J^\alpha \Sigma_\alpha$ is the total charge Q that flows across $\vec{\Sigma}$ in its positive sense.

This property of the charge-current 4-vector is the foundation for our frame-independent formulation of the law of charge conservation. Let \mathcal{V} be a compact 4-dimensional region of spacetime and denote by $\partial\mathcal{V}$ its boundary, a closed 3-surface in 4-dimensional spacetime (Fig. 2.11). The charged media (fluids, solids, particles, etc.) present in spacetime carry electric charge through \mathcal{V} , from the past toward the future. The law of charge conservation says that all the charge that enters \mathcal{V} through the past part of its boundary $\partial\mathcal{V}$ must exit through the future part of its boundary. If we choose the positive sense of the boundary's 3-volume element $d\vec{\Sigma}$ to point out of \mathcal{V} (toward the past on the bottom boundary and toward the future on the top), then this *global law of charge conservation* can be expressed as

FIGURE 2.11 The 4-dimensional region \mathcal{V} in spacetime and its closed 3-boundary $\partial\mathcal{V}$ (green surface), used in formulating the law of charge conservation. The dashed lines symbolize, heuristically, the flow of charge from the past toward the future.

$$\int_{\partial\mathcal{V}} J^\alpha d\Sigma_\alpha = 0. \quad (2.58)$$

global law of charge conservation

When each tiny charge q enters \mathcal{V} through its past boundary, it contributes negatively to the integral, since it travels through $\partial\mathcal{V}$ in the negative sense (from positive side of $\partial\mathcal{V}$ toward negative side); and when that same charge exits \mathcal{V} through its future boundary, it contributes positively. Therefore, its net contribution is zero, and similarly for all other charges.

In Ex. 2.23 you will show that, when this global law of charge conservation (2.58) is subjected to a 3+1 split of spacetime into space plus time, it becomes the nonrelativistic integral law of charge conservation (1.29).

This global conservation law can be converted into a *local conservation law* with the help of the 4-dimensional Gauss's theorem (2.57), $\int_{\partial\mathcal{V}} J^\alpha d\Sigma_\alpha = \int_{\mathcal{V}} J^\alpha{}_{;\alpha} d\Sigma$. Since the left-hand side vanishes, so must the right-hand side; and for this 4-volume integral to vanish for every choice of \mathcal{V} , it is necessary that the integrand vanish everywhere in spacetime:

$$J^\alpha{}_{;\alpha} = 0; \quad \text{that is, } \vec{\nabla} \cdot \vec{J} = 0. \quad (2.59)$$

local law of charge conservation

In a specific but arbitrary Lorentz frame (i.e., in a 3+1 split of spacetime into space plus time), Eq. (2.59) becomes the standard differential law of charge conservation (1.30).

2.12.3 Conservation of Particles, Baryon Number, and Rest Mass

2.12.3

Any conserved scalar quantity obeys conservation laws of the same form as those for electric charge. For example, if the number of particles of some species (e.g., electrons, protons, or photons) is conserved, then we can introduce for that species a *number-flux 4-vector* \vec{S} (analog of charge-current 4-vector \vec{J}): in any Lorentz frame, S^0 is the number density of particles, also designated n , and S^j is the particle flux. If $\vec{\Sigma}$ is a small

number-flux 4-vector

3-volume (3-surface) in spacetime, then $\vec{S}(\vec{\Sigma}) = S^\alpha \Sigma_\alpha$ is the number of particles that pass through Σ from its negative side to its positive side. The frame-invariant global and local conservation laws for these particles take the same form as those for electric charge:

$$\int_{\partial\mathcal{V}} S^\alpha d\Sigma_\alpha = 0, \quad \text{where } \partial\mathcal{V} \text{ is any closed 3-surface in spacetime,} \quad (2.60a)$$

$$S^\alpha{}_{;\alpha} = 0; \quad \text{that is, } \vec{\nabla} \cdot \vec{S} = 0. \quad (2.60b)$$

When fundamental particles (e.g., protons and antiprotons) are created and destroyed by quantum processes, the total baryon number (number of baryons minus number of antibaryons) is still conserved—or at least this is so to the accuracy of all experiments performed thus far. We shall assume it so in this book. This law of baryon-number conservation takes the forms of Eqs. (2.60), with \vec{S} the number-flux 4-vector for baryons (with antibaryons counted negatively).

It is useful to express this baryon-number conservation law in Newtonian-like language by introducing a universally agreed-on mean rest mass per baryon \bar{m}_B . This \bar{m}_B is often taken to be 1/56 the mass of an ^{56}Fe (iron-56) atomic nucleus, since ^{56}Fe is the nucleus with the tightest nuclear binding (i.e., the endpoint of thermonuclear evolution in stars). We multiply the baryon number-flux 4-vector \vec{S} by this mean rest mass per baryon to obtain a rest-mass-flux 4-vector

$$\vec{S}_{\text{rm}} = \bar{m}_B \vec{S}, \quad (2.61)$$

which (since \bar{m}_B is, by definition, a constant) satisfies the same conservation laws (2.60) as baryon number.

For such media as fluids and solids, in which the particles travel only short distances between collisions or strong interactions, it is often useful to resolve the particle number-flux 4-vector and the rest-mass-flux 4-vector into a 4-velocity of the medium \vec{u} (i.e., the 4-velocity of the frame in which there is a vanishing net spatial flux of particles), and the particle number density n_o or rest mass density ρ_o as measured in the medium's rest frame:

$$\vec{S} = n_o \vec{u}, \quad \vec{S}_{\text{rm}} = \rho_o \vec{u}. \quad (2.62)$$

See Ex. 2.24.

We make use of the conservation laws $\vec{\nabla} \cdot \vec{S} = 0$ and $\vec{\nabla} \cdot \vec{S}_{\text{rm}} = 0$ for particles and rest mass later in this book (e.g., when studying relativistic fluids); and we shall find the expressions (2.62) for the number-flux 4-vector and rest-mass-flux 4-vector quite useful. See, for example, the discussion of relativistic shock waves in Ex. 17.9.

EXERCISES

Exercise 2.22 *Practice and Example: Evaluation of 3-Surface Integral in Spacetime*

In Minkowski spacetime, the set of all events separated from the origin by a timelike interval a^2 is a 3-surface, the hyperboloid $t^2 - x^2 - y^2 - z^2 = a^2$, where $\{t, x, y, z\}$

are Lorentz coordinates of some inertial reference frame. On this hyperboloid, introduce coordinates $\{\chi, \theta, \phi\}$ such that

$$\begin{aligned} t &= a \cosh \chi, & x &= a \sinh \chi \sin \theta \cos \phi, \\ y &= a \sinh \chi \sin \theta \sin \phi, & z &= a \sinh \chi \cos \theta. \end{aligned} \quad (2.63)$$

Note that χ is a radial coordinate and (θ, ϕ) are spherical polar coordinates. Denote by \mathcal{V}_3 the portion of the hyperboloid with radius $\chi \leq b$.

- Verify that for all values of (χ, θ, ϕ) , the points defined by Eqs. (2.63) do lie on the hyperboloid.
- On a spacetime diagram, draw a picture of \mathcal{V}_3 , the $\{\chi, \theta, \phi\}$ coordinates, and the elementary volume element (vector field) $d\vec{\Sigma}$ [Eq. (2.55)].
- Set $\vec{A} \equiv \vec{e}_0$ (the temporal basis vector), and express $\int_{\mathcal{V}_3} \vec{A} \cdot d\vec{\Sigma}$ as an integral over $\{\chi, \theta, \phi\}$. Evaluate the integral.
- Consider a closed 3-surface consisting of the segment \mathcal{V}_3 of the hyperboloid as its top, the hypercylinder $\{x^2 + y^2 + z^2 = a^2 \sinh^2 b, 0 < t < a \cosh b\}$ as its sides, and the sphere $\{x^2 + y^2 + z^2 \leq a^2 \sinh^2 b, t = 0\}$ as its bottom. Draw a picture of this closed 3-surface on a spacetime diagram. Use Gauss's theorem, applied to this 3-surface, to show that $\int_{\mathcal{V}_3} \vec{A} \cdot d\vec{\Sigma}$ is equal to the 3-volume of its spherical base.

Exercise 2.23 *Derivation and Example: Global Law of Charge Conservation in an Inertial Frame*

Consider the global law of charge conservation $\int_{\partial\mathcal{V}} J^\alpha d\Sigma_\alpha = 0$ for a special choice of the closed 3-surface $\partial\mathcal{V}$: The bottom of $\partial\mathcal{V}$ is the ball $\{t = 0, x^2 + y^2 + z^2 \leq a^2\}$, where $\{t, x, y, z\}$ are the Lorentz coordinates of some inertial frame. The sides are the spherical world tube $\{0 \leq t \leq T, x^2 + y^2 + z^2 = a^2\}$. The top is the ball $\{t = T, x^2 + y^2 + z^2 \leq a^2\}$.

- Draw this 3-surface in a spacetime diagram.
- Show that for this $\partial\mathcal{V}$, $\int_{\partial\mathcal{V}} J^\alpha d\Sigma_\alpha = 0$ is a time integral of the nonrelativistic integral conservation law (1.29) for charge.

Exercise 2.24 *Example: Rest-Mass-Flux 4-Vector, Lorentz Contraction of Rest-Mass Density, and Rest-Mass Conservation for a Fluid*

Consider a fluid with 4-velocity \vec{u} and rest-mass density ρ_o as measured in the fluid's rest frame.

- From the physical meanings of \vec{u} , ρ_o , and the rest-mass-flux 4-vector \vec{S}_{rm} , deduce Eqs. (2.62).
- Examine the components of \vec{S}_{rm} in a reference frame where the fluid moves with ordinary velocity \mathbf{v} . Show that $S^0 = \rho_o \gamma$, and $S^j = \rho_o \gamma v^j$, where $\gamma = 1/\sqrt{1 - \mathbf{v}^2}$. Explain the physical interpretation of these formulas in terms of Lorentz contraction.

(c) Show that the law of conservation of rest mass $\vec{\nabla} \cdot \vec{S}_{\text{rm}} = 0$ takes the form

$$\frac{d\rho_o}{d\tau} = -\rho_o \vec{\nabla} \cdot \vec{u}, \quad (2.64)$$

where $d/d\tau$ is derivative with respect to proper time moving with the fluid.

(d) Consider a small 3-dimensional volume V of the fluid, whose walls move with the fluid (so if the fluid expands, V increases). Explain why the law of rest-mass conservation must take the form $d(\rho_o V)/d\tau = 0$. Thereby deduce that

$$\vec{\nabla} \cdot \vec{u} = (1/V)(dV/d\tau). \quad (2.65)$$

2.13

2.13 Stress-Energy Tensor and Conservation of 4-Momentum

2.13.1

2.13.1 Stress-Energy Tensor

GEOMETRIC DEFINITION

We conclude this chapter by formulating the law of 4-momentum conservation in ways analogous to our laws of conservation of charge, particles, baryon number, and rest mass. This task is not trivial, since 4-momentum is a vector in spacetime, while charge, particle number, baryon number, and rest mass are scalar quantities. Correspondingly, the density-flux of 4-momentum must have one more slot than the density-fluxes of charge, baryon number, and rest mass, \vec{J} , \vec{S} and \vec{S}_{rm} , respectively; it must be a second-rank tensor. We call it the *stress-energy tensor* and denote it $\mathcal{T}(_, _)$. It is a generalization of the Newtonian stress tensor to 4-dimensional spacetime.

Consider a medium or field flowing through 4-dimensional spacetime. As it crosses a tiny 3-surface $\vec{\Sigma}$, it transports a net electric charge $\vec{J}(\vec{\Sigma})$ from the negative side of $\vec{\Sigma}$ to the positive side, and net baryon number $\vec{S}(\vec{\Sigma})$ and net rest mass $\vec{S}_{\text{rm}}(\vec{\Sigma})$. Similarly, it transports a net 4-momentum $\mathcal{T}(_, \vec{\Sigma})$ from the negative side to the positive side:

$$\mathcal{T}(_, \vec{\Sigma}) \equiv (\text{total 4-momentum } \vec{P} \text{ that flows through } \vec{\Sigma}); \quad \text{or } T^{\alpha\beta} \Sigma_\beta = P^\alpha. \quad (2.66)$$

COMPONENTS

From this definition of the stress-energy tensor we can read off the physical meanings of its components on a specific, but arbitrary, Lorentz-coordinate basis: Making use of method (2.23b) for computing the components of a vector or tensor, we see that in a specific, but arbitrary, Lorentz frame (where $\vec{\Sigma} = -\vec{e}_0$ is a volume vector representing a parallelepiped with unit volume $\Delta V = 1$, at rest in that frame, with its positive sense toward the future):

$$\begin{aligned} -T_{\alpha 0} &= \mathcal{T}(\vec{e}_\alpha, -\vec{e}_0) = \vec{P}(\vec{e}_\alpha) = \left(\begin{array}{l} \alpha \text{ component of 4-momentum that} \\ \text{flows from past to future across a unit} \\ \text{volume } \Delta V = 1 \text{ in the 3-space } t = \text{const} \end{array} \right) \\ &= (\alpha \text{ component of density of 4-momentum}). \end{aligned} \quad (2.67a)$$

Specializing α to be a time or space component and raising indices, we obtain the specialized versions of (2.67a):

$$\begin{aligned} T^{00} &= (\text{energy density as measured in the chosen Lorentz frame}), \\ T^{j0} &= (\text{density of } j \text{ component of momentum in that frame}). \end{aligned} \quad (2.67b)$$

Similarly, the αx component of the stress-energy tensor (also called the $\alpha 1$ component, since $x = x^1$ and $\vec{e}_x = \vec{e}_1$) has the meaning

$$\begin{aligned} T_{\alpha 1} \equiv T_{\alpha x} \equiv \mathbf{T}(\vec{e}_\alpha, \vec{e}_x) &= \left(\begin{array}{l} \alpha \text{ component of 4-momentum that crosses} \\ \text{a unit area } \Delta y \Delta z = 1 \text{ lying in a surface of} \\ \text{constant } x, \text{ during unit time } \Delta t, \text{ crossing} \\ \text{from the } -x \text{ side toward the } +x \text{ side} \end{array} \right) \\ &= \left(\begin{array}{l} \alpha \text{ component of flux of 4-momentum} \\ \text{across a surface lying perpendicular to } \vec{e}_x \end{array} \right). \end{aligned} \quad (2.67c)$$

The specific forms of this for temporal and spatial α are (after raising indices)

$$T^{0x} = \left(\begin{array}{l} \text{energy flux across a surface perpendicular to } \vec{e}_x, \\ \text{from the } -x \text{ side to the } +x \text{ side} \end{array} \right), \quad (2.67d)$$

$$\begin{aligned} T^{jx} &= \left(\begin{array}{l} \text{flux of } j \text{ component of momentum across a surface} \\ \text{perpendicular to } \vec{e}_x, \text{ from the } -x \text{ side to the } +x \text{ side} \end{array} \right) \\ &= \left(\begin{array}{l} jx \text{ component} \\ \text{of stress} \end{array} \right). \end{aligned} \quad (2.67e)$$

The αy and αz components have the obvious, analogous interpretations.

These interpretations, restated much more briefly, are:

$$\boxed{\begin{aligned} T^{00} &= (\text{energy density}), & T^{j0} &= (\text{momentum density}), \\ T^{0j} &= (\text{energy flux}), & T^{jk} &= (\text{stress}). \end{aligned}} \quad (2.67f)$$

components of stress-energy tensor

SYMMETRY

Although it might not be obvious at first sight, *the 4-dimensional stress-energy tensor is always symmetric*: in index notation (where indices can be thought of as representing the names of slots, or equally well, components on an arbitrary basis)

$$T^{\alpha\beta} = T^{\beta\alpha}. \quad (2.68)$$

symmetry of stress-energy tensor

This symmetry can be deduced by physical arguments in a specific, but arbitrary, Lorentz frame: Consider, first, the $x0$ and $0x$ components, that is, the x components of momentum density and energy flux. A little thought, symbolized by the following heuristic equation, reveals that they must be equal:

$$T^{x0} = \left(\begin{array}{l} \text{momentum} \\ \text{density} \end{array} \right) = \frac{(\Delta\mathcal{E})dx/dt}{\Delta x \Delta y \Delta z} = \frac{\Delta\mathcal{E}}{\Delta y \Delta z \Delta t} = \left(\begin{array}{l} \text{energy} \\ \text{flux} \end{array} \right), \quad (2.69)$$

and similarly for the other space-time and time-space components: $T^{j0} = T^{0j}$. [In the first expression of Eq. (2.69) $\Delta\mathcal{E}$ is the total energy (or equivalently mass) in the volume $\Delta x \Delta y \Delta z$, $(\Delta\mathcal{E})dx/dt$ is the total momentum, and when divided by the volume we get the momentum density. The third equality is just elementary algebra, and the resulting expression is obviously the energy flux.] The space-space components, being equal to the stress tensor, are also symmetric, $T^{jk} = T^{kj}$, by the argument embodied in Fig. 1.6. Since $T^{0j} = T^{j0}$ and $T^{jk} = T^{kj}$, all components in our chosen Lorentz frame are symmetric, $T^{\alpha\beta} = T^{\beta\alpha}$. Therefore, if we insert arbitrary vectors into the slots of \mathbf{T} and evaluate the resulting number in our chosen Lorentz frame, we find

$$\mathbf{T}(\vec{A}, \vec{B}) = T^{\alpha\beta} A_\alpha B_\beta = T^{\beta\alpha} A_\alpha B_\beta = \mathbf{T}(\vec{B}, \vec{A}); \quad (2.70)$$

that is, \mathbf{T} is symmetric under interchange of its slots.

Let us return to the physical meanings (2.67f) of the components of the stress-energy tensor. With the aid of \mathbf{T} 's symmetry, we can restate those meanings in the language of a 3+1 split of spacetime into space plus time: *When one chooses a specific reference frame, that choice splits the stress-energy tensor up into three parts. Its time-time part is the energy density T^{00} , its time-space part $T^{0j} = T^{j0}$ is the energy flux or equivalently the momentum density, and its space-space part T^{jk} is the stress tensor.*

2.13.2

2.13.2 4-Momentum Conservation

Our interpretation of $\vec{J}(\vec{\Sigma}) \equiv J^\alpha \Sigma_\alpha$ as the net charge that flows through a small 3-surface $\vec{\Sigma}$ from its negative side to its positive side gave rise to the global conservation law for charge, $\int_{\partial\mathcal{V}} J^\alpha d\Sigma_\alpha = 0$ [Eq. (2.58) and Fig. 2.11]. Similarly the role of $\mathbf{T}(_, \vec{\Sigma})$ [$T^{\alpha\beta} \Sigma_\beta$ in slot-naming index notation] as the net 4-momentum that flows through $\vec{\Sigma}$ from its negative side to positive gives rise to the following equation for conservation of 4-momentum:

$$\int_{\partial\mathcal{V}} T^{\alpha\beta} d\Sigma_\beta = 0. \quad (2.71)$$

global law of 4-momentum conservation

(The time component of this equation is energy conservation; the spatial part is momentum conservation.) This equation says that all the 4-momentum that flows into the 4-volume \mathcal{V} of Fig. 2.11 through its 3-surface $\partial\mathcal{V}$ must also leave \mathcal{V} through $\partial\mathcal{V}$; it gets counted negatively when it enters (since it is traveling from the positive side of $\partial\mathcal{V}$ to the negative), and it gets counted positively when it leaves, so its net contribution to the integral (2.71) is zero.

This global law of 4-momentum conservation can be converted into a local law (analogous to $\vec{\nabla} \cdot \vec{J} = 0$ for charge) with the help of the 4-dimensional Gauss's theorem (2.57). Gauss's theorem, generalized in the obvious way from a vectorial integrand to a tensorial one, is:

$$\int_{\mathcal{V}} T^{\alpha\beta}{}_{;\beta} d\Sigma = \int_{\partial\mathcal{V}} T^{\alpha\beta} d\Sigma_\beta. \quad (2.72)$$

Since the right-hand side vanishes, so must the left-hand side; and for this 4-volume integral to vanish for every choice of \mathcal{V} , the integrand must vanish everywhere in spacetime:

$$\boxed{T^{\alpha\beta}{}_{;\beta} = 0; \quad \text{or} \quad \vec{\nabla} \cdot \mathbf{T} = 0.} \quad (2.73a)$$

local law of 4-momentum conservation

In the second, index-free version of this local conservation law, the ambiguity about which slot the divergence is taken on is unimportant, since \mathbf{T} is symmetric in its two slots: $T^{\alpha\beta}{}_{;\beta} = T^{\beta\alpha}{}_{;\beta}$.

In a specific but arbitrary Lorentz frame, the local conservation law (2.73a) for 4-momentum has as its temporal part

$$\frac{\partial T^{00}}{\partial t} + \frac{\partial T^{0k}}{\partial x^k} = 0, \quad (2.73b)$$

that is, the time derivative of the energy density plus the 3-divergence of the energy flux vanishes; and as its spatial part

$$\frac{\partial T^{j0}}{\partial t} + \frac{\partial T^{jk}}{\partial x^k} = 0, \quad (2.73c)$$

that is, the time derivative of the momentum density plus the 3-divergence of the stress (i.e., of momentum flux) vanishes. Thus, as one should expect, the geometric, frame-independent law of 4-momentum conservation includes as special cases both the conservation of energy and the conservation of momentum; and their differential conservation laws have the standard form that one expects both in Newtonian physics and in special relativity: time derivative of density plus divergence of flux vanishes; cf. Eq. (1.36) and associated discussion.

2.13.3 Stress-Energy Tensors for Perfect Fluids and Electromagnetic Fields

2.13.3

As an important example that illustrates the stress-energy tensor, consider a *perfect fluid*—a medium whose stress-energy tensor, evaluated in its *local rest frame* (a Lorentz frame where $T^{j0} = T^{0j} = 0$), has the form

$$T^{00} = \rho, \quad T^{jk} = P\delta^{jk} \quad (2.74a)$$

perfect-fluid stress-energy tensor

[Eq. (1.34) and associated discussion]. Here ρ is a short-hand notation for the energy density T^{00} (density of total mass-energy, including rest mass) as measured in the local rest frame, and the stress tensor T^{jk} in that frame is an isotropic pressure P . From this special form of $T^{\alpha\beta}$ in the local rest frame, one can derive the following geometric, frame-independent expression for the stress-energy tensor in terms of the 4-velocity \vec{u} of the local rest frame (i.e., of the fluid itself), the metric tensor of spacetime \mathbf{g} , and the rest-frame energy density ρ and pressure P :

$$\boxed{T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P g^{\alpha\beta}; \quad \text{i.e., } \mathbf{T} = (\rho + P)\vec{u} \otimes \vec{u} + P\mathbf{g}.} \quad (2.74b)$$

See Ex. 2.26.

In Sec. 13.8, we develop and explore the laws of relativistic fluid dynamics that follow from energy-momentum conservation $\vec{\nabla} \cdot \mathbf{T} = 0$ for this stress-energy tensor and from rest-mass conservation $\vec{\nabla} \cdot \vec{S}_{\text{rm}} = 0$. By constructing the Newtonian limit of the relativistic laws, we shall deduce the nonrelativistic laws of fluid mechanics, which are the central theme of Part V. Notice, in particular, that the Newtonian limit ($P \ll \rho$, $u^0 \simeq 1$, $u^j \simeq v^j$) of the stress part of the stress-energy tensor (2.74b) is $T^{jk} = \rho v^j v^k + P \delta^{jk}$, which we met in Ex. 1.13.

Another example of a stress-energy tensor is that for the electromagnetic field, which takes the following form in Gaussian units (with $4\pi \rightarrow \mu_0 = 1/\epsilon_0$ in SI units):

electromagnetic stress-energy tensor

$$T^{\alpha\beta} = \frac{1}{4\pi} \left(F^{\alpha\mu} F^{\beta}_{\mu} - \frac{1}{4} g^{\alpha\beta} F^{\mu\nu} F_{\mu\nu} \right). \quad (2.75)$$

We explore this stress-energy tensor in Ex. 2.28.

EXERCISES

Exercise 2.25 Example: Global Conservation of Energy in an Inertial Frame

Consider the 4-dimensional parallelepiped \mathcal{V} whose legs are $\Delta t \vec{e}_t$, $\Delta x \vec{e}_x$, $\Delta y \vec{e}_y$, $\Delta z \vec{e}_z$, where $(t, x, y, z) = (x^0, x^1, x^2, x^3)$ are the coordinates of some inertial frame. The boundary $\partial\mathcal{V}$ of this \mathcal{V} has eight 3-dimensional “faces.” Identify these faces, and write the integral $\int_{\partial\mathcal{V}} T^{0\beta} d\Sigma_{\beta}$ as the sum of contributions from each of them. According to the law of energy conservation, this sum must vanish. Explain the physical interpretation of each of the eight contributions to this energy conservation law. (See Ex. 2.23 for an analogous interpretation of charge conservation.)

Exercise 2.26 **Derivation and Example: Stress-Energy Tensor and Energy-Momentum Conservation for a Perfect Fluid

- Derive the frame-independent expression (2.74b) for the perfect fluid stress-energy tensor from its rest-frame components (2.74a).
- Explain why the projection of $\vec{\nabla} \cdot \mathbf{T} = 0$ along the fluid 4-velocity, $\vec{u} \cdot (\vec{\nabla} \cdot \mathbf{T}) = 0$, should represent energy conservation as viewed by the fluid itself. Show that this equation reduces to

$$\frac{d\rho}{d\tau} = -(\rho + P) \vec{\nabla} \cdot \vec{u}. \quad (2.76a)$$

With the aid of Eq. (2.65), bring this into the form

$$\frac{d(\rho V)}{d\tau} = -P \frac{dV}{d\tau}, \quad (2.76b)$$

where V is the 3-volume of some small fluid element as measured in the fluid’s local rest frame. What are the physical interpretations of the left- and right-hand sides of this equation, and how is it related to the first law of thermodynamics?

- Read the discussion in Ex. 2.10 about the tensor $\mathbf{P} = \mathbf{g} + \vec{u} \otimes \vec{u}$ that projects into the 3-space of the fluid’s rest frame. Explain why $P_{\mu\alpha} T^{\alpha\beta}_{;\beta} = 0$ should represent

the law of force balance (momentum conservation) as seen by the fluid. Show that this equation reduces to

$$(\rho + P)\vec{a} = -\mathbf{P} \cdot \vec{\nabla} P, \quad (2.76c)$$

where $\vec{a} = d\vec{u}/d\tau$ is the fluid's 4-acceleration. This equation is a relativistic version of Newton's $\mathbf{F} = m\mathbf{a}$. Explain the physical meanings of the left- and right-hand sides. Infer that $\rho + P$ must be the fluid's inertial mass per unit volume. It is also the enthalpy per unit volume, including the contribution of rest mass; see Ex. 5.5 and Box 13.2.

Exercise 2.27 ***Example: Inertial Mass per Unit Volume*

Suppose that some medium has a rest frame (unprimed frame) in which its energy flux and momentum density vanish, $T^{0j} = T^{j0} = 0$. Suppose that the medium moves in the x direction with speed very small compared to light, $v \ll 1$, as seen in a (primed) laboratory frame, and ignore factors of order v^2 . The ratio of the medium's momentum density $G_{j'} = T^{j'0'}$ (as measured in the laboratory frame) to its velocity $v_i = v\delta_{ix}$ is called its total *inertial mass per unit volume* and is denoted ρ_{ji}^{inert} :

$$T^{j'0'} = \rho_{ji}^{\text{inert}} v_i. \quad (2.77)$$

In other words, ρ_{ji}^{inert} is the 3-dimensional tensor that gives the momentum density $G_{j'}$ when the medium's small velocity is put into its second slot.

- (a) Using a Lorentz transformation from the medium's (unprimed) rest frame to the (primed) laboratory frame, show that

$$\rho_{ji}^{\text{inert}} = T^{00}\delta_{ji} + T_{ji}. \quad (2.78)$$

- (b) Give a physical explanation of the contribution $T_{ji}v_i$ to the momentum density.
 (c) Show that for a perfect fluid [Eq. (2.74b)] the inertial mass per unit volume is isotropic and has magnitude $\rho + P$, where ρ is the mass-energy density, and P is the pressure measured in the fluid's rest frame:

$$\boxed{\rho_{ji}^{\text{inert}} = (\rho + P)\delta_{ji}}. \quad (2.79)$$

See Ex. 2.26 for this inertial-mass role of $\rho + P$ in the law of force balance.

Exercise 2.28 ***Example: Stress-Energy Tensor, and Energy-Momentum Conservation for the Electromagnetic Field*

- (a) From Eqs. (2.75) and (2.45) compute the components of the electromagnetic stress-energy tensor in an inertial reference frame (in Gaussian units). Your

answer should be the expressions given in electrodynamics textbooks:

$$T^{00} = \frac{\mathbf{E}^2 + \mathbf{B}^2}{8\pi}, \quad \mathbf{G} = T^{0j} \mathbf{e}_j = T^{j0} \mathbf{e}_j = \frac{\mathbf{E} \times \mathbf{B}}{4\pi},$$

$$T^{jk} = \frac{1}{8\pi} \left[(\mathbf{E}^2 + \mathbf{B}^2) \delta_{jk} - 2(E_j E_k + B_j B_k) \right]. \quad (2.80)$$

(In SI units, $4\pi \rightarrow \mu_0 = 1/\epsilon_0$.) See also Ex. 1.14 for an alternative derivation of the stress tensor T_{jk} .

(b) Show that the divergence of the stress-energy tensor (2.75) is given by

$$T^{\mu\nu}{}_{;\nu} = \frac{1}{4\pi} (F^{\mu\alpha}{}_{;\nu} F^\nu{}_\alpha + F^{\mu\alpha} F^\nu{}_{\alpha;\nu} - \frac{1}{2} F_{\alpha\beta}{}^{;\mu} F^{\alpha\beta}). \quad (2.81a)$$

(c) Combine this with Maxwell's equations (2.48) to show that

$$\nabla \cdot \mathbf{T} = -\mathbf{F}(\underline{\quad}, \vec{\mathbf{J}}); \quad \text{i.e., } T^{\alpha\beta}{}_{;\beta} = -F^{\alpha\beta} J_\beta. \quad (2.81b)$$

(d) The matter that carries the electric charge and current can exchange energy and momentum with the electromagnetic field. Explain why Eq. (2.81b) is the rate per unit volume at which that matter feeds 4-momentum into the electromagnetic field, and conversely, $+F^{\alpha\mu} J_\mu$ is the rate per unit volume at which the electromagnetic field feeds 4-momentum into the matter. Show, further, that (as viewed in any reference frame) the time and space components of this quantity are

$$\frac{d\mathcal{E}_{\text{matter}}}{dt dV} = F^{0j} J_j = \mathbf{E} \cdot \mathbf{j}, \quad \frac{d\mathbf{P}_{\text{matter}}}{dt dV} = \rho_e \mathbf{E} + \mathbf{j} \times \mathbf{B}, \quad (2.81c)$$

where ρ_e is charge density, and \mathbf{j} is current density [Eq. (2.49)]. The first of these equations describes ohmic heating of the matter by the electric field, and the second gives the Lorentz force per unit volume on the matter (cf. Ex. 1.14b).

Bibliographic Note

For an inspiring taste of the history of special relativity, see the original papers by Einstein, Lorentz, and Minkowski, translated into English and archived in Lorentz et al. (1923).

Early relativity textbooks [see the bibliography in Jackson (1999, pp. 566–567)] emphasized the transformation properties of physical quantities, in going from one inertial frame to another, rather than their roles as frame-invariant geometric objects. Minkowski (1908) introduced geometric thinking, but only in recent decades—in large measure due to the influence of John Wheeler—has the geometric viewpoint gained ascendancy.

In our opinion, the best elementary introduction to special relativity is the first edition of Taylor and Wheeler (1966); the more ponderous second edition (Taylor

and Wheeler, 1992) is also good. At an intermediate level we strongly recommend the special relativity portions of Hartle (2003).

At a more advanced level, comparable to this chapter, we recommend Goldstein, Poole, and Safko (2002) and the special relativity sections of Misner, Thorne, and Wheeler (1973), Carroll (2004), and Schutz (2009).

These all adopt the geometric viewpoint that we espouse. In this chapter, so far as possible, we have minimized the proliferation of mathematical concepts (avoiding, e.g., differential forms and dual bases). By contrast, the other advanced treatments cited above embrace the richer mathematics.

Much less geometric than these references but still good, in our view, are the special relativity sections of popular electrodynamics texts: Griffiths (1999) at an intermediate level and Jackson (1999) at a more advanced level. We recommend avoiding special relativity treatments that use imaginary time and thereby obfuscate (e.g., earlier editions of Goldstein and of Jackson, and also the more modern and otherwise excellent Zangwill (2013)).

STATISTICAL PHYSICS

In this second part of the book, we study aspects of classical statistical physics that every physicist should know but that are not usually treated in elementary thermodynamics courses. Our study lays the microphysical (particle-scale) foundations for the continuum physics of Parts III–VII, and it elucidates the intimate connections between relativistic statistical physics and the Newtonian theory, and between quantum statistical physics and the classical theory. Our treatment is both Newtonian and relativistic. Readers who prefer a solely Newtonian treatment can skip the (rather few) relativistic sections. Throughout, we presume that readers are familiar with elementary thermodynamics but not with other aspects of statistical physics.

In Chap. 3, we study *kinetic theory*—the simplest of all formalisms for analyzing systems of huge numbers of particles (e.g., molecules of air, neutrons diffusing through a nuclear reactor, or photons produced in the big-bang origin of the universe). In kinetic theory, the key concept is the distribution function, or number density of particles in phase space, \mathcal{N} , that is, the number of particles of some species (e.g., electrons) per unit of physical space and of momentum space. In special relativity, despite first appearances, this \mathcal{N} turns out to be a geometric, reference-frame-independent entity (a scalar field in phase space). This \mathcal{N} and the frame-independent laws it obeys provide us with a means for computing, from microphysics, the macroscopic quantities of continuum physics: mass density, thermal energy density, pressure, equations of state, thermal and electrical conductivities, viscosities, diffusion coefficients,

In Chap. 4, we develop the foundations of *statistical mechanics*. Here our statistical study is more sophisticated than in kinetic theory: we deal with ensembles of physical systems. Each ensemble is a (conceptual) collection of a huge number of physical systems that are identical in the sense that they all have the same degrees of freedom, but different in that their degrees of freedom may be in different physical states. For example, the systems in an ensemble might be balloons that are each filled with 10^{23} air molecules so each is describable by 3×10^{23} spatial coordinates (the $\{x, y, z\}$ of all the molecules) and 3×10^{23} momentum coordinates (the $\{p_x, p_y, p_z\}$ of all the molecules). The state of one of the balloons is fully described, then,

by 6×10^{23} numbers. We introduce a distribution function \mathcal{N} that is a function of these 6×10^{23} different coordinates (i.e., it is defined in a phase space with 6×10^{23} dimensions). This distribution function tells us how many systems (balloons) in our ensemble lie in a unit volume of that phase space. Using this distribution function, we study such issues as the statistical meaning of entropy, the relationship between entropy and information, the statistical origin of the second law of thermodynamics, the statistical meaning of “thermal equilibrium,” and the evolution of ensembles into thermal equilibrium. Our applications include derivations of the Fermi-Dirac distribution for fermions in thermal equilibrium and the Bose-Einstein distribution for bosons, a study of Bose-Einstein condensation in a dilute gas, and explorations of the meaning and role of entropy in gases, black holes, and the universe as a whole.

In Chap. 5, we use the tools of statistical mechanics to study *statistical thermodynamics*: ensembles of systems that are in or near thermal equilibrium (also called statistical equilibrium). Using statistical mechanics, we derive the laws of thermodynamics, and we learn how to use thermodynamic and statistical mechanical tools, hand in hand, to study not only equilibria but also the probabilities for random, spontaneous fluctuations away from equilibrium. Among the applications we study are: (i) chemical and particle reactions, such as ionization equilibrium in a hot gas, and electron-positron pair formation in a still hotter gas and (ii) phase transitions, such as the freezing, melting, vaporization, and condensation of water. We focus special attention on a ferromagnetic phase transition, in which the magnetic moments of atoms spontaneously align with one another as iron is cooled, using it to illustrate two elegant and powerful techniques of statistical physics: the renormalization group and Monte Carlo methods.

In Chap. 6, we develop the theory of random processes (a modern, mathematical component of which is the theory of stochastic differential equations). Here we study the dynamical evolution of processes that are influenced by a huge number of factors over which we have little control and little knowledge, except of their statistical properties. One example is the Brownian motion of a dust particle being buffeted by air molecules; another is the motion of a pendulum used, say, in a gravitational-wave interferometer, where one monitors that motion so accurately that one can see the influences of seismic vibrations and of fluctuating thermal (Nyquist) forces in the pendulum’s suspension wire. The position of such a dust particle or pendulum cannot be predicted as a function of time, but one can compute the probability that it will evolve in a given manner. The theory of random processes is a theory of the evolution of the position’s probability distribution (and the probability distribution for any other entity driven by random, fluctuating influences). Among the random-process concepts we study are spectral densities, correlation functions, the Fokker-Planck equation (which governs the evolution of probability distributions), and the fluctuation-dissipation theorem (which says that, associated with any kind of friction,

there must be fluctuating forces whose statistical properties are determined by the strength of the friction and the temperature of the entities that produce the friction).

The theory of random processes, as treated in Chap. 6, also includes the theory of signals and noise. At first sight this undeniably important topic, which lies at the heart of experimental and observational science, might seem outside the scope of this book. However, we shall discover that it is intimately connected to statistical physics and that similar principles to those used to describe, say, Brownian motion, are appropriate when thinking about, for example, how to detect the electronic signal of a rare particle event against a strong and random background. We study, for example, techniques for extracting weak signals from noisy data by filtering the data, and the limits that noise places on the accuracies of physics experiments and on the reliability of communications channels.

Kinetic Theory

The gaseous condition is exemplified in the soirée, where the members rush about confusedly, and the only communication is during a collision, which in some instances may be prolonged by button-holing.

JAMES CLERK MAXWELL (1873)

3.1 Overview

3.1

In this chapter, we study kinetic theory, the simplest of all branches of statistical physics. Kinetic theory deals with the statistical distribution of a “gas” made from a huge number of “particles” that travel freely, without collisions, for distances (*mean free paths*) long compared to their sizes.

Examples of particles (*italicized*) and phenomena that can be studied via kinetic theory are:

- Whether *neutrons* in a nuclear reactor can survive long enough to maintain a nuclear chain reaction and keep the reactor hot.
- How *galaxies*, formed in the early universe, congregate into clusters as the universe expands.
- How spiral structure develops in the distribution of a galaxy’s *stars*.
- How, deep inside a white-dwarf star, relativistic degeneracy influences the equation of state of the star’s *electrons and protons*.
- How a supernova explosion affects the evolution of the density and temperature of *interstellar molecules*.
- How anisotropies in the expansion of the universe affect the temperature distribution of the *cosmic microwave photons*—the remnants of the big bang.
- How changes of a metal’s temperature affect its thermal and electrical conductivity (with the heat and current carried by *electrons*).

Most of these applications involve particle speeds small compared to that of light and so can be studied with Newtonian theory, but some involve speeds near or at the speed of light and require relativity. Accordingly, we develop both versions of the theory, Newtonian and relativistic, and demonstrate that the Newtonian theory is the low-speed limit of the relativistic theory. As is discussed in the Readers’ Guide

BOX 3.1. READERS' GUIDE

- This chapter develops nonrelativistic (Newtonian) kinetic theory and also the relativistic theory. Sections and exercises labeled **N** are Newtonian, and those labeled **R** are relativistic. The **N** material can be read without the **R** material, but the **R** material requires the **N** material as a foundation. The **R** material is all Track Two.
- This chapter relies on the geometric viewpoint about physics developed in Chap. 1 for Newtonian physics and in Chap. 2 for relativistic physics. It especially relies on
 - Secs. 1.4 and 1.5.2 on Newtonian particle kinetics,
 - Secs. 2.4.1 and 2.6 on relativistic particle kinetics,
 - Sec. 1.8 for the Newtonian conservation laws for particles,
 - Sec. 2.12.3 for the relativistic number-flux 4-vector and its conservation law,
 - Sec. 1.9 on the Newtonian stress tensor and its role in conservation laws for momentum,
 - Sec. 2.13 on the relativistic stress-energy tensor and its role in conservation laws for 4-momentum, and
 - Sec. 1.10 on aspects of relativity theory that Newtonian readers will need.
- The Newtonian parts of this chapter are a crucial foundation for the remainder of Part II (Statistical Physics) of this book, for small portions of Part V (Fluid Dynamics; especially equations of state, the origin of viscosity, and the diffusion of heat in fluids), and for half of Part VI (Plasma Physics; Chaps. 22 and 23).

(Box 3.1), the relativistic material is all Track Two and can be skipped by readers who are focusing on the (nonrelativistic) Newtonian theory.

We begin in Sec. 3.2 by introducing the concepts of momentum space, phase space (the union of physical space and momentum space), and the distribution function (number density of particles in phase space). We meet several different versions of the distribution function, all equivalent, but each designed to optimize conceptual thinking or computations in a particular arena (e.g., photons, plasma physics, and the interface with quantum theory). In Sec. 3.3, we study the distribution functions that characterize systems of particles in thermal equilibrium. There are three such equilibrium distributions: one for quantum mechanical particles with half-integral spin (fermions), another for quantum particles with integral spin (bosons), and a

third for classical particles. As special applications, we derive the Maxwell velocity distribution for low-speed, classical particles (Ex. 3.4) and its high-speed relativistic analog (Ex. 3.5 and Fig. 3.6 below), and we compute the effects of observers' motions on their measurements of the cosmic microwave radiation created in our universe's big-bang origin (Ex. 3.7). In Sec. 3.4, we learn how to compute macroscopic, physical-space quantities (particle density and flux, energy density, stress tensor, stress-energy tensor, . . .) by integrating over the momentum portion of phase space. In Sec. 3.5, we show that, if the distribution function is isotropic in momentum space, in some reference frame, then on macroscopic scales the particles constitute a perfect fluid. We use our momentum-space integrals to evaluate the equations of state of various kinds of perfect fluids: a nonrelativistic hydrogen gas in both the classical, nondegenerate regime and the regime of electron degeneracy (Sec. 3.5.2), a relativistically degenerate gas (Sec. 3.5.4), and a photon gas (Sec. 3.5.5). We use our results to discuss the physical nature of matter as a function of density and temperature (see Fig. 3.7).

In Sec. 3.6, we study the evolution of the distribution function, as described by Liouville's theorem and by the associated collisionless Boltzmann equation when collisions between particles are unimportant, and by the Boltzmann transport equation when collisions are significant. We use a simple variant of these evolution laws to study the heating of Earth by the Sun, and the key role played by the greenhouse effect (Ex. 3.15). Finally, in Sec. 3.7, we learn how to use the Boltzmann transport equation to compute the transport coefficients (diffusion coefficient, electrical conductivity, thermal conductivity, and viscosity) that describe the diffusive transport of particles, charge, energy, and momentum through a gas of particles that collide frequently. We then use the Boltzmann transport equation to study a chain reaction in a nuclear reactor (Ex. 3.21).

Readers who feel overwhelmed by the enormous amount and variety of applications in this chapter (and throughout this book) should remember the authors' goals: We want readers to learn the fundamental concepts of kinetic theory (and other topics in this book), and we want them to meet a variety of applications, so they will understand how the fundamental concepts are used. However, we do not expect readers to become expert in or even remember all these applications. To do so would require much more time and effort than most readers can afford or should expend.

3.2 Phase Space and Distribution Function

3.2.1 Newtonian Number Density in Phase Space, \mathcal{N}

In Newtonian, 3-dimensional space (*physical space*), consider a particle with rest mass m that moves along a path $\mathbf{x}(t)$ as universal time t passes (Fig. 3.1a). The particle's time-varying velocity and momentum are $\mathbf{v}(t) = d\mathbf{x}/dt$ and $\mathbf{p}(t) = m\mathbf{v}$. The path $\mathbf{x}(t)$ is a curve in the physical space, and the momentum $\mathbf{p}(t)$ is a time-varying, coordinate-independent vector in the physical space.

3.2

3.2.1

physical space

FIGURE 3.1 (a) Euclidean physical space, in which a particle moves along a curve $\mathbf{x}(t)$ that is parameterized by universal time t . In this space, the particle’s momentum $\mathbf{p}(t)$ is a vector tangent to the curve. (b) Momentum space, in which the particle’s momentum vector \mathbf{p} is placed, unchanged, with its tail at the origin. As time passes, the momentum’s tip sweeps out the indicated curve $\mathbf{p}(t)$.

momentum space

It is useful to introduce an auxiliary 3-dimensional space, called *momentum space*, in which we place the tail of $\mathbf{p}(t)$ at the origin. As time passes, the tip of $\mathbf{p}(t)$ sweeps out a curve in momentum space (Fig. 3.1b). This momentum space is “secondary” in the sense that it relies for its existence on the physical space of Fig. 3.1a. Any Cartesian coordinate system of physical space, in which the location $\mathbf{x}(t)$ of the particle has coordinates $\{x, y, z\}$, induces in momentum space a corresponding coordinate system $\{p_x, p_y, p_z\}$. The 3-dimensional physical space and 3-dimensional momentum space together constitute a 6-dimensional *phase space*, with coordinates $\{x, y, z, p_x, p_y, p_z\}$.

phase space

In this chapter, we study a collection of a very large number of identical particles (all with the same rest mass m).¹ As tools for this study, consider a tiny 3-dimensional volume $d\mathcal{V}_x$ centered on some location \mathbf{x} in physical space and a tiny 3-dimensional volume $d\mathcal{V}_p$ centered on location \mathbf{p} in momentum space. Together these make up a tiny 6-dimensional volume

$$d^2\mathcal{V} \equiv d\mathcal{V}_x d\mathcal{V}_p. \tag{3.1}$$

In any Cartesian coordinate system, we can think of $d\mathcal{V}_x$ as being a tiny cube located at (x, y, z) and having edge lengths dx, dy, dz , and similarly for $d\mathcal{V}_p$. Then, as computed in this coordinate system, these tiny volumes are

$$d\mathcal{V}_x = dx \, dy \, dz, \quad d\mathcal{V}_p = dp_x \, dp_y \, dp_z, \quad d^2\mathcal{V} = dx \, dy \, dz \, dp_x \, dp_y \, dp_z. \tag{3.2}$$

1. In Ex. 3.2 and Box 3.2, we extend kinetic theory to particles with a range of rest masses.

Denote by dN the number of particles (all with rest mass m) that reside inside $d^2\mathcal{V}$ in phase space (at some moment of time t). Stated more fully: dN is the number of particles that, at time t , are located in the 3-volume $d\mathcal{V}_x$ centered on the location \mathbf{x} in physical space and that also have momentum vectors whose tips at time t lie in the 3-volume $d\mathcal{V}_p$ centered on location \mathbf{p} in momentum space. Denote by

$$\mathcal{N}(\mathbf{x}, \mathbf{p}, t) \equiv \frac{dN}{d^2\mathcal{V}} = \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} \quad (3.3)$$

distribution function

the *number density of particles at location (\mathbf{x}, \mathbf{p}) in phase space at time t* . This is also called the *distribution function*.

This distribution function is kinetic theory's principal tool for describing any collection of a large number of identical particles.

In Newtonian theory, the volumes $d\mathcal{V}_x$ and $d\mathcal{V}_p$ occupied by our collection of dN particles are independent of the reference frame that we use to view them. Not so in relativity theory: $d\mathcal{V}_x$ undergoes a Lorentz contraction when one views it from a moving frame, and $d\mathcal{V}_p$ also changes; but (as we shall see in Sec. 3.2.2) their product $d^2\mathcal{V} = d\mathcal{V}_x d\mathcal{V}_p$ is the same in all frames. Therefore, in both Newtonian theory and relativity theory, the distribution function $\mathcal{N} = dN/d^2\mathcal{V}$ is independent of reference frame, and also, of course, independent of any choice of coordinates. It is a coordinate-independent scalar in phase space.

3.2.2 Relativistic Number Density in Phase Space, \mathcal{N} R T2

3.2.2

SPACETIME

We define the special relativistic distribution function in precisely the same way as the nonrelativistic one, $\mathcal{N}(\mathbf{x}, \mathbf{p}, t) \equiv dN/d^2\mathcal{V} = dN/d\mathcal{V}_x d\mathcal{V}_p$, except that now \mathbf{p} is the relativistic momentum ($\mathbf{p} = m\mathbf{v}/\sqrt{1 - \mathbf{v}^2}$ if the particle has nonzero rest mass m). This definition of \mathcal{N} appears, at first sight, to be frame dependent, since the physical 3-volume $d\mathcal{V}_x$ and momentum 3-volume $d\mathcal{V}_p$ do not even exist until we have selected a specific reference frame. In other words, this definition appears to violate our insistence that relativistic physical quantities be described by frame-independent geometric objects that live in 4-dimensional spacetime. In fact, the distribution function defined in this way *is* frame independent, though it does not look so. To elucidate this, we shall develop carefully and somewhat slowly the 4-dimensional spacetime ideas that underlie this relativistic distribution function.

Consider, as shown in Fig. 3.2a, a classical particle with rest mass m moving through spacetime along a world line $\mathcal{P}(\zeta)$, or equivalently $\vec{x}(\zeta)$, where ζ is an affine parameter related to the particle's 4-momentum by

$$\vec{p} = d\vec{x}/d\zeta \quad (3.4a)$$

FIGURE 3.2 (a) The world line $\vec{x}(\zeta)$ of a particle in spacetime (with one spatial coordinate, z , suppressed), parameterized by a parameter ζ that is related to the particle's 4-momentum by $\vec{p} = d\vec{x}/d\zeta$. (b) The trajectory of the particle in momentum space. The particle's 4-momentum is confined to the mass hyperboloid, $\vec{p}^2 = -m^2$ (also known as the mass shell).

[as discussed following Eq. (2.10)]. If the particle has nonzero rest mass, then its 4-velocity \vec{u} and proper time τ are related to its 4-momentum and affine parameter by

$$\vec{p} = m\vec{u}, \quad \zeta = \tau/m \tag{3.4b}$$

[Eqs. (2.10) and (2.11)], and we can parameterize the world line by either τ or ζ . If the particle has zero rest mass, then its world line is null, and τ does not change along it, so we have no choice but to use ζ as the world line's parameter.

MOMENTUM SPACE AND MASS HYPERBOLOID

The particle can be thought of not only as living in 4-dimensional spacetime (Fig. 3.2a), but also as living in a 4-dimensional momentum space (Fig. 3.2b). Momentum space, like spacetime, is a geometric, coordinate-independent concept: each point in momentum space corresponds to a specific 4-momentum \vec{p} . The tail of the vector \vec{p} sits at the origin of momentum space, and its tip sits at the point representing \vec{p} . The momentum-space diagram drawn in Fig. 3.2b has as its coordinate axes the components ($p^0, p^1 = p_1 \equiv p_x, p^2 = p_2 \equiv p_y, p^3 = p_3 \equiv p_z$) of the 4-momentum as measured in some arbitrary inertial frame. Because the squared length of the 4-momentum is always $-m^2$,

$$\vec{p} \cdot \vec{p} = -(p^0)^2 + (p_x)^2 + (p_y)^2 + (p_z)^2 = -m^2, \tag{3.4c}$$

the particle's 4-momentum (the tip of the 4-vector \vec{p}) is confined to a hyperboloid in momentum space. This *mass hyperboloid* requires no coordinates for its existence; it is the frame-independent set of points in momentum space for which $\vec{p} \cdot \vec{p} = -m^2$. If

4-dimensional momentum space

mass hyperboloid

the particle has zero rest mass, then \vec{p} is null, and the mass hyperboloid is a cone with vertex at the origin of momentum space. As in Chap. 2, we often denote the particle's energy p^0 by

$$\mathcal{E} \equiv p^0 \quad (3.4d)$$

(with the \mathcal{E} in script font to distinguish it from the energy $E = \mathcal{E} - m$ with rest mass removed and its nonrelativistic limit $E = \frac{1}{2}mv^2$), and we embody the particle's spatial momentum in the 3-vector $\mathbf{p} = p_x \mathbf{e}_x + p_y \mathbf{e}_y + p_z \mathbf{e}_z$. Therefore, we rewrite the mass-hyperboloid relation (3.4c) as

$$\mathcal{E}^2 = m^2 + |\mathbf{p}|^2. \quad (3.4e)$$

If no forces act on the particle, then its momentum is conserved, and its location in momentum space remains fixed. A force (e.g., due to an electromagnetic field) pushes the particle's 4-momentum along some curve in momentum space that lies on the mass hyperboloid. If we parameterize that curve by the same parameter ζ as we use in spacetime, then the particle's trajectory in momentum space can be written abstractly as $\vec{p}(\zeta)$. Such a trajectory is shown in Fig. 3.2b.

Because the mass hyperboloid is 3-dimensional, we can characterize the particle's location on it by just three coordinates rather than four. We typically use as those coordinates the spatial components of the particle's 4-momentum, (p_x, p_y, p_z) , or the spatial momentum vector \mathbf{p} as measured in some specific (but usually arbitrary) inertial frame.

PHASE SPACE

Momentum space and spacetime, taken together, constitute the relativistic *phase space*. We can regard phase space as 8-dimensional (four spacetime dimensions plus four momentum space dimensions). Alternatively, if we think of the 4-momentum as confined to the 3-dimensional mass hyperboloid, then we can regard phase space as 7-dimensional. This 7- or 8-dimensional phase space, by contrast with the non-relativistic 6-dimensional phase space, is frame independent. No coordinates or reference frame are actually needed to define spacetime and explore its properties, and none are needed to define and explore 4-momentum space or the mass hyperboloid—though inertial (Lorentz) coordinates are often helpful in practical situations.

phase space

VOLUMES IN PHASE SPACE AND DISTRIBUTION FUNCTION

Now turn attention from an individual particle to a collection of a huge number of identical particles, each with the same rest mass m , and allow m to be finite or zero (it does not matter which). Examine those particles that pass close to a specific event \mathcal{P} (also denoted \vec{x}) in spacetime; and *examine them from the viewpoint of a specific observer, who lives in a specific inertial reference frame*. Figure 3.3a is a spacetime diagram drawn in that observer's frame. As seen in that frame, the event \mathcal{P} occurs at time t and spatial location (x, y, z) .

FIGURE 3.3 Definition of the distribution function from the viewpoint of a specific observer in a specific inertial reference frame, whose coordinate axes are used in these drawings. (a) At the event \mathcal{P} , the observer selects a 3-volume $d\mathcal{V}_x$ and focuses on the set \mathcal{S} of particles that lie in $d\mathcal{V}_x$. (b) These particles have momenta lying in a region of the mass hyperboloid that is centered on \vec{p} and has 3-momentum volume $d\mathcal{V}_p$. If dN is the number of particles in that set \mathcal{S} , then $\mathcal{N}(\mathcal{P}, \vec{p}) \equiv dN/d\mathcal{V}_x d\mathcal{V}_p$.

We ask the observer, at the time t of the chosen event, to define the distribution function \mathcal{N} in identically the same way as in Newtonian theory, except that \mathbf{p} is the relativistic spatial momentum $\mathbf{p} = m\mathbf{v}/\sqrt{1 - v^2}$ instead of the nonrelativistic $\mathbf{p} = m\mathbf{v}$. Specifically, the observer, in her inertial frame, chooses a tiny 3-volume

$$d\mathcal{V}_x = dx \, dy \, dz \tag{3.5a}$$

centered on location \mathcal{P} (little horizontal rectangle shown in Fig. 3.3a) and a tiny 3-volume

$$d\mathcal{V}_p = dp_x \, dp_y \, dp_z \tag{3.5b}$$

centered on \mathbf{p} in momentum space (little rectangle in the p_x - p_y plane in Fig. 3.3b). Ask the observer to focus on the set \mathcal{S} of particles that lie in $d\mathcal{V}_x$ and have spatial momenta in $d\mathcal{V}_p$ (Fig. 3.3). If there are dN particles in this set \mathcal{S} , then the observer will identify

$$\mathcal{N} \equiv \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} \equiv \frac{dN}{d^2\mathcal{V}} \tag{3.6}$$

as the number density of particles in phase space or *distribution function*.

Notice in Fig. 3.3b that the 4-momenta of the particles in \mathcal{S} have their tails at the origin of momentum space (as by definition do all 4-momenta) and have their tips in a tiny rectangular box on the mass hyperboloid—a box centered on the 4-momentum \vec{p} whose spatial part is \mathbf{p} and temporal part is $p^0 = \mathcal{E} = \sqrt{m^2 + \mathbf{p}^2}$.

relativistic distribution function

The momentum volume element $d\mathcal{V}_p$ is the projection of that mass-hyperboloid box onto the horizontal (p_x, p_y, p_z) plane in momentum space. [The mass-hyperboloid box itself can be thought of as a (frame-independent) vectorial 3-volume $d\vec{\Sigma}_p$ —the momentum-space version of the vectorial 3-volume introduced in Sec. 2.12.1; see below.]

The number density \mathcal{N} depends on the location \mathcal{P} in spacetime of the 3-volume $d\mathcal{V}_x$ and on the 4-momentum \vec{p} about which the momentum volume on the mass hyperboloid is centered: $\mathcal{N} = \mathcal{N}(\mathcal{P}, \vec{p})$. From the chosen observer's viewpoint, it can be regarded as a function of time t and spatial location \mathbf{x} (the coordinates of \mathcal{P}) and of spatial momentum \mathbf{p} .

At first sight, one might expect \mathcal{N} to depend also on the inertial reference frame used in its definition (i.e., on the 4-velocity of the observer). If this were the case (i.e., if \mathcal{N} at fixed \mathcal{P} and \vec{p} were different when computed by the above prescription using different inertial frames), then we would feel compelled to seek some other object—one that is frame-independent—to serve as our foundation for kinetic theory. This is because the principle of relativity insists that all fundamental physical laws should be expressible in frame-independent language.

Fortunately, the distribution function (3.6) is frame independent by itself: it is a frame-independent scalar field in phase space, so we need seek no further.

PROOF OF FRAME INDEPENDENCE OF $\mathcal{N} = dN/d^2\mathcal{V}$

To prove the frame independence of \mathcal{N} , we shall consider the frame dependence of the spatial 3-volume $d\mathcal{V}_x$, then the frame dependence of the momentum 3-volume $d\mathcal{V}_p$, and finally the frame dependence of their product $d^2\mathcal{V} = d\mathcal{V}_x d\mathcal{V}_p$ and thence of the distribution function $\mathcal{N} = dN/d^2\mathcal{V}$.

The thing that identifies the 3-volume $d\mathcal{V}_x$ and 3-momentum $d\mathcal{V}_p$ is the set of particles \mathcal{S} . We select that set once and for all and hold it fixed, and correspondingly, the number of particles dN in the set is fixed. Moreover, we assume that the particles' rest mass m is nonzero and shall deal with the zero-rest-mass case at the end by taking the limit $m \rightarrow 0$. Then there is a preferred frame in which to observe the particles \mathcal{S} : their own rest frame, which we identify by a prime.

In their rest frame and at a chosen event \mathcal{P} , the particles \mathcal{S} occupy the interior of some box with imaginary walls that has some 3-volume $d\mathcal{V}_{x'}$. As seen in some other “laboratory” frame, their box has a Lorentz-contracted volume $d\mathcal{V}_x = \sqrt{1 - v^2} d\mathcal{V}_{x'}$. Here v is their speed as seen in the laboratory frame. The Lorentz-contraction factor is related to the particles' energy, as measured in the laboratory frame, by $\sqrt{1 - v^2} = m/\mathcal{E}$, and therefore $\mathcal{E}d\mathcal{V}_x = md\mathcal{V}_{x'}$. The right-hand side is a frame-independent constant m times a well-defined number that everyone can agree on: the particles' rest-frame volume $d\mathcal{V}_{x'}$, i.e.,

$$\boxed{\mathcal{E}d\mathcal{V}_x = (\text{a frame-independent quantity}).} \quad (3.7a)$$

Thus, the spatial volume $d\mathcal{V}_x$ occupied by the particles is frame dependent, and their energy \mathcal{E} is frame dependent, but the product of the two is independent of reference frame.

Turn now to the frame dependence of the particles' 3-volume $d\mathcal{V}_p$. As one sees from Fig. 3.3b, $d\mathcal{V}_p$ is the projection of the frame-independent mass-hyperboloid region $d\vec{\Sigma}_p$ onto the laboratory's xyz 3-space. Equivalently, it is the time component $d\Sigma_p^0$ of $d\vec{\Sigma}_p$. Now, the 4-vector $d\vec{\Sigma}_p$, like the 4-momentum \vec{p} , is orthogonal to the mass hyperboloid at the common point where they intersect it, and therefore $d\vec{\Sigma}_p$ is parallel to \vec{p} . This means that, when one goes from one reference frame to another, the time components of these two vectors will grow or shrink in the same manner: $d\Sigma_p^0 = d\mathcal{V}_p$ is proportional to $p^0 = \mathcal{E}$, so their ratio must be frame independent:

$$\boxed{\frac{d\mathcal{V}_p}{\mathcal{E}} = \text{(a frame-independent quantity)}}. \quad (3.7b)$$

(If this sophisticated argument seems too slippery to you, then you can develop an alternative, more elementary proof using simpler 2-dimensional spacetime diagrams: Ex. 3.1.)

By taking the product of Eqs. (3.7a) and (3.7b) we see that for our chosen set of particles \mathcal{S} ,

$$d\mathcal{V}_x d\mathcal{V}_p = d^2\mathcal{V} = \text{(a frame-independent quantity)}; \quad (3.7c)$$

and since the number of particles in the set, dN , is obviously frame-independent, we conclude that

$$\boxed{\mathcal{N} = \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} \equiv \frac{dN}{d^2\mathcal{V}} = \text{(a frame-independent quantity)}}. \quad (3.8)$$

Although we assumed nonzero rest mass ($m \neq 0$) in our derivation, the conclusions that $\mathcal{E}d\mathcal{V}_x$ and $d\mathcal{V}_p/\mathcal{E}$ are frame independent continue to hold if we take the limit as $m \rightarrow 0$ and the 4-momenta become null. Correspondingly, Eqs. (3.7a)–(3.8) are valid for particles with zero as well as nonzero rest mass.

EXERCISES

Exercise 3.1 *Derivation and Practice: Frame Dependences of $d\mathcal{V}_x$ and $d\mathcal{V}_p$* R T2
 Use the 2-dimensional spacetime diagrams of Fig. 3.4 to show that $\mathcal{E}d\mathcal{V}_x$ and $d\mathcal{V}_p/\mathcal{E}$ are frame independent [Eqs. (3.7a) and (3.7b)].

Exercise 3.2 ***Example: Distribution Function for Particles with a Range of Rest Masses* R T2

A galaxy such as our Milky Way contains $\sim 10^{12}$ stars—easily enough to permit a kinetic-theory description of their distribution; each star contains so many atoms ($\sim 10^{56}$) that the masses of the stars can be regarded as continuously distributed, not

FIGURE 3.4 (a) Spacetime diagram drawn from the viewpoint of the (primed) rest frame of the particles S for the special case where the laboratory frame moves in the $-x'$ direction with respect to them. (b) Momentum-space diagram drawn from viewpoint of the unprimed observer.

discrete. Almost everywhere in a galaxy, the stars move with speeds small compared to light, but deep in the cores of most galaxies there resides a massive black hole near which the stars move with relativistic speeds. In this exercise we explore the foundations for treating such a system: “particles” with continuously distributed rest masses and relativistic speeds.

- (a) For a subset S of particles like that of Fig. 3.3 and associated discussion, but with a range of rest masses dm centered on some value m , introduce the phase-space volume $d^2\mathcal{V} \equiv d\mathcal{V}_x d\mathcal{V}_p dm$ that the particles S occupy. Explain why this occupied volume is frame invariant.
- (b) Show that this invariant occupied volume can be rewritten as $d^2\mathcal{V} = (d\mathcal{V}_x \mathcal{E}/m)(d\mathcal{V}_p d\mathcal{E}) = (d\mathcal{V}_x \mathcal{E}/m)(dp^0 dp^x dp^y dp^z)$. Explain the physical meaning of each term in parentheses, and show that each is frame invariant.

If the number of particles in the set S is dN , then we define the frame-invariant distribution function by

$$\mathcal{N} \equiv \frac{dN}{d^2\mathcal{V}} = \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p dm}. \tag{3.9}$$

This is a function of location \mathcal{P} in 4-dimensional spacetime and location \vec{p} in 4-dimensional momentum space (not confined to the mass hyperboloid), and thus a function of location in 8-dimensional phase space. We explore the evolution of this distribution function in Box 3.2 (near the end of Sec. 3.6).

3.2.3 Distribution Function $f(\mathbf{x}, \mathbf{v}, t)$ for Particles in a Plasma N

3.2.3

The normalization that one uses for the distribution function is arbitrary: renormalize \mathcal{N} by multiplying with any constant, and \mathcal{N} will still be a geometric, coordinate-independent, and frame-independent quantity and will still contain the same information as before. In this book, we use several renormalized versions of \mathcal{N} , depending

on the situation. We now introduce them, beginning with the version used in plasma physics.

In Part VI, when dealing with nonrelativistic plasmas (collections of electrons and ions that have speeds small compared to light), we regard the distribution function as depending on time t , location \mathbf{x} in Euclidean space, and velocity \mathbf{v} (instead of momentum $\mathbf{p} = m\mathbf{v}$), and we denote it by²

plasma distribution
function

$$f(t, \mathbf{x}, \mathbf{v}) \equiv \frac{dN}{d\mathcal{V}_x d\mathcal{V}_v} = \frac{dN}{dx dy dz dv_x dv_y dv_z} = m^3 \mathcal{N}. \quad (3.10)$$

(This change of viewpoint and notation when transitioning to plasma physics is typical of this textbook. When presenting any subfield of physics, we usually adopt the conventions, notation, and also the system of units that are generally used in that subfield.)

3.2.4

3.2.4 Distribution Function I_ν/ν^3 for Photons N R

[For readers restricting themselves to the Newtonian portions of this book: Please read Sec. 1.10, which lists a few items of special relativity that you need for the discussion here. As described there, you can deal with photons fairly easily by simply remembering that a photon has zero rest mass, energy $\mathcal{E} = h\nu$, and momentum $\mathbf{p} = (h\nu/c)\mathbf{n}$, where ν is its frequency and \mathbf{n} is a unit vector tangent to the photon's spatial trajectory.]

When dealing with photons or other zero-rest-mass particles, one often expresses \mathcal{N} in terms of the *specific intensity* I_ν . This quantity is defined as follows (see Fig. 3.5). An observer places a CCD (or other measuring device) perpendicular to the photons' propagation direction \mathbf{n} —perpendicular as measured in her reference frame. The region of the CCD that the photons hit has surface area dA as measured by her, and because the photons move at the speed of light c , the product of that surface area with c times the time dt that they take to all go through the CCD is equal to the volume they occupy at a specific moment of time:

$$d\mathcal{V}_x = dA c dt. \quad (3.11a)$$

Focus attention on a set \mathcal{S} of photons in this volume that all have nearly the same frequency ν and propagation direction \mathbf{n} as measured by the observer. Their energies \mathcal{E} and momenta \mathbf{p} are related to ν and \mathbf{n} by

$$\mathcal{E} = h\nu, \quad \mathbf{p} = (h\nu/c)\mathbf{n}, \quad (3.11b)$$

where h is Planck's constant. Their frequencies lie in a range $d\nu$ centered on ν , and they come from a small solid angle $d\Omega$ centered on $-\mathbf{n}$; the volume they occupy in momentum space is related to these quantities by

$$d\mathcal{V}_p = |\mathbf{p}|^2 d\Omega d|\mathbf{p}| = (h\nu/c)^2 d\Omega (hd\nu/c) = (h/c)^3 \nu^2 d\Omega d\nu. \quad (3.11c)$$

2. The generalization to relativistic plasmas is straightforward; see, e.g., Ex. 23.12.

FIGURE 3.5 Geometric construction used in defining the specific intensity I_ν .

The photons' specific intensity, as measured by the observer, is defined to be the total energy

$$d\mathcal{E} = h\nu dN \tag{3.11d}$$

(where dN is the number of photons) that crosses the CCD per unit area dA , per unit time dt , per unit frequency $d\nu$, and per unit solid angle $d\Omega$ (i.e., per unit everything):

$$I_\nu \equiv \frac{d\mathcal{E}}{dA dt d\nu d\Omega}. \tag{3.12}$$

specific intensity

(This I_ν is sometimes denoted $I_{\nu\Omega}$.) From Eqs. (3.8), (3.11), and (3.12) we readily deduce the following relationship between this specific intensity and the distribution function:

$$\mathcal{N} = \frac{c^2}{h^4} \frac{I_\nu}{\nu^3}. \tag{3.13}$$

photon distribution function

This relation shows that, with an appropriate renormalization, I_ν/ν^3 is the photons' distribution function.

Astronomers and opticians regard the specific intensity (or equally well, I_ν/ν^3) as a function of the photon propagation direction \mathbf{n} , photon frequency ν , location \mathbf{x} in space, and time t . By contrast, nonrelativistic physicists regard the distribution function \mathcal{N} as a function of the photon momentum \mathbf{p} , location in space, and time; relativistic physicists regard it as a function of the photon 4-momentum \vec{p} (on the photons' mass hyperboloid, which is the light cone) and of location \mathcal{P} in spacetime. Clearly, the information contained in these three sets of variables, the astronomers' set and the two physicists' sets, is the same.

If two different physicists in two different reference frames at the same event in spacetime examine the same set of photons, they will measure the photons to have different frequencies ν (because of the Doppler shift between their two frames). They will also measure different specific intensities I_ν (because of Doppler shifts of frequencies, Doppler shifts of energies, dilation of times, Lorentz contraction of areas of CCDs, and aberrations of photon propagation directions and thence distortions of

solid angles). However, if each physicist computes the ratio of the specific intensity that she measures to the cube of the frequency she measures, that ratio, according to Eq. (3.13), will be the same as computed by the other astronomer: the distribution function I_ν/ν^3 will be frame independent.

3.2.5 Mean Occupation Number η N R

Although this book is about classical physics, we cannot avoid making frequent contact with quantum theory. The reason is that modern classical physics rests on a quantum mechanical foundation. Classical physics is an approximation to quantum physics, not conversely. Classical physics is derivable from quantum physics, not conversely.

In statistical physics, the classical theory cannot fully shake itself free from its quantum roots; it must rely on them in crucial ways that we shall meet in this chapter and the next. Therefore, rather than try to free it from its roots, we expose these roots and profit from them by introducing a quantum mechanics-based normalization for the distribution function: the mean occupation number η .

As an aid in defining the mean occupation number, we introduce the concept of the *density of states*: Consider a particle of mass m , described quantum mechanically. Suppose that the particle is known to be located in a volume $d\mathcal{V}_x$ (as observed in a specific inertial reference frame) and to have a spatial momentum in the region $d\mathcal{V}_p$ centered on \mathbf{p} . Suppose, further, that *the particle does not interact with any other particles or fields*; for example, ignore Coulomb interactions. (In portions of Chaps. 4 and 5, we include interactions.) Then how many single-particle quantum mechanical states³ are available to the free particle? This question is answered most easily by constructing (in some arbitrary inertial frame) a complete set of wave functions for the particle's spatial degrees of freedom, with the wave functions (i) confined to be eigenfunctions of the momentum operator and (ii) confined to satisfy the standard periodic boundary conditions on the walls of a box with volume $d\mathcal{V}_x$. For simplicity, let the box have edge length L along each of the three spatial axes of the Cartesian spatial coordinates, so $d\mathcal{V}_x = L^3$. (This L is arbitrary and will drop out of our analysis shortly.) Then a complete set of wave functions satisfying (i) and (ii) is the set $\{\psi_{j,k,l}\}$ with

$$\psi_{j,k,l}(x, y, z) = \frac{1}{L^{3/2}} e^{i(2\pi/L)(jx+ky+lz)} e^{-i\omega t} \quad (3.14a)$$

[cf., e.g., Cohen-Tannoudji, Diu, and Laloë (1977, pp. 1440–1442), especially the Comment at the end of this page range]. Here the demand that the wave function take

3. A quantum mechanical state for a single particle is called an “orbital” in the chemistry literature (where the particle is an electron) and in the classic thermal physics textbook by Kittel and Kroemer (1980); we shall use physicists’ more conventional but cumbersome phrase “single-particle quantum state,” and also, sometimes, “mode.”

on the same values at the left and right faces of the box ($x = -L/2$ and $x = +L/2$), at the front and back faces, and at the top and bottom faces (the demand for periodic boundary conditions) dictates that the quantum numbers j , k , and l be integers. The basis states (3.14a) are eigenfunctions of the momentum operator $(\hbar/i)\nabla$ with momentum eigenvalues

$$p_x = \frac{2\pi\hbar}{L}j, \quad p_y = \frac{2\pi\hbar}{L}k, \quad p_z = \frac{2\pi\hbar}{L}l; \quad (3.14b)$$

correspondingly, the wave function's frequency ω has the following values in Newtonian theory **N** and relativity **R**:

$$\mathbf{N} \quad \hbar\omega = E = \frac{\mathbf{p}^2}{2m} = \frac{1}{2m} \left(\frac{2\pi\hbar}{L} \right)^2 (j^2 + k^2 + l^2); \quad (3.14c)$$

$$\mathbf{R} \quad \hbar\omega = \mathcal{E} = \sqrt{m^2 + \mathbf{p}^2} \rightarrow m + E \text{ in the Newtonian limit.} \quad (3.14d)$$

Equations (3.14b) tell us that the allowed values of the momentum are confined to lattice sites in 3-momentum space with one site in each cube of side $2\pi\hbar/L$. Correspondingly, the total number of states in the region $d\mathcal{V}_x d\mathcal{V}_p$ of phase space is the number of cubes of side $2\pi\hbar/L$ in the region $d\mathcal{V}_p$ of momentum space:

$$dN_{\text{states}} = \frac{d\mathcal{V}_p}{(2\pi\hbar/L)^3} = \frac{L^3 d\mathcal{V}_p}{(2\pi\hbar)^3} = \frac{d\mathcal{V}_x d\mathcal{V}_p}{h^3}. \quad (3.15)$$

This is true no matter how relativistic or nonrelativistic the particle may be.

Thus far we have considered only the particle's spatial degrees of freedom. Particles can also have an internal degree of freedom called "spin." For a particle with spin s , the number of independent spin states is

$$g_s = \begin{cases} 2s + 1 & \text{if } m \neq 0 \text{ (e.g., an electron, proton, or atomic nucleus)} \\ 2 & \text{if } m = 0 \text{ and } s > 0 \text{ [e.g., a photon } (s = 1) \text{ or graviton } (s = 2)] \\ 1 & \text{if } m = 0 \text{ and } s = 0 \text{ (i.e., a hypothetical massless scalar particle)} \end{cases} \quad (3.16)$$

A notable exception is each species of neutrino or antineutrino, which has nonzero rest mass and spin 1/2, but $g_s = 1$ rather than $g_s = 2s + 1 = 2$.⁴ We call this number of internal spin states g_s the particle's *multiplicity*. [It will turn out to play a crucial role in computing the entropy of a system of particles (Chap. 4); thus, it places the imprint of quantum theory on the entropy of even a highly classical system.]

particle's multiplicity

Taking account of both the particle's spatial degrees of freedom and its spin degree of freedom, we conclude that the total number of independent quantum states

4. The reason for the exception is the particle's fixed chirality: -1 for neutrinos and $+1$ for antineutrinos; to have $g_s = 2$, a spin-1/2 particle must admit both chiralities.

available in the region $dV_x dV_p \equiv d^2V$ of phase space is $dN_{\text{states}} = (g_s/h^3)d^2V$, and correspondingly the *number density of states in phase space* is

density of states in phase space

$$\mathcal{N}_{\text{states}} \equiv \frac{dN_{\text{states}}}{d^2V} = \frac{g_s}{h^3}. \quad (3.17)$$

[Relativistic remark: Note that, although we derived this number density of states using a specific inertial frame, it is a frame-independent quantity, with a numerical value depending only on Planck's constant and (through g_s) the particle's rest mass m and spin s .]

The ratio of the number density of particles to the number density of quantum states is obviously the number of particles in each state (the state's *occupation number*) averaged over many neighboring states—but few enough that the averaging region is small by macroscopic standards. In other words, this ratio is the quantum states' *mean occupation number* η :

mean occupation number

$$\eta = \frac{\mathcal{N}}{\mathcal{N}_{\text{states}}} = \frac{h^3}{g_s} \mathcal{N}; \quad \text{i.e.,} \quad \boxed{\mathcal{N} = \mathcal{N}_{\text{states}} \eta = \frac{g_s}{h^3} \eta}. \quad (3.18)$$

The mean occupation number η plays an important role in quantum statistical mechanics, and its quantum roots have a profound impact on classical statistical physics.

fermions and bosons

From quantum theory we learn that the allowed values of the occupation number for a quantum state depend on whether the state is that of a *fermion* (a particle with spin $1/2, 3/2, 5/2, \dots$) or that of a *boson* (a particle with spin $0, 1, 2, \dots$). For fermions, no two particles can occupy the same quantum state, so the occupation number can only take on the eigenvalues 0 and 1. For bosons, one can shove any number of particles one wishes into the same quantum state, so the occupation number can take on the eigenvalues $0, 1, 2, 3, \dots$. Correspondingly, the mean occupation numbers must lie in the ranges

$$0 \leq \eta \leq 1 \text{ for fermions,} \quad 0 \leq \eta < \infty \text{ for bosons.} \quad (3.19)$$

classical distinguishable particles and classical waves

Quantum theory also teaches us that, when $\eta \ll 1$, the particles, whether fermions or bosons, behave like classical, discrete, distinguishable particles; and when $\eta \gg 1$ (possible only for bosons), the particles behave like a classical wave—if the particles are photons ($s = 1$), like a classical electromagnetic wave; and if they are gravitons ($s = 2$), like a classical gravitational wave. This role of η in revealing the particles' physical behavior will motivate us frequently to use η as our distribution function instead of \mathcal{N} .

Of course η , like \mathcal{N} , is a function of location in phase space, $\eta(\mathcal{P}, \vec{p})$ in relativity with no inertial frame chosen; or $\eta(t, \mathbf{x}, \mathbf{p})$ in both relativity and Newtonian theory when an inertial frame is in use.

Exercise 3.3 ***Practice and Example: Regimes of Particulate and Wave-Like Behavior* **N** **R**

- (a) Cygnus X-1 is a source of X-rays that has been studied extensively by astronomers. The observations (X-ray, optical, and radio) show that it is a distance $r \sim 6,000$ light-years from Earth. It consists of a very hot disk of X-ray-emitting gas that surrounds a black hole with mass $15M_{\odot}$, and the hole in turn is in a binary orbit with a heavy companion star. Most of the X-ray photons have energies $\mathcal{E} \sim 2$ keV, their energy flux arriving at Earth is $F \sim 10^{-10} \text{ W m}^{-2}$, and the portion of the disk that emits most of them has radius roughly 7 times that of the black hole (i.e., $R \sim 300 \text{ km}$).⁵ Make a rough estimate of the mean occupation number of the X-rays' photon states. Your answer should be in the region $\eta \ll 1$, so the photons behave like classical, distinguishable particles. Will the occupation number change as the photons propagate from the source to Earth?
- (b) A highly nonspherical supernova in the Virgo cluster of galaxies (40 million light-years from Earth) emits a burst of gravitational radiation with frequencies spread over the band 0.5–2.0 kHz, as measured at Earth. The burst comes out in a time of about 10 ms, so it lasts only a few cycles, and it carries a total energy of roughly $10^{-3}M_{\odot}c^2$, where $M_{\odot} = 2 \times 10^{30} \text{ kg}$ is the mass of the Sun. The emitting region is about the size of the newly forming neutron-star core (10 km), which is small compared to the wavelength of the waves; so if one were to try to resolve the source spatially by imaging the gravitational waves with a gravitational lens, one would see only a blur of spatial size one wavelength rather than seeing the neutron star. What is the mean occupation number of the burst's graviton states? Your answer should be in the region $\eta \gg 1$, so the gravitons behave like a classical gravitational wave.

3.3 Thermal-Equilibrium Distribution Functions **N** **R**

3.3

In Chap. 4, we introduce with care and explore in detail the concept of statistical equilibrium—also called “thermal equilibrium.” That exploration will lead to a set of distribution functions for particles that are in statistical equilibrium. In this section, we summarize those equilibrium distribution functions, so as to be able to use them for examples and applications of kinetic theory.

If a collection of many identical particles is in thermal equilibrium in the neighborhood of an event \mathcal{P} , then, as we shall see in Chap. 4, there is a special inertial reference frame (the *mean rest frame* of the particles near \mathcal{P}) in which the distribution function is isotropic, so the mean occupation number η is a function only of the magnitude $|\mathbf{p}|$

5. These numbers refer to what astronomers call Cygnus X-1's soft (red) state. It also, sometimes, is seen in a hard (blue) state.

of the particle momentum and does not depend on the momentum's direction. Equivalently, η is a function of the particle's energy. In the relativistic regime, we use two different energies, one denoted \mathcal{E} that includes the contribution of the particle's rest mass and the other denoted E that omits the rest mass and thus represents kinetic energy (cf. Sec. 1.10):

$$E \equiv \mathcal{E} - m = \sqrt{m^2 + \mathbf{p}^2} - m \rightarrow \frac{\mathbf{p}^2}{2m} \text{ in the low-velocity, Newtonian limit.} \tag{3.20}$$

In the nonrelativistic, Newtonian regime we use only $E = \mathbf{p}^2/(2m)$.

Most readers already know that the details of the thermal equilibrium are fixed by two quantities: the mean density of particles and the mean energy per particle, or equivalently (as we shall see) by the *chemical potential* μ and the *temperature* T . By analogy with our treatment of relativistic energy, we use two different chemical potentials: one, $\tilde{\mu}$, that includes rest mass and the other,

$$\mu \equiv \tilde{\mu} - m, \tag{3.21}$$

that does not. In the Newtonian regime we use only μ .

As we prove by an elegant argument in Chap. 4, in thermal equilibrium the mean occupation number has the following form at all energies, relativistic or nonrelativistic:

$$\eta = \frac{1}{e^{(E-\mu)/(k_B T)} \pm 1} \text{ for fermions,} \tag{3.22a}$$

$$\eta = \frac{1}{e^{(E-\mu)/(k_B T)} - 1} \text{ for bosons.} \tag{3.22b}$$

Here $k_B = 1.381 \times 10^{-16} \text{ erg K}^{-1} = 1.381 \times 10^{-23} \text{ J K}^{-1}$ is Boltzmann's constant. Equation (3.22a) for fermions is the *Fermi-Dirac distribution*; Eq. (3.22b) for bosons is the *Bose-Einstein distribution*. In the relativistic regime, we can also write these distribution functions in terms of the energy \mathcal{E} that includes the rest mass as

$$\mathbf{R} \quad \eta = \frac{1}{e^{(E-\mu)/(k_B T)} \pm 1} = \frac{1}{e^{(\mathcal{E}-\tilde{\mu})/(k_B T)} \pm 1}. \tag{3.22c}$$

Notice that the equilibrium mean occupation number (3.22a) for fermions lies in the range 0–1 as required, while that (3.22b) for bosons lies in the range 0 to ∞ . In the regime $\mu \ll -k_B T$, the mean occupation number is small compared to unity for all particle energies E (since E is never negative; i.e., \mathcal{E} is never less than m). This is the domain of distinguishable, classical particles, and in it both the Fermi-Dirac and Bose-Einstein distributions become

$$\eta \simeq e^{-(E-\mu)/(k_B T)} = e^{-(\mathcal{E}-\tilde{\mu})/(k_B T)} \quad (3.22d)$$

when $\mu \equiv \tilde{\mu} - m \ll -k_B T$ (classical particles).

N R

Boltzmann distribution

This limiting distribution is the *Boltzmann distribution*.⁶

By scrutinizing the distribution functions (3.22), one can deduce that the larger the temperature T at fixed μ , the larger will be the typical energies of the particles; the larger the chemical potential μ at fixed T , the larger will be the total density of particles [see Ex. 3.4 and Eqs. (3.39)]. For bosons, μ must always be negative or zero, that is, $\tilde{\mu}$ cannot exceed the particle rest mass m ; otherwise, η would be negative at low energies, which is physically impossible. For bosons with μ extremely close to zero, there exist huge numbers of very-low-energy particles, leading quantum mechanically to a *Bose-Einstein condensate*; we study such condensates in Sec. 4.9.

In the special case that the particles of interest can be created and destroyed completely freely, with creation and destruction constrained only by the laws of 4-momentum conservation, the particles quickly achieve a thermal equilibrium in which the relativistic chemical potential vanishes, $\tilde{\mu} = 0$ (as we shall see in Sec. 5.5). For example, inside a box whose walls are perfectly emitting and absorbing and have temperature T , the photons acquire the mean occupation number (3.22b) with zero chemical potential, leading to the standard *blackbody (Planck)* form

$$\eta = \frac{1}{e^{h\nu/(k_B T)} - 1}, \quad \mathcal{N} = \frac{2}{h^3} \frac{1}{e^{h\nu/(k_B T)} - 1}, \quad I_\nu = \frac{(2h/c^2)\nu^3}{e^{h\nu/(k_B T)} - 1}. \quad (3.23)$$

Planck distribution

(Here we have set $\mathcal{E} = h\nu$, where ν is the photon frequency as measured in the box's rest frame, and in the third expression we have inserted the factor c^{-2} , so that I_ν will be in ordinary units.)

By contrast, if one places a fixed number of photons inside a box whose walls cannot emit or absorb them but can scatter them, exchanging energy with them in the process, then the photons will acquire the Bose-Einstein distribution (3.22b) with temperature T equal to that of the walls and with nonzero chemical potential μ fixed by the number of photons present; the more photons there are, the larger will be the chemical potential.

Exercise 3.4 **Example: Maxwell Velocity Distribution N

EXERCISES

Consider a collection of thermalized, classical particles with nonzero rest mass, so they have the Boltzmann distribution (3.22d). Assume that the temperature is low enough ($k_B T \ll mc^2$) that they are nonrelativistic.

(a) Explain why the total number density of particles n in physical space (as measured in the particles' mean rest frame) is given by the integral $n = \int \mathcal{N} d\mathcal{V}_p$. Show

6. Lynden-Bell (1967) identifies a fourth type of thermal distribution that occurs in the theory of violent relaxation of star clusters. It corresponds to individually distinguishable, classical particles (in his case stars with a range of masses) that obey the same kind of exclusion principle as fermions.

that $n \propto e^{\mu/k_B T}$, and derive the proportionality constant. [Hint: Use spherical coordinates in momentum space, so $d\mathcal{V}_p = 4\pi p^2 dp$ with $p \equiv |\mathbf{p}|$.] Your answer should be Eq. (3.39a) below.

- (b) Explain why the mean energy per particle is given by $\bar{E} = n^{-1} \int (p^2/2m)\mathcal{N}d\mathcal{V}_p$. Show that $\bar{E} = \frac{3}{2}k_B T$.
- (c) Show that $P(v)dv \equiv$ (probability that a randomly chosen particle will have speed $v \equiv |\mathbf{v}|$ in the range dv) is given by

$$P(v) = \frac{4}{\sqrt{\pi}} \frac{v^2}{v_o^3} e^{-v^2/v_o^2}, \quad \text{where } v_o = \sqrt{\frac{2k_B T}{m}}. \tag{3.24}$$

This is called the *Maxwell velocity distribution*; it is graphed in Fig. 3.6a. Notice that the peak of the distribution is at speed v_o .

[Side remark: In the normalization of probability distributions such as this one, you will often encounter integrals of the form $\int_0^\infty x^{2n} e^{-x^2} dx$. You can evaluate this quickly via integration by parts, if you have memorized that $\int_0^\infty e^{-x^2} dx = \sqrt{\pi}/2$.]

- (d) Consider particles confined to move in a plane or in one dimension (on a line). What is their speed distribution $P(v)$ and at what speed does it peak?

Exercise 3.5 *Problem: Maxwell-Jüttner Velocity Distribution for Thermalized, Classical, Relativistic Particles* R T2

Show that for thermalized, classical relativistic particles the probability distribution for the speed [relativistic version of the Maxwell distribution (3.24)] is

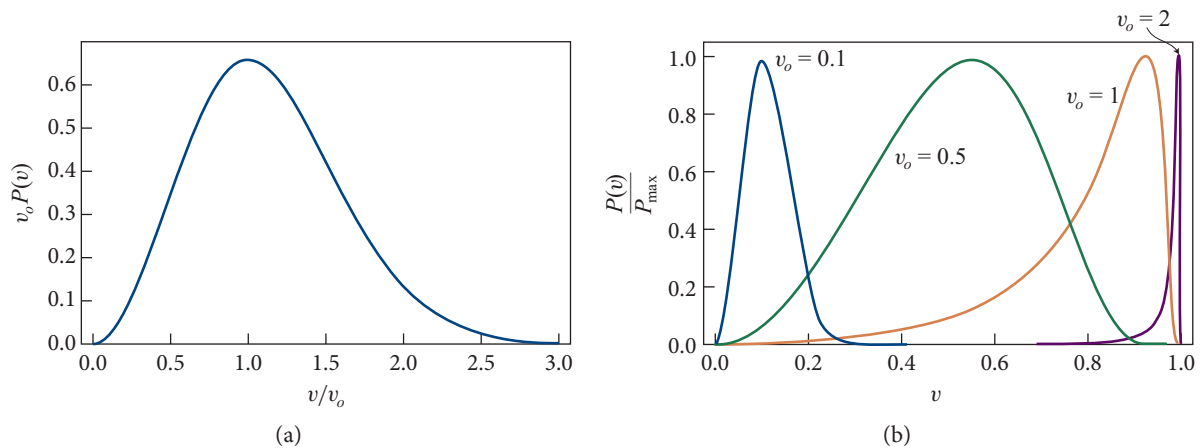

FIGURE 3.6 (a) Maxwell velocity distribution for thermalized, classical, nonrelativistic particles. (b) Extension of the Maxwell velocity distribution into the relativistic domain. In both plots $v_o = \sqrt{2k_B T/m}$.

$$P(v) = \frac{2/v_0^2}{K_2(2/v_0^2)} \frac{v^2}{(1-v^2)^{5/2}} \exp\left[-\frac{2/v_0^2}{\sqrt{1-v^2}}\right], \quad \text{where } v_0 = \sqrt{\frac{2k_B T}{m}}. \quad (3.25)$$

Where K_2 is the modified Bessel function of the second kind and order 2. This is sometimes called the Maxwell-Jüttner distribution, and it is plotted in Fig. 3.6b for a sequence of four temperatures ranging from the nonrelativistic regime $k_B T \ll m$ toward the ultrarelativistic regime $k_B T \gg m$. In the ultrarelativistic regime the particles are (almost) all moving at very close to the speed of light, $v = 1$.

Exercise 3.6 *Example and Challenge: Radiative Processes* R T2

We have described distribution functions for particles and photons and the forms that they have in thermodynamic equilibrium. An extension of these principles can be used to constrain the manner in which particles and photons interact, specifically, to relate the emission and absorption of radiation.

- (a) Consider a two-level (two-state) electron system with energy separation $\mathcal{E} = h\nu_0$. Suppose that an electron can transition with a probability per unit time, A , from the upper level (u) to the lower level (l), creating a photon in a specific state. Use the Boltzmann distribution, ignoring degeneracy, Eq. (3.22d), and the expression for the mean photon occupation number, Eq. (3.23), to show that, when the electrons and photons are in thermal equilibrium at the same temperature T , then:

$$An_u + An_u\eta_\gamma = An_l\eta_\gamma, \quad (3.26)$$

where $n_{l,u}$ are the number densities of the electrons in the two states, and η_γ is the photon mean occupation number.

- (b) The three terms in Eq. (3.26) are often called the rates per unit volume for *spontaneous emission*, *stimulated emission*, and (*stimulated*) *absorption*, respectively. (The second and third terms are sometimes expressed using Einstein B coefficients.) The expressions An_u , $An_u\eta_\gamma$, and $An_l\eta_\gamma$ for the rates of these three types of transition are commonly (and usually correctly) assumed to apply out of thermodynamic equilibrium as well as in equilibrium. Discuss briefly two conditions that need to be satisfied for this to be so: that all three types of transition proceed in a manner that is independent of anything else present, and that the stimulated transitions are time reversible.⁷ What additional condition needs to be satisfied if the electron system is more complex than a two-level system? (We return to these issues in the context of cosmology, in Secs. 28.4.4 and 28.6.3.)
- (c) Typical transitions have some duration τ , which implies that the photons will be emitted with a distribution of frequencies with width $\Delta\nu \sim \tau^{-1}$ about ν_0 . They may also not be emitted isotropically and can carry polarization. Denote the state of a photon by its frequency ν , direction of travel $\hat{\Omega}$, and polarization $i = 1$ or 2 ,

7. These principles are quite classical in origin but the full justification of the heuristic argument presented here requires quantum electrodynamics.

and denote by $P_{\nu\hat{\Omega}}^i$ the photons' probability distribution, normalized such that $\Sigma_i \int d\nu d\Omega P_{\nu\hat{\Omega}}^i = 1$, with $d\Omega$ an element of solid angle around $\hat{\Omega}$. Now define a classical emissivity and a classical absorption coefficient by

$$j_{\nu\hat{\Omega}}^i \equiv n_u h\nu A P_{\nu\hat{\Omega}}^i, \quad \kappa^i \equiv n_l A (1 - e^{-h\nu_0/(k_B T_e)}) P_{\nu\hat{\Omega}}^i c^2/\nu^2, \quad (3.27)$$

respectively, where T_e is the electron temperature. Interpret these two quantities and prove *Kirchhoff's law*, namely, that $j_{\nu\hat{\Omega}}^i/\kappa^i$ is the blackbody radiation intensity for one polarization mode. What happens when $h\nu_0 \ll k_B T_e$?

- (d) Further generalize the results in part c by assuming that, instead of occupying just two states, the electrons have a continuous distribution of momenta and radiate throughout this distribution. Express the classical emissivity and absorption coefficient as integrals over electron momentum space.
- (e) Finally, consider the weak nuclear transformation $\nu + n \rightarrow e + p$, where the neutron n and the proton p can be considered as stationary. (This is important in the early universe, as we discuss further in Sec. 28.4.2.) Explain carefully why the rate at which this transformation occurs can be expressed as

$$\frac{dn_p}{dt} = n_n \int \left(\frac{d\mathcal{V}_{p\nu}}{h^3} \eta_\nu \right) \left(\frac{h^6 W}{m_e^5} \delta(E_\nu + m_n - E_e - m_p) \right) \left(2 \frac{d\mathcal{V}_{pe}}{h^3} (1 - \eta_e) \right) \quad (3.28)$$

for some W . It turns out that W is a constant (Weinberg, 2008). What is the corresponding rate for the inverse reaction?

Exercise 3.7 ***Example: Observations of Cosmic Microwave Radiation from Earth* R T2

The universe is filled with cosmic microwave radiation left over from the big bang. At each event in spacetime the microwave radiation has a mean rest frame. As seen in that mean rest frame the radiation's distribution function η is almost precisely isotropic and thermal with zero chemical potential:

$$\eta = \frac{1}{e^{h\nu/(k_B T_o)} - 1}, \quad \text{with } T_o = 2.725 \text{ K.} \quad (3.29)$$

Here ν is the frequency of a photon as measured in the mean rest frame.

- (a) Show that the specific intensity of the radiation as measured in its mean rest frame has the *Planck spectrum*, Eq. (3.23). Plot this specific intensity as a function of frequency, and from your plot determine the frequency of the intensity peak.
- (b) Show that η can be rewritten in the frame-independent form

$$\eta = \frac{1}{e^{-\vec{p} \cdot \vec{u}_o/(k_B T_o)} - 1}, \quad (3.30)$$

where \vec{p} is the photon 4-momentum, and \vec{u}_o is the 4-velocity of the mean rest frame. [Hint: See Sec. 2.6 and especially Eq. (2.29).]

- (c) In actuality, Earth moves relative to the mean rest frame of the microwave background with a speed v of roughly 400 km s^{-1} toward the Hydra-Centaurus region of the sky. An observer on Earth points his microwave receiver in a direction that makes an angle θ with the direction of that motion, as measured in Earth's frame. Show that the specific intensity of the radiation received is precisely Planckian in form [Eqs. (3.23)], but with a direction-dependent *Doppler-shifted temperature*

$$T = T_o \left(\frac{\sqrt{1-v^2}}{1-v \cos \theta} \right). \quad (3.31)$$

Note that this Doppler shift of T is precisely the same as the Doppler shift of the frequency of any specific photon [Eq. (2.33)]. Note also that the θ dependence corresponds to an anisotropy of the microwave radiation as seen from Earth. Show that because Earth's velocity is small compared to the speed of light, the anisotropy is very nearly dipolar in form. Measurements by the WMAP satellite give $T_o = 2.725 \text{ K}$ and (averaged over a year) an amplitude of $3.346 \times 10^{-3} \text{ K}$ for the dipolar temperature variations (Bennett et al., 2003). What, precisely, is the value of Earth's year-averaged speed v ?

3.4 Macroscopic Properties of Matter as Integrals over Momentum Space

3.4

3.4.1 Particle Density n , Flux \mathbf{S} , and Stress Tensor \mathbf{T} N

3.4.1

If one knows the Newtonian distribution function $\mathcal{N} = (g_s/h^3)\eta$ as a function of momentum \mathbf{p} at some location (\mathbf{x}, t) in space and time, one can use it to compute various macroscopic properties of the particles.

From the definition $\mathcal{N} \equiv dN/d\mathcal{V}_x d\mathcal{V}_p$ of the distribution function, it is clear that the number density of particles $n(\mathbf{x}, t)$ in physical space is given by the integral

$$n = \frac{dN}{d\mathcal{V}_x} = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} d\mathcal{V}_p = \int \mathcal{N} d\mathcal{V}_p. \quad (3.32a)$$

Newtonian particle density

Similarly, the number of particles crossing a unit surface in the y - z plane per unit time (i.e., the x component of the flux of particles) is

$$S_x = \frac{dN}{dydzdt} = \int \frac{dN}{dx dy dz d\mathcal{V}_p} \frac{dx}{dt} d\mathcal{V}_p = \int \mathcal{N} \frac{p_x}{m} d\mathcal{V}_p,$$

where $dx/dt = p_x/m$ is the x component of the particle velocity. This and the analogous equations for S_y and S_z can be combined into a single geometric, coordinate-independent integral for the vectorial particle flux:

$$\mathbf{S} = \int \mathcal{N} \mathbf{p} \frac{d\mathcal{V}_p}{m}. \quad (3.32b)$$

Newtonian particle flux

Notice that, if we multiply this \mathbf{S} by the particles' mass m , the integral becomes the momentum density:

Newtonian momentum density

$$\mathbf{G} = m\mathbf{S} = \int \mathcal{N} \mathbf{p} d\mathcal{V}_p. \quad (3.32c)$$

Finally, since the stress tensor \mathbf{T} is the flux of momentum [Eq. (1.33)], its j - x component (j component of momentum crossing a unit area in the y - z plane per unit time) must be

$$T_{jx} = \int \frac{dN}{dydzdt d\mathcal{V}_p} p_j d\mathcal{V}_p = \int \frac{dN}{dx dy dz d\mathcal{V}_p} \frac{dx}{dt} p_j d\mathcal{V}_p = \int \mathcal{N} p_j \frac{p_x}{m} d\mathcal{V}_p.$$

This and the corresponding equations for T_{jy} and T_{jz} can be collected together into a single geometric, coordinate-independent integral:

Newtonian stress tensor

$$T_{jk} = \int \mathcal{N} p_j p_k \frac{d\mathcal{V}_p}{m}, \quad \text{i.e.,} \quad \mathbf{T} = \int \mathcal{N} \mathbf{p} \otimes \mathbf{p} \frac{d\mathcal{V}_p}{m}. \quad (3.32d)$$

Notice that the number density n is the zeroth moment of the distribution function in momentum space [Eq. (3.32a)], and aside from factors $1/m$, the particle flux vector is the first moment [Eq. (3.32b)], and the stress tensor is the second moment [Eq. (3.32d)]. All three moments are geometric, coordinate-independent quantities, and they are the simplest such quantities that one can construct by integrating the distribution function over momentum space.

3.4.2

3.4.2 Relativistic Number-Flux 4-Vector \vec{S} and Stress-Energy Tensor \mathbf{T} R T2

When we switch from Newtonian theory to special relativity's 4-dimensional spacetime viewpoint, we require that all physical quantities be described by geometric, frame-independent objects (scalars, vectors, tensors, ...) in 4-dimensional spacetime. We can construct such objects as momentum-space integrals over the frame-independent, relativistic distribution function $\mathcal{N}(\mathcal{P}, \vec{p}) = (g_s/h^3)\eta$. The frame-independent quantities that can appear in these integrals are (i) \mathcal{N} itself, (ii) the particle 4-momentum \vec{p} , and (iii) the frame-independent integration element $d\mathcal{V}_p/\mathcal{E}$ [Eq. (3.7b)], which takes the form $dp_x dp_y dp_z / \sqrt{m^2 + \mathbf{p}^2}$ in any inertial reference frame. By analogy with the Newtonian regime, the most interesting such integrals are the lowest three moments of the distribution function:

$$R \equiv \int \mathcal{N} \frac{d\mathcal{V}_p}{\mathcal{E}}; \quad (3.33a)$$

$$\vec{S} \equiv \int \mathcal{N} \vec{p} \frac{d\mathcal{V}_p}{\mathcal{E}}, \quad \text{i.e.,} \quad S^\mu \equiv \int \mathcal{N} p^\mu \frac{d\mathcal{V}_p}{\mathcal{E}}; \quad (3.33b)$$

$$\mathbf{T} \equiv \int \mathcal{N} \vec{p} \otimes \vec{p} \frac{d\mathcal{V}_p}{\mathcal{E}}, \quad \text{i.e.,} \quad T^{\mu\nu} \equiv \int \mathcal{N} p^\mu p^\nu \frac{d\mathcal{V}_p}{\mathcal{E}}. \quad (3.33c)$$

Here and throughout this chapter, relativistic momentum-space integrals are taken over the entire mass hyperboloid unless otherwise specified.

We can learn the physical meanings of each of the momentum-space integrals (3.33) by introducing a specific but arbitrary inertial reference frame and using it to perform a 3+1 split of spacetime into space plus time [cf. the paragraph containing Eq. (2.28)]. When we do this and rewrite \mathcal{N} as $dN/d\mathcal{V}_x d\mathcal{V}_p$, the scalar field R of Eq. (3.33a) takes the form

$$R = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} \frac{1}{\mathcal{E}} d\mathcal{V}_p \quad (3.34)$$

(where of course $d\mathcal{V}_x = dx dy dz$ and $d\mathcal{V}_p = dp_x dp_y dp_z$). This is the sum, over all particles in a unit 3-volume, of the inverse energy. Although it is intriguing that this quantity is a frame-independent scalar, it is not a quantity that appears in any important way in the laws of physics.

By contrast, the 4-vector field \vec{S} of Eq. (3.33b) plays a very important role in physics. Its time component in our chosen frame is

$$S^0 = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} \frac{p^0}{\mathcal{E}} d\mathcal{V}_p = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} d\mathcal{V}_p \quad (3.35a)$$

(since p^0 and \mathcal{E} are just different notations for the same thing—the relativistic energy $\sqrt{m^2 + \mathbf{p}^2}$ of a particle). Obviously, this S^0 is the number of particles per unit spatial volume as measured in our chosen inertial frame:

$$S^0 = n = (\text{number density of particles}). \quad (3.35b)$$

The x component of \vec{S} is

$$S^x = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} \frac{p^x}{\mathcal{E}} d\mathcal{V}_p = \int \frac{dN}{dx dy dz d\mathcal{V}_p} \frac{dx}{dt} d\mathcal{V}_p = \int \frac{dN}{dt dy dz d\mathcal{V}_p} d\mathcal{V}_p, \quad (3.35c)$$

which is the number of particles crossing a unit area in the y - z plane per unit time (i.e., the x component of the particle flux); similarly for other directions j :

$$S^j = (j \text{ component of the particle flux vector } \mathbf{S}). \quad (3.35d)$$

[In Eq. (3.35c), the second equality follows from

$$\frac{p^j}{\mathcal{E}} = \frac{p^j}{p^0} = \frac{dx^j/d\zeta}{dt/d\zeta} = \frac{dx^j}{dt} = (j \text{ component of velocity}), \quad (3.35e)$$

where ζ is the affine parameter such that $\vec{p} = d\vec{x}/d\zeta$.] Since S^0 is the particle number density and S^j is the particle flux, \vec{S} [Eq. (3.33b)] *must be the number-flux 4-vector* introduced and studied in Sec. 2.12.3. Notice that in the Newtonian limit, where $p^0 = \mathcal{E} \rightarrow m$, the temporal and spatial parts of the formula $\vec{S} = \int \mathcal{N} \vec{p} (d\mathcal{V}_p/\mathcal{E})$ reduce

number-flux 4-vector

to $S^0 = \int \mathcal{N} d\mathcal{V}_p$ and $\mathbf{S} = \int \mathcal{N} \mathbf{p} (d\mathcal{V}_p/m)$, respectively, which are the coordinate-independent expressions (3.32a) and (3.32b) for the Newtonian number density of particles and flux of particles, respectively.

Turn to the quantity \mathbf{T} defined by the integral (3.33c). When we perform a 3+1 split of it in our chosen inertial frame, we find the following for its various parts:

$$T^{\mu 0} = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} p^\mu p^0 \frac{d\mathcal{V}_p}{p^0} = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} p^\mu d\mathcal{V}_p \quad (3.36a)$$

is the μ component of 4-momentum per unit volume (i.e., T^{00} is the energy density, and T^{j0} is the momentum density). Also,

$$T^{\mu x} = \int \frac{dN}{d\mathcal{V}_x d\mathcal{V}_p} p^\mu p^x \frac{d\mathcal{V}_p}{p^0} = \int \frac{dN}{dx dy dz d\mathcal{V}_p} \frac{dx}{dt} p^\mu d\mathcal{V}_p = \int \frac{dN}{dt dy dz d\mathcal{V}_p} p^\mu d\mathcal{V}_p \quad (3.36b)$$

is the amount of μ component of 4-momentum that crosses a unit area in the y - z plane per unit time (i.e., it is the x component of flux of μ component of 4-momentum). More specifically, T^{0x} is the x component of energy flux (which is the same as the momentum density T^{x0}), and T^{jx} is the x component of spatial-momentum flux—or, equivalently, the jx component of the stress tensor. These and the analogous expressions and interpretations of $T^{\mu y}$ and $T^{\mu z}$ can be summarized by

$$\begin{aligned} T^{00} &= (\text{energy density}), & T^{j0} &= (\text{momentum density}) = T^{0j} = (\text{energy flux}), \\ T^{jk} &= (\text{stress tensor}). \end{aligned} \quad (3.36c)$$

stress-energy tensor

Therefore [cf. Eq. (2.67f)], the \mathbf{T} of Eq. (3.33c) must be the stress-energy tensor introduced and studied in Sec. 2.13. Notice that in the Newtonian limit, where $\mathcal{E} \rightarrow m$, the coordinate-independent Eq. (3.33c) for the spatial part of the stress-energy tensor (the stress) becomes $\int \mathcal{N} \mathbf{p} \otimes \mathbf{p} d\mathcal{V}_p/m$, which is the same as our coordinate-independent Eq. (3.32d) for the stress tensor.

3.5 Isotropic Distribution Functions and Equations of State

3.5.1 Newtonian Density, Pressure, Energy Density, and Equation of State N

Let us return to Newtonian theory.

If the Newtonian distribution function is isotropic in momentum space (i.e., is a function only of the magnitude $p \equiv |\mathbf{p}| = \sqrt{p_x^2 + p_y^2 + p_z^2}$ of the momentum, as is the case, e.g., when the particle distribution is thermalized), then the particle flux \mathbf{S} vanishes (equal numbers of particles travel in all directions), and the stress tensor is isotropic: $\mathbf{T} = P\mathbf{g}$, or $T_{jk} = P\delta_{jk}$. Thus, it is the stress tensor of a perfect fluid. [Here P is the isotropic pressure, and \mathbf{g} is the metric tensor of Euclidian 3-space, with Cartesian components equal to the Kronecker delta; Eq. (1.9f).] In this isotropic case, the pressure can be computed most easily as 1/3 the trace of the stress tensor (3.32d):

$$\begin{aligned}
P &= \frac{1}{3} T_{jj} = \frac{1}{3} \int \mathcal{N} (p_x^2 + p_y^2 + p_z^2) \frac{d\mathcal{V}_p}{m} \\
&= \frac{1}{3} \int_0^\infty \mathcal{N} p^2 \frac{4\pi p^2 dp}{m} = \frac{4\pi}{3m} \int_0^\infty \mathcal{N} p^4 dp. \quad (3.37a)
\end{aligned}$$

Newtonian pressure

Here in the third step we have written the momentum-volume element in spherical polar coordinates as $d\mathcal{V}_p = p^2 \sin \theta d\theta d\phi dp$ and have integrated over angles to get $4\pi p^2 dp$. Similarly, we can reexpress the number density of particles (3.32a) and the corresponding mass density as

$$n = 4\pi \int_0^\infty \mathcal{N} p^2 dp, \quad \rho \equiv mn = 4\pi m \int_0^\infty \mathcal{N} p^2 dp. \quad (3.37b)$$

Newtonian particle and mass density

Finally, because each particle carries an energy $E = p^2/(2m)$, the energy density in this isotropic case (which we shall denote by U) is $3/2$ the pressure:

$$U = \int \frac{p^2}{2m} \mathcal{N} d\mathcal{V}_p = \frac{4\pi}{2m} \int_0^\infty \mathcal{N} p^4 dp = \frac{3}{2} P \quad (3.37c)$$

Newtonian energy density

[cf. Eq. (3.37a)].

If we know the distribution function for an isotropic collection of particles, Eqs. (3.37) give us a straightforward way of computing the collection's number density of particles n , mass density $\rho = nm$, perfect-fluid energy density U , and perfect-fluid pressure P as measured in the particles' mean rest frame. For a thermalized gas, the distribution functions (3.22a), (3.22b), and (3.22d) [with $\mathcal{N} = (g_s/h^3)\eta$] depend on two parameters: the temperature T and chemical potential μ , so this calculation gives n , U , and P in terms of μ and T . One can then invert $n(\mu, T)$ to get $\mu(n, T)$ and insert the result into the expressions for U and P to obtain *equations of state* for thermalized, nonrelativistic particles:

$$U = U(\rho, T), \quad P = P(\rho, T). \quad (3.38)$$

equations of state

For a gas of nonrelativistic, classical particles, the distribution function is Boltzmann [Eq. (3.22d)], $\mathcal{N} = (g_s/h^3)e^{(\mu-E)/(k_B T)}$, with $E = p^2/(2m)$, and this procedure gives, quite easily (Ex. 3.8):

thermalized, classical, nonrelativistic gas

$$n = \frac{g_s e^{\mu/(k_B T)}}{\lambda_{TdB}^3} = \frac{g_s}{h^3} (2\pi m k_B T)^{3/2} e^{\mu/(k_B T)}, \quad (3.39a)$$

$$U = \frac{3}{2} n k_B T, \quad P = n k_B T. \quad (3.39b)$$

Notice that the mean energy per particle is (cf. Ex. 3.4b)

$$\bar{E} = \frac{3}{2} k_B T. \quad (3.39c)$$

N

In Eq. (3.39a), $\lambda_{T\text{dB}} \equiv h/\sqrt{2\pi mk_B T}$ is the particles' *thermal de Broglie wavelength*: the wavelength of Schrödinger wave-function oscillations for a particle with thermal kinetic energy $E = \pi k_B T$. Note that the classical regime $\eta \ll 1$ (i.e., $\mu/(k_B T) \ll -1$), in which our computation is being performed, corresponds to a mean number of particles in a thermal de Broglie wavelength small compared to 1, $n\lambda_{T\text{dB}}^3 \ll 1$, which should not be surprising.

3.5.2 Equations of State for a Nonrelativistic Hydrogen Gas N

As an application, consider ordinary matter. Figure 3.7 shows its physical nature as a function of density and temperature, near and above room temperature (300 K). We study solids (lower right) in Part IV, fluids (lower middle) in Part V, and plasmas (middle) in Part VI.

Our kinetic-theory tools are well suited to any situation where the particles have mean free paths large compared to their sizes. This is generally true in plasmas and sometimes in fluids (e.g., air and other gases, but not water and other liquids), and even sometimes in solids (e.g., electrons in a metal). Here we focus on a nonrelativistic

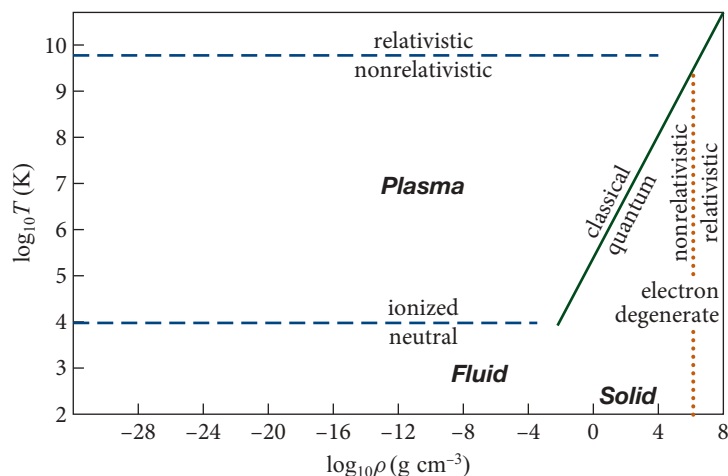

FIGURE 3.7 Physical nature of hydrogen at various densities and temperatures. The plasma regime is discussed in great detail in Part VI, and the equation of state in this regime is Eq. (3.40). The region of relativistic electron degeneracy (to the right of the vertical dotted line) is analyzed in Sec. 3.5.4, and that for the nonrelativistic regime (between slanted solid line and vertical dotted line) in the second half of Sec. 3.5.2. The boundary between the plasma regime and the electron-degenerate regime (slanted solid line) is Eq. (3.41); that between nonrelativistic degeneracy and relativistic degeneracy (vertical dotted line) is Eq. (3.46). The upper relativistic/nonrelativistic boundary is governed by electron-positron pair production (Ex. 5.9 and Fig. 5.7) and is only crudely approximated by the upper dashed line. The ionized-neutral boundary is governed by the Saha equation (Ex. 5.10 and Fig. 20.1) and is crudely approximated by the lower dashed line. For a more accurate and detailed version of this figure, including greater detail on the plasma regime and its boundaries, see Fig. 20.1.

plasma (i.e., the region of Fig. 3.7 that is bounded by the two dashed lines and the slanted solid line). For concreteness and simplicity, we regard the plasma as made solely of hydrogen.⁸

A nonrelativistic hydrogen plasma consists of a mixture of two fluids (gases): free electrons and free protons, in equal numbers. Each fluid has a particle number density $n = \rho/m_p$, where ρ is the total mass density and m_p is the proton mass. (The electrons are so light that they do not contribute significantly to ρ .) Correspondingly, the energy density and pressure include equal contributions from the electrons and protons and are given by [cf. Eqs. (3.39b)]

$$U = 3(k_B/m_p)\rho T, \quad P = 2(k_B/m_p)\rho T. \quad (3.40)$$

In zeroth approximation, the high-temperature boundary of validity for this equation of state is the temperature $T_{\text{rel}} = m_e c^2/k_B = 6 \times 10^9$ K, at which the electrons become highly relativistic (top dashed line in Fig. 3.7). In Ex. 5.9, we compute the thermal production of electron-positron pairs in the hot plasma and thereby discover that the upper boundary is actually somewhat lower than this (Figs. 5.7 and 20.1). The bottom dashed line in Fig. 3.7 is the temperature $T_{\text{ion}} \sim$ (ionization energy of hydrogen)/(a few k_B) $\sim 10^4$ K, at which electrons and protons begin to recombine and form neutral hydrogen. In Ex. 5.10 on the Saha equation, we analyze the conditions for ionization-recombination equilibrium and thereby refine this boundary (Fig. 20.1). The solid right boundary is the point at which the electrons cease to behave like classical particles, because their mean occupation number η_e ceases to be $\ll 1$. As one can see from the Fermi-Dirac distribution (3.22a), for typical electrons (which have energies $E \sim k_B T$), the regime of classical behavior ($\eta_e \ll 1$; to the left of the solid line) is $\mu_e \ll -k_B T$ and the regime of strong quantum behavior ($\eta_e \simeq 1$; *electron degeneracy*; to the right of the solid line) is $\mu_e \gg +k_B T$. The slanted solid boundary in Fig. 3.7 is thus the location $\mu_e = 0$, which translates via Eq. (3.39a) to

$$\rho = \rho_{\text{deg}} \equiv 2m_p/\lambda_{\text{TdB}}^3 = (2m_p/h^3)(2\pi m_e k_B T)^{3/2} = 0.00808(T/10^4 \text{ K})^{3/2} \text{ g cm}^{-3}. \quad (3.41)$$

Although the hydrogen gas is *degenerate* to the right of this boundary, we can still compute its equation of state using our kinetic-theory equations (3.37), so long as we use the quantum mechanically correct distribution function for the electrons—the Fermi-Dirac distribution (3.22a).⁹ In this electron-degenerate region, $\mu_e \gg k_B T$, the electron mean occupation number $\eta_e = 1/(e^{(E-\mu_e)/(k_B T)} + 1)$ has the form shown

nondegenerate hydrogen
gas

degenerate hydrogen gas

8. For both astrophysical and laboratory applications, the non-hydrogen elemental composition often matters, and involves straightforward corrections to purely hydrogen formulae given here.
9. Our kinetic-theory analysis and the Fermi-Dirac distribution ignore Coulomb interactions between the electrons, and between the electrons and the ions. They thereby miss so-called *Coulomb corrections* to the equation of state (Sec. 22.6.3) and other phenomena that are often important in condensed matter physics, but rarely important in astrophysics.

FIGURE 3.8 The Fermi-Dirac distribution function for electrons in the nonrelativistic, degenerate regime $k_B T \ll \mu_e \ll m_e$, with temperature such that $k_B T/\mu_e = 0.03$. Note that η_e drops from near 1 to near 0 over the range $\mu_e - 2k_B T \lesssim E \lesssim \mu_e + 2k_B T$. See Ex. 3.11b.

in Fig. 3.8 and thus can be well approximated by $\eta_e = 1$ for $E = p^2/(2m_e) < \mu_e$ and $\eta_e = 0$ for $E > \mu_e$; or equivalently by

$$\eta_e = 1 \text{ for } p < p_F \equiv \sqrt{2m_e\mu_e}, \quad \eta_e = 0 \text{ for } p > p_F. \quad (3.42)$$

Fermi momentum

Here p_F is called the *Fermi momentum*. (The word “degenerate” refers to the fact that almost all the quantum states are fully occupied or are empty; i.e., η_e is everywhere nearly 1 or 0.) By inserting this degenerate distribution function [or, more precisely, $\mathcal{N}_e = (2/h^3)\eta_e$] into Eqs. (3.37) and integrating, we obtain $n_e \propto p_F^3$ and $P_e \propto p_F^5$. By then setting $n_e = n_p = \rho/m_p$ and solving for $p_F \propto n_e^{1/3} \propto \rho^{1/3}$ and inserting into the expression for P_e and evaluating the constants, we obtain (Ex. 3.9) the following equation of state for the electron pressure:

$$P_e = \frac{1}{20} \left(\frac{3}{\pi} \right)^{2/3} \frac{m_e c^2}{\lambda_c^3} \left(\frac{\rho}{m_p/\lambda_c^3} \right)^{5/3}. \quad (3.43)$$

Here

$$\lambda_c = h/(m_e c) = 2.426 \times 10^{-10} \text{ cm} \quad (3.44)$$

is the electron Compton wavelength.

The rapid growth $P_e \propto \rho^{5/3}$ of the electron pressure with increasing density is due to the degenerate electrons’ being confined by the Pauli Exclusion Principle to regions of ever-shrinking size, causing their zero-point motions and associated pressure to grow. By contrast, the protons, with their far larger rest masses, remain nondegenerate [until their density becomes $(m_p/m_e)^{3/2} \sim 10^5$ times higher than Eq. (3.41)], and so

their pressure is negligible compared to that of the electrons: the total pressure is

$$P = P_e = \text{Eq. (3.43)} \quad (3.45)$$

in the regime of nonrelativistic electron degeneracy. This is the equation of state for the interior of a low-mass white-dwarf star and for the outer layers of a high-mass white dwarf—aside from tiny corrections due to Coulomb interactions. In Sec. 13.3.2 we shall see how it can be used to explore the structures of white dwarfs. It is also the equation of state for a neutron star, with m_e replaced by the rest mass of a neutron m_n (since neutron degeneracy pressure dominates over that due to the star's tiny number of electrons and protons) and ρ/m_p replaced by the number density of neutrons—except that for neutron stars there are large corrections due to the strong nuclear force (see, e.g., Shapiro and Teukolsky, 1983).

When the density of hydrogen in this degenerate regime is pushed on upward to

$$\rho_{\text{rel deg}} = \frac{8\pi m_p}{3\lambda_c^3} \simeq 9.8 \times 10^5 \text{ g cm}^{-3} \quad (3.46)$$

(dotted vertical line in Fig. 3.7), the electrons' zero-point motions become relativistically fast (the electron chemical potential μ_e becomes of order $m_e c^2$ and the Fermi momentum p_F of order $m_e c$), so the nonrelativistic, Newtonian analysis fails, and the matter enters a domain of relativistic degeneracy (Sec. 3.5.4). Both domains, nonrelativistic degeneracy ($\mu_e \ll m_e c^2$) and relativistic degeneracy ($\mu_e \gtrsim m_e c^2$), occur for matter inside a massive white-dwarf star—the type of star that the Sun will become when it dies (see Shapiro and Teukolsky, 1983). In Sec. 26.3.5, we shall see how general relativity (spacetime curvature) modifies a star's structure. It also helps force sufficiently massive white dwarfs to collapse (Sec. 6.10 of Shapiro and Teukolsky, 1983).

The (almost) degenerate Fermi-Dirac distribution function shown in Fig. 3.8 has a thermal tail whose energy width is $4k_B T/\mu_e$. As the temperature T is increased, the number of electrons in this tail increases, thereby increasing the electrons' total energy E_{tot} . This increase is responsible for the electrons' *specific heat* (Ex. 3.11)—a quantity of importance for both the electrons in a metal (e.g., a copper wire) and the electrons in a white-dwarf star. The electrons dominate the specific heat when the temperature is sufficiently low; but at higher temperatures it is dominated by the energies of sound waves (see Ex. 3.12, where we use the kinetic theory of phonons to compute the sound waves' specific heat).

3.5.3 Relativistic Density, Pressure, Energy Density, and Equation of State R T2

3.5.3

Now we turn to the relativistic domain of kinetic theory, initially for a single species of particle with rest mass m and then (in the next subsection) for matter composed of electrons and protons.

The relativistic *mean rest frame* of the particles, at some event \mathcal{P} in spacetime, is that frame in which the particle flux \mathbf{S} vanishes. We denote by \vec{u}_{rf} the 4-velocity of this mean rest frame. As in Newtonian theory (Sec. 3.5.2), we are especially interested

in distribution functions \mathcal{N} that are *isotropic* in the mean rest frame: distribution functions that depend on the magnitude $|\mathbf{p}| \equiv p$ of the spatial momentum of a particle but not on its direction—or equivalently, that depend solely on the particles' energy

$$\begin{aligned}\mathcal{E} &= -\vec{u}_{\text{rf}} \cdot \vec{p} \quad \text{expressed in frame-independent form [Eq. (2.29)],} \\ \mathcal{E} &= p^0 = \sqrt{m^2 + p^2} \quad \text{in mean rest frame.}\end{aligned}\tag{3.47}$$

Such isotropy is readily produced by particle collisions (Sec. 3.7).

Notice that isotropy in the mean rest frame [i.e., $\mathcal{N} = \mathcal{N}(\mathcal{P}, \mathcal{E})$] does not imply isotropy in any other inertial frame. As seen in some other (primed) frame, \vec{u}_{rf} will have a time component $u_{\text{rf}}^{0'} = \gamma$ and a space component $\mathbf{u}'_{\text{rf}} = \gamma \mathbf{V}$ [where \mathbf{V} is the mean rest frame's velocity relative to the primed frame, and $\gamma = (1 - \mathbf{V}^2)^{-1/2}$]; and correspondingly, in the primed frame, \mathcal{N} will be a function of

$$\mathcal{E} = -\vec{u}'_{\text{rf}} \cdot \vec{p}' = \gamma[(m^2 + \mathbf{p}'^2)^{\frac{1}{2}} - \mathbf{V} \cdot \mathbf{p}'],\tag{3.48}$$

which is anisotropic: it depends on the direction of the spatial momentum \mathbf{p}' relative to the velocity \mathbf{V} of the particle's mean rest frame. An example is the cosmic microwave radiation as viewed from Earth (Ex. 3.7).

As in Newtonian theory, isotropy greatly simplifies the momentum-space integrals (3.33) that we use to compute macroscopic properties of the particles: (i) The integrands of the expressions $S^j = \int \mathcal{N} p^j (d\mathcal{V}_p/\mathcal{E})$ and $T^{j0} = T^{0j} = \int \mathcal{N} p^j p^0 (d\mathcal{V}_p/\mathcal{E})$ for the particle flux, energy flux, and momentum density are all odd in the momentum-space coordinate p^j and therefore give vanishing integrals: $S^j = T^{j0} = T^{0j} = 0$. (ii) The integral $T^{jk} = \int \mathcal{N} p^j p^k d\mathcal{V}_p/\mathcal{E}$ produces an isotropic stress tensor, $T^{jk} = P g^{jk} = P \delta^{jk}$, whose pressure is most easily computed from its trace, $P = \frac{1}{3} T^{jj}$. Using these results and the relations $|\mathbf{p}| \equiv p$ for the magnitude of the momentum, $d\mathcal{V}_p = 4\pi p^2 dp$ for the momentum-space volume element, and $\mathcal{E} = p^0 = \sqrt{m^2 + p^2}$ for the particle energy, we can easily evaluate Eqs. (3.33) for the particle number density $n = S^0$, the total density of mass-energy T^{00} (which we denote ρ —the same notation as we use for mass density in Newtonian theory), and the pressure P . The results are

$$n \equiv S^0 = \int \mathcal{N} d\mathcal{V}_p = 4\pi \int_0^\infty \mathcal{N} p^2 dp,\tag{3.49a}$$

$$\rho \equiv T^{00} = \int \mathcal{N} \mathcal{E} d\mathcal{V}_p = 4\pi \int_0^\infty \mathcal{N} \mathcal{E} p^2 dp,\tag{3.49b}$$

$$P = \frac{1}{3} \int \mathcal{N} p^2 \frac{d\mathcal{V}_p}{\mathcal{E}} = \frac{4\pi}{3} \int_0^\infty \mathcal{N} \frac{p^4 dp}{\sqrt{m^2 + p^2}}.\tag{3.49c}$$

relativistic particle density, mass-energy density, and pressure

3.5.4 3.5.4 Equation of State for a Relativistic Degenerate Hydrogen Gas R T2

Return to the hydrogen gas whose nonrelativistic equations of state were computed in Sec. 3.5.1. As we deduced there, at densities $\rho \gtrsim 10^5 \text{ g cm}^{-3}$ (near and to the right of

the vertical dotted line in Fig. 3.7) the electrons are squeezed into such tiny volumes that their zero-point energies are $\gtrsim m_e c^2$, forcing us to treat them relativistically.

We can do so with the aid of the following approximation for the relativistic Fermi-Dirac mean occupation number $\eta_e = 1/[e^{(\mathcal{E} - \tilde{\mu}_e)/(k_B T)} + 1]$:

$$\eta_e \simeq 1 \text{ for } \mathcal{E} < \tilde{\mu}_e \equiv \mathcal{E}_F; \text{ i.e., for } p < p_F = \sqrt{\mathcal{E}_F^2 - m^2}, \quad (3.50)$$

$$\eta_e \simeq 0 \text{ for } \mathcal{E} > \mathcal{E}_F; \text{ i.e., for } p > p_F. \quad (3.51)$$

Here \mathcal{E}_F is called the relativistic *Fermi energy* and p_F the relativistic *Fermi momentum*. By inserting this η_e along with $\mathcal{N}_e = (2/h^3)\eta_e$ into the integrals (3.49) for the electron number density n_e , total density of mass-energy ρ_e , and pressure P_e , and performing the integrals (Ex. 3.10), we obtain results that are expressed most simply in terms of a parameter t (not to be confused with time) defined by

$$\mathcal{E}_F \equiv \tilde{\mu}_e \equiv m_e \cosh(t/4), \quad p_F \equiv \sqrt{\mathcal{E}_F^2 - m_e^2} \equiv m_e \sinh(t/4). \quad (3.52a)$$

The results are

$$n_e = \frac{8\pi}{3\lambda_c^3} \left(\frac{p_F}{m_e}\right)^3 = \frac{8\pi}{3\lambda_c^3} \sinh^3(t/4), \quad (3.52b)$$

$$\rho_e = \frac{8\pi m_e}{\lambda_c^3} \int_0^{p_F/m_e} x^2 \sqrt{1+x^2} dx = \frac{\pi m_e}{4\lambda_c^3} [\sinh(t) - t], \quad (3.52c)$$

$$P_e = \frac{8\pi m_e}{\lambda_c^3} \int_0^{p_F/m_e} \frac{x^4}{\sqrt{1+x^2}} dx = \frac{\pi m_e}{12\lambda_c^3} [\sinh(t) - 8 \sinh(t/2) + 3t]. \quad (3.52d)$$

These parametric relationships for ρ_e and P_e as functions of the electron number density n_e are sometimes called the Anderson-Stoner equation of state, because they were first derived by Wilhelm Anderson and Edmund Stoner in 1930 (see Thorne, 1994, pp. 153–154). They are valid throughout the full range of electron degeneracy, from nonrelativistic up to ultrarelativistic.

In a white-dwarf star, the protons, with their high rest mass, are nondegenerate, the total density of mass-energy is dominated by the proton rest-mass density, and since there is one proton for each electron in the hydrogen gas, that total is

$$\rho \simeq m_p n_e = \frac{8\pi m_p}{3\lambda_c^3} \sinh^3(t/4). \quad (3.53a)$$

By contrast (as in the nonrelativistic regime), the pressure is dominated by the electrons (because of their huge zero-point motions), not the protons; and so the total pressure is

$$P = P_e = \frac{\pi m_e}{12\lambda_c^3} [\sinh(t) - 8 \sinh(t/2) + 3t]. \quad (3.53b)$$

relativistically degenerate
electrons

relativistically degenerate
hydrogen gas

In the low-density limit, where $t \ll 1$ so $p_F \ll m_e = m_e c$, we can solve the relativistic equation (3.52b) for t as a function of $n_e = \rho/m_p$ and insert the result into the relativistic expression (3.53b); the result is the nonrelativistic equation of state (3.43).

The dividing line $\rho = \rho_{\text{rel deg}} = 8\pi m_p / (3\lambda_c^3) \simeq 1.0 \times 10^6 \text{ g cm}^{-3}$ [Eq. (3.46)] between nonrelativistic and relativistic degeneracy is the point where the electron Fermi momentum is equal to the electron rest mass [i.e., $\sinh(t/4) = 1$]. The equation of state (3.53a) and (3.53b) implies

$$\begin{aligned} P_e &\propto \rho^{5/3} && \text{in the nonrelativistic regime, } \rho \ll \rho_{\text{rel deg}}, \\ P_e &\propto \rho^{4/3} && \text{in the relativistic regime, } \rho \gg \rho_{\text{rel deg}}. \end{aligned} \quad (3.53c)$$

These asymptotic equations of state turn out to play a crucial role in the structure and stability of white dwarf stars (Secs. 13.3.2 and 26.3.5; Shapiro and Teukolsky, 1983; Thorne, 1994, Chap. 4).

3.5.5

3.5.5 Equation of State for Radiation N R

thermalized radiation

As was discussed at the end of Sec. 3.3, for a gas of thermalized photons in an environment where photons are readily created and absorbed, the distribution function has the blackbody (Planck) form $\eta = 1/(e^{\mathcal{E}/(k_B T)} - 1)$, which we can rewrite as $1/(e^{p/(k_B T)} - 1)$, since the energy \mathcal{E} of a photon is the same as the magnitude p of its momentum. In this case, the relativistic integrals (3.49) give (see Ex. 3.13)

$$\boxed{n = bT^3, \quad \rho = aT^4, \quad P = \frac{1}{3}\rho,} \quad (3.54a)$$

where

$$b = 16\pi \zeta(3) \frac{k_B^3}{h^3 c^3} = 20.28 \text{ cm}^{-3} \text{ K}^{-3}, \quad (3.54b)$$

$$a = \frac{8\pi^5}{15} \frac{k_B^4}{h^3 c^3} = 7.566 \times 10^{-15} \text{ erg cm}^{-3} \text{ K}^{-4} = 7.566 \times 10^{-16} \text{ J m}^{-3} \text{ K}^{-4} \quad (3.54c)$$

are *radiation constants*. Here $\zeta(3) = \sum_{n=1}^{\infty} n^{-3} = 1.2020569 \dots$ is the Riemann zeta function.

As we shall see in Sec. 28.4, when the universe was younger than about 100,000 years, its energy density and pressure were predominantly due to thermalized photons plus neutrinos (which contributed approximately the same as the photons), so its equation of state was given by Eq. (3.54a) with the coefficient changed by a factor of order unity. Einstein's general relativistic field equations (Sec. 25.8 and Chap. 28) relate the energy density ρ of these photons and neutrinos to the age of the universe t as measured in the photons' and neutrinos' mean rest frame:

$$\frac{3}{32\pi G t^2} = \rho \simeq aT^4. \quad (3.55a)$$

Here G is Newton's gravitation constant. Putting in numbers, we find that

$$\rho = \frac{4.5 \times 10^{-10} \text{ g cm}^{-3}}{(\tau/1 \text{ yr})^2}, \quad T \simeq \frac{2.7 \times 10^6 \text{ K}}{(\tau/1 \text{ yr})^{1/2}}. \quad (3.55b)$$

This implies that, when the universe was 1 minute old, its radiation density and temperature were about 100 g cm^{-3} and $2 \times 10^9 \text{ K}$, respectively. These conditions and the proton density were well suited for burning hydrogen to helium; and, indeed, about 1/4 of all the mass of the universe did get burned to helium at this early epoch. We shall examine this in further detail in Sec. 28.4.2.

EXERCISES

Exercise 3.8 *Derivation and Practice: Equation of State for Nonrelativistic, Classical Gas* N

Consider a collection of identical, classical (i.e., with $\eta \ll 1$) particles with a distribution function \mathcal{N} that is thermalized at a temperature T such that $k_B T \ll mc^2$ (nonrelativistic temperature).

- (a) Show that the distribution function, expressed in terms of the particles' momenta or velocities in their mean rest frame, is

$$\mathcal{N} = \frac{g_s}{h^3} e^{\mu/(k_B T)} e^{-p^2/(2mk_B T)}, \quad \text{where } p = |\mathbf{p}| = mv, \quad (3.56)$$

with v being the speed of a particle.

- (b) Show that the number density of particles in the mean rest frame is given by Eq. (3.39a).
 (c) Show that this gas satisfies the equations of state (3.39b).

Note: The following integrals, for nonnegative integral values of q , will be useful:

$$\int_0^\infty x^{2q} e^{-x^2} dx = \frac{(2q-1)!!}{2^{q+1}} \sqrt{\pi}, \quad (3.57)$$

where $n!! \equiv n(n-2)(n-4) \dots (2 \text{ or } 1)$; and

$$\int_0^\infty x^{2q+1} e^{-x^2} dx = \frac{1}{2} q!. \quad (3.58)$$

Exercise 3.9 *Derivation and Practice: Equation of State for Nonrelativistic, Electron-Degenerate Hydrogen* N

Derive Eq. (3.43) for the electron pressure in a nonrelativistic, electron-degenerate hydrogen gas.

Exercise 3.10 *Derivation and Practice: Equation of State for Relativistic, Electron-Degenerate Hydrogen* R T2

Derive the equations of state (3.52) for an electron-degenerate hydrogen gas. (Note: It might be easiest to compute the integrals with the help of symbolic manipulation software, such as Mathematica, Matlab, or Maple.)

Exercise 3.11 *Example: Specific Heat for Nonrelativistic, Degenerate Electrons in White Dwarfs and in Metals* N

Consider a nonrelativistically degenerate electron gas at finite but small temperature.

- (a) Show that the inequalities $k_B T \ll \mu_e \ll m_e$ are equivalent to the words “nonrelativistically degenerate.”
- (b) Show that the electron mean occupation number $\eta_e(E)$ has the form depicted in Fig. 3.8: It is near unity out to (nonrelativistic) energy $E \simeq \mu_e - 2k_B T$, and it then drops to nearly zero over a range of energies $\Delta E \sim 4k_B T$.
- (c) If the electrons were nonrelativistic but *nondegenerate*, their thermal energy density would be $U = \frac{3}{2}nk_B T$, so the total electron energy (excluding rest mass) in a volume V containing $N = nV$ electrons would be $E_{\text{tot}} = \frac{3}{2}Nk_B T$, and the electron specific heat, at fixed volume, would be

$$C_V \equiv \left(\frac{\partial E_{\text{tot}}}{\partial T} \right)_V = \frac{3}{2}Nk_B \quad (\text{nondegenerate, nonrelativistic}). \quad (3.59)$$

Using the semiquantitative form of η_e depicted in Fig. 3.8, show that to within a factor of order unity the specific heat of degenerate electrons is smaller than in the nondegenerate case by a factor $\sim k_B T / \mu_e$:

$$C_V \equiv \left(\frac{\partial E_{\text{tot}}}{\partial T} \right)_V \sim \left(\frac{k_B T}{\mu_e} \right) Nk_B \quad (\text{degenerate, nonrelativistic}). \quad (3.60)$$

- (d) Compute the multiplicative factor in Eq. (3.60) for C_V . More specifically, show that, to first order in $k_B T / \mu_e$,

$$C_V = \frac{\pi^2}{2} \left(\frac{k_B T}{\mu_e} \right) Nk_B. \quad (3.61)$$

- (e) As an application, consider hydrogen inside a white dwarf with density $\rho = 10^5 \text{ g cm}^{-3}$ and temperature $T = 10^6 \text{ K}$. (These are typical values for a white-dwarf interior). What are the numerical values of μ_e / m_e and $k_B T / \mu_e$ for the electrons? What is the numerical value of the dimensionless factor $(\pi^2/2)(k_B T / \mu_e)$ by which degeneracy reduces the electron specific heat?
- (f) As a second application, consider the electrons inside a copper wire in a laboratory on Earth at room temperature. Each copper atom donates about one electron to a “gas” of freely traveling (conducting) electrons and keeps the rest of its electrons bound to itself. (We neglect interaction of this electron gas with the ions, thereby missing important condensed matter complexities, such as conduction bands and what distinguishes conducting materials from insulators.)

What are the numerical values of μ_e / m_e and $k_B T / \mu_e$ for the conducting electron gas? Verify that these are in the range corresponding to nonrelativistic degeneracy. What is the value of the factor $(\pi^2/2)(k_B T / \mu_e)$ by which degeneracy reduces the electron specific heat? At room temperature, this electron contribu-

tion to the specific heat is far smaller than the contribution from thermal vibrations of the copper atoms (i.e., thermal sound waves, i.e., thermal *phonons*), but at very low temperatures the electron contribution dominates, as we shall see in the next exercise.

Exercise 3.12 *Example: Specific Heat for Phonons in an Isotropic Solid* N

In Sec. 12.2 we will study classical sound waves propagating through an isotropic, elastic solid. As we shall see, there are two types of sound waves: *longitudinal* with frequency-independent speed C_L , and *transverse* with a somewhat smaller frequency-independent speed C_T . For each type of wave, $s = L$ or T , the material of the solid undergoes an elastic displacement $\boldsymbol{\xi} = A\mathbf{f}_s \exp(i\mathbf{k} \cdot \mathbf{x} - \omega t)$, where A is the wave amplitude, \mathbf{f}_s is a unit vector (polarization vector) pointing in the direction of the displacement, \mathbf{k} is the wave vector, and ω is the wave frequency. The wave speed is $C_s = \omega/|\mathbf{k}|$ ($= C_L$ or C_T). Associated with these waves are quanta called phonons. As for any wave, each phonon has a momentum related to its wave vector by $\mathbf{p} = \hbar\mathbf{k}$, and an energy related to its frequency by $E = \hbar\omega$. Combining these relations we learn that the relationship between a phonon's energy and the magnitude $p = |\mathbf{p}|$ of its momentum is $E = C_s p$. This is the same relationship as for photons, but with the speed of light replaced by the speed of sound! For longitudinal waves \mathbf{f}_L is in the propagation direction \mathbf{k} , so there is just one polarization, $g_L = 1$. For transverse waves \mathbf{f}_T is orthogonal to \mathbf{k} , so there are two orthogonal polarizations (e.g., $\mathbf{f}_T = \mathbf{e}_x$ and $\mathbf{f}_T = \mathbf{e}_y$ when \mathbf{k} points in the \mathbf{e}_z direction), $g_T = 2$.

- (a) Phonons of both types, longitudinal and transverse, are bosons. Why? [Hint: Each normal mode of an elastic body can be described mathematically as a harmonic oscillator.]
- (b) Phonons are fairly easily created, absorbed, scattered, and thermalized. A general argument that we will give for chemical reactions in Sec. 5.5 can be applied to phonon creation and absorption to deduce that, once they reach complete thermal equilibrium with their environment, the phonons will have vanishing chemical potential $\mu = 0$. What, then, will be their distribution functions η and \mathcal{N} ?
- (c) Ignoring the fact that the sound waves' wavelengths $\lambda = 2\pi/|\mathbf{k}|$ cannot be smaller than about twice the spacing between the atoms of the solid, show that the total phonon energy (wave energy) in a volume V of the solid is identical to that for blackbody photons in a volume V , but with the speed of light c replaced by the speed of sound C_s , and with the photon number of spin states, 2, replaced by $g_s = 3$ (2 for transverse waves plus 1 for longitudinal): $E_{\text{tot}} = a_s T^4 V$, with $a_s = g_s(4\pi^5/15)(k_B^4/(h^3 C_s^3))$ [cf. Eqs. (3.54)].
- (d) Show that the specific heat of the phonon gas (the sound waves) is $C_V = 4a_s T^3 V$. This scales as T^3 , whereas in a metal the specific heat of the degenerate electrons scales as T (previous exercise), so at sufficiently low temperatures the electron specific heat will dominate over that of the phonons.

N

- (e) Show that in the phonon gas, only phonon modes with wavelengths longer than $\sim \lambda_T = C_s h / (k_B T)$ are excited; that is, for $\lambda \ll \lambda_T$ the mean occupation number is $\eta \ll 1$; for $\lambda \sim \lambda_T$, $\eta \sim 1$; and for $\lambda \gg \lambda_T$, $\eta \gg 1$. As T is increased, λ_T gets reduced. Ultimately it becomes of order the interatomic spacing, and our computation fails, because most of the modes that our calculation assumes are thermalized actually don't exist. What is the critical temperature (*Debye temperature*) at which our computation fails and the T^3 law for C_V changes? Show by a roughly one-line argument that above the Debye temperature, C_V is independent of temperature.

Exercise 3.13 *Derivation and Practice: Equation of State for a Photon Gas* N R

- (a) Consider a collection of photons with a distribution function \mathcal{N} that, in the mean rest frame of the photons, is isotropic. Show, using Eqs. (3.49b) and (3.49c), that this photon gas obeys the equation of state $P = \frac{1}{3}\rho$.
- (b) Suppose the photons are thermalized with zero chemical potential (i.e., they are isotropic with a blackbody spectrum). Show that $\rho = aT^4$, where a is the radiation constant of Eq. (3.54c). [Note: Do not hesitate to use Mathematica, Matlab, or Maple, or other computer programs to evaluate integrals!]
- (c) Show that for this isotropic, blackbody photon gas the number density of photons is $n = bT^3$, where b is given by Eq. (3.54b), and that the mean energy of a photon in the gas is

$$\bar{\mathcal{E}}_\gamma = \frac{\pi^4}{30\zeta(3)} k_B T \simeq 2.701 k_B T. \quad (3.62)$$

3.6

3.6 Evolution of the Distribution Function: Liouville's Theorem, the Collisionless Boltzmann Equation, and the Boltzmann Transport Equation N R

We now turn to the issue of how the distribution function $\eta(\mathcal{P}, \vec{p})$, or equivalently, $\mathcal{N} = (g_s/h^3)\eta$, evolves from point to point in phase space. We explore the evolution under the simple assumption that between their very brief collisions, the particles all move freely, uninfluenced by any forces. It is straightforward to generalize to a situation where the particles interact with electromagnetic, gravitational, or other fields as they move, and we do so in Box 3.2, and Sec. 4.3. However, in the body of this chapter, we restrict attention to the common situation of free motion between collisions.

Initially we even rule out collisions; only at the end of this section do we restore them by inserting them as an additional term in our collision-free evolution equation for η .

The foundation for the collision-free evolution law will be *Liouville's theorem*. Consider a set \mathcal{S} of particles that are initially all near some location in phase space

and initially occupy an infinitesimal (frame-independent) phase-space volume $d^2\mathcal{V} = d\mathcal{V}_x d\mathcal{V}_p$. Pick a particle at the center of the set \mathcal{S} and call it the “fiducial particle.” Since all the particles in \mathcal{S} have nearly the same initial position and velocity, they subsequently all move along nearly the same trajectory (world line): they all remain congregated around the fiducial particle. Liouville’s theorem says that the phase-space volume occupied by the set of particles \mathcal{S} is conserved along the trajectory of the fiducial particle:

$$\frac{d}{d\ell}(d\mathcal{V}_x d\mathcal{V}_p) = 0. \tag{3.63}$$

Liouville’s theorem

Here ℓ is an arbitrary parameter along the trajectory. For example, in Newtonian theory ℓ could be universal time t or distance l traveled, and in relativity it could be proper time τ as measured by the fiducial particle (if its rest mass is nonzero) or the affine parameter ζ that is related to the fiducial particle’s 4-momentum by $\vec{p} = d\vec{x}/d\zeta$.

We shall prove Liouville’s theorem with the aid of the diagrams in Fig. 3.9. Assume, for simplicity, that the particles have nonzero rest mass. Consider the region in phase space occupied by the particles, as seen in the inertial reference frame (rest frame) of the fiducial particle, and choose for ℓ the time t of that inertial frame (or in Newtonian theory the universal time t). Choose the particles’ region $d\mathcal{V}_x d\mathcal{V}_p$ at $t = 0$ to be a rectangular box centered on the fiducial particle (i.e., on the origin $x^j = 0$ of its inertial frame; Fig. 3.9a). Examine the evolution with time t of the 2-dimensional slice $y = p_y = z = p_z = 0$ through the occupied region. The evolution of other slices will be similar. Then, as t passes, the particle at location (x, p_x) moves with velocity $dx/dt = p_x/m$ (where the nonrelativistic approximation to the velocity is used, because all the particles are very nearly at rest in the fiducial particle’s inertial frame). Because the particles move freely, each has a conserved p_x , and their motion $dx/dt = p_x/m$ (larger speeds are higher in the diagram) deforms the particles’ phase space region into a skewed parallelogram as shown in Fig. 3.9b. Obviously, the area of the occupied region, $\Delta x \Delta p_x$, is conserved.

FIGURE 3.9 The phase-space region (x - p_x part) occupied by a set \mathcal{S} of particles with finite rest mass, as seen in the inertial frame of the central, fiducial particle. (a) The initial region. (b) The region after a short time.

This same argument shows that the x - p_x area is conserved at *all* values of y, z, p_y, p_z ; similarly for the areas in the y - p_y planes and those in the z - p_z planes. As a consequence, the total volume in phase space, $d\mathcal{V}_x d\mathcal{V}_p = \Delta x \Delta p_x \Delta y \Delta p_y \Delta z \Delta p_z$, is conserved.

Although this proof of Liouville's theorem relies on the assumption that the particles have nonzero rest mass, the theorem is also true for particles with zero rest mass—as one can deduce by taking the relativistic limit as the rest mass goes to zero and the particles' 4-momenta become null.

Since, in the absence of collisions or other nongravitational interactions, the number dN of particles in the set \mathcal{S} is conserved, Liouville's theorem immediately implies the conservation of the number density in phase space, $\mathcal{N} = dN/(d\mathcal{V}_x d\mathcal{V}_p)$:

collisionless Boltzmann equation

$$\frac{d\mathcal{N}}{d\ell} = 0 \quad \text{along the trajectory of a fiducial particle.} \quad (3.64)$$

This conservation law is called the *collisionless Boltzmann equation*; in the context of plasma physics (Part VI) it is sometimes called the *Vlasov equation*. Note that it says that *not only is the distribution function \mathcal{N} frame independent; \mathcal{N} also is constant along the phase-space trajectory of any freely moving particle.*

The collisionless Boltzmann equation is actually far more general than is suggested by the above derivation; see Box 3.2, which is best read after finishing this section.

The collisionless Boltzmann equation is most nicely expressed in the frame-independent form Eq. (3.64). For some purposes, however, it is helpful to express the equation in a form that relies on a specific but arbitrary choice of inertial reference frame. Then \mathcal{N} can be regarded as a function of the reference frame's seven phase-space coordinates, $\mathcal{N} = \mathcal{N}(t, x^j, p_k)$, and the collisionless Boltzmann equation (3.64) takes the coordinate-dependent form

$$\frac{d\mathcal{N}}{d\ell} = \frac{dt}{d\ell} \frac{\partial \mathcal{N}}{\partial t} + \frac{dx_j}{d\ell} \frac{\partial \mathcal{N}}{\partial x_j} + \frac{dp_j}{d\ell} \frac{\partial \mathcal{N}}{\partial p_j} = \frac{dt}{d\ell} \left(\frac{\partial \mathcal{N}}{\partial t} + v_j \frac{\partial \mathcal{N}}{\partial x_j} \right) = 0. \quad (3.65)$$

Here we have used the equation of straight-line motion $dp_j/dt = 0$ for the particles and have set dx_j/dt equal to the particle velocity v_j .

Since our derivation of the collisionless Boltzmann equation relies on the assumption that no particles are created or destroyed as time passes, the collisionless Boltzmann equation in turn should guarantee conservation of the number of particles, $\partial n/\partial t + \nabla \cdot \mathbf{S} = 0$ in Newtonian theory (Sec. 1.8), and $\vec{\nabla} \cdot \vec{S} = 0$ relativistically (Sec. 2.12.3). Indeed, this is so; see Ex. 3.14. Similarly, since the collisionless Boltzmann equation is based on the law of momentum (or 4-momentum) conservation for all the individual particles, it is reasonable to expect that the collisionless Boltzmann equation will guarantee the conservation of their total Newtonian momentum [$\partial \mathbf{G}/\partial t + \nabla \cdot \mathbf{T} = 0$, Eq. (1.36)] and their relativistic 4-momentum [$\vec{\nabla} \cdot \mathbf{T} = 0$,

Eq. (2.73a)]. And indeed, these conservation laws do follow from the collisionless Boltzmann equation; see Ex. 3.14.

Thus far we have assumed that the particles move freely through phase space with no collisions. If collisions occur, they will produce some nonconservation of \mathcal{N} along the trajectory of a freely moving, noncolliding fiducial particle, and correspondingly, the collisionless Boltzmann equation will be modified to read

$$\boxed{\frac{d\mathcal{N}}{d\ell} = \left(\frac{d\mathcal{N}}{d\ell}\right)_{\text{collisions}}}, \quad (3.66)$$

Boltzmann transport equation

where the right-hand side represents the effects of collisions. This equation, with collision terms present, is called the *Boltzmann transport equation*. The actual form of the collision terms depends, of course, on the details of the collisions. We meet some specific examples in the next section [Eqs. (3.79), (3.86a), (3.87), and Ex. 3.21] and in our study of plasmas (Chaps. 22 and 23).

When one applies the collisionless Boltzmann equation or Boltzmann transport equation to a given situation, it is helpful to simplify one's thinking in two ways: (i) Adjust the normalization of the distribution function so it is naturally tuned to the situation. For example, when dealing with photons, I_ν/ν^3 is typically best, and if—as is usually the case—the photons do not change their frequencies as they move and only a single reference frame is of any importance, then I_ν alone may do; see Ex. 3.15. (ii) Adjust the differentiation parameter ℓ so it is also naturally tuned to the situation.

Exercise 3.14 *Derivation and Problem: Collisionless Boltzmann Equation Implies Conservation of Particles and of 4-Momentum* N R

Consider a collection of freely moving, noncolliding particles that satisfy the collisionless Boltzmann equation $d\mathcal{N}/d\ell = 0$.

- Show that this equation guarantees that the Newtonian particle conservation law $\partial n/\partial t + \nabla \cdot \mathbf{S} = 0$ and momentum conservation law $\partial \mathbf{G}/\partial t + \nabla \cdot \mathbf{T} = 0$ are satisfied, where n , \mathbf{S} , \mathbf{G} , and \mathbf{T} are expressed in terms of the distribution function \mathcal{N} by the Newtonian momentum-space integrals (3.32).
- Show that the relativistic Boltzmann equation guarantees the relativistic conservation laws $\vec{\nabla} \cdot \vec{S} = 0$ and $\vec{\nabla} \cdot \mathbf{T} = 0$, where the number-flux 4-vector \vec{S} and the stress-energy tensor \mathbf{T} are expressed in terms of \mathcal{N} by the momentum-space integrals (3.33).

Exercise 3.15 ***Example: Solar Heating of Earth: The Greenhouse Effect* N

In this example we study the heating of Earth by the Sun. Along the way, we derive some important relations for blackbody radiation.

EXERCISES

BOX 3.2. SOPHISTICATED DERIVATION OF RELATIVISTIC COLLISIONLESS BOLTZMANN EQUATION R

Denote by $\vec{X} \equiv \{\mathcal{P}, \vec{p}\}$ a point in 8-dimensional phase space. In an inertial frame the coordinates of \vec{X} are $\{x^0, x^1, x^2, x^3, p_0, p_1, p_2, p_3\}$. [We use up (contravariant) indices on x and down (covariant) indices on p , because this is the form required in Hamilton's equations below; i.e., it is p_α and not p^α that is canonically conjugate to x^α .] Regard \mathcal{N} as a function of location \vec{X} in 8-dimensional phase space. Our particles all have the same rest mass, so \mathcal{N} is nonzero only on the mass hyperboloid, which means that as a function of \vec{X} , \mathcal{N} entails a delta function. For the following derivation, that delta function is irrelevant; the derivation is valid also for distributions of nonidentical particles, as treated in Ex. 3.2.

A particle in our distribution \mathcal{N} at location \vec{X} moves through phase space along a world line with tangent vector $d\vec{X}/d\zeta$, where ζ is its affine parameter. The product $\mathcal{N}d\vec{X}/d\zeta$ represents the number-flux 8-vector of particles through spacetime, as one can see by an argument analogous to Eq. (3.35c). We presume that, as the particles move through phase space, none are created or destroyed. The law of particle conservation in phase space, by analogy with $\vec{\nabla} \cdot \vec{S} = 0$ in spacetime, takes the form $\vec{\nabla} \cdot (\mathcal{N}d\vec{X}/d\zeta) = 0$. In terms of coordinates in an inertial frame, this conservation law says

$$\frac{\partial}{\partial x^\alpha} \left(\mathcal{N} \frac{dx^\alpha}{d\zeta} \right) + \frac{\partial}{\partial p_\alpha} \left(\mathcal{N} \frac{dp_\alpha}{d\zeta} \right) = 0. \quad (1)$$

The motions of individual particles in phase space are governed by Hamilton's equations

$$\frac{dx^\alpha}{d\zeta} = \frac{\partial \mathcal{H}}{\partial p_\alpha}, \quad \frac{dp_\alpha}{d\zeta} = -\frac{\partial \mathcal{H}}{\partial x^\alpha}. \quad (2)$$

For the freely moving particles of this chapter, a convenient form for the relativistic hamiltonian is [cf. Goldstein, Poole, and Safko (2002, Sec. 8.4) or Misner, Thorne, and Wheeler (1973, p. 489), who call it the super-hamiltonian]

$$\mathcal{H} = \frac{1}{2}(p_\alpha p_\beta g^{\alpha\beta} + m^2). \quad (3)$$

Our derivation of the collisionless Boltzmann equation does not depend on this specific form of the hamiltonian; it is valid for any hamiltonian and thus, for example, for particles interacting with an electromagnetic field or even a relativistic gravitational field (spacetime curvature; Part VII). By inserting Hamilton's equations (2) into the 8-dimensional law of particle conservation (1), we obtain

(continued)

BOX 3.2. (continued)

$$\frac{\partial}{\partial x^\alpha} \left(\mathcal{N} \frac{\partial \mathcal{H}}{\partial p_\alpha} \right) - \frac{\partial}{\partial p_\alpha} \left(\mathcal{N} \frac{\partial \mathcal{H}}{\partial x^\alpha} \right) = 0. \quad (4)$$

Using the rule for differentiating products and noting that the terms involving two derivatives of \mathcal{H} cancel, we bring this into the form

$$0 = \frac{\partial \mathcal{N}}{\partial x^\alpha} \frac{\partial \mathcal{H}}{\partial p_\alpha} - \frac{\partial \mathcal{N}}{\partial p_\alpha} \frac{\partial \mathcal{H}}{\partial x^\alpha} = \frac{\partial \mathcal{N}}{\partial x^\alpha} \frac{dx^\alpha}{d\zeta} - \frac{\partial \mathcal{N}}{\partial p_\alpha} \frac{dp_\alpha}{d\zeta} = \frac{d\mathcal{N}}{d\zeta}, \quad (5)$$

which is the collisionless Boltzmann equation. (To get the second expression we have used Hamilton's equations, and the third follows directly from the formulas of differential calculus.) *Thus, the collisionless Boltzmann equation is a consequence of just two assumptions: conservation of particles and Hamilton's equations for the motion of each particle. This implies that the Boltzmann equation has very great generality. We extend and explore this generality in the next chapter.*

Since we will study photon propagation from the Sun to Earth with Doppler shifts playing a negligible role, there is a preferred inertial reference frame: that of the Sun and Earth with their relative motion neglected. We carry out our analysis in that frame. Since we are dealing with thermalized photons, the natural choice for the distribution function is I_ν/ν^3 ; and since we use just one unique reference frame, each photon has a fixed frequency ν , so we can forget about the ν^3 and use I_ν .

- (a) Assume, as is very nearly true, that each spot on the Sun emits blackbody radiation in all outward directions with a common temperature $T_\odot = 5,800$ K. Show, by integrating over the blackbody I_ν , that the total energy flux (i.e., power per unit surface area) F emitted by the Sun is

$$F \equiv \frac{d\mathcal{E}}{dt dA} = \sigma T_\odot^4, \quad \text{where} \quad \sigma = \frac{ac}{4} = \frac{2\pi^5}{15} \frac{k_B^4}{h^3 c^2} = 5.67 \times 10^{-5} \frac{\text{erg}}{\text{cm}^2 \text{ s K}^4}. \quad (3.67)$$

- (b) Since the distribution function I_ν is conserved along each photon's trajectory, observers on Earth, looking at the Sun, see the same blackbody specific intensity I_ν as they would if they were on the Sun's surface, and similarly for any other star. By integrating over I_ν at Earth [and not by the simpler method of using Eq. (3.67) for the flux leaving the Sun], show that the energy flux arriving at Earth is $F = \sigma T_\odot^4 (R_\odot/r)^2$, where $R_\odot = 696,000$ km is the Sun's radius and $r = 1.496 \times 10^8$ km is the mean distance from the Sun to Earth.

- (c) Our goal is to compute the temperature T_{\oplus} of Earth's surface. As a first attempt, assume that all the Sun's flux arriving at Earth is absorbed by Earth's surface, heating it to the temperature T_{\oplus} , and then is reradiated into space as blackbody radiation at temperature T_{\oplus} . Show that this leads to a surface temperature of

$$T_{\oplus} = T_{\odot} \left(\frac{R_{\odot}}{2r} \right)^{1/2} = 280 \text{ K} = 7 \text{ }^{\circ}\text{C}. \quad (3.68)$$

This is a bit cooler than the correct mean surface temperature (287 K = 14 °C).

- (d) Actually, Earth has an albedo of $A \simeq 0.30$, which means that 30% of the sunlight that falls onto it gets reflected back into space with an essentially unchanged spectrum, rather than being absorbed. Show that with only a fraction $1 - A = 0.70$ of the solar radiation being absorbed, the above estimate of Earth's temperature becomes

$$T_{\oplus} = T_{\odot} \left(\frac{\sqrt{1 - A} R_{\odot}}{2r} \right)^{1/2} = 256 \text{ K} = -17 \text{ }^{\circ}\text{C}. \quad (3.69)$$

This is even farther from the correct answer.

- (e) The missing piece of physics, which raises the temperature from $-17 \text{ }^{\circ}\text{C}$ to something much nearer the correct $14 \text{ }^{\circ}\text{C}$, is the *greenhouse effect*: The absorbed solar radiation has most of its energy at wavelengths $\sim 0.5 \mu\text{m}$ (in the visual band), which pass rather easily through Earth's atmosphere. By contrast, the blackbody radiation that Earth's surface wants to radiate back into space, with its temperature $\sim 300 \text{ K}$, is concentrated in the infrared range from $\sim 8 \mu\text{m}$ to $\sim 30 \mu\text{m}$. Water molecules, carbon dioxide and methane in Earth's atmosphere absorb about 40% of the energy that Earth tries to reradiate at these energies (Cox, 2000, Sec. 11.22), causing the reradiated energy to be about 60% that of a blackbody at Earth's surface temperature. Show that with this (oversimplified!) greenhouse correction, T_{\oplus} becomes about $290 \text{ K} = +17 \text{ }^{\circ}\text{C}$, which is within a few degrees of the true mean temperature. There is overwhelming evidence that the measured increase in the average Earth temperature in recent decades is mostly caused by the measured increase in carbon dioxide and methane, which, in turn, is mostly due to human activity. Although the atmospheric chemistry is not well enough understood to make accurate predictions, mankind is performing a very dangerous experiment.

Exercise 3.16 ***Challenge: Olbers' Paradox and Solar Furnace* N

Consider a universe (not ours!) in which spacetime is flat and infinite in size and is populated throughout by stars that cluster into galaxies like our own and our neighbors, with interstellar and intergalactic distances similar to those in our neighborhood. Assume that the galaxies are *not* moving apart—there is no universal expansion. Using the collisionless Boltzmann equation for photons, show that Earth's temperature in this universe would be about the same as the surface temperatures of the universe's hotter stars, $\sim 10,000 \text{ K}$, so we would all be fried. This is Olbers' Paradox. What features of our universe protect us from this fate?

Motivated by this model universe, describe a design for a furnace that relies on sunlight for its heat and achieves a temperature nearly equal to that of the Sun's surface, 5,800 K.

3.7 Transport Coefficients N

3.7

In this section we turn to a practical application of kinetic theory: the computation of *transport coefficients*. Our primary objective is to illustrate the use of kinetic theory, but the transport coefficients themselves are also of interest: they play important roles in Parts V and VI (Fluid Dynamics and Plasma Physics) of this book.

What are transport coefficients? An example is electrical conductivity κ_e . When an electric field \mathbf{E} is imposed on a sample of matter, Ohm's law tells us that the matter responds by developing a current density

electrical conductivity

$$\mathbf{j} = \kappa_e \mathbf{E}. \quad (3.70a)$$

The electrical conductivity is high if electrons can move through the material with ease; it is low if electrons have difficulty moving. The impediment to electron motion is scattering off other particles—off ions, other electrons, phonons (sound waves), plasmons (plasma waves), Ohm's law is valid when (as almost always) the electrons scatter many times, so they *diffuse* (random-walk their way) through the material. To compute the electrical conductivity, one must analyze, statistically, the effects of the many scatterings on the electrons' motions. The foundation for an accurate analysis is the Boltzmann transport equation (3.66).

Another example of a transport coefficient is thermal conductivity κ , which appears in the law of heat conduction

thermal conductivity

$$\mathbf{F} = -\kappa \nabla T. \quad (3.70b)$$

Here \mathbf{F} is the diffusive energy flux from regions of high temperature T to low. The impediment to heat flow is scattering of the conducting particles; and, correspondingly, the foundation for accurately computing κ is the Boltzmann transport equation.

Other examples of transport coefficients are (i) the coefficient of shear viscosity η_{shear} , which determines the stress T_{ij} (diffusive flux of momentum) that arises in a shearing fluid [Eq. (13.68)]

coefficient of shear viscosity

$$T_{ij} = -2\eta_{\text{shear}}\sigma_{ij}, \quad (3.70c)$$

where σ_{ij} is the fluid's rate of shear (Ex. 3.19), and (ii) the diffusion coefficient D , which determines the diffusive flux of particles \mathbf{S} from regions of high particle density n to low (Fick's law):

diffusion coefficient

$$\mathbf{S} = -D\nabla n. \quad (3.70d)$$

There is a *diffusion equation* associated with each of these transport coefficients. For example, the differential law of particle conservation $\partial n/\partial t + \nabla \cdot \mathbf{S} = 0$ [Eq. (1.30)], when applied to material in which the particles scatter many times so $\mathbf{S} = -D\nabla n$, gives the following diffusion equation for the particle number density:

diffusion equation

$$\boxed{\frac{\partial n}{\partial t} = D\nabla^2 n}, \quad (3.71)$$

where we have assumed that D is spatially constant. In Ex. 3.17, by exploring solutions to this equation, we shall see that the root mean square (rms) distance \bar{l} the particles travel is proportional to the square root of their travel time, $\bar{l} = \sqrt{4Dt}$, a behavior characteristic of diffusive random walks.¹⁰ See Sec. 6.3 for deeper insights into this.

Similarly, the law of energy conservation, when applied to diffusive heat flow $\mathbf{F} = -\kappa\nabla T$, leads to a diffusion equation for the thermal energy density U and thence for temperature [Ex. 3.18 and Eq. (18.4)]. Maxwell's equations in a magnetized fluid, when combined with Ohm's law $\mathbf{j} = \kappa_e \mathbf{E}$, lead to diffusion equation (19.6) for magnetic field lines. And the law of angular momentum conservation, when applied to a shearing fluid with $T_{ij} = -2\eta_{\text{shear}}\sigma_{ij}$, leads to diffusion equation (14.6) for vorticity.

These diffusion equations, and all other physical laws involving transport coefficients, are approximations to the real world—approximations that are valid if and only if (i) many particles are involved in the transport of the quantity of interest (e.g., charge, heat, momentum, particles) and (ii) on average each particle undergoes many scatterings in moving over the length scale of the macroscopic inhomogeneities that drive the transport. This second requirement can be expressed quantitatively in terms of the *mean free path* λ between scatterings (i.e., the mean distance a particle travels between scatterings, as measured in the mean rest frame of the matter) and the *macroscopic inhomogeneity scale* \mathcal{L} for the quantity that drives the transport (e.g., in heat transport that scale is $\mathcal{L} \sim T/|\nabla T|$; i.e., it is the scale on which the temperature changes by an amount of order itself). In terms of these quantities, the second criterion of validity is $\lambda \ll \mathcal{L}$. These two criteria (many particles and $\lambda \ll \mathcal{L}$) together are called *diffusion criteria*, since they guarantee that the quantity being transported (charge, heat, momentum, particles) will diffuse through the matter. If either of the two diffusion criteria fails, then the standard transport law (Ohm's law, the law of heat conduction, the Navier-Stokes equation, or the particle diffusion equation) breaks down and the corresponding transport coefficient becomes irrelevant and meaningless.

mean free path

diffusion criteria

The accuracy with which one can compute a transport coefficient using the Boltzmann transport equation depends on the accuracy of one's description of the scattering. If one uses a high-accuracy collision term $(d\mathcal{N}/d\ell)_{\text{collisions}}$ in the Boltzmann

10. Einstein derived this diffusion law $\bar{l} = \sqrt{4Dt}$, and he used it and his formula for the diffusion coefficient D , along with observational data about the diffusion of sugar molecules in water, to demonstrate the physical reality of molecules, determine their sizes, and deduce the numerical value of Avogadro's number; see the historical discussion in Pais (1982, Chap. 5).

equation, one can derive a highly accurate transport coefficient. If one uses a very crude approximation for the collision term, the resulting transport coefficient might be accurate only to within an order of magnitude—in which case, it was probably not worth the effort to use the Boltzmann equation; a simple order-of-magnitude argument would have done just as well. If the interaction between the diffusing particles and the scatterers is electrostatic or gravitational (long-range $1/r^2$ interaction forces), then the particles cannot be idealized as moving freely between collisions, and an accurate computation of transport coefficients requires a more sophisticated analysis: the Fokker-Planck equation developed in Sec. 6.9 and discussed, for plasmas, in Secs. 20.4.3 and 20.5.

In the following three subsections, we compute the coefficient of thermal conductivity κ for hot gas inside a star (where short-range collisions hold sway and the Boltzmann transport equation is highly accurate). We do so first by an order-of-magnitude argument and then by the Boltzmann equation with an accurate collision term. In Exs. 3.19 and 3.20, readers have the opportunity to compute the coefficient of viscosity and the diffusion coefficient for particles using moderately accurate collision terms, and in Ex. 3.21 (neutron diffusion in a nuclear reactor), we will meet diffusion in momentum space, by contrast with diffusion in physical space.

Exercise 3.17 ***Example: Solution of Diffusion Equation in an Infinite*

Homogeneous Medium N

EXERCISES

- (a) Show that the following is a solution to the diffusion equation (3.71) for particles in a homogeneous infinite medium:

$$n = \frac{N}{(4\pi Dt)^{3/2}} e^{-r^2/(4Dt)}, \quad (3.72)$$

(where $r \equiv \sqrt{x^2 + y^2 + z^2}$ is radius), and that it satisfies $\int n dV_x = N$, so N is the total number of particles. Note that this is a Gaussian distribution with width $\sigma = \sqrt{4Dt}$. Plot this solution for several values of σ . In the limit as $t \rightarrow 0$, the particles are all localized at the origin. As time passes, they random-walk (diffuse) away from the origin, traveling a mean distance $\alpha\sigma = \alpha\sqrt{4Dt}$ after time t , where α is a coefficient of order one. We will meet this square-root-of-time evolution in other random-walk situations elsewhere in this book; see especially Exs. 6.3 and 6.4, and Sec. 6.7.2.

- (b) Suppose that the particles have an arbitrary initial distribution $n_o(\mathbf{x})$ at time $t = 0$. Show that their distribution at a later time t is given by the following Green's-function integral:

$$n(\mathbf{x}, t) = \int \frac{n_o(\mathbf{x}')}{(4\pi Dt)^{3/2}} e^{-|\mathbf{x}-\mathbf{x}'|^2/(4Dt)} dV_{x'}. \quad (3.73)$$

- (c) What form does the solution take in one dimension? And in two dimensions?

N

Exercise 3.18 **Problem: Diffusion Equation for Temperature

N

Use the law of energy conservation to show that, when heat diffuses through a homogeneous medium whose pressure is being kept fixed, the evolution of the temperature perturbation $\delta T \equiv T - \langle T \rangle$ (average temperature) is governed by the diffusion equation

$$\frac{\partial T}{\partial t} = \chi \nabla^2 T, \quad \text{where} \quad \chi = \kappa / (\rho c_p) \quad (3.74)$$

is called the *thermal diffusivity*. Here c_p is the specific heat per unit mass at fixed pressure, and ρc_p is that specific heat per unit volume. For the extension of this to heat flow in a moving fluid, see Eq. (18.4).

3.7.1

3.7.1 Diffusive Heat Conduction inside a Star

N

photon diffusion through scattering electrons

The specific transport-coefficient problem we treat here is for heat transport through hot gas deep inside a young, massive star. We confine attention to that portion of the star in which the temperature is $10^7 \text{ K} \lesssim T \lesssim 10^9 \text{ K}$, the mass density is $\rho \lesssim 10 \text{ g cm}^{-3} (T/10^7 \text{ K})^2$, and heat is carried primarily by diffusing photons rather than by diffusing electrons or ions or by convection. (We study convection in Chap. 18.) In this regime the primary impediment to the photons' flow is collisions with electrons. The lower limit on temperature, 10^7 K , guarantees that the gas is almost fully ionized, so there is a plethora of electrons to do the scattering. The upper limit on density, $\rho \sim 10 \text{ g cm}^{-3} (T/10^7 \text{ K})^2$, guarantees that (i) the inelastic scattering, absorption, and emission of photons by electrons accelerating in the Coulomb fields of ions (bremsstrahlung processes) are unimportant as impediments to heat flow compared to scattering off free electrons and (ii) the scattering electrons are nondegenerate (i.e., they have mean occupation numbers η small compared to unity) and thus behave like classical, free, charged particles. The upper limit on temperature, $T \sim 10^9 \text{ K}$, guarantees that (i) the electrons doing the scattering are moving thermally at much less than the speed of light (the mean thermal energy $\frac{3}{2} k_B T$ of an electron is much less than its rest mass-energy $m_e c^2$) and (ii) the scattering is nearly elastic, with negligible energy exchange between photon and electron, and is describable with good accuracy by the *Thomson scattering cross section*.

In the rest frame of the electron (which to good accuracy will be the same as the mean rest frame of the gas, since the electron's speed relative to the mean rest frame is $\ll c$), the differential cross section $d\sigma$ for a photon to scatter from its initial propagation direction \mathbf{n}' into a unit solid angle $d\Omega$ centered on a new propagation direction \mathbf{n} is

$$\frac{d\sigma(\mathbf{n}' \rightarrow \mathbf{n})}{d\Omega} = \frac{3}{16\pi} \sigma_T [1 + (\mathbf{n} \cdot \mathbf{n}')^2]. \quad (3.75a)$$

Here σ_T is the total Thomson cross section [the integral of the differential cross section (3.75a) over solid angle]:

$$\sigma_T = \int \frac{d\sigma(\mathbf{n}' \rightarrow \mathbf{n})}{d\Omega} d\Omega = \frac{8\pi}{3} r_o^2 = 0.665 \times 10^{-24} \text{ cm}^2, \quad (3.75b)$$

Thomson cross section

where $r_o = e^2/(m_e c^2)$ is the classical electron radius. [For a derivation and discussion of the Thomson cross sections (3.75), see, e.g., Jackson (1999, Sec. 14.8).]

3.7.2 Order-of-Magnitude Analysis N

3.7.2

Before embarking on any complicated calculation, it is always helpful to do a rough, order-of-magnitude analysis, thereby identifying the key physics and the approximate answer. The first step of a rough analysis of our heat transport problem is to identify the magnitudes of the relevant lengthscales. The inhomogeneity scale \mathcal{L} for the temperature, which drives the heat flow, is the size of the hot stellar core, a moderate fraction of the Sun's radius: $\mathcal{L} \sim 10^5$ km. The mean free path of a photon can be estimated by noting that, since each electron presents a cross section σ_T to the photon and there are n_e electrons per unit volume, the probability of a photon being scattered when it travels a distance l through the gas is of order $n_e \sigma_T l$. Therefore, to build up to unit probability for scattering, the photon must travel a distance

$$\lambda \sim \frac{1}{n_e \sigma_T} \sim \frac{m_p}{\rho \sigma_T} \sim 3 \text{ cm} \left(\frac{1 \text{ g cm}^{-3}}{\rho} \right) \sim 3 \text{ cm}. \tag{3.76}$$

photon mean free path

Here m_p is the proton rest mass, $\rho \sim 1 \text{ g cm}^{-3}$ is the mass density in the core of a young, massive star, and we have used the fact that stellar gas is mostly hydrogen to infer that there is approximately one nucleon per electron in the gas and hence that $n_e \sim \rho/m_p$. Note that $\mathcal{L} \sim 10^5$ km is 3×10^9 times larger than $\lambda \sim 3$ cm, and the number of electrons and photons inside a cube of side \mathcal{L} is enormous, so the diffusion description of heat transport is highly accurate.

In the diffusion description, the heat flux \mathbf{F} as measured in the gas's rest frame is related to the temperature gradient ∇T by the law of diffusive heat conduction $\mathbf{F} = -\kappa \nabla T$. To estimate the thermal conductivity κ , orient the coordinates so the temperature gradient is in the z direction, and consider the rate of heat exchange between a gas layer located near $z = 0$ and a layer one photon mean free path away, at $z = \lambda$ (Fig. 3.10). The heat exchange is carried by photons that are emitted from one layer, propagate nearly unimpeded to the other, and then scatter. Although the individual scatterings are nearly elastic (and we thus are ignoring changes of photon

FIGURE 3.10 Heat exchange between two layers of gas separated by a distance of one photon mean free path in the direction of the gas's temperature gradient.

N

frequency in the Boltzmann equation), tiny changes of photon energy add up over many scatterings to keep the photons nearly in local thermal equilibrium with the gas. Thus, we approximate the photons and gas in the layer at $z = 0$ to have a common temperature T_0 and those in the layer at $z = \lambda$ to have a common temperature $T_\lambda = T_0 + \lambda dT/dz$. Then the photons propagating from the layer at $z = 0$ to that at $z = \lambda$ carry an energy flux

$$F_{0 \rightarrow \lambda} = \alpha ca(T_0)^4, \quad (3.77a)$$

where a is the radiation constant of Eq. (3.54c); $a(T_0)^4$ is the photon energy density at $z = 0$; and α is a dimensionless constant of order 1/4 that accounts for what fraction of the photons at $z = 0$ are moving rightward rather than leftward, and at what mean angle to the z direction. (Throughout this section, by contrast with early sections of this chapter, we use nongeometrized units, with the speed of light c present explicitly.) Similarly, the flux of energy from the layer at $z = \lambda$ to the layer at $z = 0$ is

$$F_{\lambda \rightarrow 0} = -\alpha ca(T_\lambda)^4; \quad (3.77b)$$

and the net rightward flux, the sum of Eqs. (3.77a) and (3.77b), is

$$F = \alpha ca[(T_0)^4 - (T_\lambda)^4] = -4\alpha caT^3\lambda \frac{dT}{dz}. \quad (3.77c)$$

Noting that 4α is approximately 1, inserting expression (3.76) for the photon mean free path, and comparing with the law of diffusive heat flow $\mathbf{F} = -\kappa \nabla T$, we conclude that the thermal conductivity is

$$\kappa \sim aT^3c\lambda = \frac{acT^3}{\sigma_T n_e}. \quad (3.78)$$

thermal conductivity:
order of magnitude
estimate

3.7.3

3.7.3 Analysis Using the Boltzmann Transport Equation N

With these physical insights and rough answer in hand, we turn to a Boltzmann transport analysis of the heat transfer. Our first step is to formulate the Boltzmann transport equation for the photons (including effects of Thomson scattering off the electrons) in the rest frame of the gas. Our second step will be to solve that equation to determine the influence of the heat flow on the distribution function \mathcal{N} , and our third step will be to compute the thermal conductivity κ by an integral over that \mathcal{N} .

To simplify the analysis we use, as the parameter ℓ in the Boltzmann transport equation $d\mathcal{N}/d\ell = (d\mathcal{N}/d\ell)_{\text{collisions}}$, the distance l that a fiducial photon travels, and we regard the distribution function \mathcal{N} as a function of location \mathbf{x} in space, the photon propagation direction (unit vector) \mathbf{n} , and the photon frequency ν : $\mathcal{N}(\mathbf{x}, \mathbf{n}, \nu)$. Because the photon frequency does not change during free propagation or Thomson scattering, it can be treated as a constant when solving the Boltzmann equation.

Along the trajectory of a fiducial photon, $\mathcal{N}(\mathbf{x}, \mathbf{n}, \nu)$ will change as a result of two things: (i) the scattering of photons out of the \mathbf{n} direction and into other directions and (ii) the scattering of photons from other directions \mathbf{n}' into the \mathbf{n} direction. These

effects produce the following two collision terms in the Boltzmann transport equation (3.66):

$$\frac{d\mathcal{N}(\mathbf{x}, \mathbf{n}, \nu)}{dl} = -\sigma_T n_e \mathcal{N}(\mathbf{x}, \mathbf{n}, \nu) + \int \frac{d\sigma(\mathbf{n}' \rightarrow \mathbf{n})}{d\Omega} n_e \mathcal{N}(\mathbf{x}, \mathbf{n}', \nu) d\Omega'. \quad (3.79)$$

(The second scattering term would be more obvious if we were to use I_ν (which is per unit solid angle) as our distribution function rather than \mathcal{N} ; but they just differ by a constant.) Because the mean free path $\lambda = 1/(\sigma_T n_e) \sim 3$ cm is so short compared to the length scale $\mathcal{L} \sim 10^5$ km of the temperature gradient, the heat flow will show up as a tiny correction to an otherwise isotropic, perfectly thermal distribution function. Thus, we can write the photon distribution function as the sum of an unperturbed, perfectly isotropic and thermalized piece \mathcal{N}_0 and a tiny, anisotropic perturbation \mathcal{N}_1 :

$$\mathcal{N} = \mathcal{N}_0 + \mathcal{N}_1, \quad \text{where } \mathcal{N}_0 = \frac{2}{h^3} \frac{1}{e^{h\nu/(k_B T)} - 1}. \quad (3.80a)$$

Here the perfectly thermal piece $\mathcal{N}_0(\mathbf{x}, \mathbf{n}, \nu)$ has the standard blackbody form (3.23); it is independent of \mathbf{n} , and it depends on \mathbf{x} only through the temperature $T = T(\mathbf{x})$. If the photon mean free path were vanishingly small, there would be no way for photons at different locations \mathbf{x} to discover that the temperature is inhomogeneous; correspondingly, \mathcal{N}_1 would be vanishingly small. The finiteness of the mean free path permits \mathcal{N}_1 to be finite, and so it is reasonable to expect (and turns out to be true) that the magnitude of \mathcal{N}_1 is

$$\mathcal{N}_1 \sim \frac{\lambda}{\mathcal{L}} \mathcal{N}_0. \quad (3.80b)$$

Thus, \mathcal{N}_0 is the leading-order term, and \mathcal{N}_1 is the first-order correction in an expansion of the distribution function \mathcal{N} in powers of λ/\mathcal{L} . This is called a *two-lengthscale expansion*; see Box 3.3.

Inserting $\mathcal{N} = \mathcal{N}_0 + \mathcal{N}_1$ into our Boltzmann transport equation (3.79) and using $d/dl = \mathbf{n} \cdot \nabla$ for the derivative with respect to distance along the fiducial photon trajectory, we obtain

$$\begin{aligned} n_j \frac{\partial \mathcal{N}_0}{\partial x_j} + n_j \frac{\partial \mathcal{N}_1}{\partial x_j} = & \left[-\sigma_T n_e \mathcal{N}_0 + \int \frac{d\sigma(\mathbf{n}' \rightarrow \mathbf{n})}{d\Omega} n_e c \mathcal{N}_0 d\Omega' \right] \\ & + \left[-\sigma_T n_e c \mathcal{N}_1(\mathbf{n}, \nu) + \int \frac{d\sigma(\mathbf{n}' \rightarrow \mathbf{n})}{d\Omega} n_e c \mathcal{N}_1(\mathbf{n}', \nu) d\Omega' \right]. \end{aligned} \quad (3.80c)$$

Because \mathcal{N}_0 is isotropic (i.e., is independent of photon direction \mathbf{n}'), it can be pulled out of the integral over \mathbf{n}' in the first square bracket on the right-hand side. When this is done, the first and second terms in that square bracket cancel each other. Thus, the unperturbed part of the distribution, \mathcal{N}_0 , completely drops out of the right-hand side of Eq. (3.80c). On the left-hand side the term involving the perturbation \mathcal{N}_1 is tiny compared to that involving the unperturbed distribution \mathcal{N}_0 , so we shall drop it.

Boltzmann transport equation for diffusing photons

expand \mathcal{N} in powers of λ/\mathcal{L}

perturbative Boltzmann equation for \mathcal{N}_1

BOX 3.3. TWO-LENGTHSCALE EXPANSIONS

Equation (3.80b) is indicative of the mathematical technique that underlies Boltzmann-transport computations: a perturbative expansion in the dimensionless ratio of two lengthscales, the tiny mean free path λ of the transporter particles and the far larger macroscopic scale \mathcal{L} of the inhomogeneities that drive the transport. Expansions in lengthscales ratios λ/\mathcal{L} are called *two-lengthscale expansions* and are widely used in physics and engineering. Most readers will previously have met such an expansion in quantum mechanics: the WKB approximation, where λ is the lengthscales on which the wave function changes, and \mathcal{L} is the scale of changes in the potential $V(x)$ that drives the wave function. Kinetic theory itself is the result of a two-lengthscale expansion: it follows from the more sophisticated statistical-mechanics formalism of Chap. 4, in the limit where the particle sizes are small compared to their mean free paths. In this book we use two-lengthscale expansions frequently—for instance, in the geometric optics approximation to wave propagation (Chap. 7), in the study of boundary layers in fluid mechanics (Secs. 14.4, 14.5.4, and 15.5), in the quasi-linear formalism for plasma physics (Chap. 23), and in the definition of a gravitational wave (Sec. 27.4).

Because the spatial dependence of \mathcal{N}_0 is entirely due to the temperature gradient, we can bring the first term and the whole transport equation into the form

$$n_j \frac{\partial T}{\partial x_j} \frac{\partial \mathcal{N}_0}{\partial T} = -\sigma_T n_e \mathcal{N}_1(\mathbf{n}, \nu) + \int \frac{d\sigma(\mathbf{n}' \rightarrow \mathbf{n})}{d\Omega} n_e \mathcal{N}_1(\mathbf{n}', \nu) d\Omega'. \quad (3.80d)$$

The left-hand side of this equation is the amount by which the temperature gradient causes \mathcal{N}_0 to fail to satisfy the Boltzmann equation, and the right-hand side is the manner in which the perturbation \mathcal{N}_1 steps into the breach and enables the Boltzmann equation to be satisfied.

Because the left-hand side is linear in the photon propagation direction n_j (i.e., it has a $\cos \theta$ dependence in coordinates where ∇T is in the z -direction; i.e., it has a dipolar, $l = 1$, angular dependence), \mathcal{N}_1 must also be linear in n_j (i.e., dipolar), in order to fulfill Eq. (3.80d). Thus, we write \mathcal{N}_1 in the dipolar form

$$\mathcal{N}_1 = K_j(\mathbf{x}, \nu) n_j, \quad (3.80e)$$

and we shall solve the transport equation (3.80d) for the function K_j .

[Side remark: This is a special case of a general situation. When solving the Boltzmann transport equation in diffusion situations, one is performing a power series expansion in λ/\mathcal{L} ; see Box 3.3. The lowest-order term in the expansion, \mathcal{N}_0 , is isotropic (i.e., it is monopolar in its dependence on the direction of motion of the

multipolar expansion of \mathcal{N}

diffusing particles). The first-order correction, \mathcal{N}_1 , is down in magnitude by λ/\mathcal{L} from \mathcal{N}_0 and is dipolar (or sometimes quadrupolar; see Ex. 3.19) in its dependence on the particles' direction of motion. The second-order correction, \mathcal{N}_2 , is down in magnitude by $(\lambda/\mathcal{L})^2$ from \mathcal{N}_0 and its multipolar order is one higher than \mathcal{N}_1 (quadrupolar here; octupolar in Ex. 3.19). And so it continues to higher and higher orders.^{11]}

When we insert the dipolar expression (3.80e) into the angular integral on the right-hand side of the transport equation (3.80d) and notice that the differential scattering cross section (3.75a) is unchanged under $\mathbf{n}' \rightarrow -\mathbf{n}'$, but $K_j n'_j$ changes sign, we find that the integral vanishes. As a result the transport equation (3.80d) takes the simplified form

$$n_j \frac{\partial T}{\partial x_j} \frac{\partial \mathcal{N}_0}{\partial T} = -\sigma_T n_e K_j n_j, \quad (3.80f)$$

from which we can read off the function K_j and thence $\mathcal{N}_1 = K_j n_j$:

$$\mathcal{N}_1 = -\frac{\partial \mathcal{N}_0 / \partial T}{\sigma_T n_e} \frac{\partial T}{\partial x_j} n_j. \quad (3.80g)$$

solution for \mathcal{N}_1

Notice that, as claimed in Eq. (3.80b), the perturbation has a magnitude

$$\frac{\mathcal{N}_1}{\mathcal{N}_0} \sim \frac{1}{\sigma_T n_e} \frac{1}{T} |\nabla T| \sim \frac{\lambda}{\mathcal{L}}. \quad (3.80h)$$

Having solved the Boltzmann transport equation to obtain \mathcal{N}_1 , we can now evaluate the energy flux F_i carried by the diffusing photons. Relativity physicists will recognize that flux as the T^{0i} part of the stress-energy tensor and will therefore evaluate it as

$$F_i = T^{0i} = c^2 \int \mathcal{N} p^0 p^i \frac{d\mathcal{V}_p}{p^0} = c^2 \int \mathcal{N} p_i d\mathcal{V}_p \quad (3.81)$$

[cf. Eq. (3.33c) with the factors of c restored]. Newtonian physicists can deduce this formula by noticing that photons with momentum \mathbf{p} in $d\mathcal{V}_p$ carry energy $E = |\mathbf{p}|c$ and move with velocity $\mathbf{v} = c\mathbf{p}/|\mathbf{p}|$, so their energy flux is $\mathcal{N} E \mathbf{v} d\mathcal{V}_p = c^2 \mathcal{N} \mathbf{p} d\mathcal{V}_p$; integrating this over momentum space gives Eq. (3.81). Inserting $\mathcal{N} = \mathcal{N}_0 + \mathcal{N}_1$ into this equation and noting that the integral over \mathcal{N}_0 vanishes, and inserting Eq. (3.80g) for \mathcal{N}_1 , we obtain

$$F_i = c^2 \int \mathcal{N}_1 p_i d\mathcal{V}_p = -\frac{c}{\sigma_T n_e} \frac{\partial T}{\partial x_j} \frac{\partial}{\partial T} \int \mathcal{N}_0 c n_j p_i d\mathcal{V}_p. \quad (3.82a)$$

energy flux from \mathcal{N}_1

The relativity physicist will identify this integral as Eq. (3.33c) for the photons' stress tensor T_{ij} (since $n_j = p_j/p_0 = p_j/\mathcal{E}$). The Newtonian physicist, with a little thought, will recognize the integral in Eq. (3.82a) as the j component of the flux of i component

11. For full details of this “method-of-moments” analysis in nonrelativistic situations, see, e.g., Grad (1958); and for full relativistic details, see, e.g., Thorne (1981).

of momentum, which is precisely the stress tensor. Since this stress tensor is being computed with the isotropic, thermalized part of \mathcal{N} , it is isotropic, $T_{ji} = P\delta_{ji}$, and its pressure has the standard blackbody-radiation form $P = \frac{1}{3}aT^4$ [Eqs. (3.54a)]. Replacing the integral in Eq. (3.82a) by this blackbody stress tensor, we obtain our final answer for the photons' energy flux:

$$F_i = -\frac{c}{\sigma_{\text{T}}n_e} \frac{\partial T}{\partial x_j} \frac{d}{dT} \left(\frac{1}{3}aT^4\delta_{ji} \right) = -\frac{c}{\sigma_{\text{T}}n_e} \frac{4}{3}aT^3 \frac{\partial T}{\partial x_i}. \quad (3.82b)$$

Thus, from the Boltzmann transport equation we have simultaneously derived the law of diffusive heat conduction $\mathbf{q} = -\kappa\nabla T$ and evaluated the coefficient of thermal conductivity

$$\kappa = \frac{4}{3} \frac{acT^3}{\sigma_{\text{T}}n_e}. \quad (3.83)$$

Notice that this heat conductivity is 4/3 times our crude, order-of-magnitude estimate (3.78).

The above calculation, while somewhat complicated in its details, is conceptually fairly simple. The reader is encouraged to go back through the calculation and identify the main conceptual steps [expansion of distribution function in powers of λ/\mathcal{L} , insertion of zero-order plus first-order parts into the Boltzmann equation, multipolar decomposition of the zero- and first-order parts (with zero-order being monopolar and first-order being dipolar), neglect of terms in the Boltzmann equation that are smaller than the leading ones by factors λ/\mathcal{L} , solution for the coefficient of the multipolar decomposition of the first-order part, reconstruction of the first-order part from that coefficient, and insertion into a momentum-space integral to get the flux of the quantity being transported]. Precisely these same steps are used to evaluate all other transport coefficients that are governed by classical physics. [For examples of other such calculations, see, e.g., Shkarofsky, Johnston, and Bachynski (1966).]

As an application of the thermal conductivity (3.83), consider a young (main-sequence) 7-solar-mass ($7 M_{\odot}$) star as modeled, for example, on pages 480 and 481 of Clayton (1968). Just outside the star's convective core, at radius $r \simeq 0.7R_{\odot} \simeq 5 \times 10^5 \text{ km}$ (where R_{\odot} is the Sun's radius), the density and temperature are $\rho \simeq 5.5 \text{ g cm}^{-3}$ and $T \simeq 1.9 \times 10^7 \text{ K}$, so the number density of electrons is $n_e \simeq \rho/(1.4m_p) \simeq 2.3 \times 10^{24} \text{ cm}^{-3}$ where the 1.4 accounts for the star's chemical composition. For these parameters, Eq. (3.83) gives a thermal conductivity $\kappa \simeq 1.3 \times 10^{18} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ K}^{-1}$. The lengthscale \mathcal{L} on which the temperature is changing is approximately the same as the radius, so the temperature gradient is $|\nabla T| \sim T/r \sim 4 \times 10^{-4} \text{ K cm}^{-1}$. The law of diffusive heat transfer then predicts a heat flux $F = \kappa|\nabla T| \sim 5 \times 10^{14} \text{ erg s}^{-1} \text{ cm}^{-2}$, and thus a total luminosity $L = 4\pi r^2 F \sim 1.5 \times 10^{37} \text{ erg s}^{-1} \simeq 4000L_{\odot}$ (4,000 solar luminosities). (This estimate is a little high. The correct value is about $3,600L_{\odot}$.) What a difference the mass makes! The heavier a star, the hotter its core, the faster it burns, and the higher its luminosity will be. Increasing the mass by a factor of 7 drives the luminosity up by 4,000.

from Boltzmann transport
equation

Exercise 3.19 **Example: Viscosity of a Monatomic Gas

Consider a nonrelativistic fluid that, in the neighborhood of the origin, has fluid velocity

$$v_i = \sigma_{ij}x_j, \quad (3.84)$$

with σ_{ij} symmetric and trace-free. As we shall see in Sec. 13.7.1, this represents a purely shearing flow, with no rotation or volume changes of fluid elements; σ_{ij} is called the fluid's *rate of shear*. Just as a gradient of temperature produces a diffusive flow of heat, so the gradient of velocity embodied in σ_{ij} produces a diffusive flow of momentum (i.e., a stress). In this exercise we use kinetic theory to show that, for a monatomic gas with isotropic scattering of atoms off one another, this stress is

$$T_{ij} = -2\eta_{\text{shear}}\sigma_{ij}, \quad (3.85a)$$

with the coefficient of shear viscosity

$$\eta_{\text{shear}} \simeq \frac{1}{3}\rho\lambda v_{th}, \quad (3.85b)$$

where ρ is the gas density, λ is the atoms' mean free path between collisions, and $v_{th} = \sqrt{3k_B T/m}$ is the atoms' rms speed. Our analysis follows the same route as the analysis of heat conduction in Secs. 3.7.2 and 3.7.3.

- Derive Eq. (3.85b) for the shear viscosity, to within a factor of order unity, by an order-of-magnitude analysis like that in Sec. 3.7.2.
- Regard the atoms' distribution function \mathcal{N} as being a function of the magnitude p and direction \mathbf{n} of an atom's momentum, and of location \mathbf{x} in space. Show that, if the scattering is isotropic with cross section σ_s and the number density of atoms is n , then the Boltzmann transport equation can be written as

$$\frac{d\mathcal{N}}{dl} = \mathbf{n} \cdot \nabla \mathcal{N} = -\frac{1}{\lambda}\mathcal{N} + \int \frac{1}{4\pi\lambda}\mathcal{N}(p, \mathbf{n}', \mathbf{x})d\Omega', \quad (3.86a)$$

where $\lambda = 1/n\sigma_s$ is the atomic mean free path (mean distance traveled between scatterings) and l is distance traveled by a fiducial atom.

- Explain why, in the limit of vanishingly small mean free path, the distribution function has the following form:

$$\mathcal{N}_0 = \frac{n}{(2\pi mk_B T)^{3/2}} \exp[-(\mathbf{p} - m\boldsymbol{\sigma} \cdot \mathbf{x})^2/(2mk_B T)]. \quad (3.86b)$$

- Solve the Boltzmann transport equation (3.86a) to obtain the leading-order correction \mathcal{N}_1 to the distribution function at $\mathbf{x} = 0$.

$$[\text{Answer: } \mathcal{N}_1 = -(\lambda p/(k_B T))\sigma_{ab}n_a n_b \mathcal{N}_0.]$$

- (e) Compute the stress at $\mathbf{x} = 0$ via a momentum-space integral. Your answer should be Eq. (3.85a) with η_{shear} given by Eq. (3.85b) to within a few tens of percent accuracy. [Hint: Along the way you will need the following angular integral:

$$\int n_a n_b n_i n_j d\Omega = \frac{4\pi}{15} (\delta_{ab}\delta_{ij} + \delta_{ai}\delta_{bj} + \delta_{aj}\delta_{bi}). \quad (3.86c)$$

Derive this by arguing that the integral must have the above delta-function structure, and then computing the multiplicative constant by performing the integral for $a = b = i = j = z$.]

Exercise 3.20 *Example: Diffusion Coefficient in the Collision-Time*

Approximation **N**

Consider a collection of identical test particles with rest mass $m \neq 0$ that diffuse through a collection of thermalized scattering centers. (The test particles might be molecules of one species, and the scattering centers might be molecules of a much more numerous species.) The scattering centers have a temperature T such that $k_B T \ll mc^2$, so if the test particles acquire this temperature, they will have thermal speeds small compared to the speed of light as measured in the mean rest frame of the scattering centers. We study the effects of scattering on the test particles using the following collision-time approximation for the collision terms in the Boltzmann equation, which we write in the mean rest frame of the scattering centers:

$$\left(\frac{d\mathcal{N}}{dt} \right)_{\text{collision}} = \frac{1}{\tau} (\mathcal{N}_0 - \mathcal{N}), \quad \text{where } \mathcal{N}_0 \equiv \frac{e^{-p^2/(2mk_B T)}}{(2\pi mk_B T)^{3/2}} n. \quad (3.87)$$

Here the time derivative d/dt is taken moving with a fiducial test particle along its unscattered trajectory, $p = |\mathbf{p}|$ is the magnitude of the test particles' spatial momentum, $n = \int \mathcal{N} d\mathcal{V}_p$ is the number density of test particles, and τ is a constant to be discussed below.

- (a) Show that this collision term preserves test particles in the sense that

$$\left(\frac{dn}{dt} \right)_{\text{collision}} \equiv \int \left(\frac{d\mathcal{N}}{dt} \right)_{\text{collision}} dp_x dp_y dp_z = 0. \quad (3.88)$$

- (b) Explain why this collision term corresponds to the following physical picture: Each test particle has a probability $1/\tau$ per unit time of scattering; when it scatters, its direction of motion is randomized and its energy is thermalized at the scattering centers' temperature.
- (c) Suppose that the temperature T is homogeneous (spatially constant), but the test particles are distributed inhomogeneously, $n = n(\mathbf{x}) \neq \text{const}$. Let \mathcal{L} be the lengthscale on which their number density n varies. What condition must \mathcal{L} , τ , T , and m satisfy for the diffusion approximation to be reasonably accurate? Assume that this condition is satisfied.

- (d) Compute, in order of magnitude, the particle flux $\mathbf{S} = -D\nabla n$ produced by the gradient of the number density n , and thereby evaluate the diffusion coefficient D .
- (e) Show that the Boltzmann transport equation takes the form (sometimes known as the BKG or Crook model)

$$\frac{\partial \mathcal{N}}{\partial t} + \frac{p_j}{m} \frac{\partial \mathcal{N}}{\partial x_j} = \frac{1}{\tau} (\mathcal{N}_0 - \mathcal{N}). \quad (3.89a)$$

- (f) Show that to first order in a small diffusion-approximation parameter, the solution of this equation is $\mathcal{N} = \mathcal{N}_0 + \mathcal{N}_1$, where \mathcal{N}_0 is as defined in Eq. (3.87), and

$$\mathcal{N}_1 = -\frac{p_j \tau}{m} \frac{\partial n}{\partial x_j} \frac{e^{-p^2/(2mk_B T)}}{(2\pi mk_B T)^{3/2}}. \quad (3.89b)$$

Note that \mathcal{N}_0 is monopolar (independent of the direction of \mathbf{p}), while \mathcal{N}_1 is dipolar (linear in \mathbf{p}).

- (g) Show that the perturbation \mathcal{N}_1 gives rise to a particle flux given by Eq. (3.70d), with the diffusion coefficient

$$D = \frac{k_B T}{m} \tau. \quad (3.90)$$

How does this compare with your order-of-magnitude estimate in part (d)?

Exercise 3.21 ****Example: Neutron Diffusion in a Nuclear Reactor** N

A simplified version of a commercial nuclear reactor involves *fissile material* such as enriched uranium¹² and a *moderator* such as graphite, both of which will be assumed in this exercise. Slow (thermalized) neutrons, with kinetic energies ~ 0.1 eV, are captured by the ^{235}U nuclei and cause them to undergo fission, releasing ~ 170 MeV of kinetic energy per fission which appears as heat. Some of this energy is then converted into electric power. The fission releases an average of two or three (assume two) fast neutrons with kinetic energies ~ 1 MeV. (This is an underestimate.) The fast neutrons must be slowed to thermal speeds where they can be captured by ^{235}U atoms and induce further fissions. The slowing is achieved by scattering off the moderator atoms—a scattering in which the crucial effect, energy loss, occurs in momentum space. The momentum-space scattering is elastic and isotropic in the center-of-mass frame, with total cross section (to scatter off one of the moderator's carbon atoms) $\sigma_s \simeq 4.8 \times 10^{-24} \text{ cm}^2 \equiv 4.8$ barns. Using the fact that in the moderator's rest frame, the incoming neutron has a much higher kinetic energy than the moderator carbon atoms, and using energy and momentum conservation and the isotropy of the scattering, one can show that in the moderator's rest frame, the logarithm of the neutron's

12. Natural uranium contains ~ 0.007 of the fissile isotope ^{235}U ; the fraction is increased to ~ 0.01 – 0.05 in enriched uranium.

energy is reduced in each scattering by an average amount ξ that is independent of energy and is given by

$$\xi \equiv -\overline{\Delta \ln E} = 1 + \frac{(A-1)^2}{2A} \ln \left(\frac{A-1}{A+1} \right) \simeq 0.16, \quad (3.91)$$

a quantity sometimes known as *lethargy*. Here $A \simeq 12$ is the ratio of the mass of the scattering atom to that of the scattered neutron.

There is a dangerous hurdle that the diffusing neutrons must overcome during their slowdown: as the neutrons pass through a critical energy region of about ~ 7 to ~ 6 eV, the ^{238}U atoms can absorb them. The absorption cross section has a huge resonance there, with width ~ 1 eV and resonance integral $\int \sigma_a d \ln E \simeq 240$ barns. For simplicity, we approximate the cross section in this absorption resonance by $\sigma_a \simeq 1600$ barns at $6 \text{ eV} < E < 7 \text{ eV}$, and zero outside this range. To achieve a viable fission chain reaction and keep the reactor hot requires about half of the neutrons (one per original ^{235}U fission) to slow down through this resonant energy without getting absorbed. Those that make it through will thermalize and trigger new ^{235}U fissions (about one per original fission), maintaining the chain reaction.

We idealize the uranium and moderator atoms as homogeneously mixed on lengthscales small compared to the neutron mean free path, $\lambda_s = 1/(\sigma_s n_s) \simeq 2$ cm, where n_s is the number density of moderator (carbon) atoms. Then the neutrons' distribution function \mathcal{N} , as they slow down, is isotropic in direction and independent of position; and in our steady-state situation, it is independent of time. It therefore depends only on the magnitude p of the neutron momentum or equivalently, on the neutron kinetic energy $E = p^2/(2m)$: $\mathcal{N} = \mathcal{N}(E)$.

Use the Boltzmann transport equation or other considerations to develop the theory of the slowing of the neutrons in momentum space and of their struggle to pass through the ^{238}U resonance region without getting absorbed. More specifically, do the following.

- (a) Use as the distribution function not $\mathcal{N}(E)$ but rather $n_E(E) \equiv dN/d\mathcal{V}_x dE$ = (number of neutrons per unit volume and per unit kinetic energy), and denote by $q(E)$ the number of neutrons per unit volume that slow down through energy E per unit time. Show that outside the resonant absorption region these two quantities are related by

$$q = \sigma_s n_s \xi E n_E v, \quad \text{where } v = \sqrt{2mE} \quad (3.92)$$

is the neutron speed, so q contains the same information as the distribution function n_E . Explain why the steady-state operation of the nuclear reactor requires q to be independent of energy in this nonabsorption region, and infer that $n_E \propto E^{-3/2}$.

- (b) Show further that inside the resonant absorption region, $6 \text{ eV} < E < 7 \text{ eV}$, the relationship between q and E is modified:

$$q = (\sigma_s n_s + \sigma_a n_a) \xi E n_E v. \quad (3.93)$$

Here n_s is the number density of scattering (carbon) atoms, and n_a is the number density of absorbing (^{238}U) atoms. [Hint: Require that the rate at which neutrons scatter into a tiny interval of energy $\delta E \ll \xi E$ is equal to the rate at which they leave that tiny interval.] Then show that the absorption causes q to vary with energy according to the following differential equation:

$$\frac{d \ln q}{d \ln E} = \frac{\sigma_a n_a}{(\sigma_s n_s + \sigma_a n_a) \xi}. \quad (3.94)$$

- (c) By solving this differential equation in our idealization of constant σ_a over the range 7 to 6 eV, show that the condition to maintain the chain reaction is

$$\frac{n_s}{n_a} \simeq \frac{\sigma_a}{\sigma_s} \left(\frac{\ln(7/6)}{\xi \ln 2} - 1 \right) \simeq 0.41 \frac{\sigma_a}{\sigma_s} \simeq 140. \quad (3.95)$$

Thus, to maintain the reaction in the presence of the huge ^{238}U absorption resonance for neutrons, it is necessary that approximately 99% of the reactor volume be taken up by moderator atoms and 1% by uranium atoms.

This is a rather idealized version of what happens inside a nuclear reactor, but it provides insight into some of the important processes and the magnitudes of various relevant quantities. For a graphic example of an additional complexity, see the description of “xenon poisoning” of the chain reaction in the first production-scale nuclear reactor (built during World War II to make plutonium for the first American atomic bombs) in John Archibald Wheeler’s autobiography (Wheeler, 2000).

Bibliographic Note

Newtonian kinetic theory is treated in many textbooks on statistical physics. At an elementary level, Kittel and Kroemer (1980, Chap. 14) is rather good. Texts at a more advanced level include Kardar (2007, Chap. 3), Reif (2008, Secs. 7.9–7.13 and Chaps. 12–14), and Reichl (2009, Chap. 11). For a very advanced treatment with extensive applications to electrons and ions in plasmas, and electrons, phonons, and quasi-particles in liquids and solids, see Lifshitz and Pitaevskii (1981).

Relativistic kinetic theory is rarely touched on in statistical-physics textbooks but should be. It is well known to astrophysicists. The treatment in this chapter is easily lifted into general relativity theory (see, e.g., Misner, Thorne, and Wheeler, 1973, Sec. 22.6).

Statistical Mechanics

Willard Gibbs did for statistical mechanics and for thermodynamics what Laplace did for celestial mechanics and Maxwell did for electrodynamics, namely, made his field a well-nigh finished theoretical structure.

ROBERT A. MILLIKAN (1938)

4.1 Overview

4.1

While kinetic theory (Chap. 3) gives a powerful description of some statistical features of matter, other features are outside its realm and must be treated using the more sophisticated tools of statistical mechanics. Examples include:

- *Correlations:* Kinetic theory's distribution function \mathcal{N} tells us, on average, how many particles will occupy a given phase-space volume, but it says nothing about whether the particles like to clump or prefer to avoid one another. It is therefore inadequate to describe, for example, the distributions of galaxies and stars, which cluster under their mutual gravitational attraction (Sec. 4.10.1), or that of electrons in a plasma, which are mutually repulsive and thus are spatially anticorrelated (Sec. 22.6).
- *Fluctuations:* In experiments to measure a very weak mechanical force (e.g., tests of the equivalence principle and searches for gravitational waves), one typically monitors the motion of a pendulum's test mass, on which the force acts. Molecules of gas hitting the test mass also make it move. Kinetic theory predicts how many molecules will hit in 1 ms, on average, and how strong is the resulting pressure acting in all directions; but kinetic theory's distribution function \mathcal{N} cannot tell us the probability that in 1 ms more molecules will hit one side of the test mass than the other, mimicking the force one is trying to measure. The probability distribution for fluctuations is an essential tool for analyzing the noise in this and any other physical experiment, and it falls in the domain of statistical mechanics, not kinetic theory (Sec. 5.6).
- *Strongly interacting particles:* As should be familiar, the thermal motions of an ionic crystal are best described not in terms of individual atoms (as in the Einstein theory), but instead by decomposing the atoms' motion into

BOX 4.1. READERS' GUIDE

- Relativity enters into portions of this chapter solely via the relativistic energies and momenta of high-speed particles (Sec. 1.10). We presume that all readers are familiar with at least this much relativity and accordingly, we do not provide a Newtonian track through this chapter. We make occasional additional side remarks for the benefit of relativistic readers, but a Newtonian reader's failure to understand them will not compromise mastering all of this chapter's material.
- This chapter relies in crucial ways on Secs. 3.2, 3.3, 3.5.1, 3.5.2, 3.5.5, and 3.6, and Box 3.3.
- Chapter 5 is an extension of this chapter. To understand it and portions of Chap. 6, one must master the fundamental concepts of statistical mechanics in this chapter (Secs. 4.2–4.8).
- Other chapters do not depend strongly on this one.

normal modes (phonons; Debye theory). The thermal excitation of phonons is governed by statistical mechanics [Eq. (4.26)].

- *Microscopic origin of thermodynamic laws:* The laws of classical thermodynamics can be (and often are) derived from a few elementary, macroscopic postulates without any reference to the microscopic, atomic nature of matter. Kinetic theory provides a microscopic foundation for some of thermodynamics' abstract macroscopic ideas (e.g., the first law of thermodynamics) and permits the computation of equations of state. However, a full appreciation of entropy and the second law of thermodynamics (Sec. 4.7), and of behavior at phase transitions (Secs. 4.9, 5.5.2, 5.8.2, and 5.8.4) requires the machinery of statistical mechanics.

In this chapter, we develop the conceptual foundations for classical statistical mechanics and its interface with quantum physics, and we also delve deeply enough into the quantum world to be able to treat a few simple quantum problems. More specifically, in Sec. 4.2, we introduce the concepts of systems, ensembles of systems, and the distribution function for an ensemble. In Sec. 4.3, we use Hamiltonian dynamics to study the evolution of an ensemble's distribution function and derive the statistical mechanical version of Liouville's theorem. In Sec. 4.4, we develop the concept of statistical equilibrium and derive the general form of distribution functions for ensembles of systems that have reached statistical equilibrium (Sec. 4.4.2) and specific forms that depend on what additive macroscopic quantities the systems can exchange with their thermalized environment: energy exchange (canonical distribution, Sec. 4.4.1),

energy and volume exchange (Gibbs distribution, Sec. 4.4.2), energy and particle exchange (grand canonical distribution, Sec. 4.4.2), and nothing exchanged (microcanonical distribution, Sec. 4.5).

In Chap. 5, we study these equilibrium distributions in considerable detail, especially their relationship to the laws of thermodynamics. Here in Chap. 4, we use them to explore some fundamental statistical mechanics issues:

1. a derivation of the Bose-Einstein and Fermi-Dirac distributions for the mean occupation number of a single-particle quantum state, which we studied in depth in Chap. 3 (Sec. 4.4.3);
2. a discussion and proof of the equipartition theorem for classical, quadratic degrees of freedom (Sec. 4.4.4);
3. the relationship between the microcanonical ensemble and *ergodicity* (the ergodic evolution of a single, isolated system; Sec. 4.6);
4. the concept of the entropy of an arbitrary ensemble of systems, and the increase of entropy (second law of thermodynamics) as an ensemble of isolated (“closed”) systems evolves into its equilibrium, microcanonical form via *phase mixing*, *coarse graining*, and (quantum mechanically) via *discarding quantum correlations*—it’s the physicist’s fault!—(Sec. 4.7);
5. the entropy increase when two gases are mixed, and how quantum mechanics resolved the highly classical Gibbs Paradox (Ex. 4.8);
6. the power of entropy per particle as a tool for studying the evolution of physical systems (Sec. 4.8 and Ex. 4.10); and
7. Bose-Einstein condensation of a dilute gas of bosonic atoms (Sec. 4.9).

We conclude with a discussion of statistical mechanics in the presence of gravity (applications to galaxies, black holes, and the universe as a whole; Sec. 4.10) and a brief introduction to the concept of *information* and its connection to entropy (Sec. 4.11).

4.2 Systems, Ensembles, and Distribution Functions

4.2

4.2.1 Systems

4.2.1

Systems play the same role in statistical mechanics as is played by particles in kinetic theory. A system is any physical entity. (Obviously, this is an exceedingly general concept!) Examples are a galaxy, the Sun, a sapphire crystal, the fundamental mode of vibration of that crystal, an aluminum atom in that crystal, an electron from that aluminum atom, a quantum state in which that electron could reside,

systems

SEMICLOSED SYSTEMS

Statistical mechanics focuses special attention on systems that couple only weakly to the rest of the universe. Stated more precisely, we are interested in systems whose **relevant** internal evolution timescales, τ_{int} , are short compared with the external timescales, τ_{ext} , on which they exchange energy, entropy, particles, and so forth,

internal and external timescales

semiclosed systems

closed systems

with their surroundings. Such systems are said to be *semiclosed*, and in the idealized limit where one completely ignores their external interactions, they are said to be *closed*. The statistical mechanics formalism for dealing with them relies on the assumption $\tau_{\text{int}}/\tau_{\text{ext}} \ll 1$; in this sense, it is a variant of a two-lengthscale expansion (Box 3.3).

Some examples will elucidate these concepts. For a galaxy of, say, 10^{11} stars, τ_{int} is the time it takes a star to cross the galaxy, so $\tau_{\text{int}} \sim 10^8$ yr. The external timescale is the time since the galaxy's last collision with a neighboring galaxy or the time since it was born by separating from the material that formed neighboring galaxies; both these times are $\tau_{\text{ext}} \sim 10^{10}$ yr, so $\tau_{\text{int}}/\tau_{\text{ext}} \sim 1/100$, and the galaxy is semiclosed. For a small volume of gas inside the Sun (say, 1 m on a side), τ_{int} is the timescale for the constituent electrons, ions, and photons to interact through collisions, $\tau_{\text{int}} \lesssim 10^{-10}$ s; this is much smaller than the time for external heat or particles to diffuse from the cube's surface to its center, $\tau_{\text{ext}} \gtrsim 10^{-5}$ s, so the cube is semiclosed. An individual atom in a crystal is so strongly coupled to its neighboring atoms by electrostatic forces that $\tau_{\text{int}} \sim \tau_{\text{ext}}$, which means the atom is not semiclosed. By contrast, for a vibrational mode of the crystal, τ_{int} is the mode's vibration period, and τ_{ext} is the time to exchange energy with other modes and thereby damp the chosen mode's vibrations; quite generally, the damping time is far longer than the period, so the mode is semiclosed. (For a highly polished, cold sapphire crystal weighing several kilograms, τ_{ext} can be $\sim 10^9 \tau_{\text{int}}$.) Therefore, it is the crystal's vibrational normal modes and not its atoms that are amenable to the statistical mechanical tools we shall develop.

CLOSED SYSTEMS AND THEIR HAMILTONIANS

When a semiclosed classical system is idealized as closed, so its interactions with the external universe are ignored, then its evolution can be described using Hamiltonian dynamics (see, e.g., Marion and Thornton, 1995; Landau and Lifshitz, 1976; Goldstein, Poole, and Safko, 2002). The system's classical state is described by *generalized coordinates* $\mathbf{q} \equiv \{q_j\}$ and *generalized momenta* $\mathbf{p} \equiv \{p_j\}$, where the index j runs from 1 to W (the system's number of degrees of freedom). The evolution of \mathbf{q}, \mathbf{p} is governed by *Hamilton's equations*

Hamilton's equations for a closed system

$$\boxed{\frac{dq_j}{dt} = \frac{\partial H}{\partial p_j}, \quad \frac{dp_j}{dt} = -\frac{\partial H}{\partial q_j}}, \quad (4.1)$$

where $H(\mathbf{q}, \mathbf{p})$ is the *hamiltonian*, and each equation is really W separate equations. Note that, because the system is idealized as closed, there is no explicit time dependence in the hamiltonian. Of course, not all physical systems (e.g., not those with strong internal dissipation) are describable by Hamiltonian dynamics, though in prin-

ple this restriction can usually be circumvented by increasing the number of degrees of freedom to include the cause of the dissipation.¹

EXAMPLES

Let us return to our examples. For an individual star inside a galaxy, there are three degrees of freedom ($W = 3$), which we might choose to be the motion along three mutually orthogonal Cartesian directions, so $q_1 = x, q_2 = y, q_3 = z$. Because the star's speed is small compared to that of light, its hamiltonian has the standard form for a nonrelativistic particle:

$$H(\mathbf{q}, \mathbf{p}) = \frac{1}{2m}(p_1^2 + p_2^2 + p_3^2) + m\Phi(q_1, q_2, q_3). \quad (4.2)$$

Here m is the stellar mass, and $\Phi(q_1, q_2, q_3)$ is the galaxy's Newtonian gravitational potential (whose sign we take to be negative). Now, consider not just one star, but $K \sim 10^{11}$ of them in a galaxy. There are now $W = 3K$ degrees of freedom, and the hamiltonian is simply the sum of the hamiltonians for each individual star, so long as we ignore interactions between pairs of stars. The great power of the principles that we will develop is that they do not depend on whether $W = 1$ or $W = 3 \times 10^{11}$.

If our system is the fundamental mode of a sapphire crystal, then the number of degrees of freedom is only $W = 1$, and we can take the single generalized coordinate q to be the displacement of one end of the crystal from equilibrium. There will be an effective mass M for the mode (approximately equal to the actual mass of the crystal) such that the mode's generalized momentum is $p = Mdq/dt$. The hamiltonian will be the standard one for a harmonic oscillator:

$$H(p, q) = \frac{p^2}{2M} + \frac{1}{2}M\omega^2q^2, \quad (4.3a)$$

where ω is the mode's angular frequency of oscillation.

If we want to describe a whole crystal weighing several kilograms and having $K \sim 10^{26}$ atoms, then we obtain H by summing over $W = 3K$ oscillator hamiltonians for the crystal's W normal modes and adding an interaction potential H_{int} that accounts for the very weak interactions among modes:

$$H = \sum_{j=1}^W \left\{ \frac{p_j^2}{2M_j} + \frac{1}{2}M_j\omega_j^2q_j^2 \right\} + H_{\text{int}}(q_1, \dots, q_W, p_1, \dots, p_W). \quad (4.3b)$$

Here M_j is the effective mass of mode j , and ω_j is the mode's angular frequency. This description of the crystal is preferable to one in which we use, as our generalized coordinates and momenta, the coordinate locations and momentum components of each of the 10^{26} atoms. Why? Because the normal modes are so weakly coupled to one

1. For example, if we add damping to a simple harmonic oscillator, we can either treat the system as (in principle) hamiltonian by allowing for all the internal degrees of freedom associated with the damping, for example friction, or as (in practice) non-hamiltonian with an external heat sink.

another that they are semiclosed subsystems of the crystal, whereas the atoms are so strongly coupled that they are not, individually, semiclosed. As we shall see, there is great power in decomposing a complicated system into semiclosed subsystems.

4.2.2

ensemble of systems

4.2.2 Ensembles

In kinetic theory, we study statistically a collection of a huge number of particles. Similarly, in statistical mechanics, we study statistically a collection or *ensemble* of a huge number of systems. This ensemble is actually only a conceptual device, a foundation for statistical arguments that take the form of thought experiments. As we shall see, there are many different ways that one can imagine forming an ensemble, and this freedom can be used to solve many different types of problems.

In some applications, we require that all the systems in the ensemble be closed and be identical in the sense that they all have the same number of degrees of freedom, W ; are governed by hamiltonians with the same functional forms $H(\mathbf{q}, \mathbf{p})$; and have the same volume V and total internal energy E (or \mathcal{E} , including rest masses). However, the values of the generalized coordinates and momenta at a specific time t , $\{\mathbf{q}(t), \mathbf{p}(t)\}$, need not be the same (i.e., the systems need not be in the same state at time t). If such a conceptual ensemble of identical closed systems (first studied by Boltzmann) evolves until it reaches statistical equilibrium (Sec. 4.5), it then is called *microcanonical*; see Table 4.1.

microcanonical ensemble

Sometimes we deal with an ensemble of systems that can exchange energy (heat) with their identical surroundings, so the internal energy of each system can fluctuate. If the surroundings (sometimes called *heat baths*) have far greater heat capacity than the individual systems, and if statistical equilibrium has been reached, then we call this sort of ensemble (introduced by Gibbs) *canonical*.

heat baths

canonical ensemble

At the next level of generality, the systems can also expand (i.e., they can exchange volume as well as energy with their identical surroundings). This case was also studied by Gibbs—his text (Gibbs, 1902) still repays reading—and in equilibrium it is known as the *Gibbs ensemble*; its environment is a heat and volume bath. A fourth ensemble in common use is Pauli's *grand canonical ensemble*, in which each system can exchange

Gibbs ensemble

Pauli's grand canonical ensemble

TABLE 4.1: Statistical-equilibrium ensembles used in this chapter

Ensemble	Quantities exchanged with surroundings
Microcanonical	Nothing
Canonical	Energy E
Gibbs	Energy E and volume V
Grand canonical	Energy E and number of particles N_I of various species I

Note: For relativistic systems we usually include the rest masses of all particles in the energy, so E is replaced by \mathcal{E} in the above formulas.

energy and particles (but not volume) with its surroundings; see Table 4.1. We study these equilibrium ensembles and their baths in Secs. 4.4 and 4.5.

4.2.3 Distribution Function

4.2.3

DISTRIBUTION FUNCTION AS A PROBABILITY

In kinetic theory (Chap. 3), we described the statistical properties of a collection of identical particles by a distribution function, and we found it useful to tie that distribution function's normalization to quantum theory: $\eta(t; \mathbf{x}, \mathbf{p})$ = (mean number of particles that occupy a quantum state at location $\{\mathbf{x}, \mathbf{p}\}$ in 6-dimensional phase space at time t). In statistical mechanics, we use the obvious generalization of this: η = (mean number of systems that occupy a quantum state at location $\{\mathbf{q}, \mathbf{p}\}$ in an ensemble's $2W$ -dimensional phase space, at time t)—except that we need two modifications:

1. This generalized η is proportional to the number of systems N_{sys} in our ensemble. (If we double N_{sys} , then η will double.) Because our ensemble is only a conceptual device, we don't really care how many systems it contains, so we divide η by N_{sys} to get a renormalized, N_{sys} -independent distribution function, $\rho = \eta/N_{\text{sys}}$, whose physical interpretation is

$$\rho(t; \mathbf{q}, \mathbf{p}) = \left(\begin{array}{l} \text{probability that a system, drawn randomly} \\ \text{from our ensemble, will be in a quantum state} \\ \text{at location } (\mathbf{q}, \mathbf{p}) \text{ in phase space at time } t \end{array} \right). \quad (4.4)$$

probabilistic distribution function

2. If the systems of our ensemble can exchange particles with the external universe (as is the case, for example, in the grand canonical ensemble of Table 4.1), then their number of degrees of freedom, W , can change, so ρ may depend on W as well as on location in the $2W$ -dimensional phase space: $\rho(t; W, \mathbf{q}, \mathbf{p})$.

In the sector of the system's phase space with W degrees of freedom, denote the number density of quantum states by

$$\mathcal{N}_{\text{states}}(W, \mathbf{q}, \mathbf{p}) = \frac{dN_{\text{states}}}{d^W q d^W p} \equiv \frac{dN_{\text{states}}}{d\Gamma_W}. \quad (4.5)$$

density of states

Here we have used

$$d^W q \equiv dq_1 dq_2 \cdots dq_W, \quad d^W p \equiv dp_1 dp_2 \cdots dp_W, \quad d\Gamma_W \equiv d^W q d^W p. \quad (4.6)$$

Then the sum of the occupation probability ρ over all quantum states, which must (by the meaning of probability) be unity, takes the form

$$\sum_n \rho_n = \sum_W \int \rho \mathcal{N}_{\text{states}} d\Gamma_W = 1. \quad (4.7)$$

normalization of distribution function

On the left-hand side n is a formal index that labels the various quantum states $|n\rangle$ available to the ensemble's systems; on the right-hand side the sum is over all

possible values of the system's dimensionality W , and the integral is over all of the $2W$ -dimensional phase space, with $d\Gamma_W$ a short-hand notation for the phase-space integration element $d^Wq d^Wp$.

GEOMETRICAL VIEWPOINT

Equations (4.4)–(4.7) require some discussion. Just as the events and 4-momenta in relativistic kinetic theory are geometric, frame-independent objects, similarly *location in phase space* in statistical mechanics is a geometric, coordinate-independent concept (though our notation does not emphasize it). The quantities $\{\mathbf{q}, \mathbf{p}\} \equiv \{q_1, q_2, \dots, q_W, p_1, p_2, \dots, p_W\}$ are the coordinates of that phase-space location. When one makes a canonical transformation from one set of generalized coordinates and momenta to another (Ex. 4.1), the qs and ps change, but the geometric location in phase space does not. Moreover, just as the individual spatial and momentum volumes $d\mathcal{V}_x$ and $d\mathcal{V}_p$ occupied by a set of relativistic particles in kinetic theory are frame dependent, but their product $d\mathcal{V}_x d\mathcal{V}_p$ is frame-independent [cf. Eqs. (3.7a)–(3.7c)], so also in statistical mechanics the volumes d^Wq and d^Wp occupied by some chosen set of systems are dependent on the choice of canonical coordinates (they change under a canonical transformation), but the product $d^Wq d^Wp \equiv d\Gamma_W$ (the systems' total volume in phase space) is independent of the choice of canonical coordinates and is unchanged by a canonical transformation. Correspondingly, *the number density of states in phase space* $\mathcal{N}_{\text{states}} = dN_{\text{states}}/d\Gamma_W$ and *the statistical mechanical distribution function* $\rho(t; W, \mathbf{q}, \mathbf{p})$, like their kinetic-theory counterparts, are geometric, coordinate-independent quantities: they are unchanged by a canonical transformation. See Ex. 4.1 and references cited there.

ρ and $\mathcal{N}_{\text{states}}$ as geometric objects

DENSITY OF STATES

Classical thermodynamics was one of the crowning achievements of nineteenth-century science. However, thermodynamics was inevitably incomplete and had to remain so until the development of quantum theory. A major difficulty, one that we have already confronted in Chap. 3, was how to count the number of states available to a system. As we saw in Chap. 3, the number density of quantum mechanical states in the 6-dimensional, single-particle phase space of kinetic theory is (ignoring particle spin) $\mathcal{N}_{\text{states}} = 1/h^3$, where h is Planck's constant. Generalizing to the $2W$ -dimensional phase space of statistical mechanics, the number density of states turns out to be $1/h^W$ [one factor of $1/h$ for each of the canonical pairs $(q_1, p_1), (q_2, p_2), \dots, (q_W, p_W)$]. Formally, this follows from the canonical quantization procedure of elementary quantum mechanics.

DISTINGUISHABILITY AND MULTIPLICITY

There was a second problem in nineteenth-century classical thermodynamics, that of *distinguishability*: If we swap two similar atoms in phase space, do we have a new state or not? If we mix two containers of the same gas at the same temperature and pressure, does the entropy increase (Ex. 4.8)? This problem was recognized classically

distinguishability of particles

but was not resolved in a completely satisfactory classical manner. When the laws of quantum mechanics were developed, it became clear that all identical particles are indistinguishable, so having particle 1 at location \mathcal{A} in phase space and an identical particle 2 at location \mathcal{B} must be counted as the same state as particle 1 at \mathcal{B} and particle 2 at \mathcal{A} . Correspondingly, if we attribute half the quantum state to the classical phase-space location $\{1 \text{ at } \mathcal{A}, 2 \text{ at } \mathcal{B}\}$ and the other half to $\{1 \text{ at } \mathcal{B}, 2 \text{ at } \mathcal{A}\}$, then the classical number density of states per unit volume of phase space must be reduced by a factor of 2—and more generally by some *multiplicity factor* \mathcal{M} . In general, therefore, we can write the actual number density of states in phase space as

$$\mathcal{N}_{\text{states}} = \frac{dN_{\text{states}}}{d\Gamma_W} = \frac{1}{\mathcal{M}h^W}, \quad (4.8a)$$

and correspondingly, we can rewrite the normalization condition (4.7) for our probabilistic distribution function as

$$\sum_n \rho_n \equiv \sum_W \int \rho \mathcal{N}_{\text{states}} d\Gamma_W = \sum_W \int \rho \frac{d\Gamma_W}{\mathcal{M}h^W} = 1. \quad (4.8b)$$

This equation can be regarded, in the classical domain, as defining the meaning of the sum over states n . We shall make extensive use of such sums over states.

For N identical and indistinguishable particles with zero spin, it is not hard to see that $\mathcal{M} = N!$. If we include the effects of quantum mechanical spin (and the spin states can be regarded as degenerate), then there are g_s [Eq. (3.16)] more states present in the phase space of each particle than we thought, so an individual state's multiplicity \mathcal{M} (the number of different phase-space locations to be attributed to the state) is reduced to

$$\mathcal{M} = \frac{N!}{g_s^N} \quad \text{for a system of } N \text{ identical particles with spin } s. \quad (4.8c)$$

This is the quantity that appears in the denominator of the sum over states [Eq. (4.8b)].

Occasionally, for conceptual purposes it is useful to introduce a renormalized distribution function \mathcal{N}_{sys} , analogous to kinetic theory's number density of particles in phase space:

$$\mathcal{N}_{\text{sys}} = N_{\text{sys}} \mathcal{N}_{\text{states}} \rho = \frac{d(\text{number of systems})}{d(\text{volume in } 2W\text{-dimensional phase space})}. \quad (4.9)$$

However, this version of the distribution function will rarely if ever be useful computationally.

ENSEMBLE AVERAGE

Each system in an ensemble is endowed with a total energy that is equal to its hamiltonian, $E = H(\mathbf{q}, \mathbf{p})$ [or relativistically, $\mathcal{E} = H(\mathbf{q}, \mathbf{p})$]. Because different systems reside at different locations (\mathbf{q}, \mathbf{p}) in phase space, they typically will have different energies.

multiplicity

density of states

number density of systems
in phase space

A quantity of much interest is the *ensemble-averaged energy*, which is the average value of E over all systems in the ensemble:

$$\langle E \rangle = \sum_n \rho_n E_n = \sum_W \int \rho E \mathcal{N}_{\text{states}} d\Gamma_W = \sum_W \int \rho E \frac{d\Gamma_W}{\mathcal{M}h^W}. \quad (4.10a)$$

For any other function $A(\mathbf{q}, \mathbf{p})$ defined on the phase space of a system (e.g., the linear momentum or the angular momentum), one can compute an ensemble average by the obvious analog of Eq. (4.10a):

ensemble average

$$\langle A \rangle = \sum_n \rho_n A_n. \quad (4.10b)$$

Our probabilistic distribution function $\rho_n = \rho(t; W, \mathbf{q}, \mathbf{p})$ has deeper connections to quantum theory than the above discussion reveals. In the quantum domain, even if we start with a system whose wave function ψ is in a *pure state* (ordinary, everyday type of quantum state), the system may evolve into a *mixed state* as a result of (i) interaction with the rest of the universe and (ii) our choice not to keep track of correlations between the universe and the system (Box 4.2 and Sec. 4.7.2). The system's initial, pure state can be described in geometric, basis-independent quantum language by a state vector (“ket”) $|\psi\rangle$; but its final, mixed state requires a different kind of quantum description: a *density operator* $\hat{\rho}$. In the classical limit, the quantum mechanical density operator $\hat{\rho}$ becomes our classical probabilistic distribution function $\rho(t, W, \mathbf{q}, \mathbf{p})$; see Box 4.2 for some details.

EXERCISES

Exercise 4.1 Example: Canonical Transformation

Canonical transformations are treated in advanced textbooks on mechanics, such as Goldstein, Poole, and Safko (2002, Chap. 9) or, more concisely, Landau and Lifshitz (1976). This exercise gives a brief introduction. For simplicity we assume the hamiltonian is time independent.

Let (q_j, p_k) be one set of generalized coordinates and momenta for a given system. We can transform to another set (Q_j, P_k) , which may be more convenient, using a *generating function* that connects the old and new sets. One type of generating function is $F(q_j, P_k)$, which depends on the old coordinates $\{q_j\}$ and new momenta $\{P_k\}$, such that

$$p_j = \frac{\partial F}{\partial q_j}, \quad Q_j = \frac{\partial F}{\partial P_j}. \quad (4.11)$$

(a) As an example, what are the new coordinates and momenta in terms of the old that result from

$$F = \sum_{i=1}^W f_i(q_1, q_2, \dots, q_W) P_i, \quad (4.12)$$

where f_i are arbitrary functions of the old coordinates?

BOX 4.2. DENSITY OPERATOR AND QUANTUM STATISTICAL MECHANICS T2

Here we describe briefly the connection of our probabilistic distribution function ρ to the full quantum statistical theory as laid out, for example, in Sethna (2006, Sec. 7.1.1) and Cohen-Tannoudji, Diu, and Laloë (1977, complement E_{III}), or in much greater detail in Pathria and Beale (2011, Chap. 5) and Feynman (1972).

Consider a single quantum mechanical system that is in a pure state $|\psi\rangle$. One can formulate the theory of such a pure state equally well in terms of $|\psi\rangle$ or the density operator $\hat{\rho} \equiv |\psi\rangle\langle\psi|$. For example, the expectation value of some observable, described by a Hermitian operator \hat{A} , can be expressed equally well as $\langle A \rangle = \langle\psi|\hat{A}|\psi\rangle$ or as $\langle A \rangle = \text{Trace}(\hat{\rho}\hat{A})$.²

If our chosen system interacts with the external universe and we have no knowledge of the correlations that the interaction creates between the system and the universe, then the interaction drives the system into a mixed state, which is describable by a density operator $\hat{\rho}$ but not by a ket vector $|\psi\rangle$. This $\hat{\rho}$ can be regarded as a classical-type average of $|\psi\rangle\langle\psi|$ over an ensemble of systems, each of which has interacted with the external universe and then has been driven into a pure state $|\psi\rangle$ by a measurement of the universe. Equivalently, $\hat{\rho}$ can be constructed from the pure state of universe plus system by “tracing over the universe’s degrees of freedom.”

If the systems in the ensemble behave nearly classically, then it turns out that in the basis $|\phi_n\rangle$, whose states are labeled by the classical variables $n = \{W, \mathbf{q}, \mathbf{p}\}$, the density matrix $\rho_{nm} \equiv \langle\phi_n|\hat{\rho}|\phi_m\rangle$ is very nearly diagonal. The classical probability ρ_n of classical statistical mechanics (and of this book when dealing with classical or quantum systems) is then equal to the diagonal value of this density matrix: $\rho_n = \rho_{nn}$.

It can be demonstrated that the equation of motion for the density operator $\hat{\rho}$, when the systems in the quantum mechanical ensemble are all evolving freely (no significant interactions with the external universe), is

$$\frac{\partial \hat{\rho}}{\partial t} + \frac{1}{i\hbar} [\hat{\rho}, \hat{H}] = 0. \quad (1)$$

This is the quantum statistical analog of the Liouville equation (4.15), and the quantum mechanical commutator $[\hat{\rho}, \hat{H}]$ appearing here is the quantum

2. In any basis $|\phi_i\rangle$, “Trace” is just the trace of the matrix product $\sum_j \rho_{ij} A_{jk}$, where $A_{jk} \equiv \langle\phi_j|\hat{A}|\phi_k\rangle$, and $\rho_{ij} \equiv \langle\phi_i|\hat{\rho}|\phi_j\rangle$ is called the *density matrix* in that basis. Sometimes $\hat{\rho}$ itself is called the density matrix, even though it is an operator.

(continued)

BOX 4.2. (continued)

mechanical analog of the Poisson bracket $[\rho, H]_{\mathbf{q}, \mathbf{p}}$, which appears in the Liouville equation. If the ensemble's quantum systems are in eigenstates of their hamiltonians, then $\hat{\rho}$ commutes with \hat{H} , so the density matrix is constant in time and there will be no transitions. This is the quantum analog of the classical ρ being constant in time and thus a constant of the motion (Sec. 4.4).

- (b) The canonical transformation generated by Eq. (4.11) for arbitrary $F(q_j, P_k)$ leaves unchanged the value, but not the functional form, of the hamiltonian at each point in phase space. In other words, H is a geometric, coordinate-independent function (scalar field) of location in phase space. Show, for the special case of a system with one degree of freedom (one q , one p , one Q , and one P), that if Hamilton's equations (4.1) are satisfied in the old variables (q, p) , then they will be satisfied in the new variables (Q, P) .
- (c) Show, for a system with one degree of freedom, that although $dq \neq dQ$ and $dp \neq dP$, the volume in phase space is unaffected by the canonical transformation: $dpdq = dPdQ$.
- (d) Hence show that for any closed path in phase space, $\oint pdq = \oint PdQ$. These results are readily generalized to more than one degree of freedom.

4.3

4.3 Liouville's Theorem and the Evolution of the Distribution Function

In kinetic theory, the distribution function \mathcal{N} is not only a frame-independent entity, it is also a constant along the trajectory of any freely moving particle, so long as collisions between particles are negligible. Similarly, in statistical mechanics, the probability ρ is not only coordinate-independent (unaffected by canonical transformations); ρ is also a constant along the phase-space trajectory of any freely evolving system, so long as the systems in the ensemble are not interacting significantly with the external universe (i.e., so long as they can be idealized as closed). This is the statistical mechanical version of Liouville's theorem, and its proof is a simple exercise in Hamiltonian mechanics, analogous to the "sophisticated" proof of the collisionless Boltzmann equation in Box 3.2.

Since the ensemble's systems are closed, no system changes its dimensionality W during its evolution. This permits us to fix W in the proof. Since no systems are created or destroyed during their evolution, the number density of systems in phase space, $\mathcal{N}_{\text{sys}} = N_{\text{sys}} \mathcal{N}_{\text{states}} \rho$ [Eq. (4.9)], must obey the same kind of conservation law as we encountered in Eq. (1.30) for electric charge and particle number in Newtonian

Liouville's theorem

physics. For particle number in a fluid, the conservation law is $\partial n/\partial t + \nabla \cdot (n\mathbf{v}) = 0$, where n is the number density of particles in physical space, \mathbf{v} is their common velocity (the fluid's velocity) in physical space, and $n\mathbf{v}$ is their flux. Our ensemble's systems have velocity $dq_j/dt = \partial H/\partial p_j$ in physical space and "velocity" $dp_j/dt = -\partial H/\partial q_j$ in momentum space, so by analogy with particle number in a fluid, the conservation law (valid for ρ as well as for \mathcal{N}_{sys} , since they are proportional to each other) is

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial q_j} \left(\rho \frac{dq_j}{dt} \right) + \frac{\partial}{\partial p_j} \left(\rho \frac{dp_j}{dt} \right) = 0. \quad (4.13)$$

conservation law for systems

Equation (4.13) has an implicit sum, from 1 to W , over the repeated index j (recall the Einstein summation convention, Sec. 1.5). Using Hamilton's equations, we can rewrite this as

$$\begin{aligned} 0 &= \frac{\partial \rho}{\partial t} + \frac{\partial}{\partial q_j} \left(\rho \frac{\partial H}{\partial p_j} \right) - \frac{\partial}{\partial p_j} \left(\rho \frac{\partial H}{\partial q_j} \right) \\ &= \frac{\partial \rho}{\partial t} + \frac{\partial \rho}{\partial q_j} \frac{\partial H}{\partial p_j} - \frac{\partial \rho}{\partial p_j} \frac{\partial H}{\partial q_j} = \frac{\partial \rho}{\partial t} + [\rho, H]_{\mathbf{q}, \mathbf{p}}, \end{aligned} \quad (4.14)$$

where $[\rho, H]_{\mathbf{q}, \mathbf{p}}$ is the *Poisson bracket* (e.g., Landau and Lifshitz, 1976; Marion and Thornton, 1995; Goldstein, Poole, and Safko, 2002). By using Hamilton's equations once again in the second expression, we discover that this is the time derivative of ρ moving with a fiducial system through the $2W$ -dimensional phase space:

$$\left(\frac{d\rho}{dt} \right)_{\text{moving with a fiducial system}} \equiv \frac{\partial \rho}{\partial t} + \frac{dq_j}{dt} \frac{\partial \rho}{\partial q_j} + \frac{dp_j}{dt} \frac{\partial \rho}{\partial p_j} = \frac{\partial \rho}{\partial t} + [\rho, H]_{\mathbf{q}, \mathbf{p}} = 0.$$

Liouville equation (collisionless Boltzmann equation)

(4.15)

Therefore, the probability ρ is constant along the system's phase space trajectory, as was to be proved.

We call Eq. (4.15), which embodies this Liouville theorem, the statistical mechanical *Liouville equation* or *collisionless Boltzmann equation*.

As a simple, qualitative example, consider a system consisting of hot gas expanding adiabatically, so its large random kinetic energy is converted into ordered radial motion. If we examine a set \mathcal{S} of such systems very close to one another in phase space, then it is apparent that, as the expansion proceeds, the size of \mathcal{S} 's physical-space volume $d^W q$ increases and the size of its momentum-space volume $d^W p$ diminishes, so that the product $d^W q d^W p$ remains constant (Fig. 4.1), and correspondingly $\rho \propto \mathcal{N}_{\text{sys}} = dN_{\text{sys}}/d^W q d^W p$ is constant.

What happens if the systems being studied interact weakly with their surroundings? We must then include an interaction term on the right-hand side of Eq. (4.15),

FIGURE 4.1 Liouville's theorem. (a) The region in the q_i - p_i part of phase space (with i fixed) occupied by a set \mathcal{S} of identical, closed systems at time $t = 0$. (b) The region occupied by the same set of systems a short time later, $t > 0$. The hamiltonian-generated evolution of the individual systems has moved them in such a manner as to skew the region they occupy, but the volume $\int dp_i dq_i$ is unchanged.

thereby converting it into the statistical mechanical version of the Boltzmann transport equation:

Boltzmann transport equation

$$\left(\frac{d\rho}{dt} \right)_{\text{moving with a fiducial system}} = \left(\frac{d\rho}{dt} \right)_{\text{interactions}} \quad (4.16)$$

The time derivative on the left is now taken moving through phase space with a fiducial system that does not interact with the external universe.

4.4 Statistical Equilibrium

In this section's discussion of statistical equilibrium, we begin by writing formulas in the relativistic form, where rest masses are included in the energy \mathcal{E} ; afterward we take the Newtonian limit.

the meaning of temperature

Before we start, we should clarify what we mean by the temperature of a system. The first point to make is that a rigorous definition presumes thermodynamic equilibrium for the system in question, which can be anything from a two-level atom to the early universe. We can then say that two systems that are in equilibrium and whose average properties do not change when they are brought into contact (so they can exchange heat) have the same temperature and that this attribute is transitive. (This is known as the zeroth law of thermodynamics.) This allows us to define the temperature of a reference system as a monotonic function that increases as heat is added to it. This reference system can then be used to assign a temperature to every other body with which it can be brought into equilibrium; cf. Sec. 5.2.3. There are several ways to specify this function. The one that we shall follow [Eqs. (4.19) and following text] is surprisingly general and depends on simple ideas from probability.³

3. Other approaches to the definition of temperature involve the engineering-inspired Carnot cycle, the mathematical Carathéodory approach, and the fluctuation-dissipation theorem expressed, for example,

STATISTICAL EQUILIBRIUM AND JEANS' THEOREM

Consider an ensemble of identical systems, all of which have the same huge number of degrees of freedom (dimensionality $W \gg 1$). Put all the systems initially in the same state, and then let them exchange heat (but not particles, volume, or anything else) with an external *thermal bath* that has a huge heat capacity and is in thermodynamic equilibrium at some temperature T . (For example, the systems might be impermeable cubes of gas 1 km on a side near the center of the Sun, and the thermal bath might be all the surrounding gas near the Sun's center; or the systems might be identical sapphire crystals inside a huge cryostat, and the thermal bath might be the cryostat's huge store of liquid helium.) After a sufficiently long time, $t \gg \tau_{\text{ext}}$, the ensemble will settle down into equilibrium with the bath (i.e., it will become the canonical ensemble mentioned in Table 4.1 above). In this final, canonical equilibrium state, the probability $\rho(t, \mathbf{q}, \mathbf{p})$ is independent of time t , and it no longer is affected by interactions with the external environment. In other words, the interaction terms in the evolution equation (4.16) have ceased to have any net effect: on average, for each interaction event that feeds energy into a system, there is an interaction event that takes away an equal amount of energy. The distribution function, therefore, satisfies the interaction-free, collisionless Boltzmann equation (4.15) with the time derivative $\partial\rho/\partial t$ removed:

$$[\rho, H]_{\mathbf{q}, \mathbf{p}} \equiv \frac{\partial\rho}{\partial q_j} \frac{\partial H}{\partial p_j} - \frac{\partial\rho}{\partial p_j} \frac{\partial H}{\partial q_j} = 0. \quad (4.17)$$

statistical equilibrium

We use the phrase *statistical equilibrium* to refer to any ensemble whose distribution function has attained such a state and thus satisfies Eq. (4.17).

Equation (4.17) is a well-known equation in Hamiltonian mechanics. It says that ρ is a function solely of constants of the individual systems' hamiltonian-induced motions (e.g., Landau and Lifshitz, 1976; Marion and Thornton, 1995; Goldstein, Poole, and Safko, 2002); in other words, ρ can depend on location (\mathbf{q}, \mathbf{p}) in phase space only through those constants of the motion. Sometimes this goes by the name *Jeans' theorem*. Among the constants of motion in typical situations (for typical hamiltonians) are the system's energy \mathcal{E} , its linear momentum \mathbf{P} , its angular momentum \mathbf{J} , its number N_I of conserved particles of various types I (e.g., electrons, protons), and its volume V . Notice that these constants of motion \mathcal{E} , \mathbf{P} , \mathbf{J} , N_I , and V are all additive: if we double the size of a system, they each double. We call such additive constants of the hamiltonian-induced motion *extensive variables* (a term borrowed from thermodynamics) and denote them by an enumerated list K_1, K_2, \dots .

Jeans' theorem

extensive variables

Now, the systems we are studying have exchanged energy \mathcal{E} with their environment (the thermal bath) and thereby have acquired some range of \mathcal{E} values; therefore, ρ

as Johnson noise (Sec. 6.8.1). These are covered in many thermodynamics texts (e.g., Reif, 2008) and lead to the same temperature scale.

can depend on \mathcal{E} . However, the systems have not exchanged anything else with their environment, and they all thus have retained their original (identical) values of the other extensive variables K_A ; therefore, ρ must be a delta function in these other variables. We write

$$\rho = \rho(\mathcal{E}) \quad (4.18a)$$

and do not write down the delta functions explicitly.

As an aid in discovering the form of the function $\rho(\mathcal{E})$, let us decompose each system in the ensemble into a huge number of subsystems. For example, each system might be a cube 1 km on a side inside the Sun, and its subsystems might be the 10^9 1-m cubes into which the system can be divided, or the systems might be identical sapphire crystals each containing 10^{26} atoms, and the subsystems might be the crystals' 3×10^{26} normal modes of vibration. We label the subsystems of each system by an integer a in such a way that subsystem a in one system has the same hamiltonian as subsystem a in any other system. (For the sapphire crystals, $a = 1$ could be the fundamental mode of vibration, $a = 2$ the first harmonic, $a = 3$ the second harmonic, etc.) The subsystems with fixed a make up a *subensemble* because of their relationship to the original ensemble.

subensembles

Because the full ensemble is in statistical equilibrium, the subensembles will also be in statistical equilibrium; therefore, their probabilities must be functions of those extensive variables \mathcal{E} , K_A that they can exchange with one another:

$$\rho_a = \rho_a(\mathcal{E}_a, K_{1a}, K_{2a}, \dots). \quad (4.18b)$$

(Although each system can exchange only energy \mathcal{E} with its heat bath, the subsystems may be able to exchange other quantities with one another; for example, if subsystem a is a 1-m cube inside the Sun with permeable walls, then it can exchange energy \mathcal{E}_a and particles of all species I , so $K_{Ia} = N_{Ia}$.)

Since there is such a huge number of subsystems in each system, it is reasonable to expect that in statistical equilibrium there will be no significant correlations at any given time between the actual state of subsystem a and the state of any other subsystem. In other words, the probability $\rho_a(W_a, \mathbf{q}_a, \mathbf{p}_a)$ that subsystem a is in a quantum state with W_a degrees of freedom and with its generalized coordinates and momenta near the values $(\mathbf{q}_a, \mathbf{p}_a)$ is independent of the state of any other subsystem. This lack of correlations, which can be written as

statistical independence

$$\rho(\mathcal{E}) = \prod_a \rho_a, \quad (4.18c)$$

is called *statistical independence*.⁴

4. Statistical independence is actually a consequence of a two-lengthscale approximation [Box 3.3]. The size of each subsystem is far smaller than that of the full system, and precise statistical independence arises in the limit as the ratio of these sizes goes to zero.

Statistical independence places a severe constraint on the functional forms of ρ and ρ_a , as the following argument shows. By taking the logarithm of Eq. (4.18c), we obtain

$$\ln \rho(\mathcal{E}) = \sum_a \ln \rho_a(\mathcal{E}_a, K_{1a}, \dots). \quad (4.18d)$$

We also know, since energy is a linearly additive quantity, that

$$\mathcal{E} = \sum_a \mathcal{E}_a. \quad (4.18e)$$

Now, we have not stipulated the way in which the systems are decomposed into subsystems. For our solar example, the subsystems might have been 2-m or 7-m cubes rather than 1-m cubes. Exploiting this freedom, one can deduce that Eqs. (4.18d) and (4.18e) can be satisfied simultaneously if and only if $\ln \rho$ and $\ln \rho_a$ depend linearly on the energies \mathcal{E} and \mathcal{E}_a , with the same proportionality constant $-\beta$:

$$\ln \rho_a = -\beta \mathcal{E}_a + (\text{some function of } K_{1a}, K_{2a}, \dots), \quad (4.19a)$$

$$\ln \rho = -\beta \mathcal{E} + \text{constant}. \quad (4.19b)$$

The reader presumably will identify β with $1/(k_B T)$, where T is the temperature of the thermal bath, as we have implicitly done in Chap. 3. However, what does this temperature actually mean and how do we define it? One approach is to choose as our subsystem a single identified atom in a classical monatomic perfect gas, with atomic rest mass high enough that the gas is nonrelativistic. The energy \mathcal{E} is then just the atom's kinetic energy (plus rest mass) and the pressure is $nk_B T$. We then repeat this for every other atom. Measuring the pressure—mechanically—in this simple system then defines $k_B T$. The choice of k_B is a mere convention; it is most commonly chosen to set the temperature of the triple point of water as 273.16 K. Much more complex systems can then be assigned the same temperature as the perfect gas with which they would be in equilibrium as outlined above. If the reader protests that gases are not perfect at low or high temperature, then we can substitute free electrons or photons and adopt their distribution functions as we have described in Sec. 3.3 and will derive in Sec. 4.4.3.

To summarize, an ensemble of identical systems with many degrees of freedom $W \gg 1$, which have reached statistical equilibrium by exchanging energy but nothing else with a huge thermal bath, has the following canonical distribution function:

$$\boxed{\rho_{\text{canonical}} = C \exp(-\mathcal{E}/k_B T),} \quad \boxed{\rho_{\text{canonical}} = C' \exp(-E/k_B T) \text{ nonrelativistically.}} \quad (4.20)$$

Here $\mathcal{E}(\mathbf{q}, \mathbf{p})$ is the energy of a system at location $\{\mathbf{q}, \mathbf{p}\}$ in phase space, k_B is Boltzmann's constant, T is the temperature of the heat bath, and C is whatever normalization constant is required to guarantee that $\sum_n \rho_n = 1$. The nonrelativistic expression is obtained by removing all the particle rest masses from the total energy \mathcal{E} and then taking the low-temperature, low-thermal-velocities limit.

definition of temperature

canonical distribution

Actually, we have proved more than Eq. (4.20). Not only must the ensemble of huge systems ($W \gg 1$) have the energy dependence $\rho \propto \exp(-\mathcal{E}/(k_B T))$, so must each subensemble of smaller systems, $\rho_a \propto \exp(-\mathcal{E}_a/(k_B T))$, even if (for example) the subensemble's identical subsystems have only one degree of freedom, $W_a = 1$. Thus, if the subsystems exchanged only heat with their parent systems, then they must have the same canonical distribution (4.20) as the parents. This shows that *the canonical distribution is the equilibrium state independently of the number of degrees of freedom W .*

4.4.2 4.4.2 General Equilibrium Ensemble and Distribution; Gibbs Ensemble; Grand Canonical Ensemble

GENERAL EQUILIBRIUM ENSEMBLE

We can easily generalize the canonical distribution to an ensemble of systems that exchange other additive conserved quantities (extensive variables) K_1, K_2, \dots , in addition to energy \mathcal{E} , with a huge, thermalized bath. By an obvious generalization of the argument in Sec. 4.4.1, the resulting statistical equilibrium distribution function must have the form

$$\rho = C \exp\left(-\beta\mathcal{E} - \sum_A \beta_A K_A\right). \quad (4.21)$$

general equilibrium
distribution

extensive variables:
energy, volume, particle
numbers, momentum,
angular momentum

When the extensive variables K_A that are exchanged with the bath (and thus appear explicitly in the distribution function ρ) are energy \mathcal{E} , momentum \mathbf{P} , angular momentum \mathbf{J} , the number N_I of the species I of conserved particles, volume V , or any combination of these quantities, it is conventional to rename the multiplicative factors β and β_A so that ρ takes on the form

$$\rho = C \exp\left[\frac{-\mathcal{E} + \mathbf{U} \cdot \mathbf{P} + \boldsymbol{\Omega} \cdot \mathbf{J} + \sum_I \tilde{\mu}_I N_I - PV}{k_B T}\right]. \quad (4.22)$$

bath's intensive variables:
temperature, pressure,
chemical potentials,
velocity, angular velocity

Here T , \mathbf{U} , $\boldsymbol{\Omega}$, $\tilde{\mu}_I$, and P are constants (called *intensive* variables) that are the same for all systems and subsystems (i.e., that characterize the full ensemble and all its subensembles and therefore must have been acquired from the bath); *any extensive variable that is not exchanged with the bath must be omitted from the exponential and be replaced by an implicit delta function.*

As we have seen in Sec. 3.3, T is the temperature that the ensemble and subensembles acquired from the bath (i.e., it is the bath temperature). From the Lorentz transformation law for energy and momentum [$\mathcal{E}' = \gamma(\mathcal{E} - \mathbf{U} \cdot \mathbf{P})$; Eqs. (2.37) and Ex. 2.13] we see that, if we were to transform to a reference frame that moves with velocity \mathbf{U} with respect to our original frame, then the $\exp(\mathbf{U} \cdot \mathbf{P}/(k_B T))$ term in ρ would disappear, and the distribution function would be isotropic in \mathbf{P} . Thus \mathbf{U} is the velocity of the bath with respect to our chosen reference frame. By a similar argument, $\boldsymbol{\Omega}$ is the bath's angular velocity with respect to an inertial frame. By comparison with

Eq. (3.22d), we see that $\tilde{\mu}_I$ is the chemical potential of the conserved species I . Finally, experience with elementary thermodynamics suggests (and it turns out to be true) that P is the bath's pressure.⁵ Note that, by contrast with the corresponding extensive variables \mathcal{E} , \mathbf{P} , \mathbf{J} , N_I , and V , the intensive variables T , \mathbf{U} , $\mathbf{\Omega}$, $\tilde{\mu}_I$, and P do not double when the size of a system is doubled (i.e., they are not additive); rather, they are properties of the ensemble as a whole and thus are independent of the systems' sizes.

By removing the rest masses m_I of all particles from each system's energy and similarly removing the particle rest mass from each chemical potential,

$$\boxed{E \equiv \mathcal{E} - \sum_I N_I m_I}, \quad \boxed{\mu_I \equiv \tilde{\mu}_I - m_I} \quad (4.23)$$

nonrelativistic energy and chemical potentials obtained by removing rest masses

[Eqs. (3.20) and (3.21)], we bring the distribution function into a form that is identical to Eq. (4.22) but with $\mathcal{E} \rightarrow E$ and $\tilde{\mu}_I \rightarrow \mu_I$:

$$\boxed{\rho = C \exp \left[\frac{-E + \mathbf{U} \cdot \mathbf{P} + \mathbf{\Omega} \cdot \mathbf{J} + \sum_I \mu_I N_I - PV}{k_B T} \right]}. \quad (4.24)$$

general equilibrium distribution

This is the form used in Newtonian theory, but it is also valid relativistically.

SPECIAL EQUILIBRIUM ENSEMBLES

Henceforth (except in Sec. 4.10.2, when discussing black-hole atmospheres), we restrict our baths always to be at rest in our chosen reference frame and to be nonrotating with respect to inertial frames, so that $\mathbf{U} = \mathbf{\Omega} = 0$. The distribution function ρ can then either be a delta function in the system momentum \mathbf{P} and angular momentum \mathbf{J} (if momentum and angular momentum are not exchanged with the bath), or it can involve no explicit dependence on \mathbf{P} and \mathbf{J} (if momentum and angular momentum are exchanged with the bath; cf. Eq. (4.22) with $\mathbf{U} = \mathbf{\Omega} = 0$). In either case, if energy is the only other quantity exchanged with the bath, then the distribution function is the canonical one [Eq. (4.20)]:

$$\boxed{\rho_{\text{canonical}} = C \exp \left[\frac{-\mathcal{E}}{k_B T} \right] = C' \exp \left[\frac{-E}{k_B T} \right]}, \quad (4.25a)$$

where (obviously) the constants C and C' are related by

$$C' = C \exp \left[- \sum_I N_I m_I / k_B T \right].$$

If, in addition to energy, volume can also be exchanged with the bath (e.g., if the systems are floppy bags of gas whose volumes can change and through which heat can

5. One can also identify these physical interpretations of T , $\tilde{\mu}_I$, and P by analyzing idealized measuring devices; cf. Sec. 5.2.2.

flow),⁶ then the equilibrium is the *Gibbs ensemble*, which has the distribution function

Gibbs distribution

$$\rho_{\text{Gibbs}} = C \exp \left[\frac{-(\mathcal{E} + PV)}{k_B T} \right] = C' \exp \left[\frac{-(E + PV)}{k_B T} \right] \quad (4.25b)$$

enthalpy

(with an implicit delta function in N_I and possibly in \mathbf{J} and \mathbf{P}). The combination $\mathcal{E} + PV$ is known as the *enthalpy* H . If the exchanged quantities are energy and particles but not volume (e.g., if the systems are 1-m cubes inside the Sun with totally imaginary walls through which particles and heat can flow), then the equilibrium is the *grand canonical ensemble*, with

grand canonical distribution

$$\rho_{\text{grand canonical}} = C \exp \left[\frac{-\mathcal{E} + \sum_I \tilde{\mu}_I N_I}{k_B T} \right] = C \exp \left[\frac{-E + \sum_I \mu_I N_I}{k_B T} \right] \quad (4.25c)$$

(with an implicit delta function in V and perhaps in \mathbf{J} and \mathbf{P}).

We mention, as a preview of an issue to be addressed in Chap. 5, that an individual system, picked randomly from the ensemble and then viewed as a bath for its own tiny subsystems, will not have the same temperature T , and/or chemical potential $\tilde{\mu}_I$, and/or pressure P as the huge bath with which the ensemble has equilibrated; rather, the individual system's T , $\tilde{\mu}_I$, and/or P can fluctuate a tiny bit around the huge bath's values (around the values that appear in the above probabilities), just as its \mathcal{E} , N_I , and/or V fluctuate. We study these fluctuations in Sec. 5.6.

4.4.3

4.4.3 Fermi-Dirac and Bose-Einstein Distributions

The concepts and results developed in this chapter have enormous generality. They are valid (when handled with sufficient care) for quantum systems as well as classical ones, and they are valid for semiclosed or closed systems of any type. The systems need not resemble the examples we have met in the text. They can be radically different, but so long as they are closed or semiclosed, our concepts and results will apply.

SINGLE-PARTICLE QUANTUM STATES (MODES)

As an important example, let each system be a single-particle quantum state of some field. These quantum states can exchange particles (quanta) with one another. As we shall see, in this case the above considerations imply that, in statistical equilibrium at temperature T , the mean number of particles in a state, whose individual particle energies are \mathcal{E} , is given by the Fermi-Dirac formula (for fermions) $\eta = 1/(e^{(\mathcal{E}-\tilde{\mu})/(k_B T)} + 1)$ and Bose-Einstein formula (for bosons) $\eta = 1/(e^{(\mathcal{E}-\tilde{\mu})/(k_B T)} - 1)$, which we used in our kinetic-theory studies in the last chapter [Eqs. (3.22a), (3.22b)]. Our derivation of these mean occupation numbers will

6. For example, the huge helium-filled balloons made of thin plastic that are used to lift scientific payloads into Earth's upper atmosphere.

illustrate the closeness of classical statistical mechanics and quantum statistical mechanics: the proof is fundamentally quantum mechanical, because the regime $\eta \sim 1$ is quantum mechanical (it violates the classical condition $\eta \ll 1$); nevertheless, the proof makes use of precisely the same concepts and techniques as we have developed for our classical studies.

As a conceptual aid in the derivation, consider an ensemble of complex systems in statistical equilibrium. Each system can be regarded as made up of a large number of fermions (electrons, protons, neutrons, neutrinos, . . .) and/or bosons (photons, gravitons, alpha particles, phonons, . . .). We analyze each system by identifying a complete set of single-particle quantum states (which we call *modes*) that the particles can occupy⁷ (see, e.g., Chandler, 1987, chap. 4). A complete enumeration of modes is the starting point for the *second quantization* formulation of quantum field theory and is also the starting point for our far simpler analysis.

Choose one specific mode \mathcal{S} [e.g., a nonrelativistic electron plane-wave mode in a box of side L with spin up and momentum $\mathbf{p} = (5, 3, 17)h/L$]. There is one such mode \mathcal{S} in each of the systems in our ensemble, and these modes (all identical in their properties) form a subensemble of our original ensemble. Our derivation focuses on this subensemble of identical modes \mathcal{S} . Because each of these modes can exchange energy and particles with all the other modes in its system, the subensemble is grand canonically distributed.

The (*many-particle*) *quantum states* allowed for mode \mathcal{S} are states in which \mathcal{S} contains a finite number n of particles (quanta). Denote by $\mathcal{E}_{\mathcal{S}}$ the energy of one particle residing in mode \mathcal{S} . Then the mode's total energy when it is in the state $|n\rangle$ (when it contains n quanta) is $\mathcal{E}_n = n\mathcal{E}_{\mathcal{S}}$. [For a freely traveling, relativistic electron mode, $\mathcal{E}_{\mathcal{S}} = \sqrt{m^2 + \mathbf{p}^2}$, Eq. (1.40), where \mathbf{p} is the mode's momentum, $p_x = jh/L$ for some integer j and similarly for p_y and p_z ; for a phonon mode with angular eigenfrequency of vibration ω , $\mathcal{E}_{\mathcal{S}} = \hbar\omega$.] Since the distribution of the ensemble's modes among the allowed quantum states is grand canonical, the probability ρ_n of being in state $|n\rangle$ is [Eq. (4.25c)]

$$\rho_n = C \exp\left(\frac{-\mathcal{E}_n + \tilde{\mu}n}{k_B T}\right) = C \exp\left(\frac{n(\tilde{\mu} - \mathcal{E}_{\mathcal{S}})}{k_B T}\right), \quad (4.26)$$

where $\tilde{\mu}$ and T are the chemical potential and temperature of the bath of other modes, with which the mode \mathcal{S} interacts.⁸

7. For photons, these modes are the normal modes of the classical electromagnetic field; for phonons in a crystal, they are the normal modes of the crystal's vibrations; for nonrelativistic electrons or protons or alpha particles, they are energy eigenstates of the nonrelativistic Schrödinger equation; for relativistic electrons, they are energy eigenstates of the Dirac equation.

8. Here and throughout Chaps. 4 and 5 we ignore quantum zero point energies, since they are unobservable in this context (though they are observed in the fluctuational forces discussed in Sec. 6.8). Equally well we could include the zero point energies in \mathcal{E}_n , $\mathcal{E}_{\mathcal{S}}$, and $\tilde{\mu}$, and they would cancel out in the combinations that appear, e.g., in Eq. (4.26): $\tilde{\mu} - \mathcal{E}_{\mathcal{S}}$, and so forth.

modes

second quantization

many-particle quantum states

FERMION MODES: FERMION-DIRAC DISTRIBUTION

Suppose that \mathcal{S} is a fermion mode (i.e., its particles have half-integral spin). Then the Pauli exclusion principle dictates that \mathcal{S} cannot contain more than one particle: n can take on only the values 0 and 1. In this case, the normalization constant in the distribution function (4.26) is determined by $\rho_0 + \rho_1 = 1$, which implies that

Fermi-Dirac distribution

$$\rho_0 = \frac{1}{1 + \exp[(\tilde{\mu} - \mathcal{E}_{\mathcal{S}})/(k_B T)]}, \quad \rho_1 = \frac{\exp[(\tilde{\mu} - \mathcal{E}_{\mathcal{S}})/(k_B T)]}{1 + \exp[(\tilde{\mu} - \mathcal{E}_{\mathcal{S}})/(k_B T)]}. \quad (4.27a)$$

This is the explicit form of the grand canonical distribution for a fermion mode. For many purposes (including all those in Chap. 3), this full probability distribution is more than one needs. Quite sufficient instead is the mode's mean occupation number

Fermi-Dirac mean occupation number

$$\eta_{\mathcal{S}} \equiv \langle n \rangle = \sum_{n=0}^1 n \rho_n = \frac{1}{\exp[(\mathcal{E}_{\mathcal{S}} - \tilde{\mu})/(k_B T)] + 1} = \frac{1}{\exp[(E_{\mathcal{S}} - \mu)/(k_B T)] + 1}. \quad (4.27b)$$

Here $E_{\mathcal{S}} = \mathcal{E}_{\mathcal{S}} - m$ is the energy of a particle in the mode with rest mass removed, and $\mu = \tilde{\mu} - m$ is the chemical potential with rest mass removed—the quantities used in the nonrelativistic (Newtonian) regime.

Equation (4.27b) is the *Fermi-Dirac mean occupation number* asserted in Chap. 3 [Eq. (3.22a)] and studied there for the special case of a gas of freely moving, non-interacting fermions. Because our derivation is completely general, we conclude that this mean occupation number and the underlying grand canonical distribution (4.27a) are valid for any mode of a fermion field—for example, the modes for an electron trapped in an external potential well or a magnetic bottle, and the (single-particle) quantum states of an electron in a hydrogen atom.

BOSON MODES: BOSE-EINSTEIN DISTRIBUTION

Suppose that \mathcal{S} is a boson mode (i.e., its particles have integral spin), so it can contain any nonnegative number of quanta; that is, n can assume the values 0, 1, 2, 3, . . . Then the normalization condition $\sum_{n=0}^{\infty} \rho_n = 1$ fixes the constant in the grand canonical distribution (4.26), resulting in

Bose-Einstein distribution

$$\rho_n = \left[1 - \exp\left(\frac{\tilde{\mu} - \mathcal{E}_{\mathcal{S}}}{k_B T}\right) \right] \exp\left(\frac{n(\tilde{\mu} - \mathcal{E}_{\mathcal{S}})}{k_B T}\right). \quad (4.28a)$$

From this grand canonical distribution we can deduce the mean number of bosons in mode \mathcal{S} :

Bose-Einstein mean occupation number

$$\eta_{\mathcal{S}} \equiv \langle n \rangle = \sum_{n=1}^{\infty} n \rho_n = \frac{1}{\exp[(\mathcal{E}_{\mathcal{S}} - \tilde{\mu})/(k_B T)] - 1} = \frac{1}{\exp[(E_{\mathcal{S}} - \mu)/(k_B T)] - 1}, \quad (4.28b)$$

in accord with Eq. (3.22b). As for fermions, this *Bose-Einstein mean occupation number* and underlying grand canonical distribution (4.28a) are valid generally, and not solely for the freely moving bosons of Chap. 3.

When the mean occupation number is small, $\eta_S \ll 1$, both the bosonic and the fermionic distribution functions are well approximated by the classical *Boltzmann mean occupation number*

$$\eta_S = \exp[-(\mathcal{E}_S - \tilde{\mu})/(k_B T)]. \quad (4.29)$$

Boltzmann mean
occupation number

In Sec. 4.9 we explore an important modern application of the Bose-Einstein mean occupation number (4.28b): *Bose-Einstein condensation* of bosonic atoms in a magnetic trap.

4.4.4 Equipartition Theorem for Quadratic, Classical Degrees of Freedom

4.4.4

As a second example of statistical equilibrium distribution functions, we derive the classical equipartition theorem using statistical methods.

To motivate this theorem, consider a diatomic molecule of nitrogen, N_2 . To a good approximation, its energy (its hamiltonian) can be written as

$$E = \frac{p_x^2}{2M} + \frac{p_y^2}{2M} + \frac{p_z^2}{2M} + \frac{P_\ell^2}{2M_\ell} + \frac{1}{2}M_\ell \omega_v^2 \ell^2 + \frac{J_x^2}{2I} + \frac{J_y^2}{2I}. \quad (4.30)$$

Here M is the molecule's mass; p_x , p_y , and p_z are the components of its translational momentum; and the first three terms are the molecule's kinetic energy of translation. The next two terms are the molecule's longitudinal vibration energy, with ℓ the change of the molecule's length (change of the separation of its two nuclei) from equilibrium, P_ℓ the generalized momentum conjugate to that length change, ω_v the vibration frequency, and M_ℓ the generalized mass associated with that vibration. The last two terms are the molecule's energy of end-over-end rotation, with J_x and J_y the components of angular momentum associated with this two-dimensional rotator and I its moment of inertia.

Notice that every term in this hamiltonian is quadratic in a generalized coordinate or generalized momentum! Moreover, each of these coordinates and momenta appears only in its single quadratic term and nowhere else, and the density of states is independent of the value of that coordinate or momentum. We refer to such a coordinate or momentum as a *quadratic degree of freedom*.

quadratic degree of
freedom

In some cases (e.g., the vibrations and rotations but not the translations), the energy $E_\xi = \alpha \xi^2$ of a quadratic degree of freedom ξ is quantized, with some energy separation ε_0 between the ground state and first excited state (and with energy separations to higher states that are $\lesssim \varepsilon_0$). If (and only if) the thermal energy $k_B T$ is significantly larger than ε_0 , then the quadratic degree of freedom ξ will be excited far above its ground state and will behave classically. The equipartition theorem applies only at these high temperatures. For diatomic nitrogen, the rotational degrees of freedom J_x and J_y have $\varepsilon_0 \sim 10^{-4}$ eV and $\varepsilon_0/k_B \sim 1$ K, so temperatures big compared

to 1 K are required for J_x and J_y to behave classically. By contrast, the vibrational degrees of freedom ℓ and P_ℓ have $\varepsilon_0 \sim 0.1$ eV and $\varepsilon_0/k_B \sim 1,000$ K, so temperatures of a few thousand Kelvins are required for them to behave classically. Above $\sim 10^4$ K, the hamiltonian (4.30) fails: electrons around the nuclei are driven into excited states, and the molecule breaks apart (dissociates into two free atoms of nitrogen).

The equipartition theorem holds for any classical, quadratic degree of freedom [i.e., at temperatures somewhat higher than $T_o = \varepsilon_o/(k_B T)$]. We derive this theorem using the canonical distribution (4.25a). We write the molecule's total energy as $E = \alpha \xi^2 + E'$, where E' does not involve ξ . Then the mean energy associated with ξ is

$$\langle E_\xi \rangle = \frac{\int \alpha \xi^2 e^{-\beta(\alpha \xi^2 + E')} d\xi d(\text{other degrees of freedom})}{\int e^{-\beta(\alpha \xi^2 + E')} d\xi d(\text{other degrees of freedom})}. \quad (4.31)$$

Here the exponential is that of the canonical distribution function (4.25a), the denominator is the normalizing factor, and we have set $\beta \equiv 1/(k_B T)$. Because ξ does not appear in the portion E' of the energy, its integral separates out from the others in both numerator and denominator, and the integrals over E' in numerator and denominator cancel. Rewriting $\int \alpha \xi^2 \exp(-\beta \alpha \xi^2) d\xi$ as $-d/d\beta [\int \exp(-\beta \alpha \xi^2) d\xi]$, Eq. (4.31) becomes

$$\begin{aligned} \langle E_\xi \rangle &= -\frac{d}{d\beta} \ln \left[\int \exp(-\beta \alpha \xi^2) d\xi \right] \\ &= -\frac{d}{d\beta} \ln \left[\frac{1}{\sqrt{\beta \alpha}} \int du e^{-u^2} du \right] = \frac{1}{2\beta} = \frac{1}{2} k_B T. \end{aligned} \quad (4.32)$$

Therefore, *in statistical equilibrium, the mean energy associated with any classical, quadratic degree of freedom is $\frac{1}{2} k_B T$* . This is the equipartition theorem. Note that the factor $\frac{1}{2}$ follows from the quadratic nature of the degrees of freedom.

For our diatomic molecule, at room temperature there are three translational and two rotational classical, quadratic degrees of freedom (p_x, p_y, p_z, J_x, J_y), so the mean total energy of the molecule is $\frac{5}{2} k_B T$. At a temperature of several thousand Kelvins, the two vibrational degrees of freedom, ℓ and P_ℓ , become classical and the molecule's mean total energy is $\frac{7}{2} k_B T$. Above $\sim 10^4$ K the molecule dissociates, and its two parts (the two nitrogen atoms) have only translational quadratic degrees of freedom, so the mean energy per atom is $\frac{3}{2} k_B T$.

The equipartition theorem is valid for any classical, quadratic degree of freedom, whether it is part of a molecule or not. For example, it applies to the generalized coordinate and momentum of any harmonic-oscillator mode of any system: a vibrational mode of Earth or of a crystal, or a mode of an electromagnetic field.

4.5 The Microcanonical Ensemble

Let us now turn from ensembles of systems that interact with an external, thermal bath (as discussed in Sec. 4.4.1) to an ensemble of identical, precisely closed systems (i.e., systems that have no interactions with the external universe). By "identical" we

equipartition theorem

mean that every system in the ensemble has (i) the same set of degrees of freedom, and thus (ii) the same number of degrees of freedom W , (iii) the same hamiltonian, and (iv) the same values for all the additive constants of motion (\mathcal{E} , K_1 , K_2 , . . .) except perhaps total momentum \mathbf{P} and total angular momentum \mathbf{J} .⁹

Suppose that these systems begin with values of (\mathbf{q}, \mathbf{p}) that are spread out in some (arbitrary) manner over a hypersurface in phase space that has $H(\mathbf{q}, \mathbf{p})$ equal to the common value of energy \mathcal{E} . Of course, we cannot choose systems whose energy is precisely equal to \mathcal{E} . For most \mathcal{E} this would be a set of measure zero (see Ex. 4.7). Instead we let the systems occupy a tiny range of energy between \mathcal{E} and $\mathcal{E} + \delta\mathcal{E}$ and then discover (in Ex. 4.7) that our results are highly insensitive to $\delta\mathcal{E}$ as long as it is extremely small compared with \mathcal{E} .

It seems reasonable to expect that this ensemble, after evolving for a time much longer than its longest internal dynamical time scale $t \gg \tau_{\text{int}}$, will achieve statistical equilibrium (i.e., will evolve into a state with $\partial\rho/\partial t = 0$). (In the next section we justify this expectation.) The distribution function ρ then satisfies the collisionless Boltzmann equation (4.15) with vanishing time derivative, and therefore is a function only of the hamiltonian's additive constants of the motion \mathcal{E} and K_A . However, we already know that ρ is a delta function in K_A and almost a delta function with a tiny but finite spread in \mathcal{E} ; and the fact that it cannot depend on any other phase-space quantities then implies ρ is a constant over the hypersurface in phase space that has the prescribed values of K_A and \mathcal{E} , and it is zero everywhere else in phase space. This equilibrium ensemble is called “microcanonical.”

microcanonical
distribution

There is a subtle aspect of this microcanonical ensemble that deserves discussion. Suppose we split each system in the ensemble up into a huge number of subsystems that can exchange energy (but for concreteness, nothing else) with one another. We thereby obtain a huge number of subensembles, in the manner of Sec. 4.4.1. The original systems can be regarded as a thermal bath for the subsystems, and correspondingly, the subensembles will have canonical distribution functions, $\rho_a = C e^{-\mathcal{E}_a/(k_B T)}$. One might also expect the subensembles to be statistically independent, so that $\rho = \prod_a \rho_a$. However, such independence is not possible, since together with additivity of energy $\mathcal{E} = \sum_a \mathcal{E}_a$, it would imply that $\rho = C e^{-\mathcal{E}/(k_B T)}$ (i.e., that the full ensemble is canonically distributed rather than microcanonical). What is wrong here?

The answer is that there is a tiny correlation between the subensembles: if, at some moment of time, subsystem $a = 1$ happens to have an unusually large energy, then the other subsystems must correspondingly have a little less energy than usual. This very slightly invalidates the statistical-independence relation $\rho = \prod_a \rho_a$, thereby

correlations in the
microcanonical ensemble

9. Exercise 4.7 below is an example of a microcanonical ensemble where \mathbf{P} and \mathbf{J} are not precisely fixed, though we do not discuss this in the exercise. The gas atoms in that example are contained inside an impermeable box whose walls cannot exchange energy or atoms with the gas, but obviously can and do exchange momentum and angular momentum when atoms collide with the walls. Because the walls are at rest in our chosen reference frame, the distribution function has $\mathbf{U} = \mathbf{\Omega} = 0$ and so is independent of \mathbf{P} and \mathbf{J} [Eq. (4.24)] rather than having precisely defined values of them.

enabling the full ensemble to be microcanonical, even though all its subensembles are canonical. In the language of two-lengthscale expansions, where one expands in the dimensionless ratio (size of subsystems)/(size of full system) [Box 3.3], this correlation is a higher-order correction to statistical independence.

We are now in a position to understand more deeply the nature of the thermalized bath that we have invoked to drive ensembles into statistical equilibrium. That bath can be any huge system that contains the systems we are studying as subsystems; the bath's thermal equilibrium can be either a microcanonical statistical equilibrium or a statistical equilibrium involving exponentials of its extensive variables.

Exercise 4.7 gives a concrete illustration of the microcanonical ensemble, but we delay presenting it until we have developed some additional concepts that it also illustrates.

4.6 The Ergodic Hypothesis

The ensembles we have been studying are almost always just conceptual ones that do not exist in the real universe. We have introduced them and paid so much attention to them not for their own sakes, but because, in the case of statistical-equilibrium ensembles, they can be powerful tools for studying the properties of a single, individual system that really does exist in the universe or in our laboratory.

This power comes about because a sequence of snapshots of the single system, taken at times separated by sufficiently large intervals Δt , has a probability distribution ρ (for the snapshots' instantaneous locations $\{\mathbf{q}, \mathbf{p}\}$ in phase space) that is the same as the distribution function ρ of some conceptual, statistical-equilibrium ensemble. If the single system is closed, so its evolution is driven solely by its own hamiltonian, then the time between snapshots should be $\Delta t \gg \tau_{\text{int}}$, and its snapshots will be (very nearly) microcanonically distributed. If the single system exchanges energy, and only energy, with a thermal bath on a timescale τ_{ext} , then the time between snapshots should be $\Delta t \gg \tau_{\text{ext}}$, and its snapshots will be canonically distributed; similarly for the other types of bath interactions. This property of snapshots is equivalent to the statement that *for the individual system, the long-term time average¹⁰ of any function of the system's location in phase space is equal to the statistical-equilibrium ensemble average:*

$$\bar{A} \equiv \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{+T/2} A(\mathbf{q}(t), \mathbf{p}(t)) dt = \langle A \rangle \equiv \sum_n A_n \rho_n. \quad (4.33)$$

This property comes about because of *ergodicity*: the individual system, as it evolves, visits each accessible quantum state n for a fraction of the time that is equal to the equilibrium ensemble's probability ρ_n . Or, stated more carefully, the system comes

10. Physicists often study a system's evolution for too short a time to perform this average, and therefore the system does not reveal itself to be ergodic.

ergodicity: equality of time average and ensemble average

ergodicity

sufficiently close to each state n for a sufficient length of time that, for practical purposes, we can approximate it as spending a fraction ρ_n of its time at n .

At first sight, ergodicity may seem trivially obvious. However, it is not a universal property of all systems. One can easily devise idealized examples of nonergodic behavior (e.g., a perfectly elastic billiard ball bouncing around a square billiard table), and some few-body systems that occur in Nature are nonergodic (e.g., fortunately, planetary systems, such as the Sun's). Moreover, one can devise realistic, nonergodic models of some many-body systems. For examples and a clear discussion see Sethna (2006, Chap. 4). On the other hand, generic closed and semiclosed systems in Nature, whose properties and parameters are not carefully fine tuned, do typically behave ergodically, though to prove so is one of the most difficult problems in statistical mechanics.¹¹

We assume throughout this book's discussion of statistical physics that all the systems we study are indeed ergodic; this is called the *ergodic hypothesis*. Correspondingly, sometimes (for ease of notation) we denote the ensemble average with a bar.

One must be cautious in practical applications of the ergodic hypothesis: it can sometimes require much longer than one might naively expect for a system to wander sufficiently close to accessible states that $\bar{A} = \langle A \rangle$ for observables A of interest.

ergodic hypothesis

4.7 Entropy and Evolution toward Statistical Equilibrium

4.7

4.7.1 Entropy and the Second Law of Thermodynamics

4.7.1

For any ensemble of systems, whether it is in statistical equilibrium or not, and also whether it is quantum mechanical or not, the ensemble's *entropy* S is defined, in words, by the following awful sentence: S is the mean value (ensemble average) of the natural logarithm of the probability that a random system in the ensemble occupies a given quantum state, summed over states and multiplied by $-k_B$. More specifically, denoting the probability that a system is in state n by ρ_n , the ensemble's entropy S is the following sum over quantum states (or the equivalent integral over phase space):

$$S \equiv -k_B \sum_n \rho_n \ln \rho_n. \quad (4.34)$$

entropy of an ensemble

If all the systems are in the same quantum state, for example, in the state $n = 17$, then $\rho_n = \delta_{n,17}$ so we know precisely the state of any system pulled at random from the ensemble, and Eq. (4.34) dictates that the entropy vanish. Vanishing entropy thus corresponds to perfect knowledge of the system's quantum state; it corresponds to the quantum state being pure.

Entropy is a measure of our lack of information about the state of any system chosen at random from an ensemble (see Sec. 4.11). In this sense, *the entropy can be*

11. The ergodic hypothesis was introduced in 1871 by Boltzmann. For detailed analyses of it from physics viewpoints, see, e.g., ter Haar (1955) and Farquhar (1964). Attempts to understand it rigorously, and the types of systems that do or do not satisfy it, have spawned a branch of mathematical physics called "ergodic theory."

regarded as a property of a random individual system in the ensemble, as well as of the ensemble itself.

By contrast, consider a system in microcanonical statistical equilibrium. In this case, all states are equally likely (ρ is constant), so if there are N_{states} states available to the system, then $\rho_n = 1/N_{\text{states}}$, and the entropy (4.34) takes the form¹²

entropy for microcanonical ensemble

$$S = k_B \ln N_{\text{states}}. \quad (4.35)$$

The entropy, so defined, has some important properties. One is that when the ensemble can be broken up into statistically independent subensembles of subsystems (as is generally the case for big systems in statistical equilibrium), so that $\rho = \prod_a \rho_a$, then the entropy is additive: $S = \sum_a S_a$ (see Ex. 4.3). This permits us to regard the entropy, like the systems' additive constants of motion, as an extensive variable.

second law of thermodynamics

A second very important property is that, as an ensemble of systems evolves, its entropy cannot decrease, and it generally tends to increase. This is the statistical mechanical version of the second law of thermodynamics.

As an example of this second law, consider two different gases (e.g., nitrogen and oxygen) in a container, separated by a thin membrane. One set of gas molecules is constrained to lie on one side of the membrane; the other set lies on the opposite side. The total number of available states N_{states} is less than if the membrane is ruptured and the two gases are allowed to mix. The mixed state is readily accessible from the partitioned state and not vice versa. When the membrane is removed, the entropy begins to increase in accord with the second law of thermodynamics (cf. Ex. 4.8).

Since any ensemble of identical, closed systems will ultimately, after a time $t \gg \tau_{\text{int}}$, evolve into microcanonical statistical equilibrium, it must be that the microcanonical distribution function $\rho = \text{constant}$ has a larger entropy than any other distribution function that the ensemble could acquire. That this is indeed so can be demonstrated formally as follows.

Consider the class of all distribution functions ρ that: (i) vanish unless the constants of motion have the prescribed values \mathcal{E} (in the tiny range $\delta\mathcal{E}$) and K_A ; (ii) can be nonzero anywhere in the region of phase space, which we call \mathcal{Y}_o , where the prescribed values \mathcal{E} , K_A are taken; and (iii) are correctly normalized so that

$$\sum_n \rho_n \equiv \int_{\mathcal{Y}_o} \rho \mathcal{N}_{\text{states}} d\Gamma = 1 \quad (4.36a)$$

[Eq. (4.8b)]. We ask which ρ in this class gives the largest entropy

$$S = -k_B \sum_n \rho_n \ln \rho_n.$$

The requirement that the entropy be extremal (stationary) under variations $\delta\rho$ of ρ that preserve the normalization (4.36a) is embodied in the variational principle (see, e.g., Boas, 2006, Chap. 9):

12. This formula, with slightly different notation, can be found on Boltzmann's tomb.

$$\delta S = \delta \int_{\mathcal{Y}_o} (-k_B \rho \ln \rho - \Lambda \rho) \mathcal{N}_{\text{states}} d\Gamma = 0. \quad (4.36b)$$

Here Λ is a Lagrange multiplier that enforces the normalization (4.36a). Performing the variation, we find that

$$\int_{\mathcal{Y}_o} (-k_B \ln \rho - k_B - \Lambda) \delta \rho \mathcal{N}_{\text{states}} d\Gamma = 0, \quad (4.36c)$$

which is satisfied if and only if ρ is a constant, $\rho = e^{-1-\Lambda/k_B}$, independent of location in the allowed region \mathcal{Y}_o of phase space (i.e., if and only if ρ is that of the microcanonical ensemble). This calculation actually only shows that the microcanonical ensemble has stationary entropy. To show it is a maximum, one must perform the second variation (i.e., compute the second-order contribution of $\delta \rho$ to $\delta S = \delta \int (-k_B \rho \ln \rho) \mathcal{N}_{\text{states}} d\Gamma$). That second-order contribution is easily seen to be

$$\delta^2 S = \int_{\mathcal{Y}_o} \left(-k_B \frac{(\delta \rho)^2}{2\rho} \right) \mathcal{N}_{\text{states}} d\Gamma < 0. \quad (4.36d)$$

Thus, the microcanonical distribution does maximize the entropy, as claimed.

entropy maximized

distribution)

4.7.2 What Causes the Entropy to Increase?

4.7.2

There is an apparent paradox at the heart of statistical mechanics, and, at various stages in the development of the subject it has led to confusion and even despair. It still creates controversy (see, e.g., Hawking and Penrose, 2010; Penrose, 1999). Its simplest and most direct expression is to ask: how can the time-reversible, microscopic laws, encoded in a time-independent hamiltonian, lead to the remorseless increase of entropy?

COARSE-GRAINING

For insight, first consider a classical, microcanonical ensemble of precisely closed systems (no interaction at all with the external universe). Assume, for simplicity, that at time $t = 0$ all the systems are concentrated in a small but finite region of phase space with volume $\Delta\Gamma$, as shown in Fig. 4.2a, with $\rho = 1/(\mathcal{N}_{\text{states}} \Delta\Gamma)$ in the occupied region and $\rho = 0$ everywhere else. As time passes each system evolves under the action of the systems' common hamiltonian. As depicted in Fig. 4.2b, this evolution distorts the occupied region of phase space; but Liouville's theorem dictates that the occupied region's volume $\Delta\Gamma$ remain unchanged and, correspondingly, that the ensemble's entropy

$$S = -k_B \int (\rho \ln \rho) \mathcal{N}_{\text{states}} d\Gamma = k_B \ln(\mathcal{N}_{\text{states}} \Delta\Gamma) \quad (4.37)$$

remain unchanged.

How can this be so? The ensemble is supposed to evolve into statistical equilibrium, with its distribution function uniformly spread out over that entire portion of

FIGURE 4.2 Evolution of a classical ensemble at $t = 0$ (a) toward statistical equilibrium by means of phase mixing (b) (cf. Fig. 4.1) followed by coarse-graining of one's viewpoint (c).

phase space allowed by the hamiltonian's constants of motion—a portion of phase space far, far larger than $\Delta\Gamma$ —and in the process the entropy is supposed to increase.

Figure 4.2b,c resolves the paradox. As time passes, the occupied region becomes more and more distorted. It retains its phase-space volume, but gets strung out into a winding, contorted surface (Fig. 4.2b), which (by virtue of the ergodic hypothesis) ultimately passes arbitrarily close to any given point in the region allowed by the constants of motion. This ergodic wandering is called *phase mixing*. Ultimately, the physicist gets tired of keeping track (or ceases to be able to keep track) of all these contortions of the occupied region and chooses instead to take a *coarse-grained* viewpoint that averages over scales larger than the distance between adjacent portions of the occupied surface, and thereby regards the ensemble as having become spread over the entire allowed region (Fig. 4.2c). More typically, the physicist will perform a coarse-grained smearing out on some given, constant scale at all times. Once the transverse scale of the ensemble's lengthening and narrowing phase-space region drops below the smearing scale, its smeared volume and its entropy start to increase. Thus, *for an ensemble of closed systems it is the physicist's choice (though often a practical necessity) to perform coarse-grain averaging that causes entropy to increase and causes the ensemble to evolve into statistical equilibrium.*

The situation is a bit more subtle for an ensemble of systems interacting with a thermal bath. The evolution toward statistical equilibrium is driven by the interactions. Thus, it might appear at first sight that the physicist is not, this time, to blame for the entropy increase and the achievement of statistical equilibrium. However, a deeper examination reveals the physicist's ultimate culpability. If the physicist were willing to keep track of all those dynamical degrees of freedom of the bath that are influenced by and influence the systems in the ensemble, then the physicist could incorporate those degrees of freedom into the description of the systems and define a phase-space volume that obeys Liouville's theorem and thus does not increase, and an entropy that correspondingly remains constant. However, physicists instead generally choose to ignore the microscopic details of the bath, and that choice forces them to

phase mixing

coarse graining causes entropy increase

attribute a growing entropy to the ensemble of systems bathed by the bath and regard the ensemble as approaching statistical equilibrium.

DISCARDING CORRELATIONS

When one reexamines these issues in quantum mechanical language, one discovers that the entropy increase is caused by the physicist's discarding the quantum mechanical correlations (the off-diagonal terms in the density matrix of Box 4.2) that get built up through the systems' interaction with the rest of the universe. This discarding of correlations is accomplished through a trace over the external universe's basis states (Box 4.2), and if the state of system plus universe was originally pure, this tracing (discarding of correlations) makes it mixed. From this viewpoint, then, *it is the physicist's choice to discard correlations with the external universe that causes the entropy increase and the evolution toward statistical equilibrium*. Heuristically, we can say that the entropy does not increase until the physicist actually (or figuratively) chooses to let it increase by ignoring the rest of the universe. For a simple example, see Box 4.3 and Ex. 4.9.

discarding quantum correlations (decoherence) causes entropy increase

This viewpoint then raises a most intriguing question. What if we regard the universe as the ultimate microcanonical system? In this case, we might expect that the entropy of the universe will remain identically zero for all time, unless physicists (or other intelligent beings) perform some sort of coarse-graining or discard some sort of correlations. However, such coarse-graining or discarding are made deeply subtle by the fact that the physicists (or other intelligent beings) are themselves part of the system being studied. Further discussion of these questions introduces fascinating, though ill-understood, quantum mechanical and cosmological considerations, which will reappear in a different context in Sec. 28.7.

Exercise 4.2 *Practice: Estimating Entropy*

Make rough estimates of the entropy of the following systems, assuming they are in statistical equilibrium.

- (a) An electron in a hydrogen atom at room temperature.
- (b) A glass of wine.
- (c) The Pacific ocean.
- (d) An ice cube.
- (e) The observable universe. [Its entropy is mostly contained in the 3-K microwave background radiation and in black holes (Sec. 4.10). Why?]

Exercise 4.3 *Derivation and Practice: Additivity of Entropy for Statistically Independent Systems*

Consider an ensemble of classical systems with each system made up of a large number of statistically independent subsystems, so $\rho = \prod_a \rho_a$. Show that the entropy of the full ensemble is equal to the sum of the entropies of the subensembles a : $S = \sum_a S_a$.

EXERCISES

BOX 4.3. ENTROPY INCREASE DUE TO DISCARDING QUANTUM CORRELATIONS

As an idealized, pedagogical example of entropy increase due to physicists' discarding quantum correlations, consider an electron that interacts with a photon. The electron's initial quantum state is $|\psi_e\rangle = \alpha|\uparrow\rangle + \beta|\downarrow\rangle$, where $|\uparrow\rangle$ is the state with spin up, $|\downarrow\rangle$ is that with spin down, and α and β are complex probability amplitudes with $|\alpha|^2 + |\beta|^2 = 1$. The interaction is so arranged that if the electron spin is up, then the photon is put into a positive helicity state $|+\rangle$, and if down, the photon is put into a negative helicity state $|-\rangle$. Therefore, after the interaction the combined system of electron plus photon is in the state $|\Psi\rangle = \alpha|\uparrow\rangle \otimes |+\rangle + \beta|\downarrow\rangle \otimes |-\rangle$, where \otimes is the tensor product [Eq. (1.5a) generalized to the vector space of quantum states].

The photon flies off into the universe leaving the electron isolated. Suppose that we measure some electron observable \hat{A}_e . The expectation values for the measurement before and after the interaction with the photon are

$$\begin{aligned} \text{Before: } \langle \psi_e | \hat{A}_e | \psi_e \rangle &= |\alpha|^2 \langle \uparrow | \hat{A}_e | \uparrow \rangle + |\beta|^2 \langle \downarrow | \hat{A}_e | \downarrow \rangle \\ &\quad + \alpha^* \beta \langle \uparrow | \hat{A}_e | \downarrow \rangle + \beta^* \alpha \langle \downarrow | \hat{A}_e | \uparrow \rangle; \end{aligned} \quad (1)$$

$$\begin{aligned} \text{After: } \langle \Psi | \hat{A}_e | \Psi \rangle &= |\alpha|^2 \langle \uparrow | \hat{A}_e | \uparrow \rangle \underbrace{\langle ++ |}_{1} + |\beta|^2 \langle \downarrow | \hat{A}_e | \downarrow \rangle \underbrace{\langle -- |}_{1} \\ &\quad + \alpha^* \beta \langle \uparrow | \hat{A}_e | \downarrow \rangle \underbrace{\langle +- |}_{0} + \beta^* \alpha \langle \downarrow | \hat{A}_e | \uparrow \rangle \underbrace{\langle -+ |}_{0} \\ &= |\alpha|^2 \langle \uparrow | \hat{A}_e | \uparrow \rangle + |\beta|^2 \langle \downarrow | \hat{A}_e | \downarrow \rangle. \end{aligned} \quad (2)$$

Comparing Eqs. (1) and (2), we see that *the correlations with the photon have removed the $\alpha^* \beta$ and $\beta^* \alpha$ quantum interference terms from the expectation value.* The two pieces $\alpha|\uparrow\rangle$ and $\beta|\downarrow\rangle$ of the electron's original quantum state $|\psi_e\rangle$ are said to have *decohered*. Since the outcomes of all measurements can be expressed in terms of expectation values, this quantum decoherence is complete in the sense that no quantum interference between the $\alpha|\uparrow\rangle$ and $\beta|\downarrow\rangle$ pieces of the electron state $|\psi_e\rangle$ will ever be seen again in any measurement on the electron, unless the photon returns, interacts with the electron, and thereby removes its correlations with the electron state.

If physicists are confident the photon will never return and the correlations will never be removed, then they are free to change their mathematical description of the electron state. Instead of describing the postinteraction state as $|\Psi\rangle = \alpha|\uparrow\rangle \otimes |+\rangle + \beta|\downarrow\rangle \otimes |-\rangle$, the physicists can discard the

(continued)

BOX 4.3. (continued)

correlations with the photon and regard the electron as having *classical* probabilities $\rho_{\uparrow} = |\alpha|^2$ for spin up and $\rho_{\downarrow} = |\beta|^2$ for spin down (i.e., as being in a *mixed* state). This new, mixed-state viewpoint leads to the same expectation value (2) for all physical measurements as the old, correlated, pure-state viewpoint $|\Psi\rangle$.

The important point for us is that, when discarding the quantum correlations with the photon (with the external universe), the physicist changes the entropy from zero (the value for any pure state including $|\Psi\rangle$) to $S = -k_B(p_{\uparrow} \ln p_{\uparrow} + p_{\downarrow} \ln p_{\downarrow}) = -k_B(|\alpha|^2 \ln |\alpha|^2 + |\beta|^2 \ln |\beta|^2) > 0$. The physicist's change of viewpoint has increased the entropy.

In Ex. 4.9, this pedagogical example is reexpressed in terms of the density operator discussed in Box 4.2.

Exercise 4.4 ***Example: Entropy of a Thermalized Mode of a Field*

Consider a mode S of a fermionic or bosonic field, as discussed in Sec. 4.4.3. Suppose that an ensemble of identical such modes is in statistical equilibrium with a heat and particle bath and thus is grand canonically distributed.

(a) Show that if S is fermionic, then the ensemble's entropy is

$$\begin{aligned} S_S &= -k_B[\eta \ln \eta + (1 - \eta) \ln(1 - \eta)] \\ &\simeq -k_B \eta (\ln \eta - 1) \quad \text{in the classical regime } \eta \ll 1, \end{aligned} \quad (4.38a)$$

where η is the mode's fermionic mean occupation number (4.27b).

(b) Show that if the mode is bosonic, then the entropy is

$$\begin{aligned} S_S &= k_B[(\eta + 1) \ln(\eta + 1) - \eta \ln \eta] \\ &\simeq -k_B \eta (\ln \eta - 1) \quad \text{in the classical regime } \eta \ll 1, \end{aligned} \quad (4.38b)$$

where η is the bosonic mean occupation number (4.28b). Note that in the classical regime, $\eta \simeq e^{-(\mathcal{E} - \tilde{\mu})/(k_B T)} \ll 1$, the entropy is insensitive to whether the mode is bosonic or fermionic.

(c) Explain why the entropy per particle in units of Boltzmann's constant is $\sigma = S_S/(\eta k_B)$. Plot σ as a function of η for fermions and for bosons. Show analytically that for degenerate fermions ($\eta \simeq 1$) and for the bosons' classical-wave regime ($\eta \gg 1$) the entropy per particle is small compared to unity. See Sec. 4.8 for the importance of the entropy per particle.

Exercise 4.5 *Example: Entropy of Thermalized Radiation Deduced from Entropy per Mode*

Consider fully thermalized electromagnetic radiation at temperature T , for which the mean occupation number has the standard Planck (blackbody) form $\eta = 1/(e^x - 1)$ with $x = h\nu/(k_B T)$.

- (a) Show that the entropy per mode of this radiation is

$$S_S = k_B [x/(e^x - 1) - \ln(1 - e^{-x})].$$

- (b) Show that the radiation's entropy per unit volume can be written as the following integral over the magnitude of the photon momentum:

$$S/V = (8\pi/h^3) \int_0^\infty S_S p^2 dp.$$

- (c) By performing the integral (e.g., using Mathematica), show that

$$\frac{S}{V} = \frac{4}{3} \frac{U}{T} = \frac{4}{3} a T^3, \quad (4.39)$$

where $U = aT^4$ is the radiation energy density, and $a = (8\pi^5 k_B^4/15)/(ch)^3$ is the radiation constant [Eqs. (3.54)].

- (d) Verify Eq. (4.39) for the entropy density by using the first law of thermodynamics $dE = TdS - PdV$ (which you are presumed to know before reading this book, and which we discuss below and study in the next chapter).

Exercise 4.6 *Problem: Entropy of a Classical, Nonrelativistic, Perfect Gas, Deduced from Entropy per Mode*

Consider a classical, nonrelativistic gas whose particles do not interact and have no excited internal degrees of freedom (a *perfect gas*—not to be confused with perfect fluid). Let the gas be contained in a volume V and be thermalized at temperature T and chemical potential μ . Using the gas's entropy per mode, Ex. 4.4, show that the total entropy in the volume V is

$$S = \left(\frac{5}{2} - \frac{\mu}{k_B T} \right) k_B N, \quad (4.40)$$

where $N = g_s (2\pi m k_B T / h^2)^{3/2} e^{\mu/(k_B T)} V$ is the number of particles in the volume V [Eq. (3.39a), derived in Chap. 3 using kinetic theory], and g_s is each particle's number of spin states.

Exercise 4.7 *Example: Entropy of a Classical, Nonrelativistic, Perfect Gas in a Microcanonical Ensemble*

Consider a microcanonical ensemble of closed cubical cells with volume V . Let each cell contain precisely N particles of a classical, nonrelativistic, perfect gas and contain a nonrelativistic total energy $E \equiv \mathcal{E} - Nmc^2$. For the moment (by contrast with the

text's discussion of the microcanonical ensemble), assume that E is precisely fixed instead of being spread over some tiny but finite range.

- (a) Explain why the region \mathcal{Y}_o of phase space accessible to each system is

$$|x_A| < L/2, \quad |y_A| < L/2, \quad |z_A| < L/2, \quad \sum_{A=1}^N \frac{1}{2m} |\mathbf{p}_A|^2 = E, \quad (4.41a)$$

where A labels the particles, and $L \equiv V^{1/3}$ is the side of the cell.

- (b) To compute the entropy of the microcanonical ensemble, we compute the volume $\Delta\Gamma$ in phase space that it occupies, multiply by the number density of states in phase space (which is independent of location in phase space), and then take the logarithm. Explain why

$$\Delta\Gamma \equiv \prod_{A=1}^N \int_{\mathcal{Y}_o} dx_A dy_A dz_A dp_A^x dp_A^y dp_A^z \quad (4.41b)$$

vanishes. This illustrates the “set of measure zero” statement in the text (second paragraph of Sec. 4.5), which we used to assert that we must allow the systems' energies to be spread over some tiny but finite range.

- (c) Now permit the energies of our ensemble's cells to lie in the tiny but finite range $E_o - \delta E_o < E < E_o$. Show that

$$\Delta\Gamma = V^N [\mathcal{V}_v(a) - \mathcal{V}_v(a - \delta a)], \quad (4.41c)$$

where $\mathcal{V}_v(a)$ is the volume of a sphere of radius a in a Euclidean space with $v \gg 1$ dimensions, and where

$$a \equiv \sqrt{2mE_o}, \quad \frac{\delta a}{a} \equiv \frac{1}{2} \frac{\delta E_o}{E_o}, \quad v \equiv 3N. \quad (4.41d)$$

It can be shown (and you might want to try to show it) that

$$\mathcal{V}_v(a) = \frac{\pi^{v/2}}{(v/2)!} a^v \quad \text{for } v \gg 1. \quad (4.41e)$$

- (d) Show that, so long as $1 \gg \delta E_o/E_o \gg 1/N$ (where N in practice is an exceedingly huge number),

$$\mathcal{V}_v(a) - \mathcal{V}_v(a - \delta a) \simeq \mathcal{V}_v(a) [1 - e^{-v\delta a/a}] \simeq \mathcal{V}_v(a), \quad (4.41f)$$

which is independent of δE_o and thus will produce a value for $\Delta\Gamma$ and thence N_{states} and S independent of δE_o , as desired. From this and with the aid of Stirling's approximation (Reif, 2008, Appendix A.6) $n! \simeq (2\pi n)^{1/2} (n/e)^n$ for large n , and taking account of the multiplicity $\mathcal{M} = N!$, show that the entropy of the microcanonically distributed cells is given by

$$S(V, E, N) = Nk_B \ln \left[\frac{V}{N} \left(\frac{E}{N} \right)^{3/2} g_s \left(\frac{4\pi m}{3h^2} \right)^{3/2} e^{5/2} \right]. \quad (4.42)$$

This is known as the *Sackur-Tetrode* equation.

- (e) Using Eqs. (3.39), show that this is equivalent to Eq. (4.40) for the entropy, which we derived by a very different method.

Exercise 4.8 ***Example: Entropy of Mixing, Indistinguishability of Atoms, and the Gibbs Paradox*

- (a) Consider two identical chambers, each with volume V , separated by an impermeable membrane. Into one chamber put energy E and N atoms of helium, and into the other, energy E and N atoms of xenon, with E/N and N/V small enough that the gases are nonrelativistic and nondegenerate. The membrane is ruptured, and the gases mix. Show that this mixing drives the entropy up by an amount $\Delta S = 2Nk_B \ln 2$. [Hint: Use the Sackur-Tetrode equation (4.42).]
- (b) Suppose that energy E and N atoms of helium are put into both chambers (no xenon). Show that, when the membrane is ruptured and the gases mix, there is no increase of entropy. Explain why this result is reasonable, and explain its relationship to entropy being an extensive variable.
- (c) Suppose that the N helium atoms were distinguishable instead of indistinguishable. Show this would mean that, in the microcanonical ensemble, they have $N!$ more states available to themselves, and their entropy would be larger by $k_B \ln N! \simeq k_B(N \ln N - N)$; and as a result, the Sackur-Tetrode formula (4.42) would be

Distinguishable particles:

$$S(V, E, N) = Nk_B \ln \left[V \left(\frac{E}{N} \right)^{3/2} \left(\frac{4\pi m}{3h^2} \right)^{3/2} e^{3/2} \right]. \quad (4.43)$$

Before the advent of quantum theory, physicists thought that atoms were distinguishable, and up to an additive multiple of N (which they could not compute), they deduced this entropy.

- (d) Show that if, as prequantum physicists believed, atoms were distinguishable, then when the membrane between two identical helium-filled chambers is ruptured, there would be an entropy increase identical to that when the membrane between helium and xenon is ruptured: $\Delta S = 2Nk_B \ln 2$ [cf. parts (a) and (b)]. This result, which made prequantum physicists rather uncomfortable, is called the *Gibbs paradox*.

Exercise 4.9 *Problem: Quantum Decoherence and Entropy Increase in Terms of the Density Operator* T2

Reexpress Box 4.3's pedagogical example of quantum decoherence and entropy increase in the language of the quantum mechanical density operator $\hat{\rho}$ (Box 4.2). Use

this example to explain the meaning of the various statements made in the next-to-last paragraph of Sec. 4.7.2.

T2

4.8 Entropy per Particle

4.8

The entropy per particle in units of Boltzmann's constant,

$$\sigma \equiv S/(Nk_B), \quad (4.44)$$

entropy per particle

is a very useful concept in both quantitative and order-of-magnitude analyses. (See, e.g., Exs. 4.10, 4.11, and 4.4c, and the discussion of entropy in the expanding universe in Sec. 4.10.3.) One reason is the second law of thermodynamics. Another is that in the real universe σ generally lies somewhere between 0 and 100 and thus is a natural quantity in terms of which to think about and remember the magnitudes of various quantities.

For example, for ionized hydrogen gas in the nonrelativistic, classical domain, the Sackur-Tetrode equation (4.42) for the entropy (derived from the microcanonical ensemble in Ex. 4.7), when specialized either to the gas's protons or to its electrons (both of which, with their spin 1/2, have $g_s = 2$), gives

$$\sigma_p = \frac{5}{2} + \ln \left[\frac{2m_p}{\rho} \left(\frac{2\pi m k_B T}{h^2} \right)^{3/2} \right]. \quad (4.45)$$

entropy of ionized hydrogen

Here we have set the number density of particles N/V (either protons or electrons) to ρ/m_p , since almost all the mass density ρ is in the protons, and we have set the thermal energy per particle E/N to $\frac{3}{2}k_B T$ [see Eq. (3.39b) derived in Chap. 3 using kinetic theory]. The only way this formula depends on which particle species we are considering, the gas's protons or its electrons, is through the particle mass m ; and this factor in Eq. (4.45) tells us that the protons' entropy per proton is a factor $\simeq 10$ higher than the electrons': $\sigma_p - \sigma_e = \frac{3}{2} \ln(m_p/m_e) = 11.27 \simeq 10$. Therefore, for an ionized hydrogen gas most of the entropy is in the protons.

The protons' entropy per proton is plotted as a function of density and temperature in Fig. 4.3. It grows logarithmically as the density ρ decreases, and it ranges from $\sigma \ll 1$ in the regime of extreme proton degeneracy (lower right of Fig. 4.3; see Ex. 4.4) to $\sigma \sim 1$ near the onset of proton degeneracy (the boundary of the classical approximation), to $\sigma \sim 100$ at the lowest density that occurs in the universe, $\rho \sim 10^{-29} \text{ g cm}^{-3}$. This range is an example of the fact that the logarithms of almost all dimensionless numbers that occur in Nature lie between approximately -100 and $+100$.

FIGURE 4.3 Proton entropy per proton σ_p for an ionized hydrogen gas. Each line is labeled with its value of σ_p . The electron entropy per electron σ_e is a factor $\simeq 10$ smaller; the electrons are degenerate when $\sigma_e \simeq \sigma_p - 10 \lesssim 1$. The protons are degenerate when $\sigma_p \lesssim 1$.

EXERCISES

Exercise 4.10 ***Problem: Primordial Element Formation*

- As we shall see in Sec. 28.4.1, when the early universe was ~ 200 s old, its principal constituents were photons, protons, neutrons, electrons, positrons, and (thermodynamically isolated) neutrinos and gravitons. The photon temperature was $\sim 9 \times 10^8$ K, and the baryon density was $\sim 0.02 \text{ kg m}^{-3}$. The photons, protons, electrons, and positrons were undergoing rapid electromagnetic interactions that kept them in thermodynamic equilibrium. Use the neutron-proton mass difference of 1.3 MeV to argue that, if the neutrons had also been in thermodynamic equilibrium, then their density would have been negligible at this time.
- However, the universe expanded too rapidly for weak interactions to keep the neutrons in equilibrium with the other particles, and so the fraction of the baryons at 200 s, in the form of neutrons that did not subsequently decay, was ~ 0.14 . At this time (Sec. 28.4.2) the neutrons began rapidly combining with protons to form alpha particles through a short chain of reactions, of which the first step—the one that was hardest to make go—was $n + p \rightarrow d + 2.22 \text{ MeV}$, with the 2.22 MeV going into heat. Only about 10^{-5} of the baryons needed to go into deuterium in order to start and then maintain the full reaction chain. Show, using entropy per particle and the first law of thermodynamics, that at time $t \sim 200$ s after the big bang, this reaction was just barely entropically favorable.
- During this epoch, roughly how do you expect the baryon density to have decreased as a function of decreasing photon temperature? (For this you can neglect the heat being released by the nuclear burning and the role of positrons.) Show that before $t \sim 200$ s, the deuterium-formation reaction could not take place, and after $t \sim 200$ s, it rapidly became strongly entropically favorable.

- (d) The nuclear reactions shut down when the neutrons had all cycled through deuterium and almost all had been incorporated into α particles, leaving only $\sim 10^{-5}$ of them in deuterium. About what fraction of all the baryons wound up in α particles (Helium 4)? (See Fig. 28.7 for details from a more complete analysis sketched in Sec. 28.4.2.)

Exercise 4.11 *Problem: Reionization of the Universe*

Following the epoch of primordial element formation (Ex. 4.10), the universe continued to expand and cool. Eventually when the temperature of the photons was $\sim 3,000$ K, the free electrons and protons combined to form atomic hydrogen; this was the *epoch of recombination*. Later, when the photon temperature had fallen to ~ 30 K, some hot stars and quasars formed and their ultraviolet radiation dissociated the hydrogen; this was the *epoch of reionization*. The details are poorly understood. (For more discussion, see Ex. 28.19.) Making the simplifying assumption that reionization happened rapidly and homogeneously, show that the increase in the entropy per baryon was $\sim 60k_B$, depending weakly on the temperature of the atomic hydrogen, which you can assume to be ~ 100 K.

4.9 Bose-Einstein Condensate

4.9

In this section, we explore an important modern application of the Bose-Einstein mean occupation number for bosons in statistical equilibrium. Our objectives are (i) to exhibit, in action, the tools developed in this chapter and (ii) to give a nice example of the connections between quantum statistical mechanics (which we use in the first 3/4 of this section) and classical statistical mechanics (which we use in the last 1/4).

For bosons in statistical equilibrium, the mean occupation number $\eta = 1/[e^{(E-\mu)/(k_B T)} - 1]$ diverges as $E \rightarrow 0$, if the chemical potential μ vanishes. This divergence is intimately connected to *Bose-Einstein condensation*.

Bose-Einstein condensation

Consider a dilute atomic gas in the form of a large number N of bosonic atoms, spatially confined by a magnetic trap. When the gas is cooled below some critical temperature T_c , μ is negative but gets very close to zero [see Eq. (4.47d)], causing η to become huge near zero energy. This huge η manifests physically as a large number N_0 of atoms collecting into the trap's mode of lowest (vanishing) energy, the Schrödinger equation's ground state [see Eq. (4.49a) and Fig. 4.4a later in this section].

This condensation was predicted by Einstein (1925), but an experimental demonstration was not technologically feasible until 1995, when two research groups independently exhibited it: one at JILA (University of Colorado) led by Eric Cornell and Carl Wieman; the other at MIT led by Wolfgang Ketterle. For these experiments, Cornell, Ketterle, and Wieman were awarded the 2001 Nobel Prize. Bose-Einstein condensates have great promise as tools for precision-measurement technology and nanotechnology.

As a concrete example of Bose-Einstein condensation, we analyze an idealized version of one of the early experiments by the JILA group (Ensher et al., 1996): a gas of 40,000 ^{87}Rb atoms placed in a magnetic trap that we approximate as a spherically symmetric, harmonic oscillator potential:¹³

$$V(r) = \frac{1}{2}m\omega_o^2 r^2 = \frac{1}{2}m\omega_o^2(x^2 + y^2 + z^2). \quad (4.46a)$$

Here x , y , z are Cartesian coordinates, and r is radius. The harmonic-oscillator frequency ω_o and associated temperature $\hbar\omega_o/k_B$, the number N of rubidium atoms trapped in the potential, and the atoms' rest mass m are

$$\omega_o/(2\pi) = 181 \text{ Hz}, \quad \hbar\omega_o/k_B = 8.7 \text{ nK}, \quad N = 40,000, \quad m = 1.444 \times 10^{-25} \text{ kg}. \quad (4.46b)$$

Our analysis is adapted, in part, from a review article by Dalfovo et al. (1999).

Each ^{87}Rb atom is made from an even number of fermions [$Z = 37$ electrons, $Z = 37$ protons, and $(A - Z) = 50$ neutrons], and the many-particle wave function Ψ for the system of $N = 40,000$ atoms is antisymmetric (changes sign) under interchange of each pair of electrons, each pair of protons, and each pair of neutrons. Therefore, when any pair of atoms is interchanged (entailing interchange of an even number of fermion pairs), there is an even number of sign flips in Ψ . Thus Ψ is symmetric (no sign change) under interchange of atoms (i.e., the atoms behave like bosons and must obey Bose-Einstein statistics).

Repulsive forces between the atoms have a moderate influence on the experiment, but only a tiny influence on the quantities that we compute (see, e.g., Dalfovo et al., 1999). We ignore those forces and treat the atoms as noninteracting.

To make contact with our derivation, in Sec. 4.4.3, of the Bose-Einstein distribution, we must identify the modes (single-atom quantum states) \mathcal{S} available to the atoms. Those modes are the energy eigenstates of the Schrödinger equation for a ^{87}Rb atom in the harmonic-oscillator potential $V(r)$. Solution of the Schrödinger equation (e.g., Cohen-Tannoudji, Diu, and Laloë, 1977, complement B_{VII}) reveals that the energy eigenstates can be labeled by the number of quanta of energy $\{n_x, n_y, n_z\}$ associated with an atom's motion along the x , y , and z directions; the energy of the mode $\{n_x, n_y, n_z\}$ is $E_{n_x, n_y, n_z} = \hbar\omega_o[(n_x + 1/2) + (n_y + 1/2) + (n_z + 1/2)]$. We simplify subsequent formulas by subtracting $\frac{3}{2}\hbar\omega_o$ from all energies and all chemical potentials. This is merely a change in what energy we regard as zero (renormalization), a change under which our statistical formalism is invariant (cf. foot-

modes: single-atom
quantum states

13. In the actual experiment, the potential was harmonic but prolate spheroidal rather than spherical, i.e., in Cartesian coordinates $V(x, y, z) = \frac{1}{2}m[\omega_x^2(x^2 + y^2) + \omega_z^2 z^2]$, with ω_z somewhat smaller than ω_x . For pedagogical simplicity we treat the potential as spherical, with ω_o set to the geometric mean of the actual frequencies along the three Cartesian axes, $\omega_o = (\omega_x^2 \omega_z^2)^{1/3}$. This choice of ω_o gives good agreement between our model's predictions and the prolate-spheroidal predictions for the quantities that we compute.

note 8 on page 175). Correspondingly, we attribute to the mode $\{n_x, n_y, n_z\}$ the energy $E_{n_x, n_y, n_z} = \hbar\omega_o(n_x + n_y + n_z)$. Our calculations will be simplified by lumping together all modes that have the same energy, so we switch from $\{n_x, n_y, n_z\}$ to $q \equiv n_x + n_y + n_z$ (the mode's total number of quanta) as our fundamental quantum number, and we write the mode's energy as

$$E_q = q\hbar\omega_o. \quad (4.47a)$$

It is straightforward to verify that the number of independent modes with q quanta (the number of independent ways to choose $\{n_x, n_y, n_z\}$ such that their sum is q) is $\frac{1}{2}(q+1)(q+2)$. (Of course, one can also derive this same formula in spherical polar coordinates.)

Of special interest is the ground-state mode of the potential, $\{n_x, n_y, n_z\} = \{0, 0, 0\}$. This mode has $q = 0$, and it is unique: $(q+1)(q+2)/2 = 1$. Its energy is $E_0 = 0$, and its Schrödinger wave function is $\psi_o = (\pi\sigma_o^2)^{-3/4} \exp(-r^2/(2\sigma_o^2))$, so for any atom that happens to be in this ground-state mode, the probability distribution for its location is the Gaussian

$$|\psi_o(r)|^2 = \left(\frac{1}{\pi\sigma_o^2}\right)^{3/2} \exp\left(-\frac{r^2}{\sigma_o^2}\right), \quad \text{where } \sigma_o = \sqrt{\frac{\hbar}{m\omega_o}} = 0.800 \mu\text{m}. \quad (4.47b)$$

The entire collection of N atoms in the magnetic trap is a system; it interacts with its environment, which is at temperature T , exchanging energy but nothing else, so a conceptual ensemble consisting of this N -atom system and a huge number of identical systems has the canonical distribution $\rho = C \exp(-E_{\text{tot}}/(k_B T))$, where E_{tot} is the total energy of all the atoms. Each mode (labeled by $\{n_x, n_y, n_z\}$ or by q and two degeneracy parameters that we have not specified) is a subsystem of this system. Because the modes can exchange atoms as well as energy with one another, a conceptual ensemble consisting of any chosen mode and its clones is grand-canonically distributed [Eq. (4.28a)], so its mean occupation number is given by the Bose-Einstein formula (4.28b) with $E_S = q\hbar\omega_o$:

$$\eta_q = \frac{1}{\exp[(q\hbar\omega_o - \mu)/(k_B T)] - 1}. \quad (4.47c)$$

The temperature T is inherited from the environment (heat bath) in which the atoms live. The chemical potential μ is common to all the modes and takes on whatever value is required to guarantee that the total number of atoms in the trap is N —or, equivalently, that the sum of the mean occupation number (4.47c) over all the modes is N .

For the temperatures of interest to us:

1. The number $N_0 \equiv \eta_0$ of atoms in the ground-state mode $q = 0$ will be large, $N_0 \gg 1$, which permits us to expand the exponential in Eq. (4.47c) with $q = 0$ to obtain $N_0 = 1/[e^{-\mu/(k_B T)} - 1] \simeq -k_B T/\mu$, that is,

$$\mu/(k_B T) = -1/N_0. \quad (4.47d)$$

ground-state mode

2. The atoms in excited modes will be spread out smoothly over many values of q , so we can approximate the total number of excited-mode atoms by an integral:

$$N - N_0 = \sum_{q=1}^{\infty} \frac{(q+1)(q+2)}{2} \eta_q \simeq \int_0^{\infty} \frac{\frac{1}{2}(q^2 + 3q + 2)dq}{\exp[(q\hbar\omega_o/(k_B T) + 1/N_0)] - 1}. \quad (4.48a)$$

The integral is dominated by large qs , so it is a rather good approximation to keep only the q^2 term in the numerator and to neglect the $1/N_0$ in the exponential:

$$N - N_0 \simeq \int_0^{\infty} \frac{q^2/2}{\exp(q\hbar\omega_o/(k_B T)) - 1} dq = \zeta(3) \left(\frac{k_B T}{\hbar\omega_o} \right)^3. \quad (4.48b)$$

Here $\zeta(3) \simeq 1.202$ is the Riemann zeta function [which also appeared in our study of the equation of state of thermalized radiation, Eq. (3.54b)]. It is useful to rewrite Eq. (4.48b) as

$$N_0 = N \left[1 - \left(\frac{T}{T_c^0} \right)^3 \right], \quad (4.49a)$$

where

$$T_c^0 = \frac{\hbar\omega_o}{k_B} \left(\frac{N}{\zeta(3)} \right)^{1/3} = 280 \text{ nK} \gg \hbar\omega_o/k_B = 8.7 \text{ nK} \quad (4.49b)$$

is our leading-order approximation to the critical temperature T_c . Obviously, we cannot have a negative number of atoms in the ground-state mode, so Eq. (4.49a) must fail for $T > T_c^0$. Presumably, N_0 becomes so small there that our approximation (4.47d) fails.

Figure 4.4a, adapted from the review article by Dalfovo et al. (1999), compares our simple prediction (4.49a) for $N_0(T)$ (dashed curve) with the experimental measurements by the JILA group (Ensher et al., 1996). Both theory and experiment show that, when one lowers the temperature T through a critical temperature T_c , the atoms suddenly begin to accumulate in large numbers in the ground-state mode. At $T \simeq 0.8T_c$, half the atoms have condensed into the ground state (Bose-Einstein condensation); at $T \simeq 0.2T_c$ almost all are in the ground state. The simple formula (4.49a) is remarkably good at $0 < T < T_c$; evidently, T_c^0 [Eq. (4.49b)] is a rather good leading-order approximation to the critical temperature T_c at which the Bose-Einstein condensate begins to form.

Exercise 4.12 and Fig. 4.4b use more accurate approximations to Eq. (4.48a) to explore the onset of condensation as T is gradually lowered through the critical temperature. The onset is actually continuous when viewed on a sufficiently fine temperature scale; but on scales $0.01T_c$ or greater, it appears to be discontinuous.

The onset of Bose-Einstein condensation is an example of a *phase transition*: a sudden (nearly) discontinuous change in the properties of a thermalized system. Among

ground-state occupation number

critical temperature

Bose-Einstein condensation

phase transition

FIGURE 4.4 The number N_0 of atoms in the Bose-Einstein condensate at the center of a magnetic trap as a function of temperature T . (a) Low resolution; (b) High resolution. The dashed curve in each panel is the prediction (4.49a) of the simple theory presented in the text, using the parameters shown in Eq. (4.46b). The dotted curve in panel b is the prediction derived in Ex. 4.12c. The solid curves are our most accurate prediction (4.54) [Ex. 4.12d], including details of the condensation turning on. The large dots are experimental data from Ensher et al. (1996). Panel a is adapted from Dalfovo et al. (1999).

the sudden changes accompanying this phase transition is a (nearly) discontinuous change of the atoms' specific heat (Ex. 4.13). We study some other phase transitions in Chap. 5.

Notice that the critical temperature T_c^0 is larger, by a factor $\sim N^{1/3} = 34$, than the temperature $\hbar\omega_o/k_B = 8.7$ nK associated with the harmonic-oscillator potential. Correspondingly, at the critical temperature there are significant numbers of atoms in modes with q as large as ~ 34 —which means that nearly all of the atoms are actually behaving rather classically at $T \simeq T_c^0$, despite our use of quantum mechanical concepts to analyze them!

It is illuminating to compute the spatial distribution of these atoms at the critical temperature using classical techniques. (This distribution could equally well be deduced using the above quantum techniques.) In the near classical, outer region of the trapping potential, the atoms' number density in phase space $\mathcal{N} = (g_s/h^3)\eta$ must have the classical, Boltzmann-distribution form (4.29): $dN/d\mathcal{V}_x d\mathcal{V}_p \propto \exp[-E/(k_B T)] = \exp\{-[V(r) + p^2/(2m)]/(k_B T_c)\}$, where $V(r)$ is the harmonic-oscillator potential (4.46a). Integrating over momentum space, $d\mathcal{V}_p = 4\pi p^2 dp$, we obtain for the number density of atoms $n = dN/d\mathcal{V}_x$

$$n(r) \propto \exp\left(\frac{-V(r)}{k_B T_c}\right) = \exp\left(\frac{-r^2}{a_o^2}\right), \quad (4.50a)$$

where [using Eqs. (4.49b) for T_c and (4.47b) for ω_o]

$$a_o = \sqrt{\frac{2k_B T_c}{m\omega_o^2}} = \frac{\sqrt{2}}{[\zeta(3)]^{1/6}} N^{1/6} \sigma_o = 1.371 N^{1/6} \sigma_o = 8.02 \sigma_o = 6.4 \mu\text{m}. \quad (4.50b)$$

Thus, at the critical temperature, the atoms have an approximately Gaussian spatial distribution with radius a_o eight times larger than the trap's $0.80 \mu\text{m}$ ground-state Gaussian distribution. This size of the distribution gives insight into the origin of the Bose-Einstein condensation: The mean inter-atom spacing at the critical temperature T_c^0 is $a_o/N^{1/3}$. It is easy to verify that this is approximately equal to the typical atom's de Broglie wavelength $\lambda_{T_{dB}} = h/\sqrt{2\pi mk_B T} = h/(\text{typical momentum})$ —which is the size of the region that we can think of each atom as occupying. The atomic separation is smaller than this in the core of the atomic cloud, so the atoms there are beginning to overlap and feel one another's presence, and thereby want to accumulate into the same quantum state (i.e., want to begin condensing). By contrast, the mean separation is larger than λ_{dB} in the outer portion of the cloud, so the atoms there continue to behave classically.

At temperatures below T_c , the N_0 condensed, ground-state-mode atoms have a spatial Gaussian distribution with radius $\sigma_o \sim a_o/8$ (i.e., eight times smaller than the region occupied by the classical, excited-state atoms). Therefore, the condensation is visually manifest by the growth of a sharply peaked core of atoms at the center of the larger, classical, thermalized cloud. In momentum space, the condensed atoms and classical cloud also have Gaussian distributions, with rms momenta $p_{\text{cloud}} \sim 8p_{\text{condensate}}$ (Ex. 4.14) or equivalently, rms speeds $v_{\text{cloud}} \sim 8v_{\text{condensate}}$. In early experiments, the existence of the condensate was observed by suddenly shutting off the trap and letting the condensate and cloud expand ballistically to sizes $v_{\text{condensate}}t$ and $v_{\text{cloud}}t$, and then observing them visually. The condensate was revealed as a sharp Gaussian peak, sticking out of the roughly eight times larger, classical cloud (Fig. 4.5).

EXERCISES

Exercise 4.12 ***Example: Onset of Bose-Einstein Condensation*

By using more accurate approximations to Eq. (4.48a), explore the onset of the condensation near $T = T_c^0$. More specifically, do the following.

- (a) Approximate the numerator in Eq. (4.48a) by $q^2 + 3q$, and keep the $1/N_0$ term in the exponential. Thereby obtain

$$N - N_0 = \left(\frac{k_B T}{\hbar\omega_o}\right)^3 \text{Li}_3(e^{-1/N_0}) + \frac{3}{2} \left(\frac{k_B T}{\hbar\omega_o}\right)^2 \text{Li}_2(e^{-1/N_0}). \quad (4.51)$$

Here

$$\text{Li}_n(u) = \sum_{p=1}^{\infty} \frac{u^p}{p^n} \quad (4.52a)$$

is a special function called the *polylogarithm* (Lewin, 1981), which is known to Mathematica and other symbolic manipulation software and has the properties

FIGURE 4.5 Velocity distribution of rubidium atoms in a Bose-Einstein condensate experiment by Anderson et al. (1995), as observed by the ballistic expansion method described in the text. In the left frame T is slightly higher than T_c , and there is only the classical cloud. In the center frame T is a bit below T_c , and the condensate sticks up sharply above the cloud. The right frame, at still lower T , shows almost pure condensate. Figure from Cornell (1996).

$$\text{Li}_n(1) = \zeta(n), \quad \frac{d\text{Li}_n(u)}{du} = \frac{\text{Li}_{n-1}(u)}{u}, \quad (4.52b)$$

where $\zeta(n)$ is the Riemann zeta function.

- (b) Show that by setting $e^{-1/N_0} = 1$ and ignoring the second polylogarithm in Eq. (4.51), one obtains the leading-order description of the condensation discussed in the text: Eqs. (4.48b) and (4.49).
- (c) By continuing to set $e^{-1/N_0} = 1$ but keeping the second polylogarithm, obtain an improved equation for $N_0(T)$. Your answer should continue to show a discontinuous turn on of the condensation, but at a more accurate, slightly lower critical temperature

$$T_c^1 = T_c^0 \left[1 - \frac{\zeta(2)}{2\zeta(3)^{2/3}} \frac{1}{N^{1/3}} \right] = 0.979T_c^0. \quad (4.53)$$

This equation illustrates the fact that our approximations are a *large- N expansion* (i.e., an expansion in powers of $1/N$).

- (d) By keeping all details of Eq. (4.51) but rewriting it in terms of T_c^0 , show that

$$N_0 = N \left[1 - \left(\frac{T}{T_c^0} \right)^3 \frac{\text{Li}_3(e^{-1/N_0})}{\zeta(3)} - \frac{3}{2\zeta(3)^{2/3}} \frac{1}{N^{1/3}} \left(\frac{T}{T_c^0} \right)^2 \text{Li}_2(e^{-1/N_0}) \right]. \quad (4.54)$$

Solve this numerically to obtain $N_0(T/T_c^0)$ for $N = 40,000$, and plot your result graphically. It should take the form of the solid curves in Fig. 4.4: a continuous turn on of the condensation over the narrow temperature range $0.98T_c^0 \lesssim T \lesssim 0.99T_c^0$ (i.e., a range $\Delta T \sim T_c^0/N^{1/3}$). In the limit of an arbitrarily large number of atoms, the turn on is instantaneous, as described by Eq. (4.49a)—an instantaneous phase transition.

Exercise 4.13 ***Problem: Discontinuous Change of Specific Heat*

Analyze the behavior of the atoms' total energy near the onset of condensation, in the limit of arbitrarily large N (i.e., keeping only the leading order in our $1/N^{1/3}$ expansion and approximating the condensation as turning on discontinuously at $T = T_c^0$). More specifically, do the following.

(a) Show that the total energy of the atoms in the magnetic trap is

$$E_{\text{total}} = \frac{3\zeta(4)}{\zeta(3)} N k_B T_c^0 \left(\frac{T}{T_c^0} \right)^4 \quad \text{when } T < T_c^0, \quad (4.55a)$$

$$E_{\text{total}} = \frac{3\text{Li}_4(e^{\mu/(k_B T)})}{\zeta(3)} N k_B T_c^0 \left(\frac{T}{T_c^0} \right)^4 \quad \text{when } T > T_c^0,$$

where (at $T > T_c^0$) $e^{\mu/(k_B T)}$ is a function of N and T determined by $N = (k_B T / (\hbar \omega_o))^3 \text{Li}_3(e^{\mu/(k_B T)})$, so $\mu = 0$ at $T = T_c^0$ (see Ex. 4.12). Because $\text{Li}_n(1) = \zeta(n)$, this energy is continuous across the critical temperature T_c^0 .

(b) Show that the specific heat $C = (\partial E_{\text{total}} / \partial T)_N$ is discontinuous across the critical temperature T_c^0 :

$$C = \frac{12\zeta(4)}{\zeta(3)} N k_B = 10.80 N k_B \quad \text{as } T \rightarrow T_c^0 \text{ from below,} \quad (4.55b)$$

$$C = \left(\frac{12\zeta(4)}{\zeta(3)} - \frac{9\zeta(3)}{\zeta(2)} \right) N k_B = 4.228 N k_B \quad \text{as } T \rightarrow T_c^0 \text{ from above.}$$

Note that for gas contained within the walls of a box, there are two specific heats: $C_V = (\partial E / \partial T)_{N, V}$ when the box volume is held fixed, and $C_P = (\partial E / \partial T)_{N, P}$ when the pressure exerted by the box walls is held fixed. For our trapped atoms, there are no physical walls; the quantity held fixed in place of V or P is the trapping potential $V(r)$.

Exercise 4.14 *Derivation: Momentum Distributions in Condensate Experiments*

Show that in the Bose-Einstein condensate discussed in the text, the momentum distribution for the ground-state-mode atoms is Gaussian with rms momentum $p_{\text{condensate}} = \sqrt{3/2} \hbar / \sigma_o = \sqrt{3 \hbar m \omega_o / 2}$ and that for the classical cloud it is Gaussian with rms momentum $p_{\text{cloud}} = \sqrt{3 m k_B T_c} \simeq \sqrt{3(N/\zeta(3))^{1/3} \hbar m \omega_o} \simeq 8 p_{\text{condensate}}$.

Exercise 4.15 *Problem: Bose-Einstein Condensation in a Cubical Box*

Analyze Bose-Einstein condensation in a cubical box with edge lengths L [i.e., for a potential $V(x, y, z)$ that is zero inside the box and infinite outside it]. In particular, using the analog of the text's simplest approximation, show that the critical temperature at which condensation begins is

$$T_c^0 = \frac{1}{8\pi m k_B} \left[\frac{2\pi \hbar}{L} \left(\frac{N}{\zeta(3/2)} \right)^{1/3} \right]^2, \quad (4.56a)$$

and the number of atoms in the ground-state condensate, when $T < T_c^0$, is

$$N_0 = N \left[1 - \left(\frac{T}{T_c^0} \right)^{3/2} \right]. \quad (4.56b)$$

4.10 Statistical Mechanics in the Presence of Gravity T2

4.10

Systems with significant gravity behave quite differently in terms of their statistical mechanics than do systems without gravity. This has led to much controversy as to whether statistical mechanics can really be applied to gravitating systems. Despite that controversy, statistical mechanics has been applied in the presence of gravity in a variety of ways, with great success, resulting in important, fundamental conclusions. In this section, we sketch some of those applications: to galaxies, black holes, the universe as a whole, and the formation of structure in the universe. Our discussion is intended to give just the flavor of these subjects and not full details, so we state some things without derivation. This is necessary in part because many of the phenomena we describe rely for their justification on general relativity (Part VII) and/or quantum field theory in curved spacetime (see, e.g., Parker and Toms, 2009).

4.10.1 Galaxies T2

4.10.1

A galaxy is dominated by a roughly spherical distribution of dark matter (believed to comprise elementary particles with negligible collision cross section) with radius $R_D \sim 3 \times 10^{21}$ m and mass $M_D \sim 10^{42}$ kg. The dark matter and roughly $N \sim 10^{11}$ stars, each with fiducial mass $m \sim 10^{30}$ kg, move in a common gravitational potential well. (As we discuss in Chap. 28, the ratio of regular, or baryonic, matter to dark matter is roughly 1:5 by mass.) The baryons (stars plus gas) are mostly contained within a radius $R \sim 3 \times 10^{20}$ m. The characteristic speed of the dark matter and the stars and gas is $v \sim (GM_D/R_D)^{1/2} \sim (GNm/R)^{1/2} \sim 200$ km s⁻¹. For the moment, focus on the stars, with total mass $M = Nm$, ignoring the dark matter and gas, whose presence does not change our conclusions.

The time it takes stars moving in the dark matter's gravitational potential to cross the baryonic galaxy is $\tau_{\text{int}} \sim 2R/v \sim 10^8$ yr.¹⁴ This time is short compared with the

14. $1 \text{ yr} \simeq \pi \times 10^7$ s.

age of a galaxy, $\sim 10^{10}$ yr. Galaxies have distant encounters with their neighbors on timescales that can be smaller than their ages but still much longer than τ_{int} ; in this sense, they can be thought of as semiclosed systems weakly coupled to their environments. In this subsection, we idealize our chosen galaxy as fully closed (no interaction with its environment). Direct collisions between stars are exceedingly rare, and strong two-star gravitational encounters, which happen when the impact parameter¹⁵ is smaller than $\sim Gm/v^2 \sim R/N$, are also negligibly rare except, sometimes, near the center of a galaxy (which we ignore until the last paragraph of this subsection). We can therefore regard each of the galaxy's stars as moving in a gravitational potential determined by the smoothed-out mass of the dark matter and all the other stars, and can use Hamiltonian dynamics to describe their motions.

Imagine that we have an ensemble of such galaxies, all with the same number of stars N , the same mass M , and the same energy E (in a tiny range δE). We begin our study of that ensemble by making an order-of-magnitude estimate of the probability ρ of finding a chosen galaxy from the ensemble in some chosen quantum state. We compute that probability from the corresponding probabilities for its subsystems, individual stars. The phase-space volume available to each star in the galaxy is $\sim R^3(mv)^3$, the density of single-particle quantum states (modes) in each star's phase space is $1/h^3$, the number of available modes is the product of these, $\sim (Rmv/h)^3$, and the probability of the star occupying the chosen mode, or any other mode, is the reciprocal of this product, $\sim [h/(Rmv)]^3$. The probability of the galaxy occupying a state in its phase space is the product of the probabilities for each of its N stars [Eq. (4.18c)]:

$$\rho \sim \left(\frac{h}{Rmv} \right)^{3N} \sim 10^{-2.7 \times 10^{13}}. \quad (4.57)$$

distribution function for stars in a galaxy

This very small number suggests that it is somewhat silly of us to use quantum mechanics to normalize the distribution function (i.e., silly to use the probabilistic distribution function ρ) when dealing with a system as classical as a whole galaxy. Silly, perhaps; but dangerous, no. The key point is that, so far as classical statistical mechanics is concerned, the only important feature of ρ is that it is proportional to the classical distribution function \mathcal{N}_{sys} ; its absolute normalization is usually not important, classically. It was this fact that permitted so much progress to be made in statistical mechanics prior to the advent of quantum mechanics.

Are real galaxies in statistical equilibrium? To gain insight into this question, we estimate the entropy of a galaxy in our ensemble and then ask whether that entropy has any chance of being the maximum value allowed to the galaxy's stars (as it must be if the galaxy is in statistical equilibrium).

Obviously, the stars (by contrast with electrons) are distinguishable, so we can assume multiplicity $\mathcal{M} = 1$ when estimating the galaxy's entropy. Ignoring the (neg-

15. The impact parameter is the closest distance between the two stars along their undeflected trajectories.

ligible) correlations among stars, the entropy computed by integrating $\rho \ln \rho$ over the galaxy's full $6N$ -dimensional phase space is just N times the entropy associated with a single star, which is $S \sim Nk_B \ln(\Delta\Gamma/h^3)$ [Eqs. (4.37) and (4.8a)], where $\Delta\Gamma$ is the phase-space volume over which the star wanders in its ergodic, hamiltonian-induced motion (i.e., the phase space volume available to the star). We express this entropy in terms of the galaxy's total mass M and its total nonrelativistic energy $E \sim -GM^2/(2R)$ as follows. Since the characteristic stellar speed is $v \sim (GM/R)^{1/2}$, the volume of phase space over which the star wanders is $\Delta\Gamma \sim (mv)^3 R^3 \sim (GMm^2R)^{3/2} \sim (-G^2M^3m^2/(2E))^{3/2}$, and the entropy is therefore

$$S_{\text{Galaxy}} \sim (M/m)k_B \ln(\Delta\Gamma/h^3) \sim (3M/(2m))k_B \ln(-G^2M^3m^2/(2Eh^2)). \quad (4.58)$$

Is this the maximum possible entropy available to the galaxy, given the constraints that its mass be M and its nonrelativistic energy be E ? No. Its entropy can be made larger by removing a single star from the galaxy to radius $r \gg R$, where the star's energy is negligible. The entropy of the remaining stars will decrease slightly, since the mass M diminishes by m at constant E . However, the entropy associated with the removed star, $\sim(3/2) \ln(GMm^2r/h^2)$, can be made arbitrarily large by making its orbital radius r arbitrarily large. By this thought experiment, we discover that galaxies cannot be in a state of maximum entropy at fixed E and M ; they therefore cannot be in a true state of statistical equilibrium.¹⁶ (One might wonder whether there is entropy associated with the galaxy's gravitational field, some of which is due to the stars, and whether that entropy invalidates our analysis. The answer is no. The gravitational field has no randomness, beyond that of the stars themselves, and thus no entropy; its structure is uniquely determined, via Newton's gravitational field equation, by the stars' spatial distribution.)

In a real galaxy or other star cluster, rare near-encounters between stars in the cluster core (ignored in the above discussion) cause individual stars to be ejected from the core into distant orbits or to be ejected from the cluster altogether. These ejections increase the entropy of the cluster plus ejected stars in just the manner of our thought experiment. The core of the galaxy shrinks, a diffuse halo grows, and the total number of stars in the galaxy gradually decreases. This evolution to ever-larger entropy is demanded by the laws of statistical mechanics, but by contrast with systems without gravity, it does not bring the cluster to statistical equilibrium. The long-range influence of gravity prevents a true equilibrium from being reached. Ultimately, the cluster's or galaxy's core may collapse to form a black hole—and, indeed, most large galaxies are observed to have massive black holes in their cores. Despite this somewhat negative conclusion, the techniques of statistical mechanics can be used to understand

galaxy never in statistical equilibrium

to increase entropy, galaxy core shrinks and halo grows

gravity as key to galaxy's behavior

16. A true equilibrium can be achieved if the galaxy is enclosed in an idealized spherical box whose walls prevent stars from escaping, or if the galaxy lives in an infinite thermalized bath of stars so that, on average, when one star is ejected into a distant orbit in the bath, another gets injected into the galaxy (see, e.g., Ogorodnikov, 1965; Lynden-Bell, 1967). However, in the real universe galaxies are not surrounded by walls or by thermalized star baths.

galactic dynamics over the comparatively short timescales of interest to astronomers (e.g., Binney and Tremaine, 2003). For a complementary description of a dark matter galaxy in which the stars are ignored, see Ex. 28.7. Further discussion of stellar and dark matter distributions in galaxies is presented in Chap. 28.

4.10.2

4.10.2 Black Holes T2

thermal atmosphere of a black hole

Quantum field theory predicts that, near the horizon of a black hole, the vacuum fluctuations of quantized fields behave thermally, as seen by stationary (non-infalling) observers. More specifically, such observers see the horizon surrounded by an atmosphere that is in statistical equilibrium (a thermalized atmosphere) and that rotates with the same angular velocity $\boldsymbol{\Omega}_H$ as the hole's horizon. This remarkable conclusion, due to Stephen Hawking (1976), William Unruh (1976), and Paul Davies (1977), is discussed pedagogically in books by Thorne, Price, and MacDonald (1986) and Frolov and Zelnikov (2011), and more rigorously in a book by Wald (1994). The atmosphere contains all types of particles that can exist in Nature. Very few of the particles manage to escape from the hole's gravitational pull; most emerge from the horizon, fly up to some maximum height, then fall back down to the horizon. Only if they start out moving almost vertically upward (i.e., with nearly zero angular momentum) do they have any hope of escaping. The few that do escape make up a tiny trickle of *Hawking radiation* (Hawking, 1975) that will ultimately cause the black hole to evaporate, unless it grows more rapidly due to infall of material from the external universe (which it will unless the black hole is far less massive than the Sun).

Hawking radiation

In discussing the distribution function for the hole's thermalized, rotating atmosphere, one must take account of the fact that the locally measured energy of a particle decreases as it climbs out of the hole's gravitational field (Ex. 26.4). One does so by attributing to the particle the energy that it would ultimately have if it were to escape from the hole's gravitational grip. This is called the particle's "redshifted energy" and is denoted by \mathcal{E}_∞ . This \mathcal{E}_∞ is conserved along the particle's world line, as is the projection $\mathbf{j} \cdot \hat{\boldsymbol{\Omega}}_H$ of the particle's orbital angular momentum \mathbf{j} along the hole's spin axis (unit direction $\hat{\boldsymbol{\Omega}}_H$).

The hole's horizon behaves like the wall of a blackbody cavity. Into each up-going mode (single-particle quantum state) a of any and every quantum field that can exist in Nature, it deposits particles that are thermalized with (redshifted) temperature T_H , vanishing chemical potential, and angular velocity $\boldsymbol{\Omega}_H$. As a result, the mode's distribution function—which is the probability of finding N_a particles in it with net redshifted energy $\mathcal{E}_{a\infty} = N_a \times$ (redshifted energy of one quantum in the mode) and with net axial component of angular momentum $\mathbf{j}_a \cdot \hat{\boldsymbol{\Omega}}_H = N_a \times$ (angular momentum of one quantum in the mode)—is

$$\rho_a = C \exp \left[\frac{-\mathcal{E}_{a\infty} + \boldsymbol{\Omega}_H \cdot \mathbf{j}_a}{k_B T_H} \right] \quad (4.59)$$

atmosphere's distribution function

[see Eq. (4.22) and note that $\boldsymbol{\Omega}_H = \Omega_H \hat{\boldsymbol{\Omega}}_H$]. The distribution function for the entire thermalized atmosphere (made of all modes that emerge from the horizon) is, of

course, $\rho = \prod_a \rho_a$. (Ingoing modes, which originate at infinity—i.e., far from the black hole—are not thermalized; they contain whatever the universe chooses to send toward the hole.) Because $\mathcal{E}_{a\infty}$ is the redshifted energy in mode a , T_H is similarly a redshifted temperature: it is the temperature that the Hawking radiation exhibits when it has escaped from the hole's gravitational grip. Near the horizon, the locally measured atmospheric temperature is gravitationally blue-shifted to much higher values than T_H .

The temperature T_H and angular velocity $\boldsymbol{\Omega}_H$, like all properties of a black hole, are determined completely by the hole's spin angular momentum \mathbf{J}_H and its mass M_H . To within factors of order unity, they have magnitudes [Ex. 26.16 and Eq. (26.77)]

$$T_H \sim \frac{\hbar}{8\pi k_B G M_H / c^3} \sim \frac{6 \times 10^{-8} \text{ K}}{M_H / M_\odot}, \quad \Omega_H \sim \frac{J_H}{M_H (2GM_H / c^2)^2}. \quad (4.60)$$

black hole temperature
and angular velocity

For a very slowly rotating hole the “ \sim ” becomes an “=” in both equations. Notice how small the hole's temperature is, if its mass is greater than or of order M_\odot . For such holes the thermal atmosphere is of no practical interest, though it has deep implications for fundamental physics. Only for tiny black holes (that might conceivably have been formed in the big bang) is T_H high enough to be physically interesting.

Suppose that the black hole evolves much more rapidly by accreting matter than by emitting Hawking radiation. Then the evolution of its entropy can be deduced from the first law of thermodynamics for its atmosphere. By techniques analogous to some developed in the next chapter, one can argue that the atmosphere's equilibrium distribution (4.59) implies the following form for the first law (where we set $c = 1$):

$$dM_H = T_H dS_H + \boldsymbol{\Omega}_H \cdot d\mathbf{J}_H \quad (4.61)$$

first law of
thermodynamics
for black hole

[cf. Eq. (26.92)]. Here dM_H is the change of the hole's mass due to the accretion (with each infalling particle contributing its \mathcal{E}_∞ to dM_H), $d\mathbf{J}_H$ is the change of the hole's spin angular momentum due to the accretion (with each infalling particle contributing its \mathbf{j}), and dS_H is the increase of the black hole's entropy.

Because this first law can be deduced using the techniques of statistical mechanics (Chap. 5), it can be argued (e.g., Zurek and Thorne, 1985) that the hole's entropy increase has the standard statistical mechanical origin and interpretation: if N_{states} is the total number of quantum states that the infalling material could have been in (subject only to the requirement that the total infalling mass-energy be dM_H and total infalling angular momentum be $d\mathbf{J}_H$), then $dS_H = k_B \log N_{\text{states}}$ [cf. Eq. (4.35)]. In other words, the hole's entropy increases by k_B times the logarithm of the number of quantum mechanically different ways that we could have produced its changes of mass and angular momentum, dM_H and $d\mathbf{J}_H$. Correspondingly, we can regard the hole's total entropy as k_B times the logarithm of the number of ways in which it could have been made. That number of ways is enormous, and correspondingly, the hole's

entropy is enormous. This analysis, when carried out in full detail (Zurek and Thorne, 1985), reveals that the entropy is [Eq. (26.93)]

black hole's entropy

$$S_H = k_B \frac{A_H}{4L_P^2} \sim 1 \times 10^{77} k_B \left(\frac{M_H}{M_\odot} \right)^2, \quad (4.62)$$

where $A_H \sim 4\pi(2GM_H/c^2)$ is the surface area of the hole's horizon, and $L_P = \sqrt{G\hbar/c^3} = 1.616 \times 10^{-33}$ cm is the Planck length—a result first proposed by Bekenstein (1972) and first proved by Hawking (1975).

horizon as key to hole's thermal behavior

What is it about a black hole that leads to this peculiar thermal behavior and enormous entropy? Why is a hole so different from a star or galaxy? The answer lies in the black-hole horizon and the fact that things that fall inward through the horizon cannot get back out. From the perspective of quantum field theory, the horizon produces the thermal behavior. From that of statistical mechanics, the horizon produces the loss of information about how the black hole was made and the corresponding entropy increase. In this sense, the horizon for a black hole plays a role analogous to coarse-graining in conventional classical statistical mechanics.¹⁷

The above statistical mechanical description of a black hole's atmosphere and thermal behavior is based on the laws of quantum field theory in curved spacetime—laws in which the atmosphere's fields (electromagnetic, neutrino, etc.) are quantized, but the hole itself is not governed by the laws of quantum mechanics. For detailed but fairly brief analyses along the lines of this section, see Zurek and Thorne (1985); Frolov and Page (1993). For a review of the literature on black-hole thermodynamics and of conundrums swept under the rug in our simple-minded discussion, see Wald (2001).¹⁸

EXERCISES

Exercise 4.16 Example: Thermal Equilibria for a Black Hole inside a Box T2

This problem was posed and partially solved by Hawking (1976), and fully solved by Page et al. (1977). Place a nonrotating black hole with mass M at the center of a spherical box with volume V that is far larger than the black hole: $V^{1/3} \gg 2GM/c^2$. Put into the box, and outside the black hole, thermalized radiation with energy $\mathcal{E} - Mc^2$ (so the total energy in the box is \mathcal{E}). The black hole will emit Hawking

17. It seems likely, as of 2017, that the information about what fell into the hole gets retained, in some manner, in the black hole's atmosphere, and we have coarse-grained it away by our faulty understanding of the relevant black-hole quantum mechanics.
18. A much deeper understanding involves string theory—the most promising approach to quantum gravity and to quantization of black holes. Indeed, the thermal properties of black holes, and most especially their entropy, are a powerful testing ground for candidate theories of quantum gravity. A recent, lively debate around the possibility that a classical event horizon might be accompanied by a *firewall* (Almheiri et al., 2013) is a testament to the challenge of these questions, and to the relevance that they have to the relationship between gravity and the other fundamental interactions.

radiation and will accrete thermal radiation very slowly, causing the hole's mass M and the radiation energy $\mathcal{E} - Mc^2$ to evolve. Assume that the radiation always thermalizes during the evolution, so its temperature T is always such that $aT^4V = \mathcal{E} - Mc^2$, where a is the radiation constant. (For simplicity assume that the only form of radiation that the black hole emits and that resides in the box is photons; the analysis is easily extended to the more complicated case where other kinds of particles are present and are emitted.) Discuss the evolution of this system using the second law of thermodynamics. More specifically, do the following.

- To simplify your calculations, use so-called *natural units* in which not only is c set equal to unity (geometrized units), but also $G = \hbar = k_B = 1$. If you have never used natural units before, verify that no dimensionless quantities can be constructed from G , c , \hbar , and k_B ; from this, show that you can always return to cgs or SI units by inserting the appropriate factors of G , c , \hbar , and k_B to get the desired units. Show that in natural units the radiation constant is $a = \pi^2/15$.
- Show that in natural units the total entropy inside the box is $S = \frac{4}{3}aVT^3 + 4\pi M^2$. The mass M and radiation temperature T will evolve so as to increase this S subject to the constraint that $\mathcal{E} = M + aVT^4$, with fixed \mathcal{E} and V .
- Find a rescaling of variables that enables \mathcal{E} to drop out of the problem. [Answer: Set $m = M/\mathcal{E}$, $\Sigma = S/(4\pi\mathcal{E}^2)$, and $\nu = Va/[(3\pi)^4\mathcal{E}^5]$, so m , Σ , and ν are rescaled black-hole mass, entropy in the box, and box volume.] Show that the rescaled entropy is given by

$$\Sigma = m^2 + \nu^{1/4}(1 - m)^{3/4}. \quad (4.63)$$

This entropy is plotted as a function of the black hole mass m in Fig. 4.6 for various ν [i.e., for various $V = (3\pi)^4(E^5/a)\nu$].

- Show that

$$\frac{d\Sigma}{dm} = \frac{3\nu^{1/4}}{4(1 - m)^{1/4}}(\tau - 1), \quad (4.64)$$

where $\tau = T/T_H = 8\pi MT$ is the ratio of the radiation temperature to the black hole's Hawking temperature. Thereby show that (i) when $\tau > 1$, the black hole accretes more energy than it emits, and its mass M grows, thereby increasing the entropy in the box and (ii) when $\tau < 1$, the black hole emits more energy than it accretes, thereby decreasing its mass and again increasing the total entropy.

- From the shapes of the curves in Fig. 4.6, it is evident that there are two critical values of the box's volume V (or equivalently, of the rescaled volume ν): V_h and V_g . For $V > V_h$, the only state of maximum entropy is $m = 0$: no black hole. For these large volumes, the black hole will gradually evaporate and disappear. For $V < V_h$, there are two local maxima: one with a black hole whose mass is somewhere between $m = M/\mathcal{E} = 4/5$ and 1; the other with no black hole, $m = 0$.

FIGURE 4.6 Total entropy S inside a box of volume V that contains a black hole with mass M and thermalized radiation with energy $\mathcal{E} - Mc^2$ and temperature $T = [(\mathcal{E} - Mc^2)/(aV)]^{1/4}$. For $V < V_h$ there is a statistical equilibrium that contains a black hole, at the local maximum of entropy (large filled circles). At that equilibrium, the radiation temperature T is equal to the black hole's Hawking temperature T_H . See Exercise 4.16e for the definitions of V_g and V_h .

If $V = V_g$, the two states have the same entropy; if $V < V_g$, the state with a black hole has the larger entropy; if $V_g < V < V_h$, the state without a black hole has the larger entropy. Show that

$$V_h = \frac{2^{20}\pi^4}{5^5 a} \mathcal{E}^5 = 4.97 \times 10^4 \left(\frac{\mathcal{E}}{M_p c^2} \right)^2 \left(\frac{G\mathcal{E}}{c^4} \right)^3, \quad V_g = 0.256 V_h, \quad (4.65)$$

where the first expression is in natural units. Here $M_p = \sqrt{\hbar c/G} = 2.177 \times 10^{-5}$ g is the Planck mass, and $G\mathcal{E}/c^4$ is half the radius of a black hole with mass \mathcal{E}/c^2 . Show that, if $V_g < V < V_h$, and if the box's volume V is made as large as possible—the size of the universe—then the mass of the equilibrium black hole will be roughly 1/100 the mass of the Sun.

When there are two entropy maxima, that is, two states of statistical equilibrium (i.e., for $V < V_h$), an entropy barrier exists between the two equilibria. In principle, quantum fluctuations should be able to carry the system through that barrier, from the equilibrium of lower entropy to that of higher entropy, though the rate will be extremely small for $\mathcal{E} \gg M_p c^2$. Those fluctuations will be governed by the laws of

quantum gravity, so studying them is a useful thought experiment in the quest to understand quantum gravity.

T2

4.10.3 The Universe T2

4.10.3

Observations and theory agree that the universe, when far younger than 1 s old, settled into a very hot, highly thermalized state. All particles except gravitons were in statistical equilibrium at a common, declining temperature, until the dark matter and the neutrinos dropped out of equilibrium and (like the gravitons) became thermodynamically isolated.

During this early relativistic era, the equations of relativistic cosmology imply (as discussed in Sec. 28.4.1) that the temperature T of the universe at age t satisfied $T/T_P \sim (t/t_P)^{-1/2}$. Here $T_P \equiv [\hbar c^5/(Gk_B^2)]^{1/2} \sim 10^{32}$ K is the Planck temperature, and $t_P \equiv (\hbar G/c^5)^{1/2} \sim 10^{-43}$ s is the Planck time. (This approximate T/T_P relationship can be justified on dimensional grounds.) Now the region that was in causal contact at time t (i.e., that was contained within a mutual cosmological horizon) had a volume $\sim (ct)^3$, and thermodynamic considerations imply that the number of relativistic particles that were in causal contact at time t was $N \sim (k_B T t / \hbar)^3 \sim (t/t_P)^{3/2}$. (This remains roughly true today when N has grown to $\sim 10^{91}$, essentially all in microwave background photons.) The associated entropy was then $S \sim Nk_B$ (cf. Sec. 4.8).

number of particles and entropy inside cosmological horizon

Although this seems like an enormous entropy, gravity can do even better. The most efficient way to create entropy, as described in Sec. 4.10.2, is to form massive black holes. Suppose that out of all the relativistic particle mass within the horizon, $M \sim Nk_B T/c^2$, a fraction f has collapsed into black holes of mass M_H . Then, with the aid of Sec. 4.10.2, we estimate that the associated entropy is $S_H \sim f(M_H/M)(t/t_P)^{1/2}S$. If we use the observation that every galaxy has a central black hole with mass in the $\sim 10^6$ – 10^9 solar mass range, we find that $f \sim 10^{-4}$ and $S_H \sim 10^{11}S$ today!

entropy in black holes

Now it might be claimed that massive black holes are thermodynamically isolated from the rest of the universe because they will take so long to evaporate. That may be so as a practical matter, but more modest gravitational condensations that create stars and starlight can produce large local departures from thermodynamic equilibrium, accompanied by (indeed, driven by) a net increase of entropy and can produce the conditions necessary for life to develop.

Given these considerations, it should not come as a surprise to learn that the behavior of entropy in the expanding universe has provided a foundation for the standard model of cosmology, which we outline in Chap. 28. It has also provided a stimulus for many imaginative proposals addressing fascinating questions that lie

beyond the standard model, some of which connect with the nature of life in the universe.¹⁹

4.10.4 4.10.4 Structure Formation in the Expanding Universe:

Violent Relaxation and Phase Mixing T2

The formation of stars and galaxies (“structure”) by gravitational condensation provides a nice illustration of the phase mixing and coarse-graining that underlie the second law of thermodynamics (Sec. 4.7.2).

It is believed that galaxies formed when slight overdensities in the dark matter and gas (presumably irregular in shape) stopped expanding and began to contract under their mutual gravitational attraction. Much of the gas was quickly converted into stars. The dark-matter particles and the stars had very little random motion at this stage relative to their random motions today, $v \sim 200 \text{ km s}^{-1}$. Correspondingly, although their physical volume \mathcal{V}_x was initially only moderately larger than today, their momentum-space volume \mathcal{V}_p was far smaller than it is today. Translated into the language of an ensemble of N such galaxies, the initial coordinate-space volume $\int d^{3N}x \sim \mathcal{V}_x^N$ occupied by each of the ensemble’s galaxies was moderately larger than it is today, while its momentum-space volume $\int d^{3N}p \sim \mathcal{V}_p^N$ was far smaller. The phase-space volume $\mathcal{V}_x^N \mathcal{V}_p^N$ must therefore have increased considerably during the galaxy formation—with the increase due to a big increase in the relative momenta of neighboring stars. For this to occur, it was necessary that the stars changed their relative energies during the contraction, which requires a time-dependent hamiltonian. In other words, the gravitational potential Φ felt by the stars must have varied rapidly, so that the individual stellar energies would vary according to

$$\frac{dE}{dt} = \frac{\partial H}{\partial t} = m \frac{\partial \Phi}{\partial t}. \quad (4.66)$$

violent relaxation of star distribution

The largest changes of energy occurred when the galaxy was contracting dynamically (collapsing), so the potential changed significantly on the timescale it took stars to cross the galaxy, $\tau_{\text{int}} \sim 2R/v$. Numerical simulations show that this energy transfer was highly efficient. This process is known as *violent relaxation*. Although violent relaxation could create the observed stellar distribution functions, it was not by itself a means of diluting the phase-space density, since Liouville’s theorem still applied.

phase mixing and coarse-graining of star distribution

The mechanism that changed the phase-space density was phase mixing and coarse-graining (Sec. 4.7.2 above). During the initial collapse, the particles and newly formed stars could be thought of as following highly perturbed radial orbits. The orbits of nearby stars were somewhat similar, though not identical. Therefore small elements of occupied phase space became highly contorted as the particles and stars moved along their phase-space paths.

19. For an early and highly influential analysis, see Schrödinger (1944), and for a more recent discussion, see Penrose (2016).

Let us make a simple model of this process by assuming the individual particles and stars initially populate a fraction $f \ll 1$ of the final occupied phase-space volume $\mathcal{V}_{\text{final}}$. After one dynamical timescale $\tau_{\text{int}} \sim R/v$, this small volume $f\mathcal{V}_{\text{final}}$ is (presumably) deformed into a convoluted surface that folds back on itself once or twice like dough being kneaded by a baker, while still occupying the same volume $f\mathcal{V}_{\text{final}}$. After n dynamical timescales, there are $\sim 2^n$ such folds (cf. Fig. 4.2b above). After $n \sim -\log_2 f$ dynamical timescales, the spacing between folds becomes comparable with the characteristic thickness of this convoluted surface, and it is no longer practical to distinguish the original distribution function. We expect that coarse-graining has been accomplished for all practical purposes; only a pathological physicist would resist it and insist on trying to continue keeping track of which contorted phase-space regions have the original high density and which do not. For a galaxy we might expect that $f \sim 10^{-3}$ and so this natural coarse-graining can occur in a time approximately equal to $-\log_2 10^{-3} \tau_{\text{int}} \sim 10 \tau_{\text{int}} \sim 10^9$ yr, which is 10 times shorter than the present age of galaxies. Therefore it need not be a surprise that the galaxy we know best, our own Milky Way, exhibits little obvious vestigial trace of its initial high-density (low phase-space-volume) distribution function.²⁰

4.11 Entropy and Information T2

4.11

4.11.1 Information Gained When Measuring the State of a System in a Microcanonical Ensemble T2

4.11.1

In Sec. 4.7, we said that entropy is a measure of our lack of information about the state of any system chosen at random from an ensemble. In this section we make this heuristic statement useful by introducing a precise definition of *information*.

Consider a microcanonical ensemble of identical systems. Each system can reside in any one of a finite number, N_{states} , of quantum states, which we label by integers $n = 1, 2, 3, \dots, N_{\text{states}}$. Because the ensemble is microcanonical, all N_{states} states are equally probable; they have probabilities $\rho_n = 1/N_{\text{states}}$. Therefore the entropy of any system chosen at random from this ensemble is $S = -k_B \sum_n \rho_n \ln \rho_n = k_B \ln N_{\text{states}}$ [Eqs. (4.34) and (4.35)].

Now suppose that we measure the state of our chosen system and find it to be (for example) state number 238 out of the N_{states} equally probable states. How much information have we gained? For this thought experiment, and more generally (see Sec. 4.11.2 below), *the amount of information gained, expressed in bits, is defined to be the minimum number of binary digits required to distinguish the measured state from all the other N_{states} states that the system could have been in.* To evaluate this information gain, we label each state n by the number $n - 1$ written in binary code (state $n = 1$ is labeled by {000}, state $n = 2$ is labeled by {001}, 3 is {010}, 4 is {011}, 5 is {100},

amount of information gained in a measurement for microcanonical ensemble

20. However, the dark-matter particles may very well not be fully coarse-grained at the present time, and this influences strategies for detecting it.

T2

6 is {101}, 7 is {110}, 8 is {111}, etc.). If $N_{\text{states}} = 4$, then the number of binary digits needed is 2 (the leading 0 in the enumeration above can be dropped), so in measuring the system's state we gain 2 bits of information. If $N_{\text{states}} = 8$, the number of binary digits needed is 3, so our measurement gives us 3 bits of information. In general, we need $\log_2 N_{\text{states}}$ binary digits to distinguish the states from one another, so *the amount of information gained in measuring the system's state is the base-2 logarithm of the number of states the system could have been in:*

$$I = \log_2 N_{\text{states}} = (1/\ln 2) \ln N_{\text{states}} = 1.4427 \ln N_{\text{states}}. \quad (4.67a)$$

Notice that this information gain is proportional to the entropy $S = k_B \ln N_{\text{states}}$ of the system before the measurement was made:

$$I = S/(k_B \ln 2). \quad (4.67b)$$

The measurement reduces the system's entropy from $S = -k_B \ln N_{\text{states}}$ to zero (and increases the entropy of the rest of the universe by at least this amount), and it gives us $I = S/(k_B \ln 2)$ bits of information about the system. We shall discover below that this entropy/information relationship is true of measurements made on a system drawn from any ensemble, not just a microcanonical ensemble. But first we must develop a more complete understanding of information.

information gain related to entropy decrease

4.11.2

4.11.2 Information in Communication Theory T2

The definition of “the amount of information I gained in a measurement” was formulated by Claude Shannon (1948) in the context of his laying the foundations of *communication theory*. Communication theory deals (among other things) with the problem of how to encode most efficiently a message as a binary string (a string of 0s and 1s) in order to transmit it across a communication channel that transports binary signals. Shannon defined the information in a message as *the number of bits required, in the most compressed such encoding, to distinguish this message from all other messages that might be transmitted.*

communication theory

general definition of information

symbols and messages

Shannon focused on messages that, before encoding, consist of a sequence of symbols. For an English-language message, each symbol might be a single character (a letter A, B, C, . . . , Z or a space; $N = 27$ distinct symbols in all), and a specific message might be the following sequence of length $L = 19$ characters: “I DO NOT UNDERSTAND”. Suppose, for simplicity, that in the possible messages, all N distinct symbols appear with equal frequency (this, of course, is not the case for English-language messages), and suppose that the length of some specific message (its number of symbols) is L . Then the number of bits needed to encode this message and distinguish it from all other possible messages of length L is

$$I = \log_2 N^L = L \log_2 N. \quad (4.68a)$$

In other words, the average number of bits per symbol (the average amount of information per symbol) is

$$\bar{I} = \log_2 N. \quad (4.68b)$$

If there are only two possible symbols, we have one bit per symbol in our message. If there are four possible (equally likely) symbols, we have two bits per symbol, and so forth.

It is usually the case that not all symbols occur with the same frequency in the allowed messages. For example, in English messages the letter “A” occurs with a frequency $p_A \simeq 0.07$, while the letter “Z” occurs with the much smaller frequency $p_Z \simeq 0.001$. All English messages, of character length $L \gg N = 27$, constructed by a typical English speaker, will have these frequencies of occurrence for “A” and “Z”. Any purported message with frequencies for “A” and “Z” differing substantially from 0.07 and 0.001 will not be real English messages, and thus need not be included in the binary encoding of messages. As a result, it turns out that the most efficient binary encoding of English messages (the most *compressed* encoding) will use an average number of bits per character somewhat less than $\log_2 N = \log_2 27 = 4.755$. In other words, the average information per character in English language messages is somewhat less than $\log_2 27$.

To deduce the average information per character when the characters do not all occur with the same frequency, we begin with a simple example: the number of distinct characters to be used in the message is just $N = 2$ (the characters “B” and “E”), and their frequencies of occurrence in very long allowed messages are $p_B = 3/5$ and $p_E = 2/5$. For example, in the case of messages with length $L = 100$, the message

BBEBBBEEBBEBBBBBBBEBBBEBBEEBEB      (4.69a)
```

contains 63 Bs and 37 Es, and thus (to within statistical variations) has the correct frequencies $p_B \simeq 0.6$, $p_E \simeq 0.4$ to be an allowed message. By contrast, the message

```
BBBBBBBBBBBBBBEBBBBBBBBBBBBBBBBBBB
BBBBBBBBBBEBBBBBBBBBBBBBBBBBBBBBBB
BBBBBBBBBBBBBBEBBBBBBBBBBBBBBBBBBB      (4.69b)
```

contains 97 Bs and 3 Es and thus is not an allowed message. To deduce the number of allowed messages and thence the number of bits required to encode them distinguishably, we map this problem of 60% probable Bs and 40% probable Es onto the problem of messages with five equally probable symbols as follows. Let the set of distinct symbols be the letters “a”, “b”, “c”, “y”, and “z”, all occurring in allowed messages equally frequently: $p_a = p_b = p_c = p_y = p_z = 1/5$. An example of an allowed message is

```
zcczzaabzccbabcccczaybacyzyzcbbyc
ayyyyayzcyzzzzcczababybbbcczabz
bbbybaazybccybaccabazaczbayycyc      (4.69c)
```

We map each such message from our new message set into one from the previous message set by identifying “a”, “b”, and “c” as from the beginning of the alphabet (and thus converting them to “B”), and identifying “y” and “z” as from the end of

the alphabet (and thus converting them to “E”). Our message (4.69c) from the new message set then maps into the message (4.69a) from the old set. This mapping enables us to deduce the number of bits required to encode the old messages, with their unequal frequencies $p_B = 3/5$ and $p_E = 2/5$, from the number required for the new messages, with their equal frequencies $p_a = p_b = \dots = p_z = 1/5$.

The number of bits needed to encode the new messages, with length $L \gg N_{\text{new}} = 5$, is $I = L \log_2 5$. The characters “a,” “b,” and “c” from the beginning of the alphabet occur $\frac{3}{5}L$ times in each new message (in the limit that L is arbitrarily large). When converting the new message to an old one, we no longer need to distinguish between “a,” “b,” and “c,” so we no longer need the $\frac{3}{5}L \log_2 3$ bits that were being used to make those distinctions. Similarly, the number of bits we no longer need when we drop the distinction between our two end-of-alphabet characters “y” and “z” is $\frac{2}{5}L \log_2 2$. As a result, the number of bits still needed to distinguish between old messages (messages with “B” occurring 3/5 of the time and “E” occurring 2/5 of the time) is

$$\begin{aligned} I &= L \log_2 5 - \frac{3}{5}L \log_2 3 - \frac{2}{5}L \log_2 2 = L \left[-\frac{3}{5} \log_2 \frac{3}{5} - \frac{2}{5} \log_2 \frac{2}{5} \right] \\ &= L(-p_B \log_2 p_B - p_E \log_2 p_E). \end{aligned} \quad (4.69d)$$

A straightforward generalization of this argument (Ex. 4.17) shows that, *when one constructs messages with very large length $L \gg N$ from a pool of N symbols that occur with frequencies p_1, p_2, \dots, p_N , the minimum number of bits required to distinguish all the allowed messages from one another (i.e., the amount of information in each message) is*

$$I = L \sum_{n=1}^N -p_n \log_2 p_n; \quad (4.70)$$

so the average information per symbol in the message is

$$\bar{I} = \sum_{n=1}^N -p_n \log_2 p_n = (1/\ln 2) \sum_{n=1}^N -p_n \ln p_n. \quad (4.71)$$

information per symbol in a message

4.11.3 Examples of Information Content T2

Notice the similarity of the general information formula (4.70) to the general formula (4.34) for the entropy of an arbitrary ensemble. This similarity has a deep consequence.

INFORMATION FROM MEASURING THE STATE OF ONE SYSTEM IN AN ENSEMBLE

Consider an arbitrary ensemble of systems in statistical mechanics. As usual, label the quantum states available to each system by the integer $n = 1, 2, \dots, N_{\text{states}}$, and denote by p_n the probability that any chosen system in the ensemble will turn out to be in state n . Now select one system out of the ensemble and measure its quantum state n_1 ;

select a second system and measure its state, n_2 . Continue this process until some large number $L \gg N_{\text{states}}$ of systems have been measured. The sequence of measurement results $\{n_1, n_2, \dots, n_L\}$ can be regarded as a message. The minimum number of bits needed to distinguish this message from all other possible such messages is given by the general information formula (4.70). This is the total information in the L system measurements. Correspondingly, *the amount of information we get from measuring the state of one system (the average information per measurement) is given by Eq. (4.71)*. This acquired information is related to the entropy of the system before measurement [Eq. (4.34)] by the same standard formula (4.67b) as we obtained earlier for the special case of the microcanonical ensemble:

$$\bar{I} = S / (k_B \ln 2). \quad (4.72)$$

INFORMATION IN AN ENGLISH-LANGUAGE MESSAGE

For another example of information content, we return to English-language messages (Shannon, 1948). Evaluating the information content of a long English message is a very difficult task, since it requires figuring out how to compress the message most compactly. We shall make a series of estimates.

A crude initial estimate of the information per character is that obtained by idealizing all the characters as occurring equally frequently: $\bar{I} = \log_2 27 \simeq 4.76$ bits per character [Eq. (4.68b)]. This is an overestimate, because the 27 characters actually occur with very different frequencies. We could get a better estimate by evaluating $\bar{I} = \sum_{n=1}^{27} -p_n \log_2 p_n$, taking account of the characters' varying frequencies p_n (the result is about $\bar{I} = 4.1$), but we can do even better by converting from characters as our symbols to words. The average number of characters in an English word is about 4.5 letters plus 1 space, or 5.5 characters per word. We can use this number to convert from characters as our symbols to words. The number of words in a typical English speaker's vocabulary is roughly 12,000. If we idealize these 12,000 words as occurring with the same frequencies, then the information per word is $\log_2 12,000 \simeq 13.6$, so the information per character is $\bar{I} = (1/5.5) \log_2 12,000 \simeq 2.46$. This is much smaller than our previous estimates. A still better estimate is obtained by using Zipf's (1935) approximation $p_n = 0.1/n$ of the frequencies of occurrence of the words in English messages.²¹ To ensure that $\sum_{n=1}^N p_n = 1$ for Zipf's approximation, we require that the number of words be $N = 12,367$. We then obtain, as our improved estimate of the information per word, $\sum_{n=1}^{12,367} (-0.1/n) \log_2(0.1/n) = 9.72$, corresponding to a value of information per character $\bar{I} \simeq 9.72/5.5 = 1.77$. This is substantially smaller than our initial, crudest estimate of 4.76 and is close to more careful estimates $\bar{I} \simeq 1.0$ to 1.5 (Schneier, 1997, Sec. 11.1).

21. The most frequently occurring word is "THE", and its frequency is about 0.1 (1 in 10 words is "THE" in a long message). The next most frequent words are "OF", "AND", and "TO"; their frequencies are about 0.1/2, 0.1/3, and 0.1/4, respectively; and so forth.

information from measurement for a general ensemble

information per character in English message

Because of the similarity of the general formulas for information and entropy (both proportional to $\sum_n -p_n \ln p_n$), information has very similar properties to entropy. In particular (Ex. 4.18):

1. Information is additive (just as entropy is additive). The information in two successive, independent messages is the sum of the information in each message.
2. If the frequencies of occurrence of the symbols in a message are $p_n = 0$ for all symbols except one, which has $p_n = 1$, then the message contains zero information. This is analogous to the vanishing entropy when all states have zero probability except for one, which has unit probability.
3. For a message L symbols long, whose symbols are drawn from a pool of N distinct symbols, the information content is maximized if the probabilities of the symbols are all equal ($p_n = 1/N$), and the maximal value of the information is $I = L \log_2 N$. This is analogous to the microcanonical ensemble having maximal entropy.

NOISELESS COMMUNICATION

A noiseless communication channel has a maximum rate (number of bits per second) at which it can transmit information. This rate is called the *channel capacity* and is denoted C . When one subscribes to a cable internet connection in the United States, one typically pays a monthly fee that depends on the connection's channel capacity; for example, in Pasadena, California, in summer 2011 the fee was \$29.99 per month for a connection with capacity $C = 12$ megabytes/s = 96 megabits/s, and \$39.99 for $C = 144$ megabits/s. (This was a 30-fold increase in capacity per dollar since 2003!)

It should be obvious from the way we have defined the information I in a message that the maximum rate at which we can transmit optimally encoded messages, each with information content I , is C/I messages per second.

NOISY COMMUNICATION

When a communication channel is noisy (as all channels actually are), for high-confidence transmission of messages one must put some specially designed redundancy into one's encoding. With cleverness, one can thereby identify and correct errors in a received message, caused by the noise (error-correcting code); see, for example, Shannon, (1948), Raisbeck (1963), and Pierce (2012).²² The redundancy needed for such error identification and correction reduces the channel's capacity. As an example, consider a *symmetric binary channel*: one that carries messages made of 0s and

22. A common form of error-correcting code is based on parity checks.

1s, with equal frequency $p_0 = p_1 = 0.5$, and whose noise randomly converts a 0 into a 1 with some small error probability p_e , and randomly converts a 1 into 0 with that same probability p_e . Then one can show (e.g., Pierce, 2012; Raisbeck, 1963) that the channel capacity is reduced—by the need to find and correct for these errors—by a factor

$$C = C_{\text{noiseless}}[1 - \bar{I}(p_e)], \quad \text{where } \bar{I}(p_e) = -p_e \log_2 p_e - (1 - p_e) \log_2(1 - p_e). \quad (4.73)$$

reduction of channel capacity due to error correction

Note that the fractional reduction of capacity is by the amount of information per symbol in messages made from symbols with frequencies equal to the probabilities p_e of making an error and $1 - p_e$ of not making an error—a remarkable and nontrivial conclusion! This is one of many important results in communication theory.

MEMORY AND ENTROPY

Information is also a key concept in the theory of computation. As an important example of the relationship of information to entropy, we cite Landauer's (1961, 1991) theorem: In a computer, when one erases L bits of information from memory, one necessarily increases the entropy of the memory and its environment by at least $\Delta S = Lk_B \ln 2$ and correspondingly, one increases the thermal energy (heat) of the memory and environment by at least $\Delta Q = T \Delta S = Lk_B T \ln 2$ (Ex. 4.21).

Landauer's theorem: entropy increase due to erasure

EXERCISES

Exercise 4.17 *Derivation: Information per Symbol When Symbols Are Not Equally Probable* T2

Derive Eq. (4.70) for the average number of bits per symbol in a long message constructed from N distinct symbols, where the frequency of occurrence of symbol n is p_n . [Hint: Generalize the text's derivation of Eq. (4.69d).]

Exercise 4.18 *Derivation: Properties of Information* T2

Prove the properties of entropy enumerated in Sec. 4.11.4.

Exercise 4.19 *Problem: Information per Symbol for Messages Built from Two Symbols* T2

Consider messages of length $L \gg 2$ constructed from just two symbols ($N = 2$), which occur with frequencies p and $(1 - p)$. Plot the average information per symbol $\bar{I}(p)$ in such messages, as a function of p . Explain why your plot has a maximum $\bar{I} = 1$ when $p = 1/2$, and has $\bar{I} = 0$ when $p = 0$ and when $p = 1$. (Relate these properties to the general properties of information.)

Exercise 4.20 *Problem: Information in a Sequence of Dice Throws* T2

Two dice are thrown randomly, and the sum of the dots showing on the upper faces is computed. This sum (an integer n in the range $2 \leq n \leq 12$) constitutes a symbol,

T2

and the sequence of results of $L \gg 12$ throws is a message. Show that the amount of information per symbol in this message is $\bar{I} \simeq 3.2744$.

Exercise 4.21 *Derivation: Landauer's Theorem* **T2**

Derive, or at least give a plausibility argument for, Landauer's theorem (stated at the end of Sec. 4.11.5).

Bibliographic Note

Statistical mechanics has inspired a variety of readable and innovative texts. The classic treatment is Tolman (1938). Classic elementary texts are Kittel (2004) and Kittel and Kroemer (1980). Among more modern approaches that deal in much greater depth with the topics covered in this chapter are Lifshitz and Pitaevskii (1980), Chandler (1987), Sethna (2006), Kardar (2007), Reif (2008), Reichl (2009), and Pathria and Beale (2011). The Landau-Lifshitz textbooks (including Lifshitz and Pitaevskii, 1980) are generally excellent after one has already learned the subject at a more elementary level. A highly individual and advanced treatment, emphasizing quantum statistical mechanics, is Feynman (1972). A particularly readable account in which statistical mechanics is used heavily to describe the properties of solids, liquids, and gases is Goodstein (2002). Readable, elementary introductions to information theory are Raisbeck (1963) and Pierce (2012); an advanced text is McEliece (2002).

Statistical Thermodynamics

One of the principal objects of theoretical research is to find the point of view from which the subject appears in the greatest simplicity.

J. WILLARD GIBBS (1881)

5.1 Overview

5.1

In Chap. 4, we introduced the concept of statistical equilibrium and briefly studied some properties of equilibrated systems. In this chapter, we develop the theory of statistical equilibrium in a more thorough way.

The title of this chapter, “Statistical Thermodynamics,” emphasizes two aspects of the theory of statistical equilibrium. The term *thermodynamics* is an ancient one that predates statistical mechanics. It refers to a study of the macroscopic properties of systems that are in or near equilibrium, such as their energy and entropy. Despite paying no attention to the microphysics, classical thermodynamics is a very powerful theory for deriving general relationships among macroscopic properties. Microphysics influences the macroscopic world in a statistical manner, so in the late nineteenth century, Willard Gibbs and others developed statistical mechanics and showed that it provides a powerful conceptual underpinning for classical thermodynamics. The resulting synthesis, *statistical thermodynamics*, adds greater power to thermodynamics by augmenting it with the statistical tools of ensembles and distribution functions.

In our study of statistical thermodynamics, we restrict attention to an ensemble of large systems that are in statistical equilibrium. By “large” is meant a system that can be broken into a large number N_{ss} of subsystems that are all macroscopically identical to the full system except for having $1/N_{ss}$ as many particles, $1/N_{ss}$ as much volume, $1/N_{ss}$ as much energy, $1/N_{ss}$ as much entropy, and so forth. (Note that this definition constrains the energy of interaction between the subsystems to be negligible.) Examples are 1 kg of plasma in the center of the Sun and a 1-kg sapphire crystal.

The equilibrium thermodynamic properties of any type of large system (e.g., an ideal gas)¹ can be derived using any one of the statistical equilibrium ensembles of the last chapter (microcanonical, canonical, grand canonical, or Gibbs). For example,

1. An *ideal gas* is one with negligible interactions among its particles.

BOX 5.1. READERS' GUIDE

- Relativity enters into portions of this chapter solely via the relativistic energies and momenta of high-speed particles (Sec. 1.10).
- This chapter relies in crucial ways on Secs. 3.2 and 3.3 of Chap. 3 and on Secs. 4.2–4.8 of Chap. 4.
- Portions of Chap. 6 rely on Sec. 5.6 of this chapter. Portions of Part V (Fluid Dynamics) rely on thermodynamic concepts and equations of state treated in this chapter, but most readers will already have met these in a course on elementary thermodynamics.
- Other chapters do not depend strongly on this one.

each of these ensembles will predict the same equation of state $P = (N/V)k_B T$ for an ideal gas, even though in one ensemble each system's number of particles N is precisely fixed, while in another ensemble N can fluctuate so that strictly speaking, one should write the equation of state as $P = (\bar{N}/V)k_B T$, with \bar{N} the ensemble average of N . (Here and throughout this chapter, for compactness we use bars rather than brackets to denote ensemble averages, i.e., \bar{N} rather than $\langle N \rangle$.) The equations of state are the same to very high accuracy because the fractional fluctuations of N are so extremely small: $\Delta N/N \sim 1/\sqrt{\bar{N}}$ (cf. Ex. 5.11).

Although the thermodynamic properties are independent of the equilibrium ensemble, specific properties are often derived most quickly, and the most insight usually accrues, from the ensemble that most closely matches the physical situation being studied. In Secs. 5.2–5.5, we use the microcanonical, grand canonical, canonical, and Gibbs ensembles to derive many useful results from statistical thermodynamics: fundamental potentials expressed as statistical sums over quantum states, variants of the first law of thermodynamics, equations of state, Maxwell relations, Euler's equation, and others. Table 5.1 summarizes the most important of those statistical-equilibrium results and some generalizations of them. Readers are advised to delay studying this table until they have read further into the chapter.

As we saw in Chap. 4, when systems are out of statistical equilibrium, their evolution toward equilibrium is driven by the law of entropy increase—the second law of thermodynamics. In Sec. 5.5, we formulate the fundamental potential (Gibbs potential) for an out-of-equilibrium ensemble that interacts with a heat and volume bath, and we discover a simple relationship between that fundamental potential and the entropy of system plus bath. From that relationship, we learn that in this case the second law is equivalent to a law of decrease of the Gibbs potential. As applications, we learn how chemical potentials drive chemical reactions and phase transitions. In Sec. 5.6, we discover how the Gibbs potential can be used to study spontaneous fluctuations of a system away from equilibrium, when it is coupled to a heat and particle bath.

TABLE 5.1: Representations and ensembles for systems in statistical equilibrium, in relativistic notation

Representation and ensemble	First law	Quantities exchanged with bath	Distribution function ρ
Energy and microcanonical (Secs. 4.5 and 5.2)	$d\mathcal{E} = TdS + \tilde{\mu}dN - PdV$	None	$\text{const} = e^{-S/k_B}$ \mathcal{E} const in $\delta\mathcal{E}$
Enthalpy (Exs. 5.5 and 5.13)	$dH = TdS + \tilde{\mu}dN + VdP$	V and \mathcal{E} $d\mathcal{E} = -PdV$	$\text{const} = e^{-S/k_B}$ H const
Physical free energy and canonical (Secs. 4.4.1 and 5.4)	$dF = -SdT + \tilde{\mu}dN - PdV$	\mathcal{E}	$e^{(F-\mathcal{E})/(k_B T)}$
Gibbs (Secs. 4.4.2 and 5.5)	$dG = -SdT + \tilde{\mu}dN + VdP$	\mathcal{E} and V	$e^{(G-\mathcal{E}-PV)/(k_B T)}$
Grand canonical (Secs. 4.4.2 and 5.3)	$d\Omega = -SdT - Nd\tilde{\mu} - PdV$	\mathcal{E} and N	$e^{(\Omega-\mathcal{E}+\tilde{\mu}N)/(k_B T)}$

Notes: The nonrelativistic formulas are the same but with the rest masses of particles removed from the chemical potentials ($\tilde{\mu} \rightarrow \mu$) and from all fundamental potentials except Ω ($\mathcal{E} \rightarrow E$, but no change of notation for H , F , and G). This table will be hard to understand until after reading the sections referenced in column one.

In Sec. 5.7, we employ these tools to explore fluctuations and the gas-to-liquid phase transition for a model of a real gas due to the Dutch physicist Johannes van der Waals. Out-of-equilibrium aspects of statistical mechanics (evolution toward equilibrium and fluctuations away from equilibrium) are summarized in Table 5.2 and discussed in Secs. 5.5.1 and 5.6, not just for heat and volume baths, but for a variety of baths.

Deriving the macroscopic properties of real materials by statistical sums over their quantum states can be formidably difficult. Fortunately, in recent years some powerful approximation techniques have been devised for performing the statistical sums. In Secs. 5.8.3 and 5.8.4, we give the reader the flavor of two of these techniques: the *renormalization group* and *Monte Carlo methods*. We illustrate and compare these techniques by using them to study a phase transition in a simple model for ferromagnetism called the *Ising model*.

5.2 Microcanonical Ensemble and the Energy Representation of Thermodynamics

5.2

5.2.1 Extensive and Intensive Variables; Fundamental Potential

5.2.1

Consider a microcanonical ensemble of large, closed systems that have attained statistical equilibrium. We can describe the ensemble macroscopically using a set of thermodynamic variables. These variables can be divided into two classes: *extensive variables* (Sec. 4.4.1), which double if one doubles the system's size, and *intensive variables* (Sec. 4.4.2), whose magnitudes are independent of the system's size. Familiar examples of extensive variables are a system's total energy \mathcal{E} , entropy S , volume V , and number of conserved particles of various species N_j . Corresponding examples of

extensive and intensive variables

intensive variables are temperature T , pressure P , and the chemical potentials $\tilde{\mu}_I$ for various species of particles.

For a large, closed system, there is a *complete set of extensive variables that we can specify independently*—usually its volume V , total energy \mathcal{E} or entropy S , and number N_I of particles of each species I . The values of the other extensive variables and all the intensive variables are determined in terms of this complete set by methods that we shall derive.

The particle species I in the complete set must only include those species whose particles are conserved on the timescales of interest. For example, if photons can be emitted and absorbed, then one must not specify N_γ , the number of photons; rather, N_γ will come to an equilibrium value that is governed by the values of the other extensive variables. Also, one must omit from the set $\{I\}$ any conserved particle species whose numbers are automatically determined by the numbers of other, included species. For example, gas inside the Sun is always charge neutral to very high precision, and therefore (neglecting all elements except hydrogen and helium), the number of electrons N_e in a sample of gas is determined by the number of protons N_p and the number of helium nuclei (alpha particles) N_α : $N_e = N_p + 2N_\alpha$. Therefore, if one includes N_p and N_α in the complete set of extensive variables being used, one must omit N_e .

As in Chap. 4, we formulate the theory relativistically correctly but formulate it solely in the mean rest frames of the systems and baths being studied. Correspondingly, in our formulation we generally include the particle rest masses m_I in the total energy \mathcal{E} and in the chemical potentials $\tilde{\mu}_I$. For very nonrelativistic systems, however, we usually replace \mathcal{E} by the nonrelativistic energy $E \equiv \mathcal{E} - \sum_I N_I m_I c^2$ and $\tilde{\mu}_I$ by the nonrelativistic chemical potential $\mu_I \equiv \tilde{\mu}_I - m_I c^2$ (though, as we shall see in Sec. 5.5 when studying chemical reactions, the identification of the appropriate rest mass m_I to subtract is a delicate issue).

5.2.2 Energy as a Fundamental Potential

For simplicity, we temporarily specialize to a microcanonical ensemble of one-species systems, which all have the same values of a complete set of three extensive variables: the energy \mathcal{E} ,² number of particles N , and volume V . Suppose that the microscopic nature of the ensemble's systems is known. Then, at least in principle and often in practice, one can identify from that microscopic nature the quantum states that are available to the system (given its constrained values of \mathcal{E} , N , and V), one can count those quantum states, and from their total number N_{states} one can compute the ensemble's total entropy $S = k_B \ln N_{\text{states}}$ [Eq. (4.35)]. The resulting entropy can be regarded as a function of the complete set of extensive variables,

$$S = S(\mathcal{E}, N, V), \quad (5.1)$$

2. In practice, as illustrated in Ex. 4.7, one must allow \mathcal{E} to fall in some tiny but finite range $\delta\mathcal{E}$ rather than constraining it precisely, and one must then check to be sure that the results of the analysis are independent of $\delta\mathcal{E}$.

and this equation can then be inverted to give the total energy in terms of the entropy and the other extensive variables:

$$\mathcal{E} = \mathcal{E}(S, N, V). \quad (5.2)$$

We call the energy \mathcal{E} , viewed as a function of S , N , and V , the *fundamental thermodynamic potential for the microcanonical ensemble*. When using this fundamental potential, we regard S , N , and V as our complete set of extensive variables rather than \mathcal{E} , N , and V . From the fundamental potential, as we shall see, one can deduce all other thermodynamic properties of the system.

energy as fundamental thermodynamic potential for microcanonical ensemble

5.2.3 Intensive Variables Identified Using Measuring Devices; First Law of Thermodynamics

5.2.3

TEMPERATURE

In Sec. 4.4.1, we used kinetic-theory considerations to identify the thermodynamic temperature T of the canonical ensemble [Eq. (4.20)]. It is instructive to discuss how this temperature arises in the microcanonical ensemble. Our discussion makes use of an idealized *thermometer* consisting of an idealized atom that has only two quantum states, $|0\rangle$ and $|1\rangle$, with energies \mathcal{E}_0 and $\mathcal{E}_1 = \mathcal{E}_0 + \Delta\mathcal{E}$. The atom, initially in its ground state, is brought into thermal contact with one of the large systems of our microcanonical ensemble and then monitored over time as it is stochastically excited and deexcited. The ergodic hypothesis (Sec. 4.6) guarantees that the atom traces out a history of excitation and deexcitation that is governed statistically by the canonical ensemble for a collection of such atoms exchanging energy (heat) with our large system (the heat bath). More specifically, if T is the (unknown) temperature of our system, then the fraction of time the atom spends in its excited state, divided by the fraction spent in its ground state, is equal to the canonical distribution's probability ratio:

idealized thermometer

$$\frac{\rho_1}{\rho_0} = \frac{e^{-\mathcal{E}_1/(k_B T)}}{e^{-\mathcal{E}_0/(k_B T)}} = e^{-\Delta\mathcal{E}/(k_B T)} \quad (5.3a)$$

[cf. Eq. (4.20)].

This ratio can also be computed from the properties of the full system augmented by the two-state atom. This augmented system is microcanonical with a total energy $\mathcal{E} + \mathcal{E}_0$, since the atom was in the ground state when first attached to the full system. Of all the quantum states available to this augmented system, the ones in which the atom is in the ground state constitute a total number $N_0 = e^{S(\mathcal{E}, N, V)/k_B}$; and those with the atom in the excited state constitute a total number $N_1 = e^{S(\mathcal{E} - \Delta\mathcal{E}, N, V)/k_B}$. Here we have used the fact that the number of states available to the augmented system is equal to that of the original, huge system with energy \mathcal{E} or $\mathcal{E} - \Delta\mathcal{E}$ (since the atom, in each of the two cases, is forced to be in a unique state), and we have expressed that number of states of the original system, for each of the two cases, in terms of the original system's entropy function [Eq. (5.1)]. The ratio of the number of states N_1/N_0 is (by the ergodic hypothesis) the ratio of the time that the augmented system spends

with the atom excited to the time spent with the atom in its ground state (i.e., it is equal to ρ_1/ρ_0):

$$\frac{\rho_1}{\rho_0} = \frac{N_1}{N_0} = \frac{e^{S(\mathcal{E}-\Delta\mathcal{E}, N, V)/k_B}}{e^{S(\mathcal{E}, N, V)/k_B}} = \exp\left[-\frac{\Delta\mathcal{E}}{k_B} \left(\frac{\partial S}{\partial \mathcal{E}}\right)_{N, V}\right]. \quad (5.3b)$$

By equating Eqs. (5.3a) and (5.3b), we obtain an expression for the original system's temperature T in terms of the partial derivative $(\partial\mathcal{E}/\partial S)_{N, V}$ of its fundamental potential $\mathcal{E}(S, N, V)$:

$$T = \frac{1}{(\partial S/\partial \mathcal{E})_{N, V}} = \left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V}, \quad (5.3c)$$

temperature from energy potential $\mathcal{E}(S, N, V)$

where we have used Eq. (3) of Box 5.2.

CHEMICAL POTENTIAL AND PRESSURE

A similar thought experiment—using a highly idealized measuring device that can exchange one particle ($\Delta N = 1$) with the system but cannot exchange any energy with it—gives for the fraction of the time spent with the extra particle in the measuring device (“state 1”) and in the system (“state 0”):

$$\begin{aligned} \frac{\rho_1}{\rho_0} &= e^{\tilde{\mu}\Delta N/k_B T} \\ &= \frac{e^{S(\mathcal{E}, N-\Delta N, V)/k_B}}{e^{S(\mathcal{E}, N, V)/k_B}} = \exp\left[-\frac{\Delta N}{k_B} \left(\frac{\partial S}{\partial N}\right)_{\mathcal{E}, V}\right]. \end{aligned} \quad (5.4a)$$

Here the first expression is computed from the viewpoint of the measuring device's equilibrium ensemble,³ and the second from the viewpoint of the combined system's microcanonical ensemble. Equating these two expressions, we obtain

$$\tilde{\mu} = -T \left(\frac{\partial S}{\partial N}\right)_{\mathcal{E}, V} = \left(\frac{\partial \mathcal{E}}{\partial N}\right)_{S, V}. \quad (5.4b)$$

chemical potential from energy potential

In the last step we use Eq. (5.3c) and Eq. (4) of Box 5.2. The reader should be able to construct a similar thought experiment involving an idealized pressure transducer (Ex. 5.1), which yields the following expression for the system's pressure:

$$P = -\left(\frac{\partial \mathcal{E}}{\partial V}\right)_{S, N}. \quad (5.5)$$

pressure from energy potential

FIRST LAW OF THERMODYNAMICS

Having identified the three intensive variables T , $\tilde{\mu}$, and P as partial derivatives [Eqs. (5.3c), (5.4b), and (5.5)], we now see that the fundamental potential's differential relation

$$d\mathcal{E}(S, N, V) = \left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} dS + \left(\frac{\partial \mathcal{E}}{\partial N}\right)_{S, V} dN + \left(\frac{\partial \mathcal{E}}{\partial V}\right)_{S, N} dV \quad (5.6)$$

3. This ensemble has $\rho = \text{constant } e^{-\tilde{\mu}N/(k_B T)}$, since only particles can be exchanged with the device's heat bath (our system).

BOX 5.2. TWO USEFUL RELATIONS BETWEEN PARTIAL DERIVATIVES

Expand a differential increment in the energy $\mathcal{E}(S, N, V)$ in terms of differentials of its arguments S , N , and V :

$$d\mathcal{E}(S, N, V) = \left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} dS + \left(\frac{\partial \mathcal{E}}{\partial N}\right)_{S, V} dN + \left(\frac{\partial \mathcal{E}}{\partial V}\right)_{S, N} dV. \quad (1)$$

Next expand the entropy $S(\mathcal{E}, N, V)$ similarly, and substitute the resulting expression for dS into the above equation to obtain

$$\begin{aligned} d\mathcal{E} &= \left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} \left(\frac{\partial S}{\partial \mathcal{E}}\right)_{N, V} d\mathcal{E} \\ &+ \left[\left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} \left(\frac{\partial S}{\partial N}\right)_{\mathcal{E}, V} + \left(\frac{\partial \mathcal{E}}{\partial N}\right)_{S, V} \right] dN \\ &+ \left[\left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} \left(\frac{\partial S}{\partial V}\right)_{N, \mathcal{E}} + \left(\frac{\partial \mathcal{E}}{\partial V}\right)_{S, N} \right] dV. \quad (2) \end{aligned}$$

Noting that this relation must be satisfied for all values of $d\mathcal{E}$, dN , and dV , we conclude that

$$\left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} = \frac{1}{(\partial S/\partial \mathcal{E})_{N, V}}, \quad (3)$$

$$\left(\frac{\partial \mathcal{E}}{\partial N}\right)_{S, V} = - \left(\frac{\partial \mathcal{E}}{\partial S}\right)_{N, V} \left(\frac{\partial S}{\partial N}\right)_{\mathcal{E}, V}, \quad (4)$$

and so forth; similarly for other pairs and triples of partial derivatives.

These equations, and their generalization to other variables, are useful in manipulations of thermodynamic equations.

is nothing more nor less than the ordinary first law of thermodynamics

$$d\mathcal{E} = TdS + \tilde{\mu}dN - PdV \quad (5.7)$$

(cf. Table 5.1 above).

Notice the pairing of intensive and extensive variables in this first law: temperature T is paired with entropy S ; chemical potential $\tilde{\mu}$ is paired with number of particles N ; and pressure P is paired with volume V . We can think of each intensive variable as a “generalized force” acting on its corresponding extensive variable to change the energy of the system. We can add additional pairs of intensive and extensive variables if appropriate, calling them X_A , Y_A (e.g., an externally imposed magnetic field \mathbf{B} and a material’s magnetization \mathbf{M} ; Sec. 5.8). We can also generalize to a multicomponent

first law of thermodynamics from energy potential

system (i.e., one that has several types of conserved particles with numbers N_I and associated chemical potentials $\tilde{\mu}_I$). We can convert to nonrelativistic language by subtracting off the rest-mass contributions (switching from \mathcal{E} to $E \equiv \mathcal{E} - \sum N_I m_I c^2$ and from $\tilde{\mu}_I$ to $\mu_I = \tilde{\mu}_I - m_I c^2$). The result is the nonrelativistic, extended first law:

extended first law

$$dE = TdS + \sum_I \mu_I dN_I - PdV + \sum_A X_A dY_A. \quad (5.8)$$

EXERCISES

Exercise 5.1 *Problem: Pressure-Measuring Device*

For the microcanonical ensemble considered in this section, derive Eq. (5.5) for the pressure using a thought experiment involving a pressure-measuring device.

5.2.4

5.2.4 Euler's Equation and Form of the Fundamental Potential

We can integrate the differential form of the first law to obtain a remarkable—though essentially trivial—relation known as *Euler's equation*. We discuss this for the one-species system whose first law is $d\mathcal{E} = TdS + \tilde{\mu}dN - PdV$. The generalization to other systems should be obvious.

We decompose our system into a large number of subsystems in equilibrium with one another. As they are in equilibrium, they will all have the same values of the intensive variables T , $\tilde{\mu}$, and P ; therefore, if we add up all their energies $d\mathcal{E}$ to obtain \mathcal{E} , their entropies dS to obtain S , and so forth, we obtain from the first law (5.7)⁴

Euler's equation for energy

$$\mathcal{E} = TS + \tilde{\mu}N - PV. \quad (5.9a)$$

Since the energy \mathcal{E} is itself extensive, Euler's equation (5.9a) must be expressible as

$$\mathcal{E} = Nf(V/N, S/N) \quad (5.9b)$$

for some function f . This is a useful functional form for the fundamental potential $\mathcal{E}(N, V, S)$. For example, for a nonrelativistic, classical, monatomic perfect gas,⁵ the

- There are a few (but very few!) systems for which some of the thermodynamic laws, including Euler's equation, take on forms different from those presented in this chapter. A black hole is an example (cf. Sec. 4.10.2). A black hole cannot be divided up into subsystems, so the above derivation of Euler's equation fails. Instead of increasing linearly with the mass $M_H = \mathcal{E}/c^2$ of the hole, the hole's extensive variables S_H (entropy) and J_H (spin angular momentum) increase quadratically with M_H . And instead of being independent of the hole's mass, the intensive variables T_H (temperature) and Ω_H (angular velocity) scale as $1/M_H$. See, e.g., Tranah and Landsberg (1980) and see Sec. 4.10.2 for some other aspects of black-hole thermodynamics.
- Recall (Ex. 4.6) that a perfect gas is one that is ideal (i.e., has negligible interactions among its particles) and whose particles have no excited internal degrees of freedom. The phrase "perfect gas" must not be confused with "perfect fluid" (a fluid whose viscosity is negligible so its stress tensor, in its rest frame, consists solely of an isotropic pressure).

Sackur-Tetrode equation (4.42) can be solved for $E = \mathcal{E} - Nmc^2$ to get the following form of the fundamental potential:

$$E(V, S, N) = N \left(\frac{3h^2}{4\pi m g_s^{2/3}} \right) \left(\frac{V}{N} \right)^{-2/3} \exp\left(\frac{2}{3k_B} \frac{S}{N} - \frac{5}{3} \right). \quad (5.9c)$$

energy potential for nonrelativistic, classical, perfect gas

Here m is the mass of each of the gas's particles, and h is Planck's constant.

5.2.5 Everything Deducible from First Law; Maxwell Relations

5.2.5

There is no need to memorize a lot of thermodynamic relations; *nearly all relations can be deduced almost trivially from the functional form of the first law of thermodynamics*, the main formula shown on the first line of Table 5.1.

For example, in the case of our simple one-species system, the first law $d\mathcal{E} = TdS + \tilde{\mu}dN - PdV$ tells us that the system energy \mathcal{E} should be regarded as a function of the things that appear as differentials on the right-hand side: S , N , and V ; that is, the fundamental potential must have the form $\mathcal{E} = \mathcal{E}(S, N, V)$. By thinking about building up our system from smaller systems by adding entropy dS , particles dN , and volume dV at fixed values of the intensive variables, we immediately deduce, from the first law, the Euler equation $\mathcal{E} = TS + \tilde{\mu}N - PV$. By writing out the differential relation (5.6)—which is just elementary calculus—and comparing with the first law, we immediately read off the intensive variables in terms of partial derivatives of the fundamental potential:

$$T = \left(\frac{\partial \mathcal{E}}{\partial S} \right)_{V, N}, \quad \tilde{\mu} = \left(\frac{\partial \mathcal{E}}{\partial N} \right)_{V, S}, \quad P = - \left(\frac{\partial \mathcal{E}}{\partial V} \right)_{S, N}. \quad (5.10a)$$

We can then go on to notice that the resulting $P(V, S, N)$, $T(V, S, N)$, and $\tilde{\mu}(V, S, N)$ are not all independent. The equality of mixed partial derivatives (e.g., $\partial^2 \mathcal{E} / \partial V \partial S = \partial^2 \mathcal{E} / \partial S \partial V$) together with Eqs. (5.10a) implies that they must satisfy the following *Maxwell relations*:

$$\left(\frac{\partial T}{\partial N} \right)_{S, V} = \left(\frac{\partial \tilde{\mu}}{\partial S} \right)_{N, V}, \quad - \left(\frac{\partial P}{\partial S} \right)_{V, N} = \left(\frac{\partial T}{\partial V} \right)_{S, N}, \quad \left(\frac{\partial \tilde{\mu}}{\partial V} \right)_{N, S} = - \left(\frac{\partial P}{\partial N} \right)_{V, S}. \quad (5.10b)$$

Maxwell relations from energy potential

Additional relations can be generated using the types of identities proved in Box 5.2—or they can be generated more easily by applying the above procedure to the fundamental potentials associated with other ensembles; see Secs. 5.3–5.5. All equations of state [i.e., all such relations as Eqs. (5.11) between intensive and extensive variables] must satisfy the Maxwell relations. For our simple example of a nonrelativistic,

classical, perfect gas, we can substitute the fundamental potential E [Eq. (5.9c)] into Eqs. (5.10a) to obtain

$$\begin{aligned} T(V, S, N) &= \left(\frac{h^2}{2\pi m k_B g_s^{2/3}} \right) \left(\frac{N}{V} \right)^{2/3} \exp \left(\frac{2S}{3k_B N} - \frac{5}{3} \right), \\ \mu(V, S, N) &= \left(\frac{h^2}{4\pi m g_s^{2/3}} \right) \left(\frac{N}{V} \right)^{2/3} \left(5 - 2 \frac{S}{k_B N} \right) \exp \left(\frac{2S}{3k_B N} - \frac{5}{3} \right) \\ P(V, S, N) &= \left(\frac{h^2}{2\pi m g_s^{2/3}} \right) \left(\frac{N}{V} \right)^{5/3} \exp \left(\frac{2S}{3k_B N} - \frac{5}{3} \right), \end{aligned} \quad (5.11)$$

(Ex. 5.2). These clearly do satisfy the Maxwell relations.

EXERCISES

Exercise 5.2 *Derivation: Energy Representation for a Nonrelativistic, Classical, Perfect Gas*

- Use the fundamental potential $E(V, S, N)$ for the nonrelativistic, classical, perfect gas [Eq. (5.9c)] to derive Eqs. (5.11) for the gas pressure, temperature, and chemical potential.
- Show that these equations of state satisfy Maxwell relations (5.10b).
- Combine these equations of state to obtain the ideal-gas equation of state

$$P = \frac{N}{V} k_B T, \quad (5.12)$$

which we derived in Ex. 3.8 using kinetic theory.

5.2.6

5.2.6 Representations of Thermodynamics

The treatment of thermodynamics given in this section is called the *energy representation*, because it is based on the fundamental potential $\mathcal{E}(S, V, N)$ in which the energy is expressed as a function of the complete set of extensive variables $\{S, V, N\}$. As we have seen, this energy representation is intimately related to the microcanonical ensemble. In Sec. 5.3, we meet the grand-potential representation for thermodynamics, which is intimately related to the grand canonical ensemble for systems of volume V in equilibrium with a heat and particle bath that has temperature T and chemical potential $\tilde{\mu}$. Then in Secs. 5.4 and 5.5, we meet the two representations of thermodynamics that are intimately related to the canonical and Gibbs ensembles, and discover their power to handle certain special issues. And in Ex. 5.5, we consider a representation and ensemble based on enthalpy. These five representations and their ensembles are summarized in Table 5.1 above.

5.3 Grand Canonical Ensemble and the Grand-Potential Representation of Thermodynamics

5.3

We now turn to the grand canonical ensemble, and its grand-potential representation of thermodynamics, for a semiclosed system that exchanges heat and particles with a thermalized bath. For simplicity, we assume that all particles are identical (just one particle species), but we allow them to be relativistic (speeds comparable to the speed of light) or not and allow them to have nontrivial internal degrees of freedom (e.g., vibrations and rotations; Sec. 5.4.2), and allow them to exert forces on one another via an interaction potential that appears in their hamiltonian (e.g., van der Waals forces; Secs. 5.3.2 and 5.7). We refer to these particles as a gas, though our analysis is more general than gases. The nonrelativistic limit of all our fundamental equations is trivially obtained by removing particle rest masses from the energy (\mathcal{E} gets replaced by $E = \mathcal{E} - mc^2$) and from the chemical potential ($\tilde{\mu}$ gets replaced by $\mu = \tilde{\mu} - mc^2$), but not from the grand potential, as it never has rest masses in it [see, e.g., Eq. (5.18) below].

We begin in Sec. 5.3.1 by deducing the grand potential representation of thermodynamics from the grand canonical ensemble, and by deducing a method for computing the thermodynamic properties of our gas from a grand canonical sum over the quantum states available to the system. In Ex. 5.3, the reader will apply this grand canonical formalism to a relativistic perfect gas. In Sec. 5.3.2, we apply the formalism to a nonrelativistic gas of particles that interact via van der Waals forces, thereby deriving the van der Waals equation of state, which is surprisingly accurate for many nonionized gases.

5.3.1 The Grand-Potential Representation, and Computation of Thermodynamic Properties as a Grand Canonical Sum

5.3.1

Figure 5.1 illustrates the ensemble of systems that we are studying and its bath. Each system is a cell of fixed volume V , with imaginary walls, inside a huge thermal bath of identical particles. Since the cells' walls are imaginary, the cells can and do exchange energy and particles with the bath. The bath is characterized by chemical potential $\tilde{\mu}$ for these particles and by temperature T . Since we allow the particles to be relativistic, we include the rest mass in the chemical potential $\tilde{\mu}$.

We presume that our ensemble of cells has reached statistical equilibrium with the bath, so its probabilistic distribution function has the grand canonical form (4.25c):

$$\rho_n = \frac{1}{Z} \exp\left(\frac{-\mathcal{E}_n + \tilde{\mu}N_n}{k_B T}\right) = \exp\left(\frac{\Omega - \mathcal{E}_n + \tilde{\mu}N_n}{k_B T}\right). \quad (5.13)$$

grand canonical
distribution function

Here the index n labels the quantum state $|n\rangle$ of a cell, N_n is the number of particles in that quantum state, \mathcal{E}_n is the total energy of that quantum state (including each particle's rest mass; its energy of translational motion; its internal energy if it has internal vibrations, rotations, or other internal excitations; and its energy of interaction with

FIGURE 5.1 An ensemble of cells, each with volume V and imaginary walls, inside a heat and particle bath.

other particles), and $1/Z \equiv e^{\Omega/(k_B T)}$ is the normalization constant that guarantees $\sum_n \rho_n = 1$:

grand partition function
and grand potential

$$Z \equiv \exp\left(\frac{-\Omega}{k_B T}\right) \equiv \sum_n \exp\left(\frac{-\mathcal{E}_n + \tilde{\mu} N_n}{k_B T}\right). \quad (5.14)$$

This normalization constant, whether embodied in Z or in Ω , is a function of the bath's temperature T and chemical potential $\tilde{\mu}$, and also of the cells' common volume V (which influences the set of available states $|n\rangle$). When regarded as a function of T , $\tilde{\mu}$, and V , the quantity $Z(V, \tilde{\mu}, T)$ is called the gas's *grand partition function*, and $\Omega(T, \tilde{\mu}, V)$ is called its *grand potential*. The following general argument shows that *once one has computed the explicit functional form for the grand potential*

$$\Omega(V, \tilde{\mu}, T) \quad (5.15)$$

[or for the grand partition function $Z(V, \tilde{\mu}, T)$], one can then derive from it all the thermodynamic properties of the thermally equilibrated system. The argument is so general that it applies to every grand canonical ensemble of systems, not just to our chosen gas of identical particles.

As key quantities in the argument, we introduce the mean energy and mean number of particles in the ensemble's systems (i.e., cells of Fig. 5.1):

$$\bar{\mathcal{E}} \equiv \sum_n \rho_n \mathcal{E}_n, \quad \bar{N} \equiv \sum_n \rho_n N_n. \quad (5.16)$$

(We denote these quantities with bars $\bar{\mathcal{E}}$ rather than brackets $\langle \mathcal{E} \rangle$ for ease of notation.) Inserting expression (5.13) for ρ_n into the log term in the definition of entropy $S = -k_B \sum_n \rho_n \ln \rho_n$ and using Eqs. (5.16), we obtain

$$S = -k_B \sum_n \rho_n \ln \rho_n = -k_B \sum_n \rho_n \left(\frac{\Omega - \mathcal{E}_n + \tilde{\mu} N_n}{k_B T} \right) = -\frac{\Omega - \bar{\mathcal{E}} + \tilde{\mu} \bar{N}}{T}; \quad (5.17)$$

or, equivalently,

Legendre transformation
between thermodynamic
representations

$$\Omega = \bar{\mathcal{E}} - T S - \tilde{\mu} \bar{N}. \quad (5.18)$$

This can be regarded as a *Legendre transformation* that leads from the energy representation of thermodynamics to the grand-potential representation. Legendre transformations are a common tool, for example, in classical mechanics (e.g., Landau and Lifshitz, 1976; Marion and Thornton, 1995; Goldstein, Poole, and Safko, 2002), for switching from one set of independent variables to another. Note that removing rest masses from $\bar{\mathcal{E}} = \bar{E} + Nmc^2$ and from $\tilde{\mu} = \mu + mc^2$ to get a nonrelativistic formula leaves Ω unchanged.

We now ask how the grand potential will change if the temperature T and chemical potential $\tilde{\mu}$ of the bath (and therefore of the ensemble) are slowly altered, and the volumes V of all the ensemble's boxes are slowly altered. Differentiating Eq. (5.18), we obtain $d\Omega = d\bar{\mathcal{E}} - TdS - SdT - \tilde{\mu}d\bar{N} - \bar{N}d\tilde{\mu}$. Expressing $d\mathcal{E}$ in terms of the energy representation's first law of thermodynamics (5.7) (with \mathcal{E} replaced by $\bar{\mathcal{E}}$ and N replaced by \bar{N}), we bring this expression into the form

$$\boxed{d\Omega = -PdV - \bar{N}d\tilde{\mu} - SdT.} \quad (5.19)$$

first law in grand potential representation

This is the *grand-potential representation* of the first law of thermodynamics. The quantities P , \bar{N} , and S paired with the independent variables V , $\tilde{\mu}$, and T , respectively, can be thought of as generalized forces that push on the independent variables as they change, to produce changes in the grand potential.

generalized forces

From this version of the first law (the key grand canonical equation listed in the last line of Table 5.1), we can easily deduce almost all other equations of the grand-potential representation of thermodynamics. We just follow the same procedure as we used for the energy representation (Sec. 5.2.5).

The grand-potential representation's complete set of independent variables consists of those that appear as differentials on the right-hand side of the first law (5.19): V , $\tilde{\mu}$, and T . From the form (5.19) of the first law we see that Ω is being regarded as a function of these three independent variables: $\Omega = \Omega(V, \tilde{\mu}, T)$. This is the fundamental potential.

The Euler equation of this representation is deduced by building up a system from small pieces that all have the same values of the intensive variables $\tilde{\mu}$, T , and P . The first law (5.19) tells us that this buildup will produce

Euler equation for grand potential

$$\boxed{\Omega = -PV.} \quad (5.20)$$

Thus, if we happen to know P as a function of this representation's independent intensive variables— $P(\tilde{\mu}, T)$ (it must be independent of the extensive variable V)—then we can simply multiply by V to get the functional form of the grand potential: $\Omega(V, \tilde{\mu}, T) = P(\tilde{\mu}, T)V$; see Eqs. (5.24a) and (5.25) as a concrete example.

By comparing the grand-potential version of the first law (5.19) with the elementary calculus equation $d\Omega = (\partial\Omega/\partial V)dV + (\partial\Omega/\partial\tilde{\mu})d\tilde{\mu} + (\partial\Omega/\partial T)dT$, we infer

equations for the system's "generalized forces," the pressure P , mean number of particles \bar{N} , and entropy S :

$$\bar{N} = - \left(\frac{\partial \Omega}{\partial \tilde{\mu}} \right)_{V, T}, \quad S = - \left(\frac{\partial \Omega}{\partial T} \right)_{V, \tilde{\mu}}, \quad P = - \left(\frac{\partial \Omega}{\partial V} \right)_{\tilde{\mu}, T}. \quad (5.21)$$

Maxwell relations from grand potential

By differentiating these relations and equating mixed partial derivatives, we can derive Maxwell relations analogous to those [Eqs. (5.10b)] of the energy representation; for example, $(\partial \bar{N} / \partial T)_{V, \tilde{\mu}} = (\partial S / \partial \tilde{\mu})_{V, T}$. Equations of state are constrained by these Maxwell relations.

If we had begun with a specific functional form of the grand potential as a function of this representation's complete set of independent variables $\Omega(V, T, \tilde{\mu})$ [e.g., Eq. (5.24a) below], then Eqs. (5.21) would give us the functional forms of almost all the other dependent thermodynamic variables. The only one we are missing is the mean energy $\bar{\mathcal{E}}(V, \tilde{\mu}, T)$ in a cell. If we have forgotten Eq. (5.18) (the Legendre transformation) for that quantity, we can easily rederive it from the grand canonical distribution function $\rho = \exp[(\Omega - \mathcal{E} + \tilde{\mu}N)/(k_B T)]$ (the other key equation, besides the first law, on the last line of Table 5.1), via the definition of entropy as $S = -k_B \sum_n \rho_n \ln \rho_n = -k_B \overline{\ln \rho}$, as we did in Eq. (5.17).

This illustrates the power of the sparse information in Table 5.1. From it and little else we can deduce all the thermodynamic equations for each representation of thermodynamics.

It should be easy to convince oneself that *the nonrelativistic versions of all the above equations in this section can be obtained by the simple replacements $\mathcal{E} \rightarrow E$ (removal of rest masses from total energy) and $\tilde{\mu} \rightarrow \mu$ (removal of rest mass from chemical potential)*.

5.3.2

computing the grand potential from a statistical sum

5.3.2 Nonrelativistic van der Waals Gas

The statistical sum $Z \equiv e^{-\Omega/(k_B T)} = \sum_n e^{(-\mathcal{E}_n + \tilde{\mu}N_n)/(k_B T)}$ [Eq. (5.14)] is a powerful method for computing the grand potential $\Omega(V, \tilde{\mu}, T)$, a method often used in condensed matter physics. Here we present a nontrivial example: a nonrelativistic, monatomic gas made of atoms or molecules (we call them "particles") that interact with so-called "van der Waals forces." In Ex. 5.3, the reader will explore a simpler example: a relativistic, perfect gas.

We assume that the heat and particle bath that bathes the cells of Fig. 5.1 has (i) sufficiently low temperature that the gas's particles are not ionized (therefore they are also nonrelativistic, $k_B T \ll mc^2$) and (ii) sufficiently low chemical potential that the mean occupation number η of the particles' quantum states is small compared to unity, so they behave classically, $\mu \equiv \tilde{\mu} - mc^2 \ll -k_B T$ [Eq. (3.22d)].

The orbital electron clouds attached to each particle repel one another when the distance r between the particles' centers of mass is smaller than about the diameter r_o of the particles. At larger separations, the particles' electric dipoles (intrinsic or induced) attract one another weakly. The interaction energy (potential energy) $u(r)$

associated with these forces has a form well approximated by the Lennard-Jones potential

$$u(r) = \varepsilon_o \left[\left(\frac{r_o}{r} \right)^{12} - \left(\frac{r_o}{r} \right)^6 \right], \quad (5.22a)$$

where ε_o is a constant energy. When a gradient is taken, the first term gives rise to the small- r repulsive force and the second to the larger- r attractive force. For simplicity of analytic calculations, we use the cruder approximation

$$u(r) = \infty \text{ for } r < r_o, \quad u(r) = -\varepsilon_o (r_o/r)^6 \text{ for } r > r_o, \quad (5.22b)$$

which has an infinitely sharp repulsion at $r = r_o$ (a *hard wall*). For simplicity, we assume that the mean interparticle separation is much larger than r_o (*dilute gas*), so it is highly unlikely that three or more particles are close enough together simultaneously, $r \sim r_o$, to interact (i.e., we confine ourselves to two-particle interactions).⁶

We compute the grand potential $\Omega(V, \mu, T)$ for an ensemble of cells embedded in a bath of these particles (Fig. 5.1), and from $\Omega(V, \mu, T)$ we compute how the particles' interaction energy $u(r)$ alters the gas's equation of state from the form $P = (\bar{N}/V)k_B T$ for an ideal gas [Eqs. (3.39b,c)]. Since this is our objective, any internal and spin degrees of freedom that the particles might have are irrelevant, and we ignore them.

For this ensemble, the nonrelativistic grand partition function $Z = \sum_n \exp[(-E_n + \mu N_n)/(k_B T)]$ is

$$Z = e^{-\Omega/(k_B T)} = \sum_{N=0}^{\infty} \frac{e^{\mu N/(k_B T)}}{N!} \int \frac{d^{3N}x d^{3N}p}{h^{3N}} \exp \left[- \sum_{i=1}^N \frac{\mathbf{p}_i^2}{2mk_B T} - \sum_{i=1}^N \sum_{j=i+1}^N \frac{u_{ij}}{k_B T} \right]. \quad (5.23a)$$

Here we have used Eq. (4.8b) for the sum over states \sum_n [with $\mathcal{M} = N!$ (the multiplicity factor of Eqs. (4.8)), $W = 3N$, and $d\Gamma_W = d^{3N}x d^{3N}p$; cf. Ex. 5.3], and we have written E_n as the sum over the kinetic energies of the N particles in the cell and the interaction energies

$$u_{ij} \equiv u(r_{ij}), \quad r_{ij} \equiv |\mathbf{x}_i - \mathbf{x}_j| \quad (5.23b)$$

of the $\frac{1}{2}N(N-1)$ pairs of particles.

Evaluation of the integrals and sum in Eq. (5.23a), with the particles' interaction energies given by Eqs. (5.23b) and (5.22b), is a rather complex task, which we relegate to the Track-Two Box 5.3. The result for the grand potential, $\Omega = -k_B T \ln Z$, accurate

6. Finding effective ways to tackle many-body problems is a major challenge in many areas of modern theoretical physics.

approximate interaction energy for van der Waals gas

to first order in the particles' interactions (in the parameters a and b below), is

$$\Omega = -k_B T V \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)} \left[1 + \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)} \left(\frac{a}{k_B T} - b \right) \right]. \quad (5.24a)$$

Here b is four times the volume of each hard-sphere particle, and a is that volume times the interaction energy ε_o of two hard-sphere particles when they are touching:

$$b = \frac{16\pi}{3} \left(\frac{r_o}{2} \right)^3, \quad a = b\varepsilon_o. \quad (5.24b)$$

By differentiating this grand potential, we obtain the following expressions for the pressure P and mean number of particles \bar{N} in a volume- V cell:

$$\begin{aligned} P &= - \left(\frac{\partial \Omega}{\partial V} \right)_{\mu, T} \\ &= k_B T \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)} \left[1 + \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)} \left(\frac{a}{k_B T} - b \right) \right], \\ \bar{N} &= - \left(\frac{\partial \Omega}{\partial \mu} \right)_{V, T} \\ &= V \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)} \left[1 + 2 \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)} \left(\frac{a}{k_B T} - b \right) \right]. \end{aligned} \quad (5.25)$$

Notice that, when the interaction energy is turned off so $a = b = 0$, the second equation gives the standard ideal-gas particle density $\bar{N}/V = (2\pi m k_B T)^{3/2} e^{\mu/(k_B T)} / h^3 = \zeta / \lambda_{T, \text{dB}}^3$ where ζ and $\lambda_{T, \text{dB}}$ are defined in Eq. (2) of Box 5.3. Inserting this into the square bracketed expression in Eqs. (5.25), taking the ratio of expressions (5.25) and multiplying by V and expanding to first order in $a/(k_B T) - b$, we obtain $P V / \bar{N} = k_B T [1 + (\bar{N}/V)(b - a/(k_B T))]$ —accurate to first order in $(b - a/(k_B T))$. Bringing the a term to the left-hand side, multiplying both sides by $[1 - (\bar{N}/V)b]$, and linearizing in b , we obtain the standard *van der Waals equation of state*:

$$\left(P + \frac{a}{(V/\bar{N})^2} \right) (V/\bar{N} - b) = k_B T. \quad (5.26)$$

The quantity V/\bar{N} is the *specific volume* (volume per particle).

A few comments are in order.

1. The factor $(V/\bar{N} - b)$ in the equation of state corresponds to an excluded volume $b = (16\pi/3)(r_o/2)^3$ that is four times larger than the actual volume of each hard-sphere particle (whose radius is $r_o/2$).
2. The term linear in a , $P = -a\bar{N}/V = -b\varepsilon_o\bar{N}/V$, is a pressure reduction due to the attractive force between particles.

BOX 5.3. DERIVATION OF VAN DER WAALS GRAND POTENTIAL T2

T2

In Eq. (5.23a) the momentum integrals and the space integrals separate, and the N momentum integrals are identical, so Z takes the form

$$\begin{aligned} Z &= \sum_{N=0}^{\infty} \frac{e^{\mu N/(k_B T)}}{N! h^{3N}} \left[\int_0^{\infty} 4\pi p^2 dp \exp\left(\frac{-p^2}{2mk_B T}\right) \right]^N J_N \\ &= \sum_{N=0}^{\infty} \frac{(\zeta/\lambda_{T \text{ dB}}^3)^N}{N!} J_N, \end{aligned} \quad (1)$$

where

$$\begin{aligned} \zeta &\equiv e^{\mu/(k_B T)}, \quad \lambda_{T \text{ dB}} \equiv \frac{h}{(2\pi mk_B T)^{1/2}}, \\ J_N &= \int d^{3N}x \exp \left[- \sum_{i=1}^N \sum_{j=i+1}^N \frac{u_{ij}}{k_B T} \right]. \end{aligned} \quad (2)$$

Note that λ is the particles' thermal deBroglie wavelength. The Boltzmann factor $e^{-u_{ij}/(k_B T)}$ is unity for large interparticle separations $r_{ij} \gg r_o$, so we write

$$e^{-u_{ij}/(k_B T)} \equiv 1 + f_{ij}, \quad (3)$$

where f_{ij} is zero except when $r_{ij} \lesssim r_o$. Using this definition and rewriting the exponential of a sum as the products of exponentials, we bring J_N into the form

$$J_N = \int d^{3N}x \prod_{i=1}^N \prod_{j=i+1}^N (1 + f_{ij}). \quad (4)$$

The product contains (i) terms linear in f_{ij} that represent the influence of pairs of particles that are close enough ($r_{ij} \lesssim r_o$) to interact, plus (ii) quadratic terms, such as $f_{14}f_{27}$, that are nonzero only if particles 1 and 4 are near each other and 2 and 7 are near each other (there are so many of these terms that we cannot neglect them!), plus (iii) quadratic terms such as $f_{14}f_{47}$ that are nonzero only if particles 1, 4, and 7 are all within a distance $\sim r_o$ of one another (because our gas is dilute, it turns out these three-particle terms can be neglected), plus (iv) cubic and higher-order terms. At all orders ℓ (linear, quadratic, cubic, quartic, etc.) for our dilute gas, we can ignore terms that require three or more particles to be near one another, so we focus only on terms $f_{ij}f_{mn} \dots f_{pq}$ where all indices are different. Eq. (4) then becomes

(continued)

BOX 5.3. (continued)

$$J_N = \int d^{3N}x [1 + \underbrace{(f_{12} + f_{13} + \cdots)}_{n_1 \text{ terms}} + \underbrace{(f_{12}f_{34} + f_{13}f_{24} + \cdots)}_{n_2 \text{ terms}} + \underbrace{(f_{12}f_{34}f_{56} + f_{13}f_{24}f_{56} + \cdots)}_{n_3 \text{ terms}} \dots], \quad (5)$$

where n_ℓ is the number of terms of order ℓ with all 2ℓ particles different.

Denoting

$$V_o \equiv \int f(r) 4\pi r^2 dr, \quad (6)$$

and performing the integrals, we bring Eq. (5) into the form

$$J_N = \sum_{\ell=0}^{\infty} n_\ell V^{N-\ell} V_o^\ell. \quad (7)$$

At order ℓ the number of unordered sets of 2ℓ particles that are all different is $N(N-1)\cdots(N-2\ell+1)/\ell!$. The number of ways that these 2ℓ particles can be assembled into unordered pairs is $(2\ell-1)(2\ell-3)(2\ell-5)\cdots 1 \equiv (2\ell-1)!!$. Therefore, the number of terms of order ℓ that appear in Eq. (7) is

$$\begin{aligned} n_\ell &= \frac{N(N-1)\cdots(N-2\ell+1)}{\ell!} (2\ell-1)!! \\ &= \frac{N(N-1)\cdots(N-2\ell+1)}{2^\ell \ell!}. \end{aligned} \quad (8)$$

Inserting Eqs. (7) and (8) into Eq. (1) for the partition function, we obtain

$$Z = \sum_{N=0}^{\infty} \frac{(\xi/\lambda^3)^N}{N!} \sum_{\ell=0}^{[N/2]} \frac{N(N-1)\cdots(N-2\ell+1)}{2^\ell \ell!} V^{N-\ell} V_o^\ell, \quad (9)$$

where $[N/2]$ means the largest integer less than or equal to $N/2$. Performing a little algebra and then reversing the order of the summations, we obtain

$$Z = \sum_{\ell=0}^{\infty} \sum_{N=2\ell}^{\infty} \frac{1}{(N-2\ell)!} \left(\frac{\xi V}{\lambda^3}\right)^{N-2\ell} \frac{1}{\ell!} \left(\frac{\xi V}{\lambda^3} \frac{\xi V_o}{2\lambda^3}\right)^\ell. \quad (10)$$

By changing the summation index from N to $N' = N - 2\ell$, we decouple the two summations. Each of the sums is equal to an exponential, giving

(continued)

$$\begin{aligned}
Z &= e^{-\Omega/(k_B T)} = \exp\left(\frac{\zeta V}{\lambda^3}\right) \exp\left(\frac{\zeta V}{\lambda^3} \frac{\zeta V_o}{2\lambda^3}\right) \\
&= \exp\left[\frac{\zeta V}{\lambda^3} \left(1 + \frac{\zeta V_o}{2\lambda^3}\right)\right]. \quad (11)
\end{aligned}$$

Therefore, the grand potential for our van der Waals gas is

$$\Omega = \frac{-k_B T \zeta V}{\lambda^3} \left(1 + \frac{\zeta V_o}{2\lambda^3}\right). \quad (12)$$

From kinetic theory [Eq. (3.39a)], we know that for an ideal gas, the mean number density is $\bar{N}/V = \zeta/\lambda^3$; this is also a good first approximation for our van der Waals gas, which differs from an ideal gas only by the weakly perturbative interaction energy $u(r)$. Thus $\zeta V_o/(2\lambda^3)$ is equal to $\frac{1}{2} V_o/(\text{mean volume per particle})$, which is $\ll 1$ by our dilute-gas assumption. If we had kept three-particle interaction terms, such as $f_{14}f_{47}$, they would have given rise to fractional corrections of order $(\zeta V_o/\lambda^3)^2$, which are much smaller than the leading-order fractional correction $\zeta V_o/(2\lambda^3)$ that we have computed [Eq. (12)]. The higher-order corrections are derived in statistical mechanics textbooks, such as Pathria and Beale (2011, Chap. 10) and Kardar (2007, Chap. 5) using a technique called the “cluster expansion.”

For the hard-wall potential (5.22b), f is -1 at $r < r_o$, and assuming that the temperature is high enough that $\varepsilon_o/(k_B T) \ll 1$, then at $r > r_o$, f is very nearly $-u/(k_B T) = (\varepsilon_o/(k_B T)) (r_o/r)^6$; therefore we have

$$\frac{V_o}{2} \equiv \frac{1}{2} \int f(r) 4\pi r^2 dr = \frac{a}{k_B T} - b, \quad \text{where } b = \frac{2\pi r_o^3}{3}, \quad a = b\varepsilon_o. \quad (13)$$

Inserting this expression for $V_o/2$ and Eqs. (2) for ζ and λ into Eq. (12), we obtain Eqs. (5.24) for the grand potential of a van der Waals gas.

3. Our derivation is actually only accurate to first order in a and b , so it does not justify the quadratic term $P = ab(\bar{N}/V)^2$ in the equation of state (5.26). However, that quadratic term does correspond to the behavior of real gases: a sharp rise in pressure at high densities due to the short-distance repulsion between particles.

We study this van der Waals equation of state in Sec. 5.7, focusing on the gas-to-liquid phase transition that it predicts and on fluctuations of thermodynamic quantities associated with that phase transition.

In this section we have presented the grand canonical analysis for a van der Waals gas not because such a gas is important (though it is), but rather as a concrete example of how one uses the formalism of statistical mechanics and introduces ingenious approximations to explore the behavior of realistic systems made of interacting particles.

EXERCISES

Exercise 5.3 *Derivation and Example: Grand Canonical Ensemble for a Classical, Relativistic, Perfect Gas*

Consider cells that reside in a heat and particle bath of a classical, relativistic, perfect gas (Fig. 5.1). Each cell has the same volume V and imaginary walls. Assume that the bath's temperature T has an arbitrary magnitude relative to the rest mass-energy mc^2 of the particles (so the thermalized particles might have relativistic velocities), but require $k_B T \ll -\mu$ (so all the particles behave classically). Ignore the particles' spin degrees of freedom, if any. For ease of notation use geometrized units (Sec. 1.10) with $c = 1$.

- (a) The number of particles in a chosen cell can be anything from $N = 0$ to $N = \infty$. Restrict attention, for the moment, to a situation in which the cell contains a precise number of particles, N . Explain why the multiplicity is $\mathcal{M} = N!$ even though the density is so low that the particles' wave functions do not overlap, and they are behaving classically (cf. Ex. 4.8).
- (b) Still holding fixed the number of particles in the cell, show that the number of degrees of freedom W , the number density of states in phase space $\mathcal{N}_{\text{states}}$, and the energy \mathcal{E}_N in the cell are

$$W = 3N, \quad \mathcal{N}_{\text{states}} = \frac{1}{N! h^{3N}}, \quad \mathcal{E}_N = \sum_{j=1}^N (\mathbf{p}_j^2 + m^2)^{\frac{1}{2}}, \quad (5.27a)$$

where \mathbf{p}_j is the momentum of classical particle number j .

- (c) Using Eq. (4.8b) to translate from the formal sum over states \sum_n to a sum over $W = 3N$ and an integral over phase space, show that the sum over states (5.14) for the grand partition function becomes

$$Z = e^{-\Omega/(k_B T)} = \sum_{N=0}^{\infty} \frac{V^N}{N! h^{3N}} e^{\tilde{\mu}N/(k_B T)} \left[\int_0^{\infty} \exp\left(-\frac{(p^2 + m^2)^{\frac{1}{2}}}{k_B T}\right) 4\pi p^2 dp \right]^N. \quad (5.27b)$$

- (d) Evaluate the momentum integral in the nonrelativistic limit $k_B T \ll m$, and thereby show that

$$\Omega(T, \mu, V) = -k_B T V \frac{(2\pi m k_B T)^{3/2}}{h^3} e^{\mu/(k_B T)}, \quad (5.28a)$$

where $\mu = \tilde{\mu} - m$ is the nonrelativistic chemical potential. This is the interaction-free limit $V_o = a = b = 0$ of our grand potential (5.24a) for a van der Waals gas.

(e) Show that in the extreme relativistic limit $k_B T \gg m$, Eq. (5.27b) gives

$$\Omega(T, \tilde{\mu}, V) = -\frac{8\pi V (k_B T)^4}{h^3} e^{\tilde{\mu}/(k_B T)}. \quad (5.29)$$

(f) For the extreme relativistic limit use your result (5.29) for the grand potential $\Omega(V, T, \tilde{\mu})$ to derive the mean number of particles \bar{N} , the pressure P , the entropy S , and the mean energy $\bar{\mathcal{E}}$ as functions of V , $\tilde{\mu}$, and T . Note that for a photon gas, because of the spin degree of freedom, the correct values of \bar{N} , $\bar{\mathcal{E}}$, and S will be twice as large as what you obtain in this calculation. Show that the energy density is $\bar{\mathcal{E}}/V = 3P$ (a relation valid for any ultrarelativistic gas); and that $\bar{\mathcal{E}}/\bar{N} = 3k_B T$ (which is higher than the $2.7011780 \dots k_B T$ for blackbody radiation, as derived in Ex. 3.13, because in the classical regime of $\eta \ll 1$, photons don't cluster in the same states at low frequency; that clustering lowers the mean photon energy for blackbody radiation).

5.4 Canonical Ensemble and the Physical-Free-Energy Representation of Thermodynamics

5.4

In this section, we turn to an ensemble of single-species systems that can exchange energy but nothing else with a heat bath at temperature T . The systems thus have variable total energy \mathcal{E} , but they all have the same, fixed values of the two remaining extensive variables N and V . We presume that the ensemble has reached statistical equilibrium, so it is canonical with a distribution function (probability of occupying any quantum state of energy \mathcal{E}) given by Eq. (4.20):

$$\rho_n = \frac{1}{z} e^{-\mathcal{E}_n/(k_B T)} \equiv e^{(F - \mathcal{E}_n)/(k_B T)}. \quad (5.30)$$

canonical distribution function

Here, as in the grand canonical ensemble [Eq. (5.13)], we have introduced special notations for the normalization constant: $1/z = e^{F/(k_B T)}$, where z (the *partition function*) and F (the *physical free energy* or *Helmholtz free energy*) are functions of the systems' fixed N and V and the bath temperature T . Once the systems' quantum states $|n\rangle$ (with fixed N and V but variable \mathcal{E}) have been identified, the functions $z(T, N, V)$ and $F(T, N, V)$ can be computed from the normalization relation $\sum_n \rho_n = 1$:

$$e^{-F/(k_B T)} \equiv z(T, N, V) = \sum_n e^{-\mathcal{E}_n/(k_B T)}. \quad (5.31)$$

partition function and physical free energy

This canonical sum over states, like the grand canonical sum (5.14) that we used for the van der Waals gas, is a powerful tool in statistical mechanics. As an example, in Secs. 5.8.2 and 5.8.3 we use the canonical sum to evaluate the physical free energy F for a model of ferromagnetism and use the resulting F to explore a ferromagnetic phase transition.

Having evaluated $z(T, N, V)$ [or equivalently, $F(T, N, V)$], one can then proceed as follows to determine other thermodynamic properties of the ensemble's systems. The entropy S can be computed from the standard expression $S = -k_B \sum_n \rho_n \ln \rho_n = -k_B \overline{\ln \rho}$, which, with Eq. (5.30) for ρ_n , implies $S = (\bar{\mathcal{E}} - F)/T$. It is helpful to rewrite this as an equation for the physical free energy F :

Legendre transformation

$$F = \bar{\mathcal{E}} - TS. \quad (5.32)$$

This is the Legendre transformation that leads from the energy representation of thermodynamics to the physical-free-energy representation.

Suppose that the canonical ensemble's parameters T , N , and V are changed slightly. By how much will the physical free energy change? Equation (5.32) tells us that $dF = d\bar{\mathcal{E}} - TdS - SdT$. Because macroscopic thermodynamics is independent of the statistical ensemble being studied, we can evaluate $d\bar{\mathcal{E}}$ using the first law of thermodynamics (5.7) with the microcanonical exact energy \mathcal{E} replaced by the canonical mean energy $\bar{\mathcal{E}}$. The result is

first law in physical-free-energy representation

$$dF = -SdT + \tilde{\mu}dN - PdV. \quad (5.33)$$

Equation (5.33) contains the same information as the first law of thermodynamics and can be thought of as the first law rewritten in the physical-free-energy representation. From this form of the first law, we can deduce the other equations of the physical-free-energy representation by the same procedure we used for the energy representation in Sec. 5.2.5 and the grand-potential representation in Sec. 5.3.1.

If we have forgotten our representation's independent variables, we read them off the first law (5.33); they appear as differentials on the right-hand side: T , N , and V . The fundamental potential is the quantity that appears on the left-hand side of the first law: $F(T, N, V)$. By building up a full system from small subsystems that all have the same intensive variables T , $\tilde{\mu}$, and P , we deduce from the first law the Euler relation for this representation:

Euler relation for physical free energy

$$F = \tilde{\mu}N - PV. \quad (5.34)$$

From the first law (5.33) we read off equations of state for this representation's generalized forces [e.g., $-S = (\partial F/\partial T)_{N,V}$]. Maxwell relations can be derived from the equality of mixed partial derivatives.

Thus, as for the energy and grand-potential representations, all the equations of the physical-free-energy representation are easily deducible from the minimal information in Table 5.1.

And as for those representations, *the Newtonian version of this representation's fundamental equations (5.30)–(5.34) is obtained by simply removing rest masses from $\tilde{\mu}$ (which becomes μ), \mathcal{E} (which becomes E), and F (whose notation does not change).*

FIGURE 5.2 Origin of the name “physical free energy” for $F(V, T, N)$.

5.4.1 Experimental Meaning of Physical Free Energy

5.4.1

The name “physical free energy” for F can be understood using the idealized experiment shown in Fig. 5.2. Gas is placed in a chamber, one wall of which is a piston, and the chamber comes into thermal equilibrium with a heat bath, with which it can exchange heat but not particles. The volume of the chamber has some initial value V_i ; and correspondingly, the gas has some initial physical free energy $F(V_i, T, N)$. The gas is then allowed to push the piston to the right sufficiently slowly for the gas to remain always in thermal equilibrium with the heat bath, at the bath’s temperature T . When the chamber has reached its final volume V_f , the total work done on the piston by the gas (i.e., the total energy extracted by the piston from this “engine”) is

$$\mathcal{E}_{\text{extracted}} = \int_{V_i}^{V_f} -PdV. \quad (5.35a)$$

Using the first law $dF = -SdT + \tilde{\mu}dN - PdV$ and remembering that T and N are kept constant, Eq. (5.35a) becomes

$$\mathcal{E}_{\text{extracted}} = F(V_f, T, N) - F(V_i, T, N) \equiv \Delta F. \quad (5.35b)$$

Thus, F is the energy that is free to be extracted in an isothermal, physical expansion of the gas.⁷

If the expansion had been done in a chamber that was perfectly thermally insulated, so no heat could flow in or out of it, then there would have been no entropy change. Correspondingly, with S and N held fixed but V changing during the expansion, the natural way to analyze the expansion would have been in the energy representation; that representation’s first law $d\mathcal{E} = -PdV + TdS + \tilde{\mu}dN$ would have told us that the total energy extracted, $\int -PdV$, was the change $\Delta\mathcal{E}$ of the gas’s total energy. Such a process, which occurs without any heat flow or entropy increase, is called *adiabatic*. Thus, the energy \mathcal{E} (or in the nonrelativistic regime, E) measures the amount of energy that can be extracted from an adiabatic engine, by contrast with F , which measures the energy extracted from an isothermal engine.

physical free energy
extracted in isothermal
expansion

7. More generally, the phrase “free energy” means the energy that can be extracted in a process that occurs in contact with some sort of environment. The nature of the free energy depends on the nature of the contact. We will meet chemical free energy in Sec. 5.5, and the free energy of a body on which a steady force is acting in Sec. 11.6.1.

5.4.2 Ideal Gas with Internal Degrees of Freedom

As an example of the canonical distribution, we explore the influence of internal molecular degrees of freedom on the properties of a nonrelativistic, ideal gas.⁸ This example is complementary to the van der Waals gas that we analyzed in Sec. 5.3.2 using the grand canonical distribution. There we assumed no internal degrees of freedom, but we allowed each pair of particles to interact via an interaction potential $u(r)$ that depended on the particles' separation r . Here, because the gas is ideal, there are no interactions, but we allow for internal degrees of freedom—rotational, vibrational, and electron excitations.

(We have previously studied internal degrees of freedom in Sec. 4.4.4, where we proved the equipartition theorem for those whose generalized coordinates and/or momenta are quadratic in the hamiltonian and are classically excited, such as the vibrations and rotations of a diatomic molecule. Here we allow the internal degrees of freedom to have any form whatsoever and to be arbitrarily excited or nonexcited.)

Our gas is confined to a fixed volume V , it has a fixed number of molecules N , it is in contact with a heat bath with temperature T , and its equilibrium distribution is therefore canonical, $\rho_n = e^{(F-E_n)/(k_B T)}$. The quantum states $|n\rangle$ available to the gas can be characterized by the locations $\{\mathbf{x}_i, \mathbf{p}_i\}$ in phase space of each of the molecules $i = 1, \dots, N$, and by the state $|K_i\rangle$ of each molecule's internal degrees of freedom. Correspondingly, the partition function and physical free energy are given by [Eq. (5.31)]

$$z = e^{-F/(k_B T)} = \frac{g_s^N}{N!} \int \frac{d^{3N}x d^{3N}p}{h^{3N}} \sum_{K_1, K_2, \dots, K_N} \exp \left[- \sum_{i=1}^N \left(\frac{\mathbf{p}_i^2}{2mk_B T} + \frac{E_{K_i}}{k_B T} \right) \right]. \quad (5.36a)$$

It is instructive to compare this with Eq. (5.23a) for the grand partition function of the van der Waals gas. In Eq. (5.36a) there is no interaction energy u_{ij} between molecules, no sum over N , and no $e^{\mu N/(k_B T)}$ (because N is fixed and there is no particle bath). However, we now have sums over the internal states K_i of each of the molecules and a factor g_s in the multiplicity to allow for the molecules' g_s different spin states [cf. Eq. (4.8c)].

Because there are no interactions between molecules, the partition function can be split up into products of independent contributions from each of the molecules. Because there are no interactions between a molecule's internal and translational degrees of freedom, the partition function can be split into a product of translational and internal terms; and because the molecules are all identical, their contributions are all identical, leading to

$$z = e^{-F/(k_B T)} = \frac{1}{N!} \left[g_s \int \frac{d^3x d^3p}{h^3} e^{-\mathbf{p}^2/(k_B T)} \right]^N \left[\sum_K e^{-E_K/(k_B T)} \right]^N. \quad (5.36b)$$

8. See footnote 5 of this chapter on p. 226 for the meaning of "ideal gas."

The $\int d^3x d^3p h^{-3} e^{-\mathbf{p}^2/(k_B T)}$ integral is the same as we encountered in the grand canonical analysis; it gives V/λ^3 , where $\lambda = h/(2\pi m k_B T)^{1/2}$ [cf. Eq. (1) in Box 5.3]. The sum over internal states gives a contribution that is some function of temperature:

$$f(T) \equiv \sum_K e^{-E_K/(k_B T)}. \quad (5.37)$$

contribution of internal states to physical free energy of an ideal gas

Correspondingly [using Stirling's approximation, $N! \simeq (N/e)^N$, to the accuracy needed here], the physical free energy becomes

$$F(N, V, T) = Nk_B T \ln \left[\frac{N}{e} \frac{h^3/g_s}{(2\pi m k_B T)^{3/2} V} \right] - Nk_B T \ln[f(T)]. \quad (5.38)$$

Note that because the molecules' translational and internal degrees of freedom are decoupled, their contributions to the free energy are additive. We could have computed them separately and then simply added their free energies.

Because the contribution of the internal degrees of freedom depends only on temperature and not on volume, the ideal gas's pressure

$$P = -(\partial F/\partial V)_{N,T} = (N/V)k_B T \quad (5.39)$$

is unaffected by the internal degrees of freedom. By contrast, the entropy and the total energy in the box do have internal contributions, which depend on temperature but not on the gas's volume and thence not on its density N/V :

$$S = -(\partial F/\partial T)_{N,V} = S_{\text{translational}} + Nk_B (\ln f + d \ln f/d \ln T), \quad (5.40)$$

where the entropy $S_{\text{translational}}$ can straightforwardly be shown to be equivalent to the Sackur-Tetrode formula (4.42) and

$$\bar{E} = F + TS = Nk_B T \left(\frac{3}{2} + \frac{d \ln f}{d \ln T} \right). \quad (5.41)$$

For degrees of freedom that are classical and quadratic, the internal contribution $Nk_B T d \ln f/d \ln T$ gives $\frac{1}{2}k_B T$ for each quadratic term in the hamiltonian, in accord with the equipartition theorem (Sec. 4.4.4).

If there is more than one particle species present (e.g., electrons and protons at high temperatures, so hydrogen is ionized), then the contributions of the species to F , P , S , and E simply add, just as the contributions of internal and translational degrees of freedom added in Eq. (5.38).

Exercise 5.4 Example and Derivation: Adiabatic Index for Ideal Gas

EXERCISES

In Part V, when studying fluid dynamics, we shall encounter an *adiabatic index*

$$\Gamma \equiv - \left(\frac{\partial \ln P}{\partial \ln V} \right)_S \quad (5.42)$$

[Eq. (13.2)] that describes how the pressure P of a fluid changes when it is compressed adiabatically (i.e., compressed at fixed entropy, with no heat being added or removed).

Derive an expression for Γ for an ideal gas that may have internal degrees of freedom (e.g., Earth's atmosphere). More specifically, do the following.

- (a) Consider a fluid element (a small sample of the fluid) that contains N molecules. These molecules can be of various species; all species contribute equally to the ideal gas's pressure $P = (N/V)k_B T$ and contribute additively to its energy. Define the fluid element's specific heat at fixed volume to be the amount of heat $T dS$ that must be inserted to raise its temperature by an amount dT while the volume V is held fixed:

$$C_V \equiv T(\partial S/\partial T)_{V,N} = (\partial E/\partial T)_{V,N}. \quad (5.43)$$

Deduce the second equality from the first law of thermodynamics. Show that in an adiabatic expansion the temperature T drops at a rate given by $C_V dT = -P dV$. [Hint: Use the first law of thermodynamics and the fact that for an ideal gas the energy of a fluid element depends only on its temperature and not on its volume (or density); Eq. (5.41).]

- (b) Combine the temperature change $dT = (-P/C_V)dV$ for an adiabatic expansion with the equation of state $PV = Nk_B T$ to obtain $\Gamma = (C_V + Nk_B)/C_V$.
- (c) To interpret the numerator $C_V + Nk_B$, imagine adding heat to a fluid element while holding its pressure fixed (which requires a simultaneous volume change). Show that in this case the ratio of heat added to temperature change is

$$C_P \equiv T(\partial S/\partial T)_{P,N} = C_V + Nk_B. \quad (5.44)$$

Combining with part (b), conclude that the adiabatic index for an ideal gas is given by

$$\Gamma = \gamma \equiv C_P/C_V, \quad (5.45)$$

a standard result in elementary thermodynamics.

Exercise 5.5 Example: The Enthalpy Representation of Thermodynamics T2

- (a) Enthalpy H is a macroscopic thermodynamic variable defined by

$$\boxed{H \equiv \mathcal{E} + PV.} \quad (5.46)$$

Show that this definition can be regarded as a Legendre transformation that converts from the energy representation of thermodynamics with $\mathcal{E}(V, S, N)$ as the fundamental potential, to an *enthalpy representation* with $H(P, S, N)$ as the fundamental potential. More specifically, show that the first law, reexpressed in terms of H , takes the form

$$\boxed{dH = VdP + TdS + \tilde{\mu}dN;} \quad (5.47)$$

and then explain why this first law dictates that $H(P, S, N)$ be taken as the fundamental potential.

- (b) For a nonrelativistic system, it is conventional to remove the particle rest masses from the enthalpy just as one does from the energy, but by contrast with energy, we do not change notation for the enthalpy:

$$H_{\text{nonrelativistic}} \equiv H_{\text{relativistic}} - Nm = E + PV. \quad (5.48)$$

What is the form of the first law (5.47) for the nonrelativistic H ?

- (c) There is an equilibrium statistical mechanics ensemble associated with the enthalpy representation. Show that each system of this ensemble (fluctuationally) exchanges volume and energy with a surrounding *pressure bath* but does not exchange heat or particles, so the exchanged energy is solely that associated with the exchanged volume, $d\mathcal{E} = -PdV$, and the enthalpy H does not fluctuate. Note that P is the common pressure of the bath and the system.
- (d) Show that this ensemble's distribution function is $\rho = e^{-S/k_B} = \text{constant}$ for those states in phase space that have a specified number of particles N and a specified enthalpy H . Why do we not need to allow for a small range δH of H , by analogy with the small range \mathcal{E} for the microcanonical ensemble (Sec. 4.5 and Ex. 4.7)?
- (e) What equations of state can be read off from the enthalpy first law? What are the Maxwell relations between these equations of state?
- (f) What is the Euler equation for H in terms of a sum of products of extensive and intensive variables?
- (g) Show that the system's enthalpy is equal to its total (relativistic) inertial mass (multiplied by the speed of light squared); cf. Exs. 2.26 and 2.27.
- (h) As another interpretation of the enthalpy, think of the system as enclosed in an impermeable box of volume V . Inject into the box a "sample" of additional material of the same sort as is already there. (It may be helpful to think of the material as a gas.) The sample is to be put into the same thermodynamic state (i.e., macrostate) as that of the box's material (i.e., it is to be given the same values of temperature T , pressure P , and chemical potential $\tilde{\mu}$). Thus, the sample's material is indistinguishable in its thermodynamic properties from the material already in the box, except that its extensive variables (denoted by Δ) are far smaller: $\Delta V/V = \Delta\mathcal{E}/\mathcal{E} = \Delta S/S \ll 1$. Perform the injection by opening up a hole in one of the box's walls, pushing aside the box's material to make a little cavity of volume ΔV equal to that of the sample, inserting the sample into the cavity, and then closing the hole in the wall. The box now has the same volume V as before, but its energy has changed. Show that the energy change (i.e., the energy required to create the sample and perform the injection) is equal to the enthalpy ΔH of the sample. Thus, *enthalpy has the physical interpretation of energy of injection at fixed volume V* . Equivalently, if a sample of material is ejected from the system, the total energy that will come

out (including the work done on the sample by the system during the ejection) is the sample's enthalpy ΔH . From this viewpoint, enthalpy is the system's free energy.

5.5 Gibbs Ensemble and Representation of Thermodynamics; Phase Transitions and Chemical Reactions

Next consider systems in which the temperature T and pressure P are both being controlled by an external environment (bath) and thus are treated as independent variables in the fundamental potential. This is the situation in most laboratory experiments and geophysical situations and is common in elementary chemistry but not chemical engineering.

In this case each of the systems has a fixed number of particles N_I for the various independent species I , and it can exchange heat and volume with its surroundings. (We explicitly allow for more than one particle species, because a major application of the Gibbs representation will be to chemical reactions.) There might be a membrane separating each system from its bath—a membrane impermeable to particles but through which heat can pass, and with negligible surface tension so the system and the bath can buffet each other freely, causing fluctuations in the system's volume. For example, this is the case for a so-called “constant-pressure balloon” of the type used to lift scientific payloads into the upper atmosphere. Usually, however, there is no membrane between system and bath. Instead, gravity might hold the system together because it has higher density than the bath (e.g., a liquid in a container); or solid-state forces might hold the system together (e.g., a crystal); or we might just introduce a conceptual, imaginary boundary around the system of interest—one that comoves with some set of particles.

The equilibrium ensemble for this type of system is that of Gibbs, with distribution function

$$\rho_n = e^{G/(k_B T)} e^{-(\mathcal{E}_n + P V_n)/(k_B T)} \quad (5.49)$$

[Eq. (4.25b), to which we have added the normalization constant $e^{G/(k_B T)}$]. As for the canonical and grand canonical distributions, the quantity G in the normalization constant becomes the fundamental potential for the Gibbs representation of thermodynamics. It is called the *Gibbs potential*, and also, sometimes, the *Gibbs free energy* or *chemical free energy* (see Ex. 5.6). It is a function of the systems' fixed numbers of particles N_I and of the bath's temperature T and pressure P , which appear in the Gibbs distribution function: $G = G(N_I, T, P)$.

The Gibbs potential can be evaluated by a sum over quantum states that follows from $\sum_n \rho_n = 1$:

$$e^{-G/(k_B T)} = \sum_n e^{-(\mathcal{E}_n + P V_n)/(k_B T)}. \quad (5.50)$$

Gibbs potential as sum over states

See Ex. 5.7 for an example. This sum has proved to be less useful than the canonical and grand canonical sums, so in most statistical mechanics textbooks there is little or no discussion of the Gibbs ensemble. By contrast, the Gibbs representation of thermodynamics is extremely useful, as we shall see, so textbooks pay a lot of attention to it.

We can deduce the equations of the Gibbs representation by the same method as we used for the canonical and grand canonical representations. We begin by writing down a Legendre transformation that takes us from the energy representation to the Gibbs representation. As for the canonical and grand canonical cases, that Legendre transformation can be inferred from the equilibrium ensemble's entropy, $S = -k_B \overline{\ln \rho} = -(G - \overline{\mathcal{E}} - P\overline{V})/T$ [cf. Eq. (5.49) for ρ]. Solving for G , we get

$$G = \overline{\mathcal{E}} + P\overline{V} - TS. \quad (5.51)$$

Legendre transformation

Once we are in the thermodynamic domain (as opposed to statistical mechanics), we can abandon the distinction between expectation values of quantities and fixed values; that is, we can remove the bars and write this Legendre transformation as $G = \mathcal{E} + PV - TS$.

Differentiating this Legendre transformation and combining with the energy representation's first law (5.8), we obtain the first law in the Gibbs representation:

$$dG = VdP - SdT + \sum_I \tilde{\mu}_I dN_I. \quad (5.52)$$

first law in Gibbs representation

From this first law we read out the independent variables of the Gibbs representation, namely $\{P, T, N_I\}$ (in case we have forgotten them!), and the values of its generalized forces [equations of state; e.g., $V = (\partial G/\partial P)_{T, N_I}$]. From the equality of mixed partial derivatives, we read off the Maxwell relations. By imagining building up a large system from many tiny subsystems (all with the same, fixed, intensive variables P, T , and $\tilde{\mu}_I$) and applying the first law (5.52) to this buildup, we obtain the Euler relation

$$G = \sum_I \tilde{\mu}_I N_I. \quad (5.53)$$

Euler relation for Gibbs potential

This Euler relation will be very useful in Sec. 5.5.3, when we discuss chemical reactions.

As with previous representations of thermodynamics, to obtain the Newtonian version of all of this section's equations, we simply remove the particle rest masses from $\tilde{\mu}_I$ (which then becomes μ_I), from \mathcal{E} (which then becomes E), and from G (which does not change notation).

Exercise 5.6 *Problem: Gibbs Potential Interpreted as Chemical Free Energy*

In Sec. 5.4.1, we explained the experimental meaning of the free energy F for a system

EXERCISES

in contact with a heat bath so its temperature is held constant, and in Ex. 5.5h we did the same for contact with a pressure bath. By combining these, give an experimental interpretation of the Gibbs potential G as the free energy for a system in contact with a heat and pressure bath—the “chemical free energy.”

Exercise 5.7 *Problem and Practice: Ideal Gas Equation of State from Gibbs Ensemble* For a nonrelativistic, classical, ideal gas (no interactions between particles), evaluate the statistical sum (5.50) to obtain $G(P, T, N)$, and from it deduce the standard formula for the ideal-gas equation of state $P\bar{V} = Nk_B T$.

5.5.1 5.5.1 Out-of-Equilibrium Ensembles and Their Fundamental Thermodynamic Potentials and Minimum Principles

Despite its lack of usefulness in practical computations of the Gibbs potential G , the Gibbs ensemble plays an important conceptual role in a *minimum principle for G* , which we now derive.

Consider an ensemble of systems, each of which is immersed in an identical heat and volume bath, and assume that the ensemble begins with some arbitrary distribution function ρ_n , one that is not in equilibrium with the baths. As time passes, each system will interact with its bath and will evolve in response to that interaction. Correspondingly, the ensemble’s distribution function ρ will evolve. At any moment of time the ensemble’s systems will have some mean (ensemble-averaged) energy $\bar{\mathcal{E}} \equiv \sum_n \rho_n \mathcal{E}_n$ and volume $\bar{V} \equiv \sum_n \rho_n V_n$, and the ensemble will have some entropy $S = -k_B \sum_n \rho_n \ln \rho_n$. From these quantities (which are well defined even though the ensemble may be very far from statistical equilibrium), we can compute a Gibbs potential G for the ensemble. This out-of-equilibrium G is defined by the analog of the equilibrium definition (5.51),

out-of-equilibrium Gibbs potential

$$G \equiv \bar{\mathcal{E}} + P_b \bar{V} - T_b S, \quad (5.54)$$

where P_b and T_b are the pressure and temperature of the identical baths with which the ensemble’s systems are interacting.⁹ As the evolution proceeds, the total entropy of the baths’ ensemble plus the systems’ ensemble will continually increase, until equilibrium is reached. Suppose that during a short stretch of evolution the systems’ mean energy changes by $\Delta\bar{\mathcal{E}}$, their mean volume changes by $\Delta\bar{V}$, and the entropy of the ensemble

9. Notice that, because the number N of particles in the system is fixed (as is the bath temperature T_b), the evolving Gibbs potential is proportional to

$$\frac{G}{Nk_B T_b} = \frac{\bar{\mathcal{E}}}{Nk_B T_b} + \frac{P_b \bar{V}}{Nk_B T_b} - \frac{S}{Nk_B}.$$

This quantity is dimensionless and generally of order unity. Note that the last term is the dimensionless entropy per particle [Eq. (4.44) and associated discussion].

changes by ΔS . Then, by conservation of energy and volume, the baths' mean energy and volume must change by

$$\Delta \bar{\mathcal{E}}_b = -\Delta \bar{\mathcal{E}}, \quad \Delta \bar{V}_b = -\Delta \bar{V}. \quad (5.55a)$$

Because the baths (by contrast with the systems) are in statistical equilibrium, we can apply to them the first law of thermodynamics for equilibrated systems:

$$\Delta \bar{\mathcal{E}}_b = -P_b \Delta \bar{V}_b + T_b \Delta S_b + \sum_I \tilde{\mu}_{Ib} \Delta N_{Ib}. \quad (5.55b)$$

Since the N_{Ib} are not changing (the systems cannot exchange particles with their baths) and since the changes of bath energy and volume are given by Eqs. (5.55a), Eq. (5.55b) tells us that the baths' entropy changes by

$$\Delta S_b = \frac{-\Delta \bar{\mathcal{E}} - P_b \Delta \bar{V}}{T_b}. \quad (5.55c)$$

Correspondingly, the sum of the baths' entropy and the systems' entropy changes by the following amount, which cannot be negative:

$$\Delta S_b + \Delta S = \frac{-\Delta \bar{\mathcal{E}} - P_b \Delta \bar{V} + T_b \Delta S}{T_b} \geq 0. \quad (5.55d)$$

Because the baths' pressure P_b and temperature T_b are not changing (the systems are so tiny compared to the baths that the energy and volume they exchange with the baths cannot have any significant effect on the baths' intensive variables), the numerator of expression (5.55d) is equal to the evolutionary change in the ensemble's out-of-equilibrium Gibbs potential (5.54):

$$\Delta S_b + \Delta S = \frac{-\Delta G}{T_b} \geq 0. \quad (5.56)$$

Thus, the second law of thermodynamics for an ensemble of arbitrary systems in contact with identical heat and volume baths is equivalent to the law that *the systems' out-of-equilibrium Gibbs potential can never increase*. As the evolution proceeds and the entropy of baths plus systems continually increases, the Gibbs potential G will be driven smaller and smaller, until ultimately, when statistical equilibrium with the baths is reached, G will stop at its final, minimum value.

The ergodic hypothesis implies that this minimum principle applies not only to an ensemble of systems but also to a single, individual system when that system is averaged over times long compared to its internal timescales τ_{int} (but times that might be short compared to the timescale for interaction with the heat and volume bath). The system's time-averaged energy $\bar{\mathcal{E}}$ and volume \bar{V} , and its entropy S (as computed, e.g., by examining the temporal wandering of its state on timescales $\sim \tau_{\text{int}}$), combine with the bath's temperature T_b and pressure P_b to give an out-of-equilibrium

minimum principle for
Gibbs potential

Gibbs potential $G = \bar{\mathcal{E}} + P_b \bar{V} - T_b S$. This G evolves on times long compared to the averaging time used to define it, and that evolution must be one of continually decreasing G . Ultimately, when the system reaches equilibrium with the bath, G achieves its minimum value.

At this point we might ask about the other thermodynamic potentials. Not surprisingly, associated with each of them is an extremum principle analogous to “minimum G ”:

1. For the energy potential $\mathcal{E}(V, S, N)$ (Sec. 5.2), one focuses on closed systems and switches to $S(V, \mathcal{E}, N)$. The extremum principle is then the standard second law of thermodynamics: an ensemble of closed systems of fixed \mathcal{E} , V , and N always must evolve toward increasing entropy S ; when it ultimately reaches equilibrium, the ensemble will be microcanonical and will have maximum entropy.
2. For the physical free energy (Helmholtz free energy) $F(T_b, V, N)$ (Sec. 5.4), one can derive, in a manner perfectly analogous to the Gibbs derivation, the following minimum principle. *For an ensemble of systems interacting with a heat bath, the out-of-equilibrium physical free energy $F = \bar{\mathcal{E}} - T_b S$ will always decrease, ultimately reaching a minimum when the ensemble reaches its final, equilibrium, canonical distribution.*
3. The grand potential $\Omega(V, T_b, \tilde{\mu}_b)$ (Sec. 5.3) satisfies the analogous minimum principle. *For an ensemble of systems interacting with a heat and particle bath, the out-of-equilibrium grand potential $\Omega = \bar{\mathcal{E}} - \tilde{\mu}_b \bar{N} - T_b S$ will always decrease, ultimately reaching a minimum when the ensemble reaches its final, equilibrium, grand canonical distribution.*
4. For the enthalpy $H(P_b, S, N)$ (Ex. 5.5) the analogous extremum principle is a bit more tricky (see Ex. 5.13). *For an ensemble of systems interacting with a volume bath, as for an ensemble of closed systems, the bath's entropy remains constant, so the systems' entropy S will always increase, ultimately reaching a maximum when the ensemble reaches its final equilibrium distribution.*

Table 5.2 summarizes these extremum principles. The first column lists the quantities that a system exchanges with its bath. The second column shows the out-of-equilibrium fundamental potential for the system, which depends on the bath variables and the system's out-of-equilibrium distribution function ρ (shown explicitly) and also on whatever quantities are fixed for the system (e.g., its volume V and/or number of particles N ; not shown explicitly). The third column expresses the total entropy of system plus bath in terms of the bath's out-of-equilibrium fundamental potential. The fourth column expresses the second law of thermodynamics for bath plus system in terms of the fundamental potential. We shall discuss the fifth column in Sec. 5.6, when we study fluctuations away from equilibrium.

TABLE 5.2: Descriptions of out-of-equilibrium ensembles with distribution function ρ

Quantities exchanged with bath	Fundamental potential	Total entropy $S + S_b$	Second law	Fluctuational probability
None	$S(\rho)$ with \mathcal{E} constant	$S + \text{const}$	$dS \geq 0$	$\propto e^{S/k_B}$
Volume and energy with $d\mathcal{E} = -P_b dV$	$S(\rho)$ with $H = \mathcal{E} + P_b V$ constant	$S + \text{const}$ (see Ex. 5.13)	$dS \geq 0$	$\propto e^{S/k_B}$
Heat	$F(T_b; \rho) = \bar{\mathcal{E}} - T_b S$	$-F/T_b + \text{const}$	$dF \leq 0$	$\propto e^{-F/(k_B T_b)}$
Heat and volume	$G(T_b, P_b; \rho) = \bar{\mathcal{E}} + P_b \bar{V} - T_b S$	$-G/T_b + \text{const}$	$dG \leq 0$	$\propto e^{-G/(k_B T_b)}$
Heat and particle	$\Omega(T_b, \tilde{\mu}_b, \rho) = \bar{\mathcal{E}} - \tilde{\mu}_b \bar{N} - T_b S$	$-\Omega/T_b + \text{const}$	$d\Omega \leq 0$	$\propto e^{-\Omega/(k_B T_b)}$

Notes: From the distribution function ρ , one computes $S = -k_B \sum_n \rho_n \ln \rho_n$, $\bar{\mathcal{E}} = \sum_n \rho_n \mathcal{E}_n$, $\bar{V} = \sum_n \rho_n V_n$, and $\bar{N}_n = \sum_n \rho_n N_n$. The systems of each ensemble are in contact with the bath shown in column one, and T_b , P_b , and $\tilde{\mu}_b$ are the bath's temperature, pressure, and chemical potential, respectively. For ensembles in statistical equilibrium, see Table 5.1. As in that table, the nonrelativistic formulas are the same as above but with the rest masses of particles removed from the chemical potentials ($\tilde{\mu} \rightarrow \mu$) and from all fundamental potentials except Ω ($\mathcal{E} \rightarrow E$, but no change of notation for H , F , and G).

5.5.2 Phase Transitions

The minimum principle for the Gibbs potential G is a powerful tool in understanding *phase transitions*. “Phase” here refers to a specific pattern into which the atoms or molecules of a substance organize themselves. The substance H_2O has three familiar phases: water vapor, liquid water, and solid ice. Over one range of pressure P and temperature T , the H_2O molecules prefer to organize themselves into the vapor phase; over another, the liquid phase; and over another, the solid ice phase. It is the Gibbs potential that governs their preferences.

To understand this role of the Gibbs potential, consider a cup of water in a refrigerator (and because the water molecules are highly nonrelativistic, adopt the nonrelativistic viewpoint with the molecules' rest masses removed from their energy E , chemical potential $\mu_{\text{H}_2\text{O}}$, and Gibbs potential). The refrigerator's air forms a heat and volume bath for the water in the cup (the system). There is no membrane between the air and the water, but none is needed. Gravity, together with the density difference between water and air, serves to keep the water molecules in the cup and the air above the water's surface, for all relevant purposes.

Allow the water to reach thermal and pressure equilibrium with the refrigerator's air, then turn down the refrigerator's temperature slightly and wait for the water to reach equilibrium again, and then repeat the process. Suppose that you are clever enough to compute from first principles the Gibbs potential G for the H_2O at each step of the cooling, using two alternative assumptions: that the H_2O molecules organize themselves into the liquid water phase, and that they organize themselves into the solid ice phase. Your calculations will produce curves for G as a function of the common

5.5.2

phase transitions

FIGURE 5.3 The Gibbs potential $G(T, P, N)$ for H_2O as a function of temperature T , with fixed P and N , near the freezing point $T = T_c = 273$ K. The solid curves correspond to the actual path traversed by the H_2O if the phase transition is allowed to proceed. The dotted curves correspond to superheated solid ice and supercooled liquid water that are unstable against the phase transition because their Gibbs potentials are higher than those of the other phase. Note that G tends to decrease with increasing temperature. This is caused by the $-TS$ term in $G = E + PV - TS$.

bath and H_2O temperature $T_b = T$ at fixed (atmospheric) pressure, with the shapes shown in Fig. 5.3. At temperatures $T > T_c = 273$ K the liquid phase has the lower Gibbs potential G , and at $T < T_c$ the solid phase has the lower G . Correspondingly, when the cup's temperature sinks slightly below 273 K, the H_2O molecules have a statistical preference for reorganizing themselves into the solid phase. The water freezes, forming ice.

It is a familiar fact that ice floats on water (i.e., ice is less dense than water), even when they are both precisely at the phase-transition temperature of 273 K. Correspondingly, when our sample of water freezes, its volume increases discontinuously by some amount ΔV ; that is, when viewed as a function of the Gibbs potential G , the volume V of the statistically preferred phase is discontinuous at the phase-transition point (see Fig. 5.4a). It is also a familiar fact that when water freezes, it releases heat into its surroundings. This is why the freezing requires a moderately long time: the solidifying water can remain at or below its freezing point and continue to solidify only if the surroundings carry away the released heat, and the surroundings typically cannot carry it away quickly. It takes time to conduct heat through the ice and convect it through the water. The heat ΔQ released during the freezing (the *latent heat*) and the volume change ΔV are related to each other in a simple way (see Ex. 5.8, which focuses on the latent heat per unit mass Δq and the density change $\Delta \rho$ instead of on ΔQ and ΔV).

first-order phase transitions

Phase transitions like this one, with finite volume jumps $\Delta V \neq 0$ and finite latent heat $\Delta Q \neq 0$, are called *first-order*. The van der Waals gas (Sec. 5.3.2) provides an analytic model for another first-order phase transition: that from water vapor to liquid water; but we delay studying this model (Sec. 5.7) until we have learned about fluctuations of systems in statistical equilibrium (Sec. 5.6), which the van der Waals gas also illustrates.

FIGURE 5.4 The changes of volume (plotted rightward) with increasing Gibbs function (plotted upward) at fixed P and N for (a) a first-order phase transition and (b) a second-order phase transition. The critical value of the Gibbs potential at which the transition occurs is G_c .

Less familiar, but also important, are *second-order phase transitions*. In such transitions, the volumes V of the two phases are the same at the transition point, but their rates of change dV/dG are different (and this is so whether one holds P fixed as G decreases, holds T fixed, or holds some combination of P and T fixed); see Fig. 5.4b.

Crystals provide examples of both first-order and second-order phase transitions. A crystal can be characterized as a 3-dimensional repetition of a unit cell, in which ions are distributed in some fixed way. For example, Fig. 5.5a shows the unit cell for a BaTiO_3 (barium titanate) crystal at relatively high temperatures. This unit cell has a cubic symmetry. The full crystal can be regarded as made up of such cells stacked side by side and one on another. A first-order phase transition occurs when, with decreasing temperature, the Gibbs potential G of some other ionic arrangement,

second-order phase transitions

FIGURE 5.5 (a) The unit cell for a BaTiO_3 crystal at relatively high temperatures. (b) The displacements of the titanium and oxygen ions relative to the corners of the unit cell that occur in this crystal with falling temperature when it undergoes its second-order phase transition. The magnitudes of the displacements are proportional to the amount $T_c - T$ by which the temperature T drops below the critical temperature T_c , for small $T_c - T$.

with a distinctly different unit cell, drops below the G of the original arrangement. Then the crystal can spontaneously rearrange itself, converting from the old unit cell to the new one with some accompanying release of heat and some discontinuous change in volume.

BaTiO_3 does not behave in this way. Rather, as the temperature falls a bit below a critical value, the unit cell begins to elongate parallel to one of its edges (i.e., the cell's atoms get displaced as indicated in Fig. 5.5b). If the temperature is only a tiny bit below critical, they are displaced by only a tiny amount. When the temperature falls further, their displacements increase. If the temperature is raised back up above critical, the ions return to the standard, rigidly fixed positions shown in Fig. 5.5a. The result is a discontinuity, at the critical temperature, in the rate of change of volume dV/dG (Fig. 5.4b), but there is no discontinuous jump of volume and no latent heat.

This BaTiO_3 example illustrates a frequent feature of phase transitions: when the transition occurs (i.e., when the atoms start to move), the unit cell's cubic symmetry gets broken. The crystal switches discontinuously to a lower type of symmetry, a tetragonal one in this case. Such spontaneous symmetry breaking is a common occurrence in phase transitions not only in condensed matter physics but also in fundamental particle physics.

Bose-Einstein condensation of a bosonic atomic gas in a magnetic trap (Sec. 4.9) is another example of a phase transition. As we saw in Ex. 4.13, for Bose-Einstein condensation the specific heat of the atoms changes discontinuously (in the limit of an arbitrarily large number of atoms) at the critical temperature; this, or often a mild divergence of the specific heat, is characteristic of second-order phase transitions. Ferromagnetism also exhibits a second-order phase transition, which we explore in Secs. 5.8.3 and 5.8.4 using two powerful computational techniques: the renormalization group and Monte Carlo methods.

EXERCISES

Exercise 5.8 *Example: The Clausius-Clapeyron Equation for Two Phases in Equilibrium with Each Other*

- (a) Consider H_2O in contact with a heat and volume bath with temperature T and pressure P . For certain values of T and P the H_2O will be liquid water; for others, ice; for others, water vapor—and for certain values it may be a two- or three-phase mixture of water, ice, and/or vapor. Show, using the Gibbs potential and its Euler equation, that, if two phases a and b are present and in equilibrium with each other, then their chemical potentials must be equal: $\mu_a = \mu_b$. Explain why, for any phase a , μ_a is a unique function of T and P . Explain why the condition $\mu_a = \mu_b$ for two phases to be present implies that the two-phase regions of the T - P plane are lines and the three-phase regions are points (see Fig. 5.6). The three-phase region is called the “triple point.” The volume V of the two- or three-phase system will vary, depending on how much of each phase is present, since the density of each phase (at fixed T and P) is different.

FIGURE 5.6 Phase diagram for H_2O . The temperature of the triple point (where the three phases meet) is 273.16 K and has been used to define the absolute scale of temperature.

- (b) Show that the slope of the ice-water interface curve in Fig. 5.6 (the “melting curve”) is given by the Clausius-Clapeyron equation

$$\frac{dP_{\text{melt}}}{dT} = \frac{\Delta q_{\text{melt}}}{T} \left(\frac{\rho_{\text{ice}} \rho_{\text{water}}}{\rho_{\text{ice}} - \rho_{\text{water}}} \right), \quad (5.57a)$$

where ρ is density (mass per unit volume), and Δq_{melt} is the latent heat per unit mass for melting (or freezing)—the amount of heat required to melt a unit mass of ice, or the amount released when a unit mass of water freezes. Notice that, because ice is less dense than water, the slope of the melting curve is negative. [Hint: Compute dP/dT by differentiating $\mu_a = \mu_b$, and then use the thermodynamic properties of $G_a = \mu_a N_a$ and $G_b = \mu_b N_b$.]

- (c) Suppose that a small amount of water is put into a closed container of much larger volume than the water. Initially there is vacuum above the water’s surface, but as time passes some of the liquid water evaporates to establish vapor-water equilibrium. The vapor pressure will vary with temperature in accord with the Clausius-Clapeyron equation

$$\frac{dP_{\text{vapor}}}{dT} = \frac{\Delta q_{\text{evaporate}}}{T} \left(\frac{\rho_{\text{water}} \rho_{\text{vapor}}}{\rho_{\text{water}} - \rho_{\text{vapor}}} \right). \quad (5.57b)$$

Now suppose that a foreign gas (not water vapor) is slowly injected into the container. Assume that this gas does not dissolve in the liquid water. Show that, as the pressure P_{gas} of the foreign gas gradually increases, it does not squeeze water vapor into the water, but rather it induces more water to vaporize:

$$\left(\frac{dP_{\text{vapor}}}{dP_{\text{total}}} \right)_{T \text{ fixed}} = \frac{\rho_{\text{vapor}}}{\rho_{\text{water}}} > 0, \quad (5.57c)$$

where $P_{\text{total}} = P_{\text{vapor}} + P_{\text{gas}}$.

chemical reactions

A second important application of the Gibbs potential is to the study of chemical reactions. Here we generalize the term “chemical reactions,” to include any change in the constituent particles of the material being studied, including for example the joining of atoms to make molecules, the liberation of electrons from atoms in an ionization process, the joining of two atomic nuclei to make a third kind of nucleus, and the decay of a free neutron to produce an electron and a proton. In other words, the “chemical” of chemical reactions encompasses the reactions studied by nuclear physicists and elementary-particle physicists as well as those studied by chemists. The Gibbs representation is the appropriate one for discussing chemical reactions, because such reactions generally occur in an environment (“bath”) of fixed temperature and pressure, with energy and volume being supplied and removed as needed.

As a specific example, in Earth’s atmosphere, consider the breakup of two molecules of water vapor to form two hydrogen molecules and one oxygen molecule: $2\text{H}_2\text{O} \rightarrow 2\text{H}_2 + \text{O}_2$. The inverse reaction $2\text{H}_2 + \text{O}_2 \rightarrow 2\text{H}_2\text{O}$ also occurs in the atmosphere,¹⁰ and it is conventional to write down the two reactions simultaneously in the form

A chosen (but arbitrary) portion of the atmosphere, with idealized walls to keep all its molecules in, can be regarded as a system. (The walls are unimportant in practice, but are pedagogically useful.) The kinetic motions of this system’s molecules reach and maintain statistical equilibrium, at fixed temperature T and pressure P , far more rapidly than chemical reactions can occur. Accordingly, if we view this system on timescales short compared to that τ_{react} for the reactions (5.58) but long compared to the kinetic relaxation time, then we can regard the system as in *partial statistical equilibrium*, with fixed numbers of water molecules $N_{\text{H}_2\text{O}}$, hydrogen molecules N_{H_2} , and oxygen molecules N_{O_2} , and with a Gibbs potential whose value is given by the Euler relation (5.53):

$$G = \tilde{\mu}_{\text{H}_2\text{O}} N_{\text{H}_2\text{O}} + \tilde{\mu}_{\text{H}_2} N_{\text{H}_2} + \tilde{\mu}_{\text{O}_2} N_{\text{O}_2}. \quad (5.59)$$

(Here, even though Earth’s atmosphere is highly nonrelativistic, we include rest masses in the chemical potentials and in the Gibbs potential; the reason will become evident at the end of this section.)

When one views the sample over a longer timescale, $\Delta t \sim \tau_{\text{react}}$, one discovers that these molecules are not inviolate; they can change into one another via the reactions (5.58), thereby changing the value of the Gibbs potential (5.59). The changes of G are more readily computed from the Gibbs representation of the first law, $dG =$

10. In the real world these two reactions are made complicated by the need for free-electron intermediaries, whose availability is influenced by external factors, such as ultraviolet radiation. This, however, does not change the issues of principle discussed here.

partial statistical equilibrium

$VdP - SdT + \sum_I \tilde{\mu}_I dN_I$, than from the Euler relation (5.59). Taking account of the constancy of P and T and the fact that the reactions entail transforming two water molecules into two hydrogen molecules and one oxygen molecule (or conversely), so that

$$dN_{\text{H}_2} = -dN_{\text{H}_2\text{O}}, \quad dN_{\text{O}_2} = -\frac{1}{2}dN_{\text{H}_2\text{O}}, \quad (5.60a)$$

the first law says

$$dG = (2\tilde{\mu}_{\text{H}_2\text{O}} - 2\tilde{\mu}_{\text{H}_2} - \tilde{\mu}_{\text{O}_2})\frac{1}{2}dN_{\text{H}_2\text{O}}. \quad (5.60b)$$

The reactions (5.58) proceed in both directions, but statistically there is a preference for one direction over the other. The preferred direction, of course, is the one that reduces the Gibbs potential (i.e., increases the entropy of the molecules and their bath). Thus, if $2\tilde{\mu}_{\text{H}_2\text{O}}$ is larger than $2\tilde{\mu}_{\text{H}_2} + \tilde{\mu}_{\text{O}_2}$, then water molecules preferentially break up to form hydrogen plus oxygen; but if $2\tilde{\mu}_{\text{H}_2\text{O}}$ is less than $2\tilde{\mu}_{\text{H}_2} + \tilde{\mu}_{\text{O}_2}$, then oxygen and hydrogen preferentially combine to form water. As the reactions proceed, the changing N_I values produce changes in the chemical potentials $\tilde{\mu}_I$. [Recall the intimate connection

$$N_I = g_s \frac{(2\pi m_I k_B T)^{3/2}}{h^3} e^{\mu_I/(k_B T)} V \quad (5.61)$$

between $\mu_I = \tilde{\mu}_I - m_I c^2$ and N_I for a gas in the nonrelativistic regime; Eq. (3.39a).] These changes in the N_I and $\tilde{\mu}_I$ values lead ultimately to a macrostate (thermodynamic state) of minimum Gibbs potential G —a state in which the reactions (5.58) can no longer reduce G . In this final state of full statistical equilibrium, the dG of expression (5.60b) must be zero. Correspondingly, the chemical potentials associated with the reactants must balance:

$$2\tilde{\mu}_{\text{H}_2\text{O}} = 2\tilde{\mu}_{\text{H}_2} + \tilde{\mu}_{\text{O}_2}. \quad (5.62)$$

The above analysis shows that the “driving force” for the chemical reactions is the combination of chemical potentials in the dG of Eq. (5.60b). Notice that this combination has coefficients in front of the $\tilde{\mu}_I$ terms that are identical to the coefficients in the reactions (5.58) themselves, and the equilibrium relation (5.62) also has the same coefficients as the reactions (5.60b). It is easy to convince oneself that this is true in general. Consider any chemical reaction. Write the reaction in the form

$$\sum_j v_j^L A_j^L \leftrightarrow \sum_j v_j^R A_j^R. \quad (5.63)$$

Here the superscripts L and R denote the “left” and “right” sides of the reaction, the A_j s are the names of the species of particle or atomic nucleus or atom or molecule involved in the reaction, and the v_j s are the number of such particles (or nuclei or atoms or molecules) involved. Suppose that this reaction is occurring in an environment of fixed temperature and pressure. Then to determine the direction in which the

reaction preferentially goes, examine the chemical-potential sums for the two sides of the reaction,

direction of a chemical reaction governed by chemical-potential sums

$$\sum_j v_j^L \tilde{\mu}_j^L, \quad \sum_j v_j^R \tilde{\mu}_j^R. \quad (5.64)$$

The reaction will proceed from the side with the larger chemical-potential sum to the side with the smaller; and ultimately, the reaction will bring the two sides into equality. That final equality is the state of full statistical equilibrium. Exercises 5.9 and 5.10 illustrate this behavior.

rationale for including rest masses in chemical potentials

When dealing with chemical reactions between extremely nonrelativistic molecules and atoms (e.g., water formation and destruction in Earth's atmosphere), one might wish to omit rest masses from the chemical potentials. If one does so, and if one wishes to preserve the criterion that the reaction goes in the direction of decreasing $dG = (2\mu_{\text{H}_2\text{O}} - 2\mu_{\text{H}_2} - \mu_{\text{O}_2})\frac{1}{2}dN_{\text{H}_2\text{O}}$ [Eq. (5.60b) with tildes removed], then one must choose as the “rest masses” to be subtracted values that do not include chemical binding energies; that is, the rest masses must be defined in such a way that $2m_{\text{H}_2\text{O}} = 2m_{\text{H}_2} + m_{\text{O}_2}$. This delicacy can be avoided by simply using the relativistic chemical potentials. The derivation of the Saha equation (Ex. 5.10) is an example.

EXERCISES

Exercise 5.9 ***Example: Electron-Positron Equilibrium at “Low” Temperatures*

Consider hydrogen gas in statistical equilibrium at a temperature $T \ll m_e c^2 / k_B \simeq 6 \times 10^9$ K. Electrons at the high-energy end of the Boltzmann energy distribution can produce electron-positron pairs by scattering off protons:

(There are many other ways of producing pairs, but in analyzing statistical equilibrium we get all the information we need—a relation among the chemical potentials—by considering just one way.)

- In statistical equilibrium, the reaction (5.65) and its inverse must proceed on average at the same rate. What does this imply about the relative magnitudes of the electron and positron chemical potentials $\tilde{\mu}_-$ and $\tilde{\mu}_+$ (with rest masses included)?
- Although these reactions require an e^- that is relativistic in energy, almost all the electrons and positrons will have kinetic energies of magnitude $E \equiv \mathcal{E} - m_e c^2 \sim k_B T \ll m_e c^2$, and thus they will have $\mathcal{E} \simeq m_e c^2 + \mathbf{p}^2 / (2m_e)$. What are the densities in phase space $\mathcal{N}_\pm = dN_\pm / (d^3x d^3p)$ for the positrons and electrons in terms of \mathbf{p} , $\tilde{\mu}_\pm$, and T ? Explain why for a hydrogen gas we must have $\tilde{\mu}_- > 0$ and $\tilde{\mu}_+ < 0$.
- Assume that the gas is very dilute, so that $\eta \ll 1$ for both electrons and positrons. Then integrate over momenta to obtain the following formula for the number

FIGURE 5.7 The temperature T_p at which electron-positron pairs form in a dilute hydrogen plasma, plotted as a function of density ρ . This is the correct upper limit (upper dashed line in Fig. 3.7) on the region where the plasma can be considered fully nonrelativistic. Above this curve, although T may be $\ll m_e c^2/k_B \simeq 6 \times 10^9$ K, a proliferation of electron-positron pairs radically changes the properties of the plasma.

densities in physical space of electrons and positrons:

$$n_{\pm} = \frac{2}{h^3} (2\pi m_e k_B T)^{3/2} \exp\left(\frac{\tilde{\mu}_{\pm} - m_e c^2}{k_B T}\right). \quad (5.66)$$

In cgs units, what does the dilute-gas assumption $\eta \ll 1$ correspond to in terms of n_{\pm} ? What region of hydrogen mass density ρ and temperature T is the dilute-gas region?

- (d) Let n be the number density of protons. Then by charge neutrality, $n = n_- - n_+$ will also be the number density of “ionization electrons” (i.e., of electrons that have been ionized off of hydrogen). Show that the ratio of positrons (and hence of pairs) to ionization electrons is given by

$$\frac{n_+}{n} = \frac{1}{2y[y + (1 + y^2)^{1/2}]}, \quad (5.67a)$$

where

$$y \equiv \frac{1}{4} n \lambda^3 e^{m_e c^2/(k_B T)}, \quad \text{and} \quad \lambda \equiv \frac{h}{\sqrt{2\pi m_e k_B T}} \quad (5.67b)$$

is the thermal deBroglie wavelength of the electrons. Figure 5.7 shows the temperature T_p at which, according to this formula, $n_+ = n$ (and $y = 0.354$), as a function of mass density $\rho \simeq m_{\text{proton}} n$. This T_p can be thought of as the temperature at which pairs form in a dilute plasma. Somewhat below T_p there are hardly any pairs; somewhat above, the pairs are profuse.

- (e) Note that at low densities pairs form at temperatures $T \sim 10^8$ K $\simeq 0.02 m_e c^2/k_B$. Explain qualitatively in terms of available phase space why the formation temperature is so low.

Exercise 5.10 ***Example: Saha Equation for Ionization Equilibrium*

Consider an optically thick hydrogen gas in statistical equilibrium at temperature T . (“Optically thick” means that photons can travel only a small distance compared to

the size of the system before being absorbed, so they are confined by the hydrogen and kept in statistical equilibrium with it.) Among the reactions that are in statistical equilibrium are $H + \gamma \leftrightarrow e + p$ (ionization and recombination of H, with the H in its ground state) and $e + p \leftrightarrow e + p + \gamma$ (emission and absorption of photons by “bremsstrahlung,” i.e., by the Coulomb-force-induced acceleration of electrons as they fly past protons). Let $\tilde{\mu}_\gamma, \tilde{\mu}_H, \tilde{\mu}_e,$ and $\tilde{\mu}_p$ be the chemical potentials including rest masses; let $m_H, m_e,$ and m_p be the rest masses; denote by I ($\equiv 13.6$ eV) the ionization energy of H, so that $m_H c^2 = m_e c^2 + m_p c^2 - I$; denote $\mu_j \equiv \tilde{\mu}_j - m_j c^2$; and assume that $T \ll m_e c^2 / k_B \simeq 6 \times 10^9$ K and that the density is low enough that the electrons, protons, and H atoms can be regarded as nondegenerate (i.e., as distinguishable, classical particles).

- What relationships hold between the chemical potentials $\tilde{\mu}_\gamma, \tilde{\mu}_H, \tilde{\mu}_e,$ and $\tilde{\mu}_p$?
- What are the number densities $n_H, n_e,$ and n_p expressed in terms of $T, \tilde{\mu}_H, \tilde{\mu}_e,$ and $\tilde{\mu}_p$ —taking account of the fact that the electron and proton both have spin $\frac{1}{2}$, and including for H all possible electron and nuclear spin states?
- Derive the Saha equation for ionization equilibrium:

$$\frac{n_e n_p}{n_H} = \frac{(2\pi m_e k_B T)^{3/2}}{h^3} e^{-I/(k_B T)}. \quad (5.68)$$

This equation is widely used in astrophysics and elsewhere.

5.6 Fluctuations away from Statistical Equilibrium

As we saw in Chap. 4, statistical mechanics is built on a distribution function ρ that is equal to the probability of finding a chosen system in a quantum state at some chosen location in the system’s phase space. For systems in statistical equilibrium, this probability is given by the microcanonical, canonical, grand canonical, Gibbs, or other distribution, depending on the nature of the system’s interactions with its surroundings. Classical thermodynamics makes use of only a tiny portion of the information in this probability distribution: the mean values of a few macroscopic parameters (energy, entropy, volume, pressure, etc.). Also contained in the distribution function, but ignored by classical thermodynamics, is detailed information about fluctuations of a system away from its mean values.

As an example, consider a microcanonical ensemble of boxes, each with volume V and each containing precisely N identical, nonrelativistic, classical gas particles and containing energy (excluding rest mass) between E and $E + \delta E$, where $\delta E \ll E$. (Remember the kludge that was necessary in Ex. 4.7). Consider a quantity y that is not fixed by the set $\{E, V, N\}$. That quantity might be discrete (e.g., the total number

N_R of particles in the right half of the box). Alternatively, it might be continuous (e.g., the total energy E_R in the right half).

In the discrete case, the total number of quantum states that correspond to specific values of y is related to the entropy S by the standard microcanonical relation $N_{\text{states}}(E, V, N; y) = \exp[S(E, V, N; y)/k_B]$; and correspondingly, since all states are equally probable in the microcanonical ensemble, the probability of finding a system of the ensemble to have the specific value y is

$$p(E, V, N; y) = \frac{N_{\text{states}}(E, V, N; y)}{\sum_y N_{\text{states}}(E, V, N; y)} = \text{const} \times \exp\left[\frac{S(E, V, N; y)}{k_B}\right]. \quad (5.69a)$$

Here the entropy S is to be computed via statistical mechanics (or, when possible, via thermodynamics) not for the original ensemble of boxes in which y was allowed to vary, but for an ensemble in which y is fixed at a chosen value.

The continuous case (e.g., $y = E_R$) can be converted into the discrete case by dividing the range of y into intervals that all have the same infinitesimal width δy . Then the probability of finding y in one of these intervals is $[dp(E, V, N; y \text{ in } \delta y)/dy]\delta y = \text{const} \times \exp[S(E, V, N; y \text{ in } \delta y)]$. Dividing both sides by δy and absorbing δy on the right-hand side into the constant, we obtain

$$\frac{dp(E, V, N; y)}{dy} = \text{const} \times \exp\left[\frac{S(E, V, N; y \text{ in } \delta y)}{k_B}\right]. \quad (5.69b)$$

Obviously, if we are interested in the joint probability for a set of y s, some discrete (e.g., $y_1 = N_R$) and some continuous (e.g., $y_2 = E_R$), that probability will be given by

$$\frac{dp(E, V, N; y_1, y_2, \dots, y_r)}{dy_1 \dots dy_r} = \text{const} \times \exp\left[\frac{S(E, V, N; y_j)}{k_B}\right], \quad (5.69c)$$

where we keep in mind (but now omit from our notation) the fact that continuous variables are to be given values y_j in some arbitrary but fixed infinitesimal range δy_j .

The probability distribution (5.69c), though exact, is not terribly instructive. To get better insight we expand S in powers of the deviations of the y_j from the values \bar{y}_j that maximize the entropy (these will turn out also to be the means of the distribution). Then for small $|y_j - \bar{y}_j|$, Eq. (5.69c) becomes

$$\frac{dp(E, V, N; y_j)}{dy_1 \dots dy_r} = \text{const} \times \exp\left[\frac{1}{2k_B} \left(\frac{\partial^2 S}{\partial y_j \partial y_k}\right) (y_j - \bar{y}_j)(y_k - \bar{y}_k)\right]. \quad (5.69d)$$

Here the second partial derivative of the entropy is to be evaluated at the maximum-entropy location, where $y_j = \bar{y}_j$ for all j . Expression (5.69d) is a (multidimensional) Gaussian probability distribution for which the means are obviously \bar{y}_j , as predicted. (That this had to be Gaussian follows from the central limit theorem, Sec. 6.3.2.)

The last entry in the first line of Table 5.2 summarizes the above equations: *for a closed system, the probability of some fluctuation away from equilibrium is proportional*

probabilities for fluctuations in closed systems

Gaussian approximation to fluctuation probabilities

to e^{S/k_B} , where S is the total entropy for the out-of-equilibrium fluctuational macrostate (e.g., the macrostate with N_R particles in the right half of the box).

For the specific example where $y_1 \equiv N_R$ = (number of perfect-gas particles in right half of box) and $y_2 \equiv E_R$ = (amount of energy in right half of box), we can infer $S(E, V, N; N_R, E_R)$ from the Sackur-Tetrode equation (4.42) as applied to the two halves of the box and then added:¹¹

$$S(E, V, N; E_R, N_R) = k_B N_R \ln \left[\left(\frac{4\pi m}{3h^2} \right)^{3/2} e^{5/2} \frac{V}{2} \frac{E_R^{3/2}}{N_R^{5/2}} \right] \\ + k_B (N - N_R) \ln \left[\left(\frac{4\pi m}{3h^2} \right)^{3/2} e^{5/2} \frac{V}{2} \frac{(E - E_R)^{3/2}}{(N - N_R)^{5/2}} \right]. \quad (5.70a)$$

It is straightforward to compute the values \bar{E}_R and \bar{N}_R that maximize this entropy:

$$\bar{E}_R = \frac{E}{2}, \quad \bar{N}_R = \frac{N}{2}. \quad (5.70b)$$

Thus, in agreement with intuition, the mean values of the energy and particle number in the right half-box are equal to half of the box's total energy and particle number. It is also straightforward to compute from expression (5.70a) the second partial derivatives of the entropy with respect to E_R and N_R , evaluate them at $E_R = \bar{E}_R$ and $N_R = \bar{N}_R$, and plug them into the probability distribution (5.69d) to obtain

$$\frac{dp_{N_R}}{dE_R} = \text{const} \times \exp \left(\frac{-(N_R - N/2)^2}{2(N/4)} + \frac{-[(E_R - E/2) - (E/N)(N_R - N/2)]^2}{2(N/6)(E/N)^2} \right). \quad (5.70c)$$

This Gaussian distribution has the following interpretation. (i) There is a correlation between the energy E_R and the particle number N_R in the right half of the box, as one might have expected: if there is an excess of particles in the right half, then we must expect an excess of energy there as well. (ii) The quantity that is not correlated with N_R is $E_R - (E/N)N_R$, again as one might have expected. (iii) For fixed N_R , dp_{N_R}/dE_R is Gaussian with mean $\bar{E}_R = E/2 + (E/N)(N_R - N/2)$ and with rms fluctuation (standard deviation; square root of variance) $\sigma_{E_R} = (E/N)\sqrt{N/6}$. (iv) After integrating over E_R , we obtain

$$p_{N_R} = \text{const} \times \exp \left[\frac{-(N_R - N/2)^2}{2N/4} \right]. \quad (5.70d)$$

This is Gaussian with mean $\bar{N}_R = N/2$ and rms fluctuation $\sigma_{N_R} = \sqrt{N/4}$. By contrast, if the right half of the box had been in equilibrium with a bath far larger than itself, N_R would have had an rms fluctuation equal to the square root of its mean, $\sigma_{N_R} = \sqrt{N/2}$

11. Note that the derivation of Eq. (4.42), as specialized to the right half of the box, requires the same kind of infinitesimal range $\delta y_2 = \delta E_R$ as we used to derive our fluctuational probability equation (5.69d).

(see Ex. 5.11). The fact that the companion of the right half has only the same size as the right half, rather than being far larger, has reduced the rms fluctuation of the number of particles in the right half from $\sqrt{N/2}$ to $\sqrt{N/4}$.

Notice that the probability distributions (5.70c) and (5.70d) are exceedingly sharply peaked about their means. Their standard deviations divided by their means (i.e., the magnitude of their fractional fluctuations) are all of order $1/\sqrt{\bar{N}}$, where \bar{N} is the mean number of particles in a system; and in realistic situations \bar{N} is very large. (For example, \bar{N} is of order 10^{26} for a cubic meter of Earth's atmosphere, and thus the fractional fluctuations of thermodynamic quantities are of order 10^{-13} .) It is this extremely sharp peaking that makes classical thermodynamics insensitive to the choice of type of equilibrium ensemble—that is, sensitive only to means and not to fluctuations about the means.

The generalization of this example to other situations should be fairly obvious; see Table 5.2. When a system is in some out-of-equilibrium macrostate, the total entropy $S + S_b$ of the system and any bath with which it may be in contact is, up to an additive constant, either the system's entropy S or the negative of its out-of-equilibrium potential divided by the bath's temperature ($-F/T_b + \text{const}$, $-G/T_b + \text{const}$, or $-\Omega/T_b + \text{const}$; see column 3 of Table 5.2). Correspondingly, the probability of a fluctuation from statistical equilibrium to this out-of-equilibrium macrostate is proportional to the exponential of this quantity in units of Boltzmann's constant (e^{-S/k_B} , $e^{-F/(k_B T_b)}$, $e^{-G/(k_B T_b)}$, or $e^{-\Omega/(k_B T_b)}$; column 5 of Table 5.2). By expanding the quantity in the exponential around the equilibrium state to second order in the fluctuations, one obtains a Gaussian probability distribution for the fluctuations, like Eq. (5.69d).

As examples, in Ex. 5.11 we study fluctuations in the number of particles in a cell that is immersed in a heat and particle bath, so the starting point is the out-of-equilibrium grand potential Ω . And in Ex. 5.12, we study temperature and volume fluctuations for a system in contact with a heat and volume bath; so the starting point is the out-of-equilibrium Gibbs function G .

probabilities for
fluctuations in systems
interacting with baths

Exercise 5.11 *Example: Probability Distribution for the Number of Particles in a Cell*
Consider a cell with volume V , like those of Fig. 5.1, that has imaginary walls and is immersed in a bath of identical, nonrelativistic, classical perfect-gas particles with temperature T_b and chemical potential μ_b . Suppose that we make a large number of measurements of the number of particles in the cell and that from those measurements we compute the probability p_N for that cell to contain N particles.

- (a) How widely spaced in time must the measurements be to guarantee that the measured probability distribution is the same as that computed, using the methods of this section, from an ensemble of cells (Fig. 5.1) at a specific moment of time?

EXERCISES

- (b) Assume that the measurements are widely enough separated for this criterion to be satisfied. Show that p_N is given by

$$\begin{aligned}
 p_N &\propto \exp \left[\frac{-\Omega(V, T_b, \mu_b; N)}{k_B T_b} \right] \\
 &\equiv \frac{1}{N!} \int \frac{d^{3N}x d^{3N}p}{h^{3N}} \exp \left[\frac{-E_n + \mu_b N_n}{k_B T_b} \right] \\
 &= \frac{1}{N!} \int \frac{d^{3N}x d^{3N}p}{h^{3N}} \exp \left[\frac{-\left(\sum_{i=1}^N \mathbf{p}_i^2 / (2m)\right) + \mu_b N}{k_B T_b} \right],
 \end{aligned} \tag{5.71}$$

where $\Omega(V, T_b, \mu_b; N)$ is the grand potential for the ensemble of cells, with each cell constrained to have precisely N particles in it (cf. the last entry in Table 5.2).

- (c) By evaluating Eq. (5.71) exactly and then computing the normalization constant, show that the probability p_N for the cell to contain N particles is given by the *Poisson distribution*

$$p_N = e^{-\bar{N}} (\bar{N}^N / N!), \tag{5.72a}$$

where \bar{N} is the mean number of particles in a cell,

$$\bar{N} = (\sqrt{2\pi m k_B T_b} / h)^3 e^{\mu_b / (k_B T_b)} V$$

[Eq. (3.39a)].

- (d) Show that for the Poisson distribution (5.72a), the expectation value is $\langle N \rangle = \bar{N}$, and the rms deviation from this is

$$\sigma_N \equiv \langle (N - \bar{N})^2 \rangle^{1/2} = \bar{N}^{1/2}. \tag{5.72b}$$

- (e) Show that for $N - \bar{N} \lesssim \sigma_N$, this Poisson distribution is exceedingly well approximated by a Gaussian with mean \bar{N} and variance σ_N .

Exercise 5.12 *Example: Fluctuations of Temperature and Volume in an Ideal Gas*

Consider a gigantic container of gas made of identical particles that might or might not interact. Regard this gas as a bath, with temperature T_b and pressure P_b . Pick out at random a sample of the bath's gas containing precisely N particles, with $N \gg 1$. Measure the volume V of the sample and the temperature T inside the sample. Then pick another sample of N particles, and measure its V and T , and repeat over and over again. Thereby map out a probability distribution $dp/dT dV$ for V and T of N -particle samples inside the bath.

(a) Explain in detail why

$$\frac{dp}{dTdV} = \text{const} \times \exp \left[-\frac{1}{2k_B T_b} \left(\frac{\partial^2 G}{\partial V^2} (V - \bar{V})^2 + \frac{\partial^2 G}{\partial T^2} (T - T_b)^2 + 2 \frac{\partial^2 G}{\partial T \partial V} (V - \bar{V})(T - T_b) \right) \right], \quad (5.73a)$$

where $G(N, T_b, P_b; T, V) = E(T, V, N) + P_b V - T_b S(T, V, N)$ is the out-of-equilibrium Gibbs function for a sample of N particles interacting with this bath (next-to-last line of Table 5.2), \bar{V} is the equilibrium volume of the sample when its temperature and pressure are those of the bath, and the double derivatives in Eq. (5.73a) are evaluated at the equilibrium temperature T_b and pressure P_b .

(b) Show that the derivatives, evaluated at $T = T_b$ and $V = \bar{V}$, are given by

$$\left(\frac{\partial^2 G}{\partial T^2} \right)_{V,N} = \frac{C_V}{T_b}, \quad \left(\frac{\partial^2 G}{\partial V^2} \right)_{T,N} = \frac{1}{\kappa}, \quad \text{and} \quad \left(\frac{\partial^2 G}{\partial T \partial V} \right)_N = 0, \quad (5.73b)$$

where C_V is the gas sample's specific heat at fixed volume and κ is its compressibility at fixed temperature β , multiplied by V/P :

$$C_V \equiv \left(\frac{\partial E}{\partial T} \right)_{V,N} = T \left(\frac{\partial S}{\partial T} \right)_{V,N}, \quad \kappa \equiv \beta V/P = - \left(\frac{\partial V}{\partial P} \right)_{T,N}, \quad (5.73c)$$

both evaluated at temperature T_b and pressure P_b . [Hint: Write $G = G_{\text{eq}} + (P_b - P)V - (T_b - T)S$, where G_{eq} is the equilibrium Gibbs function for the gas samples.] Thereby conclude that

$$\frac{dp}{dTdV} = \text{const} \times \exp \left[-\frac{(V - \bar{V})^2}{2k_B T_b \kappa} - \frac{C_V (T - T_b)^2}{2k_B T_b^2} \right]. \quad (5.73d)$$

(c) This probability distribution says that the temperature and volume fluctuations are uncorrelated. Is this physically reasonable? Why?

(d) What are the rms fluctuations of the samples' temperature and volume, σ_T and σ_V ? Show that σ_T scales as $1/\sqrt{N}$ and σ_V as \sqrt{N} , where N is the number of particles in the samples. Are these physically reasonable? Why?

Exercise 5.13 Example and Derivation: Evolution and Fluctuations of a System in Contact with a Volume Bath

Exercise 5.5 explored the enthalpy representation of thermodynamics for an equilibrium ensemble of systems in contact with a volume bath. Here we extend that analysis to an ensemble out of equilibrium. We denote by P_b the bath pressure.

(a) The systems exchange volume but not heat or particles with the bath. Explain why, even though the ensemble may be far from equilibrium, any system's volume

change dV must be accompanied by an energy change $d\mathcal{E} = -P_b dV$. This implies that the system's enthalpy $H = \mathcal{E} + P_b V$ is conserved. All systems in the ensemble are assumed to have the same enthalpy H and the same number of particles N .

- (b) Using equilibrium considerations for the bath, show that interaction with a system cannot change the bath's entropy.
- (c) Show that the ensemble will always evolve toward increasing entropy S , and that when the ensemble finally reaches statistical equilibrium with the bath, its distribution function will be that of the enthalpy ensemble (Table 5.1): $\rho = e^{-S/k_B} = \text{const}$ for all regions of phase space that have the specified particle number N and enthalpy H .
- (d) Show that fluctuations away from equilibrium are described by the probability distributions (5.69a) and (5.69c), but with the system energy E replaced by the system enthalpy H and the system volume V replaced by the bath pressure P_b (cf. Table 5.2).

5.7 Van der Waals Gas: Volume Fluctuations and Gas-to-Liquid Phase Transition

The van der Waals gas studied in Sec. 5.3.2 provides a moderately realistic model for real gases such as H_2O and their condensation (phase transition) into liquids, such as water.

The equation of state for a van der Waals gas is

$$\left(P + \frac{a}{v^2}\right)(v - b) = k_B T \quad (5.74)$$

[Eq. (5.26)]. Here a and b are constants, and $v \equiv V/N$ is the specific volume (the inverse of the number density of gas particles). In Fig. 5.8a we depict this equation of state as curves (*isotherms*) of pressure P versus specific volume v at fixed temperature T . Note [as one can easily show from Eq. (5.74)] that there is a critical temperature $T_c = 8a/(27bk_B)$ such that for $T > T_c$ the isotherms are monotonic decreasing; for $T = T_c$ they have an inflection point [at $v = v_c \equiv 3b$ and $P = P_c = a/(27b^2)$]; and for $T < T_c$ they have a maximum and a minimum.

From Eq. (5.73d), derived in Ex. 5.12, we can infer that the probability dp/dv for fluctuations of the specific volume of a portion of this gas containing N particles is

$$\frac{dp}{dv} = \text{const} \times \exp \left[\frac{N(\partial P/\partial v)_T}{2k_B T} (v - \bar{v})^2 \right]. \quad (5.75)$$

This probability is controlled by the slope $(\partial P/\partial v)_T$ of the isotherms. Where the slope is negative, the volume fluctuations are small; where it is positive, the fluid is unstable: its volume fluctuations grow. Therefore, for $T < T_c$, the region of an isotherm between its minimum M and its maximum X (Fig. 5.8b) is unphysical; the fluid cannot exist stably there. Evidently, at $T < T_c$ there are two phases: one with low density ($v > v_X$)

probability for volume fluctuations in van der Waals gas

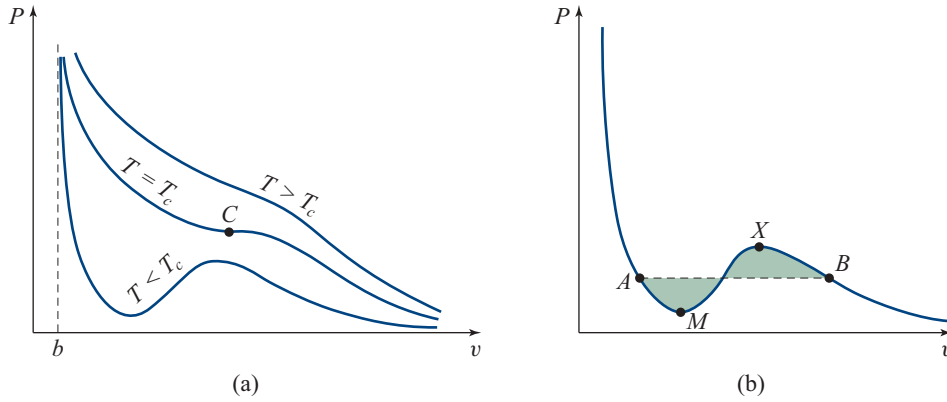

FIGURE 5.8 (a) The van der Waals equation of state $P(N, V, T)$ plotted as pressure P versus specific volume $v \equiv V/N$ at fixed temperature T , for various values of T . (b) The route of a phase transition in the van der Waals gas. The transition is a discontinuous jump from point A to point B .

is gaseous; the other with high density ($v < v_M < v_c = 3b$) is liquid. [Recall, from comment (i) at the end of Sec. 5.3.2, that $b/4$ is the volume of each of the material's particles, so in the high-density phase the particles' separations are not much larger than their diameter; this is characteristic of a fluid.]

Hold the temperature T fixed at $T < T_c$, and gradually increase the density from zero (decrease the specific volume v from infinity). At low densities, the material will be gaseous, and at high densities, it will be liquid. The phase transition from gas to liquid involves a discontinuous jump from some point B in Fig. 5.8b to another point A . The Gibbs potential controls the location of those points.

Since the two phases are in equilibrium with each other at A and B , their Gibbs potential $G = \mu N$ must be the same, which means their chemical potentials must be the same, $\mu_A = \mu_B$ —as, of course, must be their temperatures $T_A = T_B$ (they lie on the same isotherm). This in turn implies their pressures must be the same, $P_A = P(\mu_A, T) = P(\mu_B, T) = P_B$. Therefore, the points A and B in Fig 5.8b are connected by a horizontal line (the dashed line in the figure). Let us use the first law of thermodynamics in the Gibbs representation to compute the change in the chemical potential μ as one moves along the isotherm from point A to point B . The first law says $dG = -SdT + VdP + \mu dN$. Focusing on a sample of the material containing N particles, and noting that along the isotherm the sample has $G = \mu N$, $dN = 0$, $dT = 0$, and $V = vN$, we obtain $d\mu = vdP$. Integrating this relation along the isotherm from A to B , we obtain

$$0 = \mu_B - \mu_A = \int_A^B d\mu = \int_A^B vdP. \quad (5.76)$$

This integral is the area of the right green region in Fig. 5.8b minus the area of the left green region. Therefore, these two areas must be equal, which tells us the location of the points A and B that identify the two phases (liquid and gaseous) when the phase transition occurs.

Consider again volume fluctuations. Where an isotherm is flat, $(\partial P/\partial v)_T = 0$, large volume fluctuations occur [Eq. (5.75)]. For $T < T_c$, the isotherm is flat at the minimum M and the maximum X , but these do not occur in Nature—unless the phase transition is somehow delayed as one compresses or expands the material. However, for $T = T_c$, the isotherm is flat at its inflection point $v = v_c$, $P = P_c$ (the material's critical point C in Fig. 5.8a); so the volume fluctuations will be very large there.

At some temperatures T and pressures P , it is possible for two phases, liquid and gas, to exist; at other T and P , only one phase exists. The dividing line in the T - P plane between these two regions is called a *catastrophe*—a term that comes from *catastrophe theory*. We explore this in Ex. 7.16, after first introducing some ideas of catastrophe theory in the context of optics.

EXERCISES

Exercise 5.14 ***Example: Out-of-Equilibrium Gibbs Potential for Water; Surface Tension and Nucleation*¹²

Water and its vapor (liquid and gaseous H_2O) can be described moderately well by the van der Waals model, with the parameters $a = 1.52 \times 10^{-48} \text{ J m}^3$ and $b = 5.05 \times 10^{-29} \text{ m}^3$ determined by fitting to the measured pressure and temperature at the critical point (inflection point C in Fig. 5.8a: $P_c = a/(27b^2) = 22.09 \text{ MPa}$, $T_c = 8a/(27bk_B) = 647.3 \text{ K}$). [Note: 1 MPa is 10^6 Pascal; and 1 Pascal is the SI unit of pressure, 1 kg m s^{-2} .]

- (a) For an out-of-equilibrium sample of N atoms of H_2O at temperature T and pressure P that has fluctuated to a specific volume v , the van-der-Waals-modeled Gibbs potential is

$$G(N, T, P; v) = N \left[-k_B T + Pv - a/v + k_B T \ln \left(\lambda_{T \text{ dB}}^3 / (v - b) \right) \right],$$

$$\lambda_{T \text{ dB}} \equiv h / \sqrt{2\pi m k_B T}. \quad (5.77)$$

Verify that this Gibbs potential is minimized when v satisfies the van der Waals equation of state (5.74).

- (b) Plot the chemical potential $\mu = G/N$ as a function of v at room temperature, $T = 300 \text{ K}$, for various pressures in the vicinity of 1 atmosphere = 0.1013 MPa. Adjust the pressure so that the two phases, liquid and gaseous, are in equilibrium (i.e., so the two minima of the curve have the same height). [Answer: The required pressure is about 3.6 atmospheres, and the chemical-potential curve is shown in Fig. 5.9. If the gas is a mixture of air and H_2O rather than pure H_2O , then the required pressure will be lower.]
- (c) Compare the actual densities of liquid water and gaseous H_2O with the predictions of Fig. 5.9. They agree moderately well but not very well.

12. Exercise adapted from Sethna (2006, Ex. 11.3 and Sec. 11.3).

FIGURE 5.9 The out-of-equilibrium chemical potential for a van der Waals gas, with its parameters fitted to the properties of H_2O and with temperature $T = 300$ K and pressure $P = 3.6$ atmospheres at the liquid-gas interface.

- (d) At the liquid's surface there is a surface layer a few molecules thick, in which the attractive force between the water molecules, $F = -6\epsilon_o r_o^6 / r^7 = -[27/(2\pi^2)]ab/r^7$ [Eqs. (5.22b) and (5.24b)], produces surface tension. This surface tension is a force per unit length, γ , that the surface molecules on one side of any line lying in the surface exert on the molecules on the other side (Box 16.4). Explain by a simple physical argument why there is an energy γA associated with this surface tension, stored in any area A of the surface. This is a free energy at fixed T, P (a Gibbs free energy) in excess of the free energy that the surface's water molecules would have if they were in the bulk liquid or the bulk gas. This excess free energy shows up in the chemical potential of Fig. 5.9, and the numbers in that figure can be used to estimate the water's surface tension γ . Show that $\gamma \sim \Delta\mu h/v$, where h and v are the thickness and specific volume, respectively, of the surface layer, and $\Delta\mu$ is the difference between the chemical potential in the surface layer and in the bulk water and gas. Estimate γ using numbers from Fig. 5.9 and compare with the measured surface tension, $\gamma \simeq 0.0723$ N/m at $T = 300$ K.
- (e) In a cloud or fog, when water vapor is cooled below its equilibrium temperature with liquid water T_e , water drops try to form, that is, *nucleate*. However, there is a potential barrier against nucleation due to the surface tension of an incipient drop. If R is the drop's radius, show that the Gibbs free energy of a droplet (the sum of contributions from its surface layer and its interior) minus the free energy that the droplet's molecules will have if they remain gaseous, is

$$\Delta G = 4\pi R^2 \gamma - \left(\frac{4\pi}{3} R^3 \right) \frac{q \Delta T}{v_\ell T_e}. \quad (5.78)$$

Here q is the latent heat per molecule that is released when the vapor liquifies, v_ℓ is the liquid's specific volume, and ΔT is the amount by which the temperature has dropped below the equilibrium point T_e for the two phases. Plot this $\Delta G(R)$, and explain why (i) there is a minimum droplet radius R_{\min} for nucleation to succeed, and (ii) for the droplet to form with this minimum size, thermal fluctuations must put into it some excess energy, B , above statistical equilibrium. Derive these formulas:

$$R_{\min} = \frac{2\gamma T_e v_\ell}{q \Delta T}, \quad B = \frac{16\pi \gamma^3 T_e^2 v_\ell^2}{3q^2 \Delta T^2}. \quad (5.79)$$

Explain why the rate at which nucleation occurs must scale as $\exp[-B/(k_B T)]$, which is generally an exceedingly small number. Show that, if the nucleation occurs on a leaf or blade of grass or on the surface of a dust grain, so the drop's interface with the vapor is a hemisphere rather than a sphere, then the energy barrier B is reduced by a factor 8, and the rate of nucleation is enormously increased. That is why nucleation of water droplets almost always occurs on solid surfaces.

5.8

5.8 Magnetic Materials T2

The methods we have developed in this chapter can be applied to systems very different from the gases and liquids studied thus far. In this section, we focus on magnetic materials as an example, and we use this example to illustrate two powerful, modern computational techniques: the renormalization group and Monte Carlo methods.

We consider, for concreteness, the simplest type of magnetic material: one consisting of a cubic lattice of N identical atoms, each with spin 1/2 and magnetic moment m_o . The material is immersed in a uniform external magnetic field \mathbf{B} , so each atom (labeled by an index i) has two possible quantum states: one with its spin parallel to \mathbf{B} (quantum number $s_i = +1$), the other antiparallel to \mathbf{B} ($s_i = -1$). The energies of these states are $E_{s_i} = -m_o B s_i$. The atoms interact with one another's magnetic fields with a pairwise interaction energy $E_{s_i s_j}$ that we shall make more concrete in Sec. 5.8.2 below. The material's total energy, when the atoms are in the state $|n\rangle = |s_1, s_1, \dots, s_n\rangle$, is $E_n - M_n B$, where

$$E_n = \sum_{i>j}^N \sum_{j=1}^N E_{s_i s_j}, \quad M_n = m_o \sum_{j=1}^N s_j \quad (5.80a)$$

are the material's self-interaction energy (internal energy) and *magnetization*.

The atoms interact with a heat bath that has temperature T and with the external magnetic field B , which can be thought of as part of the bath.¹³ When they reach sta-

13. Arranging the electromagnetic environment to keep B fixed is a choice similar to arranging the thermal environment to keep T fixed. Other choices are possible.

model for magnetic material

quantum number s_i for spin orientation

internal energy and magnetization

tistical equilibrium with this heat and magnetic bath, the probability for the material (all N atoms) to be in state $|n\rangle = |s_1, s_1, \dots, s_n\rangle$ is, of course,

$$p_n = e^{G(N, B, T)/(k_B T)} e^{-(E_n - BM_n)/(k_B T)}. \quad (5.80b)$$

Here the first term is the normalization constant, which depends on the number N of atoms in the sample and the bath's B and T , and $G(N, B, T)$ is the fundamental thermodynamic potential for this system, which acts as the normalizing factor for the probability:

$$e^{-G(N, B, T)/(k_B T)} = \sum_n e^{-(E_n - BM_n)/(k_B T)}. \quad (5.80c)$$

Gibbs potential for magnetic material

We have denoted this potential by G , because it is analogous to the Gibbs potential for a gas, but with the gas's volume V_n replaced by minus the magnetization $-M_n$ and the gas bath's pressure P replaced by the material bath's magnetic field strength B . Not surprisingly, the Gibbs thermodynamic formalism for this magnetic material is essentially the same as for a gas, but with $V \rightarrow -M$ and $P \rightarrow B$.

5.8.1 Paramagnetism; The Curie Law T2

Paramagnetic materials have sufficiently weak self-interaction that we can set $E_n = 0$ and focus solely on the atoms' interaction with the external B field. The magnetic interaction tries to align each atom's spin with B , while thermal fluctuations try to randomize the spins. As a result, the stronger is B (at fixed temperature), the larger will be the mean magnetization \bar{M} . From Eq. (5.80b) for the spins' probability distribution we can compute the mean magnetization:

$$\begin{aligned} \bar{M} &= \sum_n p_n M_n = e^{G/(k_B T)} \sum_n M_n e^{BM_n/(k_B T)} \\ &= e^{G/(k_B T)} k_B T \left(\frac{\partial}{\partial B} \right)_{N, T} \sum_n e^{BM_n/(k_B T)}. \end{aligned} \quad (5.81a)$$

The last sum is equal to $e^{-G/(k_B T)}$ [Eq. (5.80c) with $E_n = 0$], so Eq. (5.81a) becomes

$$\bar{M} = - \left(\frac{\partial G}{\partial B} \right)_{N, T}. \quad (5.81b)$$

This is obviously our material's analog of $\bar{V} = (\partial G / \partial P)_{N, T}$ for a gas [which follows from the Gibbs representation of the first law, Eq. (5.52)].

To evaluate \bar{M} explicitly in terms of B , we must first compute the Gibbs function from the statistical sum (5.80c) with $E_n = 0$. Because the magnetization M_n in state $|n\rangle = |s_1, s_2, \dots, s_N\rangle$ is the sum of contributions from individual atoms [Eq. (5.80a)], this sum can be rewritten as the product of identical contributions from each of the N atoms:

$$e^{-G/(k_B T)} = \left(e^{-Bm_o/k_B T} + e^{+Bm_o/k_B T} \right)^N = \left(2 \cosh[Bm_o/(k_B T)] \right)^N. \quad (5.81c)$$

5.8.1

paramagnetic material

T2

Gibbs function for paramagnetic material

(In the second expression, the first term is from state $s_i = -1$ and the second from $s_i = +1$.) Taking the logarithm of both sides, we obtain

$$G(B, T, N) = -Nk_B T \ln\left(2 \cosh[Bm_o/(k_B T)]\right). \quad (5.82)$$

Differentiating with respect to B [Eq. (5.81b)], we obtain for the mean magnetization

$$\bar{M} = Nm_o \tanh [Bm_o/(k_B T)]. \quad (5.83)$$

At high temperatures, $k_B T \gg Bm_o$, the magnetization increases linearly with the applied magnetic field (the atoms begin to align with \mathbf{B}), so the magnetic susceptibility is independent of B :

$$\chi_M \equiv \left(\frac{\partial \bar{M}}{\partial B}\right)_{T, N} \simeq Nm_o^2/(k_B T). \quad (5.84)$$

Curie's law for magnetic susceptibility

The proportionality $\chi_M \propto 1/T$ for a paramagnetic material at high temperature is called *Curie's law*. At low temperatures ($k_B T \ll Bm_o$), the atoms are essentially all aligned with \mathbf{B} , and the magnetization saturates at $\bar{M} = Nm_o$.

5.8.2

5.8.2 Ferromagnetism: The Ising Model T2

ferromagnetic material

Turn now to a magnetic material for which the spins' interactions are strong, and there is no external B field. In such a material, at high temperatures the spin directions are random, while at low enough temperatures the interactions drive neighboring spins to align with one another, producing a net magnetization. This is called *ferromagnetism*, because it occurs rather strongly in iron. The transition between the two regimes is sharp (i.e., it is a phase transition).

In this section, we introduce a simple model for the spins' interaction: the Ising model.¹⁴ For simplicity, we idealize to two spatial dimensions. The corresponding 3-dimensional model is far more difficult to analyze. Studying the 2-dimensional model carefully brings out many general features of phase transitions, and the intuition it cultivates is very helpful in thinking about experiments and simulations.

Ising model and its pairwise interaction energy

In this model, the atoms are confined to a square lattice that lies in the x - y plane, and their spins can point up (along the $+z$ direction) or down. The pairwise interaction energy is nonzero only for nearest neighbor atoms:

$$E_{s_i, s_j} = -Js_i s_j \quad \text{for nearest neighbors;} \quad (5.85)$$

it vanishes for all other pairs. Here J is a positive constant (which depends on the lattice's specific volume $v = V/N$, but that will not be important for us). Note that the interaction energy $-Js_i s_j$ is negative if the spins are aligned ($s_i = s_j$) and positive if they are opposite ($s_i = -s_j$), so like spins attract and opposite spins repel. Although the Ising model does not explicitly include more distant interactions, they are present indirectly: the "knock-on" effect from one spin to the next, as we shall see, introduces

14. Named for Ernst Ising, who first investigated it, in 1925.

long-range organization that propagates across the lattice when the temperature is reduced below a critical value T_c , inducing a second-order phase transition. We use the dimensionless parameter

$$K \equiv J/(k_B T) \quad (5.86)$$

to characterize the phase transition. For $K \ll 1$ (i.e., $k_B T \gg J$), the spins will be almost randomly aligned, and the total interaction energy will be close to zero. When $K \gg 1$ (i.e., $k_B T \ll J$), the strong coupling will drive the spins to align over large (2-dimensional) volumes. At some critical intermediate temperature $K_c \sim 1$ [and corresponding temperature $T_c = J/(k_B K_c)$], the phase transition will occur.

We compute this critical K_c , and macroscopic properties of the material near it, using two modern, sophisticated computational techniques: renormalization methods in Sec. 5.8.3 and Monte Carlo methods in Sec. 5.8.4. We examine the accuracy of these methods by comparing our results with an exact solution for the 2-dimensional Ising model, derived in a celebrated paper by Lars Onsager (1944).

critical temperature T_c and critical parameter K_c

5.8.3 Renormalization Group Methods for the Ising Model T2

5.8.3

The key idea behind the renormalization group approach to the Ising model is to try to replace the full lattice by a sparser lattice that has similar thermodynamic properties, and then to iterate, making the lattice more and more sparse; see Fig. 5.10.¹⁵

idea behind renormalization group

We implement this procedure using the statistical sum (5.80c) for the Gibbs potential, except that here the external magnetic field B vanishes, so the bath is purely thermal and its potential is $F(N, V, T)$ —the physical free energy, not G —and the statistical sum (5.80c) reads $e^{-F/(k_B T)} \equiv z = \sum_n e^{-E_n/(k_B T)}$. For our Ising model, with its nearest-neighbor interaction energies (5.85), this becomes

$$e^{-F(N, V, T)/(k_B T)} \equiv z = \sum_{\{s_1=\pm 1, s_2=\pm 1, \dots\}} e^{K \sum^1 s_i s_j}. \quad (5.87a)$$

Here in the exponential \sum^1 means a sum over all pairs of nearest neighbor sites $\{i, j\}$. The dependence on the material's number of atoms N appears in the number of terms in the big sum; the dependence on V/N is via the parameter J , and on T is via the parameter $K = J/(k_B T)$.

The first step in the renormalization group method is to rewrite Eq. (5.87a) so that each of the open-circle spins of Fig. 5.10 (e.g., s_5) appears in only one term in the exponential. Then we explicitly sum each of those spins over ± 1 , so they no longer appear in the summations:

$$\begin{aligned} z &= \sum_{\{\dots, s_4=\pm 1, s_5=\pm 1, s_6=\pm 1, \dots\}} \dots e^{K(s_1+s_2+s_3+s_4)s_5} \dots \\ &= \sum_{\{\dots, s_4=\pm 1, s_6=\pm 1, \dots\}} \dots \left[e^{K(s_1+s_2+s_3+s_4)} + e^{-K(s_1+s_2+s_3+s_4)} \right] \dots \end{aligned} \quad (5.87b)$$

15. This section is based in part on Maris and Kadanoff (1978) and Chandler (1987, Sec. 5.7).

FIGURE 5.10 Partition of a square lattice into two interlaced square lattices (solid circles and open circles). In the renormalization group approach, the open-circle spins are removed from the lattice, and all their interactions are replaced by modified interactions between the remaining solid-circle spins. The new lattice is rotated by $\pi/4$ with respect to the original lattice, and the lattice spacing increases by a factor $\sqrt{2}$.

(This rewriting of z is possible because each open-circle spin interacts only with solid-circle spins.) The partition function z is now a product of terms like those in the square brackets, one for each open-circle lattice site that we have “removed.” We would like to rewrite each square-bracketed term in a form involving solely nearest-neighbor interactions of the solid-circle spins, so that we can then iterate our procedure. Such a rewrite, however, is not possible; after some experimentation, one can verify that the rewrite also requires next-nearest-neighbor interactions and four-site interactions:

$$\begin{aligned} & \left[e^{K(s_1+s_2+s_3+s_4)} + e^{-K(s_1+s_2+s_3+s_4)} \right] \\ & = f(K) e^{\left[\frac{1}{2} K_1 (s_1 s_2 + s_2 s_3 + s_3 s_4 + s_4 s_1) + K_2 (s_1 s_3 + s_2 s_4) + K_3 s_1 s_2 s_3 s_4 \right]}. \end{aligned} \quad (5.87c)$$

We can determine the four functions $K_1(K)$, $K_2(K)$, $K_3(K)$, $f(K)$ by substituting each of the four possible distinct combinations of $\{s_1, s_2, s_3, s_4\}$ into Eq. (5.87c). Those four combinations, arranged in the pattern of the solid circles of Fig. 5.10, are $++++$, $-+-$, $+--$, and $+-+-$. [Rotating the pattern or changing all signs leaves both sides of Eq. (5.87c) unchanged.] By inserting these combinations into Eq. (5.87c) and performing some algebra, we obtain

$$\begin{aligned} K_1 &= \frac{1}{4} \ln \cosh(4K), \\ K_2 &= \frac{1}{8} \ln \cosh(4K), \\ K_3 &= \frac{1}{8} \ln \cosh(4K) - \frac{1}{2} \ln \cosh(2K), \text{ and} \\ f(K) &= 2[\cosh(2K)]^{1/2} [\cosh(4K)]^{1/8}. \end{aligned} \quad (5.87d)$$

By inserting expression (5.87c) and the analogous expressions for the other terms into Eq. (5.87b), we obtain the partition function for our original N -spin lattice of open and closed circles, expressed as a sum over the $(N/2)$ -spin lattice of closed circles:

$$z(N, K) = [f(K)]^{N/2} \sum e^{[K_1 \Sigma^1 s_i s_j + K_2 \Sigma^2 s_i s_j + K_3 \Sigma^3 s_i s_j s_k s_l]}. \quad (5.87e)$$

Here the symbol Σ^1 still represents a sum over all nearest neighbors but now in the $N/2$ lattice, Σ^2 is a sum over the four next nearest neighbors, and Σ^3 is a sum over spins located at the vertices of a unit cell. [The reason we defined K_1 with the $1/2$ in Eq. (5.87c) was because each nearest neighbor interaction appears in two adjacent squares of the solid-circle lattice, thereby converting the $1/2$ to a 1 in Eq. (5.87e).]

So far, what we have done is exact. We now make two drastic approximations that Onsager did not make in his exact treatment, but are designed to simplify the remainder of the calculation and thereby elucidate the renormalization group method. First, in evaluating the partition function (5.87e), we drop completely the quadruple interaction (i.e., we set $K_3 = 0$). This is likely to be decreasingly accurate as we lower the temperature and the spins become more aligned. Second, we assume that near the critical point, in some average sense, the degree of alignment of next nearest neighbors (of which there are as many as nearest neighbors) is “similar” to that of the nearest neighbors, so that we can set $K_2 = 0$ but increase K_1 to

$$K' = K_1 + K_2 = \frac{3}{8} \ln \cosh(4K). \quad (5.88)$$

(If we simply ignored K_2 we would not get a phase transition.) This substitution ensures that the energy of a lattice with $N/2$ *aligned* spins—and therefore N nearest neighbor and N next nearest neighbor bonds, namely, $-(K_1 + K_2)Nk_B T$ —is the same as that of a lattice in which we just include the nearest neighbor bonds but strengthen the interaction from K_1 to K' . Clearly this will be unsatisfactory at high temperature, but we only need it to be true near the phase transition’s critical temperature.

These approximations bring the partition function (5.87e) into the form

$$z(N, K) = [f(K)]^{N/2} z(N/2, K'), \quad (5.89a)$$

which relates the partition function (5.87a) for our original Ising lattice of N spins and interaction constant K to that of a similar lattice with $N/2$ spins and interaction constant K' .

As the next key step in the renormalization procedure, we note that because the free energy, $F = -k_B T \ln z$, is an extensive variable, $\ln z$ must increase in direct proportion to the number of spins, so that it must have the form

$$-F/(k_B T) \equiv \ln z(N, K) = Ng(K), \quad (5.89b)$$

for some function $g(K)$. By combining Eqs. (5.89a) and (5.89b), we obtain a relation for the function $g(K)$ (the free energy, aside from constants) in terms of the function $f(K)$:

$$g(K') = 2g(K) - \ln f(K), \quad \text{where } f(K) = 2[\cosh(2K)]^{1/2}[\cosh(4K)]^{1/8} \quad (5.90)$$

[cf. Eq. (5.87d)].

Equations (5.88) and (5.90) are the fundamental equations that allow us to calculate thermodynamic properties. They are called the *renormalization group equations*, because their transformations form a mathematical group, and they are a scheme

for determining how the effective coupling parameter K changes (gets renormalized) when one views the lattice on larger and larger distance scales. Renormalization group equations like these have been widely applied in elementary-particle theory, condensed-matter theory, and elsewhere. Let us examine these in detail.

The iterative map (5.88) expresses the coupling constant K' for a lattice of enlarged physical size and reduced number of particles $N/2$ in terms of K for the smaller lattice with N particles. [And the associated map (5.90) expresses the free energy when the lattice is viewed on the larger scale in terms of that for a smaller scale.] The map (5.88) has a fixed point that is obtained by setting $K' = K$ [i.e., $K_c = \frac{3}{8} \ln \cosh(4K_c)$], which implies

$$K_c = 0.507. \quad (5.91)$$

This fixed point corresponds to the critical point for the phase transition, with critical temperature T_c such that $K_c = J/(k_B T_c)$.

We can infer that this is the critical point by the following physical argument. Suppose that T is slightly larger than T_c , so K is slightly smaller than K_c . Then, when we make successive iterations, because $dK'/dK > 1$ at $K = K_c$, K decreases with each step, moving farther from K_c ; the fixed point is unstable. What this means is that, when $T > T_c$, as we look on larger and larger scales, the effective coupling constant K becomes weaker and weaker, so the lattice becomes more disordered. Conversely, below the critical temperature ($T < T_c$ and $K > K_c$), the lattice becomes more ordered with increasing scale. Only when $K = K_c$ does the lattice appear to be comparably disordered on all scales. It is here that the increase of order with lengthscale changes from greater order at smaller scales (for high temperatures) to greater order at larger scales (for low temperatures).

To demonstrate more explicitly that $K = K_c$ is the location of a phase transition, we compute the lattice's specific heat in the vicinity of K_c . The first step is to compute the lattice's entropy, $S = -(\partial F/\partial T)_{V,N}$. Recalling that $K \propto 1/T$ at fixed V, N [Eq. (5.86)] and using expression (5.89b) for F , we see that

$$S = - \left(\frac{\partial F}{\partial T} \right)_{V,N} = Nk_B \left[g - K \left(\frac{dg}{dK} \right) \right]. \quad (5.92a)$$

The specific heat at constant volume is then, in turn, given by

$$C_V = T \left(\frac{\partial S}{\partial T} \right)_{V,N} = Nk_B K^2 \frac{d^2 g}{dK^2}. \quad (5.92b)$$

Next we note that, because the iteration (5.88) is unstable near K_c , the inverse iteration

$$K = \frac{1}{4} \cosh^{-1}[\exp(8K'/3)] \quad (5.92c)$$

is stable. The corresponding inverse transformation for the function $g(K)$ is obtained from Eq. (5.90), with K in the function f converted to K' using Eq. (5.92c):

$$g(K) = \frac{1}{2} g(K') + \frac{1}{2} \ln \{ 2 \exp(2K'/3) [\cosh(4K'/3)]^{1/4} \}. \quad (5.92d)$$

FIGURE 5.11 (a) Iteration map $K(K')$ in the vicinity of the critical point. (b) Free energy per spin. (c) Entropy per spin. (d) Specific heat per spin. Recall that $J/(k_B T) = K$.

Now, we know that at low temperature, $T \ll T_c$ and $K \gg K_c$, all the spins are aligned; correspondingly, in the statistical sum (5.87a) the two terms with all s 's identical dominate, giving $z = e^{-F/(k_B T)} = e^{Ng} = 2e^{2NK}$, whence $g(K) \simeq 2K$. Conversely, at high temperature, there is complete disorder, and $K \rightarrow 0$. This means that every one of the 2^N terms in the statistical sum (5.87a) is unity, giving $z = e^{Ng} = 2^N$, whence $g(K) \simeq \ln 2$. We can therefore use the iterative map, Eqs. (5.92c) and (5.92d), to approach $K = K_c$ from either side, starting with the high-temperature and low-temperature limits of $g(K)$ and evaluating thermodynamic quantities at each step. More specifically, at each step, we evaluate $g(K)$, dg/dK , and d^2g/dK^2 numerically, and from them we compute F , S , and C_V using Eqs. (5.89b), (5.92a), and (5.92b).

The iterated values of these quantities are plotted as points in Fig. 5.11. Note that the entropy S is continuous at K_c (panel c), but its derivative, the specific heat (panel d), diverges at K_c , as $K \rightarrow K_c$ from either side. This is characteristic of a second-order phase transition.

To calculate the explicit form of this divergence, suppose that $g(K)$ is a sum of an analytic (infinitely differentiable) function and a nonanalytic part. Suppose that

near the critical point, the nonanalytic part behaves as $g(K) \sim |K - K_c|^{2-\alpha}$ for some “critical exponent” α . This implies that C_V diverges $\propto |K - K_c|^{-\alpha} \propto |T - T_c|^{-\alpha}$. Now, from Eq. (5.92d), we have that

$$|K' - K_c|^{2-\alpha} = 2|K - K_c|^{2-\alpha}, \quad (5.93a)$$

or equivalently,

$$\frac{dK'}{dK} = 2^{1/(2-\alpha)}. \quad (5.93b)$$

Evaluating the derivative at $K = K_c$ from Eq. (5.92c), we obtain

$$\alpha = 2 - \frac{\ln 2}{\ln(dK'/dK)_c} = 0.131, \quad (5.93c)$$

which is consistent with the numerical calculation.

exact analysis of Ising model compared to our approximate analysis

The exact Onsager (1944) analysis of the Ising model gives $K_c = 0.441$ compared to our $K_c = 0.507$, and $C_V \propto -\ln|T - T_c|$ compared to our $C_V \propto |T - T_c|^{-0.131}$. Evidently, our renormalization group approach (formulated by Maris and Kadanoff, 1978) gives a fair approximation to the correct answers but not a good one.

Our approach appears to have a serious problem in that it predicts a negative value for the entropy in the vicinity of the critical point (Fig. 5.11c). This is surely unphysical. (The entropy becomes positive farther away, on either side of the critical point.) This is an artificiality associated with our approach’s ansatz [i.e., associated with our setting $K_2 = K_3 = 0$ and $K' = K_1 + K_2$ in Eq. (5.88)]. It does not seem easy to cure this in a simple renormalization-group approach.

Nonetheless, our calculations exhibit the conceptual and physical essentials of the renormalization-group approach to phase transitions.

Why did we bother to go through this cumbersome procedure when Onsager has given us an exact analytical solution to the Ising model? The answer is that it is not possible to generalize the Onsager solution to more complex and realistic problems. In particular, it has not even been possible to find an Onsager-like solution to the 3-dimensional Ising model. However, once the machinery of the renormalization group has been mastered, it can produce approximate answers, with an accuracy that can be estimated, for a variety of problems. In the following section we look at a quite different approach to the same 2-dimensional Ising problem with exactly the same motivation in mind.

EXERCISES

Exercise 5.15 Example: One-Dimensional Ising Lattice T2

- (a) Write down the partition function for a 1-dimensional Ising lattice as a sum over terms describing all possible spin organizations.

- (b) Show that by separating into even and odd numbered spins, it is possible to factor the partition function and relate $z(N, K)$ exactly to $z(N/2, K')$. Specifically, show that

$$z(N, K) = f(K)^{N/2} z(N/2, K') \quad (5.94)$$

where $K' = \ln[\cosh(2K)]/2$, and $f(K) = 2[\cosh(2K)]^{1/2}$.

- (c) Use these relations to demonstrate that the 1-dimensional Ising lattice does not exhibit a second-order phase transition.

5.8.4 Monte Carlo Methods for the Ising Model T2

5.8.4

In this section, we explore the phase transition of the 2-dimensional Ising model using our second general method: the *Monte Carlo* approach.¹⁶ This method, like the renormalization group, is a powerful tool for a much larger class of problems than just phase transitions.¹⁷

The Monte Carlo approach is much more straightforward in principle than the renormalization group. We set up a square lattice of atoms and initialize their spins randomly.¹⁸ We imagine that our lattice is in contact with a heat bath with a fixed temperature T (it is one member of a canonical ensemble of systems), and we drive it to approach statistical equilibrium and then wander onward through an equilibrium sequence of states $|n_1\rangle, |n_2\rangle, \dots$ in a prescribed, ergodic manner. Our goals are to visualize typical equilibrium states (see Fig. 5.12 later in this section) and to compute thermodynamic quantities using $\bar{X} = z^{-1} \sum_n e^{-E_n/(k_B T)} X_n$, where the sum is over the sequence of states $|n_1\rangle, |n_2\rangle, \dots$. For example, we can compute the specific heat (at constant volume) from

Monte Carlo method for Ising model

$$C_V = \frac{d\bar{E}}{dT} = \frac{\partial}{\partial T} \left(\frac{\sum_n e^{-E_n/(k_B T)} E_n}{\sum_n e^{-E_n/(k_B T)}} \right) = \frac{\overline{E^2} - \bar{E}^2}{k_B T^2}. \quad (5.95)$$

[Note that a singularity in the specific heat at a phase transition will be associated with large fluctuations in the energy, just as it is associated with large fluctuations of temperature; Eq. (5.73d).]

In constructing our sequence of lattice states $|n_1\rangle, |n_2\rangle, \dots$, we obviously cannot visit all 2^N states even just once, so we must sample them fairly. How can we prescribe the rule for changing the spins when going from one state in our sample to the next, so as to produce a fair sampling? There are many answers to this question; we describe

16. The name “Monte Carlo” is a sardonic reference to the casino whose patrons believe they will profit by exploiting random processes.

17. We shall meet it again in Sec. 28.6.1.

18. This and other random steps that follow are performed numerically and require a (pseudo) random number generator. Most programming languages supply this utility, which is mostly used uncritically, occasionally with unintended consequences. Defining and testing “randomness” is an important topic which, unfortunately, we shall not address. See, for example, Press et al. (2007).

and use one of the simplest, due to Metropolis et al. (1953). To understand this, we must appreciate that we don't need to comprehend the detailed dynamics by which a spin in a lattice actually flips. All that is required is that the rule we adopt, for going from one state to the next, should produce a sequence that is in statistical equilibrium.

Let us denote by $p_{nn'}$ the conditional probability that, if the lattice is in state $|n\rangle$, then the next step will take it to state $|n'\rangle$. For statistical equilibrium, it must be that the probability that any randomly observed step takes us out of state $|n\rangle$ is equal to the probability that it takes us into that state:

$$\rho_n \sum_{n'} p_{nn'} = \sum_{n'} \rho_{n'} p_{n'n}. \quad (5.96)$$

(Here ρ_n is the probability that the lattice was in state $|n\rangle$ just before the transition.) We know that in equilibrium, $\rho_{n'} = \rho_n e^{(E_n - E_{n'})/(k_B T)}$, so our conditional transition probabilities must satisfy

$$\sum_{n'} p_{nn'} = \sum_{n'} p_{n'n} e^{(E_n - E_{n'})/(k_B T)}. \quad (5.97)$$

Metropolis rule for transition probabilities

The Metropolis rule is simple:

$$\begin{aligned} \text{if } E_n > E_{n'}, \text{ then } p_{nn'} &= 1; \\ \text{and if } E_n < E_{n'}, \text{ then } p_{nn'} &= \exp[(E_n - E_{n'})/(k_B T)] \end{aligned} \quad (5.98)$$

up to some normalization constant. It is easy to show that this satisfies the statistical equilibrium condition (5.97) and that it drives an initial out-of-equilibrium system toward equilibrium.

The numerical implementation of the Metropolis rule (5.98) is as follows: Start with the lattice in an initial, random state, and then choose one spin at random to make a trial flip. If the new configuration has a lower energy, we always accept the change. If it has a higher energy, we only accept the change with a probability given by $\exp[-\Delta E/(k_B T)]$, where $\Delta E > 0$ is the energy change.¹⁹ In this way, we produce a sequence of states that will ultimately have the equilibrium distribution function, and we can perform our thermodynamic averages using this sequence in an unweighted fashion. This is a particularly convenient procedure for the Ising problem, because, by changing just one spin at a time, ΔE can only take one of five values ($-4, -2, 0, +2, +4$ in units of J), and it is possible to change from one state to the next very quickly. (It also helps to store the two acceptance probabilities $e^{-2J/(k_B T)}$ and $e^{-4J/(k_B T)}$ for making an energy-gaining transition, so as to avoid evaluating exponentials at every step.)

19. There is a small subtlety here. The probability of making a given transition is actually the product of the probability of making the trial flip and of accepting the trial. However, the probability of making a trial flip is the same for all the spins that we might flip ($1/N$), and these trial probabilities cancel, so it is only the ratio of the probabilities of acceptance that matters.

FIGURE 5.12 Typical equilibrium Ising lattices for temperatures $T = 1, 2, 3$ in units of J/k_B . The black regions have spins $s = +1$; the white, $s = -1$.

How big a lattice do we need, and how many states should we consider? The lattice size can be surprisingly small to get qualitatively correct results, if we adopt periodic boundary conditions. That is to say, we imagine a finite tiling of our actual finite lattice, and every time we need to know the spin at a site beyond the tiling's last column (or row), we use the corresponding spin an equal distance beyond the first column (or row). This device minimizes the effects of the boundary on the final answer. Lattices as small as 32×32 can be useful. The length of the computation depends on the required accuracy. (In practice, this is usually implemented the other way around. The time available on a computer of given speed determines the accuracy.) One thing should be clear. It is necessary that we explore a reasonable volume of state space to be able to sample it fairly and compute meaningful estimates of thermodynamic quantities. The final lattice should exhibit no vestigial patterns from the state when the computation was half complete. In practice, it is this consideration that limits the size of the lattice, and it is one drawback of the Metropolis algorithm that the step sizes are necessarily small. There is a large bag of tricks for Monte Carlo simulations that can be used for variance reduction and estimation, but we only concern ourselves here with the general method.

Returning to the Ising model, we show in Fig. 5.12 typical equilibrium states (snapshots) for three temperatures, measured in units of J/k_B . Recall that the critical temperature is $T_c = J/(k_B K_c) = J/(0.441k_B) = 2.268J/k_B$. Note the increasingly long-range order as the temperature is reduced below T_c .

We have concluded this chapter with an examination of a very simple system that can approach equilibrium according to specified rules and that can exhibit strong fluctuations. In the following chapter, we examine fluctuations more systematically.

Monte Carlo results for Ising model

Exercise 5.16 *Practice: Direct Computation of Thermodynamic Integrals* T2

Estimate how long it would take a personal computer to calculate the partition function for a 32×32 Ising lattice by evaluating every possible state.

EXERCISES

T2**Exercise 5.17** *Example: Monte Carlo Approach to Phase Transition* **T2**

Write a simple computer program to compute the energy and the specific heat of a 2-dimensional Ising lattice as described in the text. Examine the accuracy of your answers by varying the size of the lattice and the number of states sampled. (You might also try to compute a formal variance estimate.)

Exercise 5.18 *Problem: Ising Lattice with an Applied Magnetic Field* **T2**

Modify your computer program from Ex. 5.17 to deal with the 2-dimensional Ising model augmented by an externally imposed, uniform magnetic field [Eqs. (5.80)]. Compute the magnetization and the magnetic susceptibility for wisely selected values of $m_o B/J$ and $K = J/(k_B T)$.

Bibliographic Note

Most statistical mechanics textbooks include much detail on statistical thermodynamics. Among those we have found useful at an elementary level are Kittel and Kroemer (1980), and at more advanced levels, Chandler (1987), Sethna (2006), Kardar (2007), Reif (2008), and Pathria and Beale (2011). Chandler (1987) and Sethna (2006) are particularly good for phase transitions. Our treatment of the renormalization group in Sec. 5.8.3 is adapted in part from Chandler, who also covers Monte Carlo methods.

Random Processes

These motions were such as to satisfy me, after frequently repeated observation, that they arose neither from currents in the fluid, nor from its gradual evaporation, but belonged to the particle itself.

ROBERT BROWN (1828)

6.1 Overview

6.1

In this chapter we analyze, among others, the following issues:

- What is the time evolution of the distribution function for an ensemble of systems that begins out of statistical equilibrium and is brought to equilibrium through contact with a heat bath?
- How can one characterize the noise introduced into experiments or observations by noisy devices, such as resistors and amplifiers?
- What is the influence of such noise on one's ability to detect weak signals?
- What filtering strategies will improve one's ability to extract weak signals from strong noise?
- Frictional damping of a dynamical system generally arises from coupling to many other degrees of freedom (a bath) that can sap the system's energy. What is the connection between the fluctuating (noise) forces that the bath exerts on the system and its damping influence?

The mathematical foundation for analyzing such issues is the *theory of random processes* (i.e., of functions that are random and unpredictable but have predictable probabilities for their behavior). A portion of the theory of random processes is the *theory of stochastic differential equations* (equations whose solutions are probability distributions rather than ordinary functions). This chapter is an overview of these topics, sprinkled throughout with applications.

In Sec. 6.2, we introduce the concept of random processes and the various probability distributions that describe them. We introduce restrictions that we shall adhere to—the random processes that we study are stationary and ergodic—and we introduce an example that we return to time and again: a *random-walk* process, of which *Brownian motion* is an example. In Sec. 6.3, we discuss two special classes of random processes: Markov processes and Gaussian processes; we also present two important theorems: the central limit theorem, which explains why random processes so often

BOX 6.1. READERS' GUIDE

- Relativity does not enter into this chapter.
- This chapter does not rely in any major way on previous chapters, but it does make occasional reference to results from Chaps. 4 and 5 about statistical equilibrium and fluctuations in and away from statistical equilibrium.
- No subsequent chapter relies in any major way on this chapter. However:
 - The concepts of spectral density and correlation function, developed in Sec. 6.4, will be used in Ex. 9.8 when treating coherence properties of radiation, in Sec. 11.9.2 when studying thermal noise in solids, in Sec. 15.4 when studying turbulence in fluids, in Sec. 23.2.1 in treating the quasilinear formalism for weak plasma turbulence, and in Sec. 28.6.1 when discussing observations of the anisotropy of the cosmic microwave background radiation.
 - The fluctuation-dissipation theorem, developed in Sec. 6.8, will be used in Sec. 11.9.2 for thermoelastic noise in solids, and in Sec. 12.5 for normal modes of an elastic body.
 - The Fokker-Planck equation, developed in Sec. 6.9, will be referred to or used in Secs. 20.4.3, 20.5.1, and 28.6.3 and Exs. 20.8 and 20.10 when discussing thermal equilibration in a plasma and thermoelectric transport coefficients, and it will be used in Sec. 23.3.3 in developing the quasilinear theory of wave-particle interactions in a plasma.

have Gaussian probability distributions, and Doob's theorem, which says that all the statistical properties of a Markov, Gaussian process are determined by just three parameters. In Sec. 6.4, we introduce two powerful mathematical tools for the analysis of random processes: the correlation function and spectral density, and prove the Wiener-Khinchine theorem, which relates them. As applications of these tools, we use them to prove Doob's theorem and to discuss optical spectra, noise in interferometric gravitational wave detectors, and fluctuations of cosmological mass density and of the distribution of galaxies in the universe. In Secs. 6.6 and 6.7, we introduce another powerful tool, the filtering of a random process, and we use these tools to develop the theory of noise and techniques for extracting weak signals from large noise. As applications we study shot noise (which is important, e.g., in measurements with laser light), frequency fluctuations of atomic clocks, and also the Brownian motion of a dust

particle buffeted by air molecules and its connection to random walks. In Sec. 6.8, we develop another powerful tool, the fluctuation-dissipation theorem, which quantifies the relationship between the fluctuations and the dissipation (friction) produced by one and the same heat bath. As examples, we explore Brownian motion (once again), Johnson noise in a resistor and the voltage fluctuations it produces in electric circuits, thermal noise in high-precision optical measurements, and quantum limits on the accuracy of high-precision measurements and how to circumvent them. Finally, in Sec. 6.9 we derive and discuss the Fokker-Planck equation, which governs the evolution of Markov random processes, and we illustrate it with the random motion of an atom that is being cooled by interaction with laser beams (so-called *optical molasses*) and with thermal noise in a harmonic oscillator.

6.2 Fundamental Concepts

6.2

In this section we introduce a number of fundamental concepts about random processes.

6.2.1 Random Variables and Random Processes

6.2.1

RANDOM VARIABLE

A (1-dimensional) *random variable* is a (scalar) function $y(t)$, where t is usually time, for which the future evolution is not determined uniquely by any set of initial data—or at least by any set that is knowable to you and me. In other words, *random variable* is just a fancy phrase that means “unpredictable function.” Throughout this chapter, we insist for simplicity that our random variables y take on a continuum of *real* values ranging over some interval, often but not always $-\infty$ to $+\infty$. The generalizations to y with complex or discrete (e.g., integer) values, and to independent variables other than time, are straightforward.

random variable

Examples of random variables are: (i) the total energy $E(t)$ in a cell of gas that is in contact with a heat bath; (ii) the temperature $T(t)$ at the corner of Main Street and Center Street in Logan, Utah; (iii) the price per share of Google stock $P(t)$; (iv) the mass-flow rate $\dot{M}(t)$ from the Amazon River into the Atlantic Ocean. One can also deal with random variables that are vector or tensor functions of time; in Track-Two portions of this chapter we do so.

RANDOM PROCESS

A (1-dimensional) *random process* (also called “stochastic process”) is an ensemble \mathcal{E} of real random variables $y(t)$ that, in a physics context, all represent the same kind of physical entity. For example, each $y(t)$ could be the longitude of a particular oxygen molecule undergoing a random walk in Earth’s atmosphere. The individual random variables $y(t)$ in the ensemble \mathcal{E} are often called *realizations* of the random process.

random process

As an example, Fig. 6.1 shows three realizations $y(t)$ of a random process that represents the random walk of a particle in one dimension. For details, see Ex. 6.4, which shows how to generate realizations like these on a computer.

FIGURE 6.1 Three different realizations $y(t)$ of a random process that describes the location y of a particle at time t , when it is undergoing a random walk in 1 dimension (e.g., an atmospheric oxygen molecule's east-west motion).

6.2.2 Probability Distributions

PROBABILITY DISTRIBUTIONS FOR A RANDOM PROCESS

Since the precise time evolution of a random variable $y(t)$ is not predictable, if one wishes to make predictions, one can do so only probabilistically. The foundation for probabilistic predictions is a set of probability functions for the random process (i.e., for the ensemble \mathcal{E} of its realizations).

More specifically, the most general (1-dimensional) random process is fully characterized by the set of probability distributions p_1, p_2, p_3, \dots defined as

$$p_n(y_n, t_n; \dots; y_2, t_2; y_1, t_1) dy_n \dots dy_2 dy_1. \quad (6.1)$$

probability distributions
for a random process

Equation (6.1) tells us the probability that a realization $y(t)$, drawn at random from the process (the ensemble \mathcal{E}), (i) will take on a value between y_1 and $y_1 + dy_1$ at time t_1 , (ii) also will take on a value between y_2 and $y_2 + dy_2$ at a later time t_2, \dots , and (iii) also will take on a value between y_n and $y_n + dy_n$ at a later time t_n . (Note that the subscript n on p_n tells us how many independent values of y appear in p_n , and that earlier times are placed to the right—a practice common for physicists, particularly when dealing with propagators.) If we knew the values of all the process's probability distributions (an infinite number of p_n s!), then we would have full information about its statistical properties. Not surprisingly, it will turn out that, if the process in some sense is in statistical equilibrium, then we can compute all its probability distributions from a very small amount of information. But that comes later; first we must develop more formalism.

ENSEMBLE AVERAGES

From the probability distributions, we can compute ensemble averages (denoted by brackets). For example, the quantities

$$\langle y(t_1) \rangle \equiv \int y_1 p_1(y_1, t_1) dy_1 \quad \text{and} \quad \sigma_y^2(t_1) \equiv \langle [y(t_1) - \langle y(t_1) \rangle]^2 \rangle \quad (6.2a)$$

ensemble average and variance

are the ensemble-averaged value of y and the variance of y at time t_1 . Similarly,

$$\langle y(t_2)y(t_1) \rangle \equiv \int y_2 y_1 p_2(y_2, t_2; y_1, t_1) dy_2 dy_1 \quad (6.2b)$$

is the average value of the product $y(t_2)y(t_1)$.

CONDITIONAL PROBABILITIES

Besides the (absolute) probability distributions p_n , we also find useful an infinite series of *conditional* probability distributions P_2, P_3, \dots , defined as

$$P_n(y_n, t_n | y_{n-1}, t_{n-1}; \dots; y_1, t_1) dy_n. \quad (6.3)$$

conditional probability distributions

This distribution is the probability that, *if* $y(t)$ took on the values y_1, y_2, \dots, y_{n-1} at times t_1, t_2, \dots, t_{n-1} , then it will take on a value between y_n and $y_n + dy_n$ at a later time t_n .

It should be obvious from the definitions of the probability distributions that

$$\begin{aligned} p_n(y_n, t_n; \dots; y_1, t_1) \\ = P_n(y_n, t_n | y_{n-1}, t_{n-1}; \dots; y_1, t_1) p_{n-1}(y_{n-1}, t_{n-1}; \dots; y_1, t_1). \end{aligned} \quad (6.4)$$

Using this relation, one can compute all the conditional probability distributions P_n from the absolute distributions p_1, p_2, \dots . Conversely, using this relation recursively, one can build up all the absolute probability distributions p_n from $p_1(y_1, t_1)$ and all the conditional distributions P_2, P_3, \dots .

STATIONARY RANDOM PROCESSES

A random process is said to be *stationary* if and only if its probability distributions p_n depend just on time differences and not on absolute time:

$$p_n(y_n, t_n + \tau; \dots; y_2, t_2 + \tau; y_1, t_1 + \tau) = p_n(y_n, t_n; \dots; y_2, t_2; y_1, t_1). \quad (6.5)$$

If this property holds for the absolute probabilities p_n , then Eq. (6.4) guarantees it also will hold for the conditional probabilities P_n .

Nonstationary random processes arise when one is studying a system whose evolution is influenced by some sort of clock that registers absolute time, not just time differences. For example, the speeds $v(t)$ of all oxygen molecules in downtown St. Anthony, Idaho, make up random processes regulated in part by the atmospheric temperature and therefore by the rotation of Earth and its orbital motion around the Sun. The

stationary random process

FIGURE 6.2 The probability $P_2(v_2, t_2|0, t_1)$ that a molecule with vanishing speed at time t_1 will have speed v_2 (in a unit interval dv_2) at time t_2 . Although the molecular speed is a stationary random process, this probability evolves in time.

influence of these clocks makes $v(t)$ a nonstationary random process. Stationary random processes, by contrast, arise in the absence of any regulating clocks. An example is the speeds $v(t)$ of all oxygen molecules in a room kept at constant temperature.

Stationarity does not mean “no time evolution of probability distributions.” For example, suppose one knows that the speed of a specific oxygen molecule vanishes at time t_1 , and one is interested in the probability that the molecule will have speed v_2 at time t_2 . That probability, $P_2(v_2, t_2|0, t_1)$, is sharply peaked around $v_2 = 0$ for extremely small time differences $t_2 - t_1$ and is Maxwellian for large time differences $t_2 - t_1$ (Fig. 6.2). Despite this evolution, the process is stationary (assuming constant temperature) in the sense that it does not depend on the specific time t_1 at which v happened to vanish, only on the time difference $t_2 - t_1$: $P_2(v_2, t_2|0, t_1) = P_2(v_2, t_2 - t_1|0, 0)$.

Henceforth, throughout this chapter, we restrict attention to random processes that are stationary (at least on the timescales of interest to us); and, accordingly, we use

$$p_1(y) \equiv p_1(y, t_1) \tag{6.6a}$$

for the probability, since it does not depend on the time t_1 . We also denote by

$$P_2(y_2, t|y_1) \equiv P_2(y_2, t|y_1, 0) \tag{6.6b}$$

the probability that, if a (realization of a) random process begins with the value y_1 , then after the lapse of time t it has the value y_2 .

6.2.3

ergodic hypothesis

6.2.3 Ergodic Hypothesis

A (stationary) random process (ensemble \mathcal{E} of random variables) is said to satisfy the *ergodic hypothesis* (or, for brevity, it will be called *ergodic*) if and only if it has the following property.

Let $y(t)$ be a random variable in the ensemble \mathcal{E} (i.e., let $y(t)$ be any realization of the process). Construct from $y(t)$ a new ensemble \mathcal{E}' whose members are

$$Y^K(t) \equiv y(t + KT), \quad (6.7)$$

where K runs over all integers, negative and positive, and where T is some very large time interval. Then \mathcal{E}' has the same probability distributions p_n as \mathcal{E} ; that is, $p_n(Y_n, t_n; \dots; Y_1, t_1)$ has the same functional form as $p_n(y_n, t_n; \dots; y_1, t_1)$ for all times such that $|t_i - t_j| < T$.

This is essentially the same ergodic hypothesis as we met in Sec. 4.6.

Henceforth we restrict attention to random processes that satisfy the ergodic hypothesis (i.e., that are ergodic). This, in principle, is a severe restriction. In practice, for a physicist, it is not severe at all. In physics one's objective, when defining random variables that last forever ($-\infty < t < +\infty$) and when introducing ensembles, is usually to acquire computational techniques for dealing with a single, or a small number of, random variables $y(t)$, studied over finite lengths of time. One acquires those techniques by defining conceptual infinite-duration random variables and ensembles in such a way that they satisfy the ergodic hypothesis.

As in Sec. 4.6, because of the ergodic hypothesis, time averages defined using any realization $y(t)$ of a random process are equal to ensemble averages:

$$\bar{F} \equiv \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} F(y(t)) dt = \langle F(y) \rangle \equiv \int F(y) p_1(y) dy, \quad (6.8)$$

for any function $F = F(y)$. In this sense, each realization of the random process is representative, when viewed over sufficiently long times, of the statistical properties of the process's entire ensemble—and conversely. Correspondingly, we can blur the distinction between the random process and specific realizations of it—and we often do so.

6.3 Markov Processes and Gaussian Processes

6.3

6.3.1 Markov Processes; Random Walk

6.3.1

A random process $y(t)$ is said to be *Markov* (also sometimes called “Markovian”) if and only if all of its future probabilities are determined by its most recently known value:

Markov random process

$$P_n(y_n, t_n | y_{n-1}, t_{n-1}; \dots; y_1, t_1) = P_2(y_n, t_n | y_{n-1}, t_{n-1}) \quad \text{for all } t_n \geq \dots \geq t_2 \geq t_1. \quad (6.9)$$

This relation guarantees that any Markov process (which, of course, we require to be stationary without saying so) is completely characterized by the probabilities

$$p_1(y) \text{ and } P_2(y_2, t | y_1) \equiv \frac{p_2(y_2, t; y_1, 0)}{p_1(y_1)}. \quad (6.10)$$

From $p_1(y)$ and $P_2(y_2, t|y_1)$ one can reconstruct, using the Markov relation (6.9) and the general relation (6.4) between conditional and absolute probabilities, all distribution functions of the process.

Actually, for any random process that satisfies the ergodic hypothesis (which means all random processes considered in this chapter), $p_1(y)$ is determined by the conditional probability $P_2(y_2, t|y_1)$ [Ex. 6.1], so for any Markov (and ergodic) process, all the probability distributions follow from $P_2(y_2, t|y_1)$ alone!

An example of a Markov process is the x component of velocity $v_x(t)$ of a dust particle in an arbitrarily large room,¹ filled with constant-temperature air. Why? Because the molecule's equation of motion is² $mdv_x/dt = F'_x(t)$, and the force $F'_x(t)$ is due to random buffeting by other molecules that are uncorrelated (the kick now is unrelated to earlier kicks); thus, there is no way for the value of v_x in the future to be influenced by any earlier values of v_x except the most recent one.

By contrast, the position $x(t)$ of the particle is not Markov, because the probabilities of future values of x depend not just on the initial value of x , but also on the initial velocity v_x —or, equivalently, the probabilities depend on the values of x at two initial, closely spaced times. The pair $\{x(t), v_x(t)\}$ is a 2-dimensional Markov process (see Ex. 6.23).

THE SMOLUCHOWSKI EQUATION

Choose three (arbitrary) times t_1, t_2 , and t_3 that are ordered, so $t_1 < t_2 < t_3$. Consider a (realization of an) arbitrary random process that begins with a known value y_1 at t_1 , and ask for the probability $P_2(y_3, t_3|y_1)$ (per unit y_3) that it will be at y_3 at time t_3 . Since the realization must go through some value y_2 at the intermediate time t_2 (though we don't care what that value is), it must be possible to write the probability to reach y_3 as

$$P_2(y_3, t_3|y_1, t_1) = \int P_3(y_3, t_3|y_2, t_2; y_1, t_1) P_2(y_2, t_2|y_1, t_1) dy_2,$$

where the integration is over all allowed values of y_2 . This is not a terribly interesting relation. Much more interesting is its specialization to the case of a Markov process. In that case $P_3(y_3, t_3|y_2, t_2; y_1, t_1)$ can be replaced by $P_2(y_3, t_3|y_2, t_2) = P_2(y_3, t_3 - t_2|y_2, 0) \equiv P_2(y_3, t_3 - t_2|y_2)$, and the result is an integral equation involving only P_2 . Because of stationarity, it is adequate to write that equation for the case $t_1 = 0$:

$$P_2(y_3, t_3|y_1) = \int P_2(y_3, t_3 - t_2|y_2) P_2(y_2, t_2|y_1) dy_2. \quad (6.11)$$

Smoluchowski equation

This is the *Smoluchowski equation* (also called *Chapman-Kolmogorov equation*). It is valid for any Markov random process and for times $0 < t_2 < t_3$. We shall discover its power in our derivation of the Fokker-Planck equation in Sec. 6.9.1.

1. The room must be arbitrarily large so the effects of the floor, walls, and ceiling can be ignored.
2. By convention, primes are used to identify stochastic forces (i.e., forces that are random processes).

Exercise 6.1 ***Example: Limits of P_2*

Explain why, for any (stationary) random process,

$$\lim_{t \rightarrow 0} P_2(y_2, t | y_1) = \delta(y_2 - y_1). \quad (6.12a)$$

Use the ergodic hypothesis to argue that

$$\lim_{t \rightarrow \infty} P_2(y_2, t | y_1) = p_1(y_2). \quad (6.12b)$$

Thereby conclude that, for a Markov process, all the probability distributions are determined by the conditional probability $P_2(y_2, t | y_1)$. Give an algorithm for computing them.

Exercise 6.2 *Practice: Markov Processes for an Oscillator*

Consider a harmonic oscillator (e.g., a pendulum), driven by bombardment with air molecules. Explain why the oscillator's position $x(t)$ and velocity $v(t) = dx/dt$ are random processes. Is $x(t)$ Markov? Why? Is $v(t)$ Markov? Why? Is the pair $\{x(t), v(t)\}$ a 2-dimensional Markov process? Why? We study this 2-dimensional random process in Ex. 6.23.

Exercise 6.3 ***Example: Diffusion of a Particle; Random Walk*

In Ex. 3.17, we studied the diffusion of particles through an infinite 3-dimensional medium. By solving the diffusion equation, we found that, if the particles' number density at time $t = 0$ was $n_o(\mathbf{x})$, then at time t it has become

$$n(\mathbf{x}, t) = [1/(4\pi Dt)]^{3/2} \int n_o(\mathbf{x}') e^{-(\mathbf{x}-\mathbf{x}')^2/(4Dt)} d^3x',$$

where D is the diffusion coefficient [Eq. (3.73)].

- (a) For any one of the diffusing particles, the location $y(t)$ in the y direction (one of three Cartesian directions) is a 1-dimensional random process. From the above $n(\mathbf{x}, t)$, infer that the conditional probability distribution for y is

$$P_2(y_2, t | y_1) = \frac{1}{\sqrt{4\pi Dt}} e^{-(y_2 - y_1)^2/(4Dt)}. \quad (6.13)$$

- (b) Verify that the conditional probability (6.13) satisfies the Smoluchowski equation (6.11). [Hint: Consider using symbol-manipulation computer software that quickly can do straightforward calculations like this.]

At first this may seem surprising, since a particle's position y is not Markov. However (as we explore explicitly in Sec. 6.7.2), the diffusion equation from which we derived this P_2 treats as negligibly small the timescale τ_r on which the velocity dy/dt thermalizes. It thereby wipes out all information about what the particle's actual velocity is, making y effectively Markov, and forcing its P_2 to

satisfy the Smoluchowski equation. See Ex. 6.10, where we shall also discover that this diffusion is an example of a random walk.

6.3.2

6.3.2 Gaussian Processes and the Central Limit Theorem; Random Walk

GAUSSIAN PROCESSES

Gaussian random process

A random process is said to be Gaussian if and only if all of its (absolute) probability distributions are Gaussian (i.e., have the following form):

$$p_n(y_n, t_n; \dots; y_2, t_2; y_1, t_1) = A \exp \left[- \sum_{j=1}^n \sum_{k=1}^n \alpha_{jk} (y_j - \bar{y})(y_k - \bar{y}) \right], \quad (6.14a)$$

where (i) A and α_{jk} depend only on the time differences $t_2 - t_1, t_3 - t_1, \dots, t_n - t_1$; (ii) A is a positive normalization constant; (iii) $[\alpha_{jk}]$ is a *positive-definite*, symmetric matrix (otherwise p_n would not be normalizable); and (iv) \bar{y} is a constant, which one readily can show is equal to the ensemble average of y ,

$$\bar{y} \equiv \langle y \rangle = \int y p_1(y) dy. \quad (6.14b)$$

Since the conditional probabilities are all computable as ratios of absolute probabilities [Eq. (6.4)], the conditional probabilities of a Gaussian process will be Gaussian.

Gaussian random processes are very common in physics. For example, the total number of particles $N(t)$ in a gas cell that is in statistical equilibrium with a heat bath is a Gaussian random process (Ex. 5.11d); and the primordial fluctuations that gave rise to structure in our universe appear to have been Gaussian (Sec. 28.5.3). In fact, as we saw in Sec. 5.6, macroscopic variables that characterize huge systems in statistical equilibrium always have Gaussian probability distributions. The underlying reason is that, *when a random process is driven by a large number of statistically independent, random influences, its probability distributions become Gaussian*. This general fact is a consequence of the *central limit theorem* of probability. We state and prove a simple variant of this theorem.

CENTRAL LIMIT THEOREM (A SIMPLE VERSION)

central limit theorem

Let y be a random quantity [not necessarily a random variable $y(t)$; there need not be any times involved; however, our applications will be to random variables]. Suppose that y is characterized by an arbitrary probability distribution $p(y)$ (e.g., that of Fig. 6.3a), so the probability of the quantity taking on a value between y and $y + dy$ is $p(y)dy$. Denote by \bar{y} the mean value of y , and by σ_y its standard deviation (also called its rms fluctuation and the square root of its variance):

$$\bar{y} \equiv \langle y \rangle = \int y p(y) dy, \quad (\sigma_y)^2 \equiv \langle (y - \bar{y})^2 \rangle = \langle y^2 \rangle - \bar{y}^2. \quad (6.15a)$$

Randomly draw from this distribution a large number N of values $\{y_1, y_2, \dots, y_N\}$, and average them to get a number

FIGURE 6.3 Example of the central limit theorem. (a) The random variable y with the probability distribution $p(y)$. (b) This variable produces, for various values of N , the variable $Y = (y_1 + \cdots + y_N)/N$ with the probability distributions $p(Y)$. In the limit of very large N , $p(Y)$ is a Gaussian.

$$Y \equiv \frac{1}{N} \sum_{i=1}^N y_i. \quad (6.15b)$$

Repeat this process many times, and examine the resulting probability distribution for Y . In the limit of arbitrarily large N , that distribution will be Gaussian with mean and standard deviation

$$\bar{Y} = \bar{y} \quad \text{and} \quad \sigma_Y = \frac{\sigma_y}{\sqrt{N}}, \quad (6.15c)$$

that is, it will have the form

$$p(Y) = \frac{1}{\sqrt{2\pi\sigma_Y^2}} \exp\left[-\frac{(Y - \bar{Y})^2}{2\sigma_Y^2}\right], \quad (6.15d)$$

with \bar{Y} and σ_Y given by Eq. (6.15c). See Fig. 6.3b.

Proof of Central Limit Theorem. The key to proving this theorem is the Fourier transform of the probability distribution. (That Fourier transform is called the distribution's *characteristic function*, but in this chapter we do not delve into the details of characteristic functions.) Denote the Fourier transform of $p(y)$ by³

$$\tilde{p}_y(f) \equiv \int_{-\infty}^{+\infty} e^{i2\pi fy} p(y) dy = \sum_{n=0}^{\infty} \frac{(i2\pi f)^n}{n!} \langle y^n \rangle. \quad (6.16a)$$

The second expression follows from a power series expansion of $e^{i2\pi fy}$ in the first. Similarly, since a power series expansion analogous to Eq. (6.16a) must hold for $\tilde{p}_Y(f)$ and since $\langle Y^n \rangle$ can be computed from

$$\begin{aligned} \langle Y^n \rangle &= \langle N^{-n} (y_1 + y_2 + \cdots + y_N)^n \rangle \\ &= \int N^{-n} (y_1 + \cdots + y_N)^n p(y_1) \cdots p(y_N) dy_1 \cdots dy_N, \end{aligned} \quad (6.16b)$$

3. See the beginning of Sec. 6.4.2 for the conventions we use for Fourier transforms.

it must be that

$$\begin{aligned}
 \tilde{p}_Y(f) &= \sum_{n=0}^{\infty} \frac{(i2\pi f)^n}{n!} \langle Y^n \rangle \\
 &= \int \exp[i2\pi f N^{-1}(y_1 + \cdots + y_N)] p(y_1) \cdots p(y_N) dy_1 \cdots dy_n \\
 &= \left[\int e^{i2\pi f y/N} p(y) dy \right]^N = \left[1 + \frac{i2\pi f \bar{y}}{N} - \frac{(2\pi f)^2 \langle y^2 \rangle}{2N^2} + O\left(\frac{1}{N^3}\right) \right]^N \\
 &= \exp\left[i2\pi f \bar{y} - \frac{(2\pi f)^2 (\langle y^2 \rangle - \bar{y}^2)}{2N} + O\left(\frac{1}{N^2}\right) \right]. \tag{6.16c}
 \end{aligned}$$

Here the last equality can be obtained by taking the logarithm of the preceding quantity, expanding in powers of $1/N$, and then exponentiating. By inverting the Fourier transform (6.16c) and using $(\sigma_y)^2 = \langle y^2 \rangle - \bar{y}^2$, we obtain for $p(Y)$ the Gaussian (6.15d). ■

This proof is a good example of the power of Fourier transforms, a power that we exploit extensively in this chapter. As an important example to which we shall return later, Ex. 6.4 analyzes the simplest version of a random walk.

EXERCISES

Exercise 6.4 ***Example: Random Walk with Discrete Steps of Identical Length*

This exercise is designed to make the concept of random processes more familiar and also to illustrate the central limit theorem.

A particle travels in 1 dimension, along the y axis, making a sequence of steps Δy_j (labeled by the integer j), each of which is $\Delta y_j = +1$ with probability $1/2$, or $\Delta y_j = -1$ with probability $1/2$.

- After $N \gg 1$ steps, the particle has reached location $y(N) = y(0) + \sum_{j=1}^N \Delta y_j$. What does the central limit theorem predict for the probability distribution of $y(N)$? What are its mean and its standard deviation?
- Viewed on lengthscales $\gg 1$, $y(N)$ looks like a continuous random process, so we shall rename $N \equiv t$. Using the (pseudo)random number generator from your favorite computer software language, compute a few concrete realizations of $y(t)$ for $0 < t < 10^4$ and plot them.⁴ Figure 6.1 above shows one realization of this random process.
- Explain why this random process is Markov.

4. If you use Mathematica, the command `RandomInteger[]` generates a pseudorandom number that is 0 with probability $1/2$ or 1 with probability $1/2$. Therefore, the following simple script will carry out the desired computation: `y = Table[0, {10000}]; For[t = 1, t < 10000, t++, y[[t + 1]] = y[[t]] + 2 RandomInteger[] - 1]; ListPlot[y, Joined -> True]`. This was used to generate Fig. 6.1.

- (d) Use the central limit theorem to infer that the conditional probability P_2 for this random process is

$$P_2(y_2, t|y_1) = \frac{1}{\sqrt{2\pi t}} \exp \left[-\frac{(y_2 - y_1)^2}{2t} \right]. \quad (6.17)$$

- (e) Notice that this is the same probability distribution as we encountered in the diffusion exercise (Ex. 6.3) but with $D = 1/2$. Why did this have to be the case?
- (f) Using an extension of the computer program you wrote in part (b), evaluate $y(t = 10^4)$ for 1,000 realizations of this random process, each with $y(0) = 0$, then bin the results in bins of width $\delta y = 10$, and plot the number of realizations $y(10^4)$ that wind up in each bin. Repeat for 10,000 realizations. Compare your plots with the probability distribution (6.17).

6.3.3 Doob's Theorem for Gaussian-Markov Processes, and Brownian Motion

A large fraction of the random processes that one meets in physics are Gaussian, and many are Markov. Therefore, the following remarkable theorem is very important. *Any 1-dimensional random process $y(t)$ that is both Gaussian and Markov has the following form for its conditional probability distribution P_2 :*

$$P_2(y_2, t|y_1) = \frac{1}{[2\pi\sigma_{y_t}^2]^{\frac{1}{2}}} \exp \left[-\frac{(y_2 - \bar{y}_t)^2}{2\sigma_{y_t}^2} \right], \quad (6.18a)$$

where the mean \bar{y}_t and variance $\sigma_{y_t}^2$ at time t are given by

$$\bar{y}_t = \bar{y} + e^{-t/\tau_r}(y_1 - \bar{y}), \quad \sigma_{y_t}^2 = (1 - e^{-2t/\tau_r})\sigma_y^2. \quad (6.18b)$$

Here \bar{y} and σ_y^2 are respectively the process's equilibrium mean and variance (the values at $t \rightarrow \infty$), and τ_r is its *relaxation time*. This result is *Doob's theorem*.⁵ We shall prove it in Ex. 6.5, after we have developed some necessary tools.

Note the great power of Doob's theorem: Because $y(t)$ is Markov, all of its probability distributions are computable from this P_2 (Ex. 6.1), which in turn is determined by \bar{y} , σ_y , and τ_r . Correspondingly, all statistical properties of a Gaussian-Markov process are determined by just three parameters: its (equilibrium) mean \bar{y} and variance σ_y^2 ,

5. It is so named because it was first formulated and proved by J. L. Doob (1942).

6.3.3

Doob's theorem

FIGURE 6.4 Evolution of the conditional probability $P_2(y_2, t|y_1)$ for a Gaussian-Markov random process [Eq. (6.18a)], as predicted by Doob's theorem. The correlation function and spectral density for this process are shown later in the chapter in Fig. 6.8.

and its relaxation time τ_r . As an example, the first absolute probability distribution is

$$p_1(y) = \lim_{t \rightarrow \infty} P_2(y, t|y_1) = \frac{1}{\sqrt{2\pi\sigma_y^2}} \exp\left[-\frac{(y - \bar{y})^2}{2\sigma_y^2}\right]. \quad (6.18c)$$

The time evolution of P_2 [Eqs. (6.18a,b)] is plotted in Fig. 6.4. At $t = 0$ it is a delta function at y_1 , in accord with Eq. (6.12a). As t increases, its peak (its mean) moves toward \bar{y} , and it spreads out. Ultimately, at $t = \infty$, its peak asymptotes to \bar{y} , and its standard deviation (half-width) asymptotes to σ_y , so $P_2 \rightarrow p_1$ —in accord with Eqs. (6.12b) and (6.18c).

Brownian motion

An example that we explore in Sec. 6.7.2 is a dust particle being buffeted by air molecules in a large, constant-temperature room (Brownian motion). As we discussed near the beginning of Sec. 6.3.1, any Cartesian component v of the dust particle's velocity is a Markov process. It is also Gaussian (because its evolution is influenced solely by the independent forces of collisions with a huge number of independent air molecules), so $P_2(v, t|v_1)$ is given by Doob's theorem. In equilibrium, positive and negative values of the Cartesian velocity component v are equally probable, so $\bar{v} = 0$, which means that $\frac{1}{2}m\sigma_v^2 = \frac{1}{2}m\bar{v}^2$, which is the equilibrium mean kinetic energy—a quantity we know to be $\frac{1}{2}k_B T$ from the equipartition theorem (Sec. 4.4.4); thus, $\bar{v} = 0$, and $\sigma_v = \sqrt{k_B T/m}$. The relaxation time τ_r is the time required for the particle to change its velocity substantially, due to collisions with air molecules; we compute it in Sec. 6.8.1 using the fluctuation-dissipation theorem; see Eq. (6.78).

6.4 Correlation Functions and Spectral Densities

6.4

6.4.1 Correlation Functions; Proof of Doob's Theorem

6.4.1

Let $y(t)$ be a (realization of a) random process with time average \bar{y} . Then the correlation function of $y(t)$ is defined by

$$C_y(\tau) \equiv \overline{[y(t) - \bar{y}][y(t + \tau) - \bar{y}]} \equiv \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{+T/2} [y(t) - \bar{y}][y(t + \tau) - \bar{y}] dt.$$

(6.19)

correlation function

This quantity, as its name suggests, is a measure of the extent to which the values of y at times t and $t + \tau$ tend to be correlated. The quantity τ is sometimes called the *delay time*, and by convention it is taken to be positive. [One can easily see that, if one also defines $C_y(\tau)$ for negative delay times τ by Eq. (6.19), then $C_y(-\tau) = C_y(\tau)$. Thus nothing is lost by restricting attention to positive delay times.]

As an example, for a Gaussian-Markov process with P_2 given by Doob's formula (6.18a) (Fig. 6.4), we can compute $C(\tau)$ by replacing the time average in Eq. (6.19) with an ensemble average: $C_y(\tau) = \int y_2 y_1 p_2(y_2, \tau; y_1) dy_1 dy_2$. If we use $p_2(y_2, \tau; y_1) = P_2(y_2, \tau; y_1) p_1(y_1)$ [Eq. (6.10)], insert P_2 and p_1 from Eqs. (6.18), and perform the integrals, we obtain

$$C_y(\tau) = \sigma_y^2 e^{-\tau/\tau_r}.$$

(6.20)

This correlation function has two properties that are quite general:

1. The following is true for all (ergodic and stationary) random processes:

$$C_y(0) = \sigma_y^2,$$

(6.21a)

as one can see by replacing time averages with ensemble averages in definition (6.19); in particular, $C_y(0) \equiv \overline{(y - \bar{y})^2} = \langle (y - \bar{y})^2 \rangle$, which by definition is the variance σ_y^2 of y .

2. In addition, we have that

$$C_y(\tau) \text{ asymptotes to zero for } \tau \gg \tau_r,$$

(6.21b)

where τ_r is the process's *relaxation time* or *correlation time* (see Fig. 6.5). This is true for all ergodic, stationary random processes, since our definition of ergodicity in Sec. 6.2.3 relies on each realization $y(t)$ losing its memory of earlier values after some sufficiently long time T . Otherwise, it would not be possible to construct the ensemble \mathcal{E}' of random variables $Y^K(t)$ [Eq. (6.7)] and have them behave like independent random variables.

properties of correlation function

relaxation time

FIGURE 6.5 Properties (6.21) of correlation functions.

As an example of how one can use correlation functions, in Ex. 6.5 we use them to prove Doob's theorem.

EXERCISES

Exercise 6.5 Derivation: Proof of Doob's Theorem

Prove Doob's theorem. More specifically, for any Gaussian-Markov random process, show that $P_2(y_2, t|y_1)$ is given by Eqs. (6.18a,b).

[Hint: For ease of notation, set $y_{\text{new}} = (y_{\text{old}} - \bar{y}_{\text{old}})/\sigma_{y_{\text{old}}}$, so $\bar{y}_{\text{new}} = 0$ and $\sigma_{y_{\text{new}}} = 1$. If the theorem is true for y_{new} , then by the rescalings inherent in the definition of $P_2(y_2, t|y_1)$, it will also be true for y_{old} .]

(a) Show that the Gaussian process y_{new} has probability distributions

$$p_1(y) = \frac{1}{\sqrt{2\pi}} e^{-y^2/2}, \quad (6.22a)$$

$$p_2(y_2, t_2; y_1, t_1) = \frac{1}{\sqrt{(2\pi)^2(1 - C_{21}^2)}} \exp\left[-\frac{y_1^2 + y_2^2 - 2C_{21}y_1y_2}{2(1 - C_{21}^2)}\right]; \quad (6.22b)$$

and show that the constant C_{21} that appears here is the correlation function $C_{21} = C_y(t_2 - t_1)$.

(b) From the relationship between absolute and conditional probabilities [Eq. (6.4)], show that

$$P_2(y_2, t_2|y_1, t_1) = \frac{1}{\sqrt{2\pi(1 - C_{21}^2)}} \exp\left[-\frac{(y_2 - C_{21}y_1)^2}{2(1 - C_{21}^2)}\right]. \quad (6.22c)$$

(c) Show that for any three times $t_3 > t_2 > t_1$,

$$C_{31} = C_{32}C_{21}; \quad \text{i.e.,} \quad C_y(t_3 - t_1) = C_y(t_3 - t_2)C_y(t_2 - t_1). \quad (6.22d)$$

To show this, you could (i) use the relationship between absolute and conditional probabilities and the Markov nature of the random process to infer that

$$\begin{aligned} p_3(y_3, t_3; y_2, t_2; y_1, t_1) &= P_3(y_3, t_3|y_2, t_2; y_1, t_1)p_2(y_2, t_2; y_1, t_1) \\ &= P_2(y_3, t_3|y_2, t_2)p_2(y_2, t_2; y_1, t_1); \end{aligned}$$

then (ii) compute the last expression explicitly, getting

$$\frac{1}{\sqrt{2\pi(1-C_{32}^2)}} \exp\left[-\frac{(y_3 - C_{32}y_2)^2}{2(1-C_{32}^2)}\right] \\ \times \frac{1}{\sqrt{(2\pi)^2(1-C_{21}^2)}} \exp\left[-\frac{(y_1^2 + y_2^2 - 2C_{21}y_1y_2)}{2(1-C_{21}^2)}\right];$$

(iii) then using this expression, evaluate

$$C_y(t_3 - t_1) \equiv C_{31} \equiv \langle y(t_3)y(t_1) \rangle = \int p_3(y_3, t_3; y_2, t_2; y_1, t_1) y_3 y_1 dy_3 dy_2 dy_1. \quad (6.22e)$$

The result should be $C_{31} = C_{32}C_{21}$.

- (d) Argue that the unique solution to this equation, with the “initial condition” that $C_y(0) = \sigma_y^2 = 1$, is $C_y(\tau) = e^{-\tau/\tau_r}$, where τ_r is a constant (which we identify as the relaxation time). Correspondingly, $C_{21} = e^{-(t_2-t_1)/\tau_r}$.
- (e) By inserting this expression into Eq. (6.22c), complete the proof for $y_{\text{new}}(t)$, and thence conclude that Doob’s theorem is also true for our original, unrescaled $y_{\text{old}}(t)$.

6.4.2 Spectral Densities

6.4.2

There are several different normalization conventions for Fourier transforms. In this chapter, we adopt a normalization that is commonly (though not always) used in the theory of random processes and that differs from the one common in quantum theory. Specifically, instead of using the angular frequency ω , we use the ordinary frequency $f \equiv \omega/(2\pi)$. We define the Fourier transform of a function $y(t)$ and its inverse by

$$\tilde{y}(f) \equiv \int_{-\infty}^{+\infty} y(t) e^{i2\pi f t} dt, \quad y(t) \equiv \int_{-\infty}^{+\infty} \tilde{y}(f) e^{-i2\pi f t} df. \quad (6.23)$$

Fourier transform

Notice that with this set of conventions, there are no factors of $1/(2\pi)$ or $1/\sqrt{2\pi}$ multiplying the integrals. Those factors have been absorbed into the df of Eq. (6.23), since $df = d\omega/(2\pi)$.

The integrals in Eq. (6.23) are not well defined as written because a random process $y(t)$ is generally presumed to go on forever so its Fourier transform $\tilde{y}(f)$ is divergent. One gets around this problem by crude trickery. From $y(t)$ construct, by truncation, the function

$$y_T(t) \equiv \begin{cases} y(t) & \text{if } -T/2 < t < +T/2, \\ 0 & \text{otherwise.} \end{cases} \quad (6.24a)$$

Then the Fourier transform $\tilde{y}_T(f)$ is finite, and by Parseval's theorem (e.g., Arfken, Weber, and Harris, 2013) it satisfies

$$\int_{-T/2}^{+T/2} [y(t)]^2 dt = \int_{-\infty}^{+\infty} [y_T(t)]^2 dt = \int_{-\infty}^{+\infty} |\tilde{y}_T(f)|^2 df = 2 \int_0^{\infty} |\tilde{y}_T(f)|^2 df. \quad (6.24b)$$

In the last equality we have used the fact that because $y_T(t)$ is real, $\tilde{y}_T^*(f) = \tilde{y}_T(-f)$, where $*$ denotes complex conjugation. Consequently, the integral from $-\infty$ to 0 of $|\tilde{y}_T(f)|^2$ is the same as the integral from 0 to $+\infty$. Now, the quantities on the two sides of (6.24b) diverge in the limit as $T \rightarrow \infty$, and it is obvious from the left-hand side that they diverge linearly as T . Correspondingly, the limit

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{+T/2} [y(t)]^2 dt = \lim_{T \rightarrow \infty} \frac{2}{T} \int_0^{\infty} |\tilde{y}_T(f)|^2 df \quad (6.24c)$$

is convergent.

These considerations motivate the following definition of the *spectral density* (also sometimes called the *power spectrum*) $S_y(f)$ of the random process $y(t)$:

spectral density

$$S_y(f) \equiv \lim_{T \rightarrow \infty} \frac{2}{T} \left| \int_{-T/2}^{+T/2} [y(t) - \bar{y}] e^{i2\pi f t} dt \right|^2. \quad (6.25)$$

Notice that the quantity inside the absolute value sign is just $\tilde{y}_T(f)$, but with the mean of y removed before computation of the Fourier transform. (The mean is removed to avoid an uninteresting delta function in $S_y(f)$ at zero frequency.) Correspondingly, by virtue of our motivating result (6.24c), the spectral density satisfies $\int_0^{\infty} S_y(f) df = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{+T/2} [y(t) - \bar{y}]^2 dt = \overline{(y - \bar{y})^2} = \sigma_y^2$, or

integral of spectral density

$$\int_0^{\infty} S_y(f) df = C_y(0) = \sigma_y^2. \quad (6.26)$$

Thus the integral of the spectral density of y over all positive frequencies is equal to the variance of y .

By convention, our spectral density is defined only for nonnegative frequencies f . This is because, were we to define it also for negative frequencies, the fact that $y(t)$ is real would imply that $S_y(f) = S_y(-f)$, so the negative frequencies contain no new information. Our insistence that f be positive goes hand in hand with the factor 2 in the $2/T$ of definition (6.25): that factor 2 folds the negative-frequency part onto the positive-frequency part. This choice of convention is called the *single-sided spectral density*. Sometimes one encounters a *double-sided spectral density*,

$$S_y^{\text{double-sided}}(f) = \frac{1}{2} S_y(|f|), \quad (6.27)$$

in which f is regarded as both positive and negative, and frequency integrals generally run from $-\infty$ to $+\infty$ instead of 0 to ∞ (see, e.g., Ex. 6.7).

FIGURE 6.6 A spectrum obtained by sending light through a diffraction grating. The intensity of the image is proportional to $d\mathcal{E}/dtdf$, which, in turn, is proportional to the spectral density $S_E(f)$ of the electric field $E(t)$ of the light that entered the diffraction grating.

Notice that the spectral density has units of y^2 per unit frequency; or, more colloquially (since frequency f is usually measured in Hertz, i.e., cycles per second), its units are y^2/Hz .

6.4.3 Physical Meaning of Spectral Density, Light Spectra, and Noise in a Gravitational Wave Detector

6.4.3

We can infer the physical meaning of the spectral density from previous experience with light spectra. Specifically, consider the scalar electric field⁶ $E(t)$ of a plane-polarized light wave entering a telescope from a distant star, galaxy, or nebula. (We must multiply this $E(t)$ by the polarization vector to get the vectorial electric field.) This $E(t)$ is a superposition of emission from an enormous number of atoms, molecules, and high-energy particles in the source, so it is a Gaussian random process. It is not hard to convince oneself that $E(t)$'s spectral density $S_E(f)$ is proportional to the light power per unit frequency $d\mathcal{E}/dtdf$ (the light's power spectrum) entering the telescope. When we send the light through a diffraction grating, we get this power spectrum spread out as a function of frequency f in the form of spectral lines superposed on a continuum, as in Fig. 6.6. The amount of light power in this spectrum, in some narrow bandwidth Δf centered on some frequency f , is $(d\mathcal{E}/dtdf)\Delta f \propto S_E(f)\Delta f$ (assuming S_E is nearly constant over that band).

Another way to understand this role of the spectral density $S_E(f)$ is by examining the equation for the variance of the oscillating electric field E as an integral over frequency, $\sigma_E^2 = \int_0^\infty S_E(f)df$. If we filter the light so only that portion at frequency f , in a very narrow bandwidth Δf , gets through the filter, then the variance of the filtered, oscillating electric field will obviously be the portion of the integral coming from this frequency band. The rms value of the filtered electric field will be the square root of this—and similarly for any other random process $y(t)$:

$$\left(\begin{array}{c} \text{rms value of } y\text{'s oscillations} \\ \text{at frequency } f \text{ in a very narrow bandwidth } \Delta f \end{array} \right) \simeq \sqrt{S_y(f)\Delta f}. \quad (6.28)$$

rms oscillation

6. In this section, and only here, E represents the electric field rather than (nonrelativistic) energy.

FIGURE 6.7 The square root of the spectral density of the time-varying arm-length difference $\xi(t) = L_1 - L_2$ (see inset), in the Laser Interferometer Gravitational-wave Observatory (LIGO) interferometer at Hanford, Washington, as measured on February 22, 2010. See Sec. 9.5 and Fig. 9.13. The dark blue curve is the noise that was specified as this instrument's goal. The narrow spectral lines (sharp spikes in the spectrum produced by internal resonances in the instrument) contain negligible power, and so can be ignored for our purposes. At high frequencies, $f \gtrsim 150$ Hz, the noise is due to randomness in arrival times of photons used to measure the mirror motions (photon shot noise, Sec. 6.7.4). At intermediate frequencies, $40 \text{ Hz} \lesssim f \lesssim 150$ Hz, it is primarily thermal noise (end of Sec. 6.8.2). At low frequencies, $f \lesssim 40$ Hz, it is primarily mechanical vibrations that sneak through a vibration isolation system ("seismic" noise).

(In Sec. 6.7.1, we develop a mathematical formalism to describe this type of filtering).

As a practical example, consider the output of an interferometric gravitational wave detector (to be further discussed in Secs. 9.5 and 27.6). The gravitational waves from some distant source (e.g., two colliding black holes) push two mirrors (hanging by wires) back and forth with respect to each other. Laser interferometry is used to monitor the difference $\xi(t) = L_1 - L_2$ between the two arm lengths. (Here L_1 is the separation between the mirrors in one arm of the interferometer, and L_2 is that in the other arm; see inset in Fig. 6.7.) The measured $\xi(t)$ is influenced by noise in the instrument as well as by gravitational waves. Figure 6.7 shows the square root of the spectral density of the noise-induced fluctuations in $\xi(t)$. Note that this $\sqrt{S_\xi(f)}$ has units of meters/ $\sqrt{\text{Hertz}}$ (since ξ has units of meters).

The minimum of the noise power spectrum is at $f \simeq 150$ Hz. If one is searching amidst this noise for a broadband gravitational-wave signal, then one might filter the interferometer output so one's data analysis sees only a frequency band of order the frequency of interest: $\Delta f \simeq f$. Then the rms noise in this band will be $\sqrt{S_\xi(f) \times f} \simeq 10^{-19} \text{ m}/\sqrt{\text{Hz}} \times \sqrt{150 \text{ Hz}} \simeq 10^{-18} \text{ m}$, which is $\sim 1/1,000$ the diameter of a proton. If a gravitational wave with frequency ~ 150 Hz changes the mirrors' separations by much more than this miniscule amount, it should be detectable!

6.4.4 The Wiener-Khintchine Theorem; Cosmological Density Fluctuations

6.4.4

The Wiener-Khintchine theorem says that, for any random process $y(t)$, the correlation function $C_y(\tau)$ and the spectral density $S_y(f)$ are the cosine transforms of each other and thus contain precisely the same information:

Wiener-Khintchine theorem

$$C_y(\tau) = \int_0^{\infty} S_y(f) \cos(2\pi f \tau) df, \quad S_y(f) = 4 \int_0^{\infty} C_y(\tau) \cos(2\pi f \tau) d\tau.$$

(6.29)

The factor 4 results from our folding negative frequencies into positive in our definition of the spectral density.

Proof of Wiener-Khintchine Theorem. This theorem is readily proved as a consequence of Parseval's theorem: Assume, from the outset, that the mean has been subtracted from $y(t)$, so $\bar{y} = 0$. (This is not really a restriction on the proof, since C_y and S_y are insensitive to the mean of y .) Denote by $y_T(t)$ the truncated y of Eq. (6.24a) and by $\tilde{y}_T(f)$ its Fourier transform. Then the generalization of Parseval's theorem⁷

$$\int_{-\infty}^{+\infty} (gh^* + hg^*) dt = \int_{-\infty}^{+\infty} (\tilde{g}\tilde{h}^* + \tilde{h}\tilde{g}^*) df \quad (6.30a)$$

[with $g = y_T(t)$ and $h = y_T(t + \tau)$ both real and with $\tilde{g} = \tilde{y}_T(f)$, $\tilde{h} = \tilde{y}_T(f)e^{-i2\pi f\tau}$], states

$$\int_{-\infty}^{+\infty} y_T(t)y_T(t + \tau) dt = \int_{-\infty}^{+\infty} \tilde{y}_T^*(f)\tilde{y}_T(f)e^{-i2\pi f\tau} df. \quad (6.30b)$$

By dividing by T , taking the limit as $T \rightarrow \infty$, and using Eqs. (6.19) and (6.25), we obtain the first equality of Eqs. (6.29). The second follows from the first by Fourier inversion. ■

The Wiener-Khintchine theorem implies (Ex. 6.6) the following formula for the ensemble averaged self-product of the Fourier transform of the random process $y(t)$:

spectral density as mean square of random process's Fourier transform

$$2\langle \tilde{y}(f)\tilde{y}^*(f') \rangle = S_y(f)\delta(f - f'). \quad (6.31)$$

This equation quantifies the strength of the infinite value of $|\tilde{y}(f)|^2$, which motivated our definition (6.25) of the spectral density.

As an application of the Wiener-Khintchine theorem, we can deduce the spectral density $S_y(f)$ for any Gaussian-Markov process by performing the cosine transform of its correlation function $C_y(\tau) = \sigma_y^2 e^{-\tau/\tau_r}$ [Eq. (6.20)]. The result is

$$S_y(f) = \frac{(4/\tau_r)\sigma_y^2}{(2\pi f)^2 + (1/\tau_r)^2}; \quad (6.32)$$

see Fig. 6.8.

7. This follows by subtracting Parseval's theorem for g and for h from Parseval's theorem for $g + h$.

FIGURE 6.8 (a) The correlation function (6.20) and (b) the spectral density (6.32) for a Gaussian-Markov process. The conditional probability $P_2(y_2, \tau | y_1)$ for this process is shown in Fig. 6.4.

As a second application, in Ex. 6.7 we explore fluctuations in the density of galaxies in the universe, caused by gravity pulling them into clusters.

EXERCISES

Exercise 6.6 Derivation: Spectral Density as the Mean Square of Random Process's Fourier Transform

Derive Eq. (6.31).

[Hint: Write $\langle \tilde{y}(f) \tilde{y}^*(f') \rangle = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \langle y(t) y(t') \rangle e^{i2\pi f t} e^{-i2\pi f' t'} dt dt'$. Then set $t' = t + \tau$, and express the expectation value as $C_y(\tau)$, and use an expression for the Dirac delta function in terms of Fourier transforms.]

Exercise 6.7 **Example: Cosmological Density Fluctuations⁸

Random processes can be stochastic functions of some variable or variables other than time. For example, it is conventional to describe fractional fluctuations in the large-scale distribution of mass in the universe, or the distribution of galaxies, using the quantity

$$\delta(\mathbf{x}) \equiv \frac{\rho(\mathbf{x}) - \langle \rho \rangle}{\langle \rho \rangle}, \quad \text{or} \quad \delta(\mathbf{x}) \equiv \frac{n(\mathbf{x}) - \langle n \rangle}{\langle n \rangle} \quad (6.33)$$

(not to be confused with the Dirac delta function). Here $\rho(\mathbf{x})$ is mass density and $n(\mathbf{x})$ is the number density of galaxies, which we assume, for didactic purposes, to have equal mass and to be distributed in the same fashion as the dark matter (Sec. 28.3.2). This $\delta(\mathbf{x})$ is a function of 3-dimensional position rather than 1-dimensional time, and $\langle \cdot \rangle$ is to be interpreted conceptually as an ensemble average and practically as a volume average (ergodic hypothesis!).

(a) Define the Fourier transform of δ over some large averaging volume V as

$$\tilde{\delta}_V(\mathbf{k}) = \int_V e^{i\mathbf{k} \cdot \mathbf{x}} \delta(\mathbf{x}) d^3x, \quad (6.34a)$$

8. Discussed further in Sec. 28.5.4.

and define its spectral density (Sec. 28.5.4) by

$$P_\delta(\mathbf{k}) \equiv \lim_{V \rightarrow \infty} \frac{1}{V} |\tilde{\delta}_V(\mathbf{k})|^2. \quad (6.34b)$$

(Note that we here use cosmologists' "double-sided" normalization for P_δ , which is different from our normalization for a random process in time; we do not fold negative values of the Cartesian components k_j of \mathbf{k} onto positive values.) Show that the two-point correlation function for cosmological density fluctuations, defined by

$$\xi_\delta(\mathbf{r}) \equiv \langle \delta(\mathbf{x})\delta(\mathbf{x} + \mathbf{r}) \rangle, \quad (6.34c)$$

is related to $P_\delta(\mathbf{k})$ by the following version of the Wiener-Khinchine theorem:

$$\xi_\delta(\mathbf{r}) = \int P_\delta(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{r}} \frac{d^3k}{(2\pi)^3} = \int_0^\infty P_\delta(k) \operatorname{sinc}(kr) \frac{k^2 dk}{2\pi^2}, \quad (6.35a)$$

$$P_\delta(\mathbf{k}) = \int \xi_\delta(\mathbf{r}) e^{i\mathbf{k}\cdot\mathbf{r}} d^3x = \int_0^\infty \xi_\delta(r) \operatorname{sinc}(kr) 4\pi r^2 dr, \quad (6.35b)$$

where $\operatorname{sinc} x \equiv \sin x/x$. In deriving these expressions, use the fact that the universe is isotropic to infer that ξ_δ can depend only on the distance r between points and not on direction, and P_δ can depend only on the magnitude k of the wave number and not on its direction.

- (b) Figure 6.9 shows observational data for the galaxy correlation function $\xi_\delta(r)$. These data are rather well approximated at $r < 20$ Mpc by

$$\xi_\delta(r) = (r_o/r)^\gamma, \quad r_o \simeq 7 \text{ Mpc}, \quad \gamma \simeq 1.8. \quad (6.36)$$

(Here 1 Mpc means 1×10^6 parsecs or about 3×10^6 light-years.) Explain why this implies that galaxies are strongly correlated (they cluster together strongly) on lengthscales $r \lesssim r_o \simeq 7$ Mpc. (Recall that the distance between our Milky Way galaxy and the nearest other large galaxy, Andromeda, is about 0.8 Mpc.) Use the Wiener-Khinchine theorem to compute the spectral density $P_\delta(k)$ and then the rms fractional density fluctuations at wave number k in bandwidth $\Delta k = k$. From your answer, infer that the density fluctuations are very large on lengthscales $\lambda = 1/k < r_o$.

- (c) As a more precise measure of these density fluctuations, show that the variance of the total number $N(R)$ of galaxies inside a sphere of radius R is

$$\sigma_N^2 = \langle n \rangle^2 \int_0^\infty \frac{dk}{2\pi^2} k^2 P_\delta(k) W^2(kR), \quad (6.37a)$$

where

$$W(x) = \frac{3(\operatorname{sinc} x - \cos x)}{x^2}. \quad (6.37b)$$

Evaluate this for the spectral density $P_\delta(r)$ that you computed in part (b). [Hint: Although it is straightforward to calculate this directly, it is faster to regard the

FIGURE 6.9 The galaxy correlation function $\xi_\delta(r)$ [defined in Eq. (6.34c)], as measured in the Sloan Digital Sky Survey. Notice that the vertical scale is linear for $\xi_\delta \lesssim 0.04$ and logarithmic for larger ξ_δ . Adapted from Eisenstein et al. (2005).

distribution of galaxies inside the sphere as an infinite distribution multiplied by a step function in radius and to invoke the convolution theorem.]

6.5 6.5 2-Dimensional Random Processes T2

Sometimes two (or more) random processes are closely related, and one wants to study their connections. An example is the position $x(t)$ and momentum $p(t)$ of a harmonic oscillator (Ex. 6.23), and we will encounter other examples in Secs. 28.5 and 28.6. Such pairs can be regarded as a 2-dimensional random process. In this Track-Two section, we generalize the concepts of correlation function and spectral density to such related processes.

6.5.1 6.5.1 Cross Correlation and Correlation Matrix T2

If $x(t)$ and $y(t)$ are two random processes, then by analogy with the correlation function $C_y(\tau)$ we define their *cross correlation* as

cross correlation

$$C_{xy}(\tau) \equiv \overline{x(t)y(t+\tau)}. \quad (6.38a)$$

When $x = y$, the cross correlation function becomes the autocorrelation function, $C_{yy}(\tau)$ interchangeable here with $C_y(\tau)$. The matrix

$$\begin{bmatrix} C_{xx}(\tau) & C_{xy}(\tau) \\ C_{yx}(\tau) & C_{yy}(\tau) \end{bmatrix} \equiv \begin{bmatrix} C_x(\tau) & C_{xy}(\tau) \\ C_{yx}(\tau) & C_y(\tau) \end{bmatrix} \quad (6.38b)$$

correlation matrix

can be regarded as a correlation matrix for the 2-dimensional random process $\{x(t), y(t)\}$. Notice that the elements of this matrix satisfy

$$C_{ab}(-\tau) = C_{ba}(\tau). \quad (6.39)$$

6.5.2 Spectral Densities and the Wiener-Khintchine Theorem T2

6.5.2

If $x(t)$ and $y(t)$ are two random processes, then by analogy with the spectral density $S_y(f)$ we define their *cross spectral density* as

$$S_{xy}(f) = \lim_{T \rightarrow \infty} \frac{2}{T} \int_{-T/2}^{+T/2} [x(t) - \bar{x}] e^{-2\pi i f t} dt \int_{-T/2}^{+T/2} [y(t') - \bar{y}] e^{+2\pi i f t'} dt'. \quad (6.40a)$$

cross spectral density

Notice that the cross spectral density of a random process with itself is equal to its spectral density, $S_{yy}(f) = S_y(f)$, and is real, but if $x(t)$ and $y(t)$ are different random processes, then $S_{xy}(f)$ is generally complex, with

$$S_{xy}^*(f) = S_{xy}(-f) = S_{yx}(f). \quad (6.40b)$$

This relation allows us to confine attention to positive f without any loss of information. The Hermitian matrix

$$\begin{bmatrix} S_{xx}(f) & S_{xy}(f) \\ S_{yx}(f) & S_{yy}(f) \end{bmatrix} = \begin{bmatrix} S_x(f) & S_{xy}(f) \\ S_{yx}(f) & S_y(f) \end{bmatrix} \quad (6.40c)$$

spectral density matrix

can be regarded as a spectral density matrix that describes how the power in the 2-dimensional random process $\{x(t), y(t)\}$ is distributed over frequency.

A generalization of the 1-dimensional Wiener-Khintchine Theorem (6.29) states that *for any two random processes $x(t)$ and $y(t)$, the cross correlation function $C_{xy}(\tau)$ and the cross spectral density $S_{xy}(f)$ are Fourier transforms of each other and thus contain precisely the same information:*

Wiener-Khintchine theorem for cross spectral density

$$\begin{aligned} C_{xy}(\tau) &= \frac{1}{2} \int_{-\infty}^{+\infty} S_{xy}(f) e^{-i2\pi f \tau} df = \frac{1}{2} \int_0^{\infty} [S_{xy}(f) e^{-i2\pi f \tau} + S_{yx}(f) e^{+i2\pi f \tau}] df, \\ S_{xy}(f) &= 2 \int_{-\infty}^{\infty} C_{xy}(\tau) e^{i2\pi f \tau} d\tau = 2 \int_0^{\infty} [C_{xy}(f) e^{+i2\pi f \tau} + C_{yx}(f) e^{-i2\pi f \tau}] df. \end{aligned} \quad (6.41)$$

The factors 1/2 and 2 in these formulas result from folding negative frequencies into positive in our definitions of the spectral density. Equations (6.41) can be proved by the same Parseval-theorem-based argument as we used for the 1-dimensional Wiener-Khintchine theorem (Sec. 6.4.4).

T2

cross spectral density as mean product of random processes' Fourier transforms

The Wiener-Khintchine theorem implies the following formula for the ensemble averaged product of the Fourier transform of the random processes $x(t)$ and $y(t)$:

$$2\langle \tilde{x}(f)\tilde{y}^*(f') \rangle = S_{xy}(f)\delta(f - f'). \quad (6.42)$$

This can be proved by the same argument as we used in Ex. 6.6 to prove its single-process analog, $2\langle \tilde{y}(f)\tilde{y}^*(f') \rangle = S_y(f)\delta(f - f')$ [Eq. (6.31)].

EXERCISES

Exercise 6.8 *Practice: Spectral Density of the Sum of Two Random Processes* T2

Let u and v be two random processes. Show that

$$S_{u+v}(f) = S_u(f) + S_v(f) + S_{uv}(f) + S_{vu}(f) = S_u(f) + S_v(f) + 2\Re S_{uv}(f), \quad (6.43)$$

where \Re denotes the real part of the argument.

6.6 Noise and Its Types of Spectra

Experimental physicists and engineers encounter random processes in the form of noise that is superposed on signals they are trying to measure. Examples include:

1. In radio communication, static on the radio is noise.
2. When modulated laser light is used for optical communication, random fluctuations in the arrival times of photons always contaminate the signal; the effects of such fluctuations are called “shot noise” and will be studied in Sec. 6.6.1.
3. Even the best of atomic clocks fail to tick with absolutely constant angular frequencies ω . Their frequencies fluctuate ever so slightly relative to an ideal clock, and those fluctuations can be regarded as noise.

Sometimes the signal that one studies amidst noise is actually itself some very special noise. (One person's noise is another person's signal.) An example is the light passing through an optical telescope and diffraction grating, discussed in Sec. 6.4.3. There the electric field $E(t)$ of the light from a star is a random process whose spectral density the astronomer measures as a function of frequency, studying with great interest features in the spectral lines and continuum. When the source is dim, the astronomer must try to separate its spectral density from those of noise in the photodetector and noise of other sources in the sky.

6.6.1 Shot Noise, Flicker Noise, and Random-Walk Noise; Cesium Atomic Clock

Physicists, astronomers, and engineers give names to certain shapes of noise spectra:

white, flicker, and random-walk spectra

$$S_y(f) \text{ independent of } f \text{—white noise spectrum,} \quad (6.44a)$$

$$S_y(f) \propto 1/f \text{—flicker noise spectrum,} \quad (6.44b)$$

FIGURE 6.10 Examples of two random processes that have flicker noise spectra, $S_y(f) \propto 1/f$. Adapted from Press (1978).

$$S_y(f) \propto 1/f^2 \text{—random-walk spectrum.} \quad (6.44c)$$

White noise, S_y independent of f , is called “white” because it has equal amounts of power per unit frequency S_y at all frequencies, just as white light has roughly equal powers at all light frequencies. Put differently, if $y(t)$ has a white-noise spectrum, then its rms fluctuations in fixed bandwidth Δf are independent of frequency f (i.e., $\sqrt{S_y(f)\Delta f}$ is independent of f).

Flicker noise, $S_y \propto 1/f$, gets its name from the fact that, when one looks at the time evolution $y(t)$ of a random process with a flicker-noise spectrum, one sees fluctuations (“flickering”) on all timescales, and the rms amplitude of flickering is independent of the timescale one chooses. Stated more precisely, choose any timescale Δt and then choose a frequency $f \sim 3/\Delta t$, so one can fit roughly three periods of oscillation into the chosen timescale. Then the rms amplitude of the fluctuations observed will be $\sqrt{S_y(f)f/3}$, which is a constant independent of f when the spectrum is that of flicker noise, $S_y \propto 1/f$. In other words, flicker noise has the same amount of power in each octave of frequency. Figure 6.10 is an illustration: both graphs shown there depict random processes with flicker-noise spectra. (The differences between the two graphs will be explained in Sec. 6.6.2.) No matter what time interval one chooses, these processes look roughly periodic with one, two, or three oscillations in that time interval; and the amplitudes of those oscillations are independent of the chosen time interval. Flicker noise occurs widely in the real world, at low frequencies, for instance, in many electronic devices, in some atomic clocks, in geophysics (the flow rates of rivers, ocean currents, etc.), in astrophysics (the light curves of quasars, sunspot numbers, etc.); even in classical music. For an interesting discussion, see Press (1978).

Random-walk noise, $S_y \propto 1/f^2$, arises when a random process $y(t)$ undergoes a random walk. In Sec. 6.7.2, we explore an example: the time evolving position $x(t)$ of a dust particle buffeted by air molecules—the phenomenon of Brownian motion.

white noise

flicker noise

random-walk noise

FIGURE 6.11 (a) Spectral density of the fluctuations in angular frequency ω of a typical cesium atomic clock. (b) Square root of the Allan variance for the same clock; see Ex. 6.13. Adapted from Galleani (2012). The best cesium clocks in 2016 (e.g., the U.S. primary time and frequency standard) have amplitude noise, $\sqrt{S_\omega}$ and σ_τ , 1000 times lower than this.

Notice that for a Gaussian-Markov process, the spectrum [Eq. (6.32) and Fig. 6.8b] is white at frequencies $f \ll 1/(2\pi\tau_r)$, where τ_r is the relaxation time, and it is random-walk at frequencies $f \gg 1/(2\pi\tau_r)$. This is typical: random processes encountered in the real world tend to have one type of spectrum over one large frequency interval and then switch to another type over another large interval. The angular frequency ω of ticking of a cesium atomic clock is another example.⁹ It fluctuates slightly with time, $\omega = \omega(t)$, with the fluctuation spectral density shown in Fig. 6.11. At low frequencies, $f \lesssim 10^{-6}$ Hz (over long timescales $\Delta t \gtrsim 2$ weeks), ω exhibits random-walk noise. At higher frequencies, $f \gtrsim 10^{-6}$ Hz (timescales $\Delta t \lesssim 2$ weeks), it exhibits white noise—which is just the opposite of a Gaussian-Markov process (see, e.g., Galleani, 2012).

6.6.2 Information Missing from Spectral Density

In experimental studies of noise, attention focuses heavily on the spectral density $S_y(f)$ and on quantities that can be computed from it. In the special case of a Gaussian-Markov process, the spectrum $S_y(f)$ and the mean \bar{y} together contain full information about all statistical properties of the random process. However, most random processes that one encounters are not Markov (though most are Gaussian). (When the spectrum deviates from the special form shown in Fig. 6.8, one can be sure the process is not Gaussian-Markov.) Correspondingly, for most processes the spectrum contains only a tiny part of the statistical information required to characterize

9. The U.S. national primary time and frequency standard is currently (2016) a cesium atomic clock; but it might be replaced, in a few years, by an atomic clock that oscillates at optical frequencies rather than the cesium clock's microwave frequencies. In their current (2016) experimental form, such clocks have achieved frequency stabilities and accuracies as good as a few $\times 10^{-18}$, nearly 100 times better than the current U.S. standard. Optical-frequency combs (Sec. 9.4.3) can be used to lock microwave-frequency oscillators to such optical-frequency clocks.

the process. The two random processes shown in Fig. 6.10 are good examples. They were constructed on a computer as superpositions of pulses $F(t - t_o)$ with random arrival times t_o and with identical forms

$$F(t) = 0 \text{ for } t < 0, \quad F(t) = K/\sqrt{t} \text{ for } t > 0 \quad (6.45)$$

(cf. Sec. 6.7.4). The two $y(t)$ s look very different, because the first (Fig. 6.10a) involves frequent small pulses, while the second (Fig. 6.10b) involves less frequent, larger pulses. These differences are obvious to the eye in the time evolutions $y(t)$. However, they do not show up at all in the spectra $S_y(f)$, which are identical: both are flicker spectra (Ex. 6.15). Moreover, the differences do not show up in $p_1(y_1)$ or in $p_2(y_2, t_2; y_1, t_1)$, because the two processes are both superpositions of many independent pulses and thus are Gaussian, and for Gaussian processes p_1 and p_2 are determined fully by the mean and the correlation function, or equivalently by the mean and spectral density, which are the same for the two processes. Thus, the differences between the two processes show up only in the probabilities p_n of third order and higher, $n \geq 3$ [as defined in Eq. (6.1)].

6.7 Filtering Random Processes

6.7

6.7.1 Filters, Their Kernels, and the Filtered Spectral Density

6.7.1

In experimental physics and engineering, one often takes a signal $y(t)$ or a random process $y(t)$ and filters it to produce a new function $w(t)$ that is a *linear functional* of $y(t)$:

$$w(t) = \int_{-\infty}^{+\infty} K(t - t')y(t')dt'. \quad (6.46)$$

The quantity $y(t)$ is called the filter's *input*; $K(t - t')$ is the filter's *kernel*, and $w(t)$ is its *output*. We presume throughout this chapter that the kernel depends only on the time difference $t - t'$ and not on absolute time. When this is so, the filter is said to be *stationary*; and when it is violated so $K = K(t, t')$ depends on absolute time, the filter is said to be nonstationary. Our restriction to stationary filters goes hand-in-hand with our restriction to stationary random processes, since if $y(t)$ is stationary and the filter is stationary (as we require), then the filtered process $w(t) = \int_{-\infty}^{+\infty} K(t - t')y(t')dt'$ is also stationary.

a filter and its input, output, and kernel

Some examples of kernels and their filtered outputs are

$$\begin{aligned} K(\tau) = \delta(\tau) : \quad w(t) &= y(t), \\ K(\tau) = \delta'(\tau) : \quad w(t) &= dy/dt, \\ K(\tau) = 0 \text{ for } \tau < 0 \text{ and } 1 \text{ for } \tau > 0 : \quad w(t) &= \int_{-\infty}^t y(t')dt'. \end{aligned} \quad (6.47)$$

Here $\delta'(\tau)$ denotes the derivative of the Dirac δ -function.

As with any function, a knowledge of the kernel $K(\tau)$ is equivalent to a knowledge of its Fourier transform:

Fourier transform of filter's kernel

$$\tilde{K}(f) \equiv \int_{-\infty}^{+\infty} K(\tau) e^{i2\pi f\tau} d\tau. \quad (6.48)$$

This Fourier transform plays a central role in the theory of filtering (also called the theory of *linear signal processing*): the convolution theorem of Fourier transform theory states that, if $y(t)$ is a function whose Fourier transform $\tilde{y}(f)$ exists (converges), then the Fourier transform of the filter's output $w(t)$ [Eq. (6.46)] is given by

$$\tilde{w}(f) = \tilde{K}(f) \tilde{y}(f). \quad (6.49)$$

Similarly, by virtue of the definition (6.25) of spectral density in terms of Fourier transforms, if $y(t)$ is a random process with spectral density $S_y(f)$, then the filter's output $w(t)$ will be a random process with spectral density

spectral density of filter's output

$$S_w(f) = |\tilde{K}(f)|^2 S_y(f). \quad (6.50)$$

[Note that, although $\tilde{K}(f)$, like all Fourier transforms, is defined for both positive and negative frequencies, when its modulus is used in Eq. (6.50) to compute the effect of the filter on a spectral density, only positive frequencies are relevant; spectral densities are strictly positive-frequency quantities.]

easy way to compute kernel's squared Fourier transform

The quantity $|\tilde{K}(f)|^2$ that appears in the very important relation (6.50) is most easily computed not by evaluating directly the Fourier transform (6.48) and then squaring, but rather by sending the function $e^{i2\pi ft}$ through the filter (i.e., by computing the output w that results from the special input $y = e^{i2\pi ft}$), and then squaring the output: $|\tilde{K}(f)|^2 = |w|^2$. To see that this works, notice that the result of sending $y = e^{i2\pi ft}$ through the filter is

$$w = \int_{-\infty}^{+\infty} K(t-t') e^{i2\pi ft'} dt' = \tilde{K}^*(f) e^{i2\pi ft}, \quad (6.51)$$

which differs from $\tilde{K}(f)$ by complex conjugation and a change of phase, and which thus has absolute value squared of $|w|^2 = |\tilde{K}(f)|^2$.

For example, if $w(t) = d^n y/dt^n$, then when we set $y = e^{i2\pi ft}$, we get $w = d^n(e^{i2\pi ft})/dt^n = (i2\pi f)^n e^{i2\pi ft}$; and, accordingly, $|\tilde{K}(f)|^2 = |w|^2 = (2\pi f)^{2n}$, whence, for any random process $y(t)$, the quantity $w(t) = d^n y/dt^n$ will have $S_w(f) = (2\pi f)^{2n} S_y(f)$.

how differentiation and integration change spectral density

This example also shows that by differentiating a random process once, one changes its spectral density by a multiplicative factor $(2\pi f)^2$; for example, one can thereby convert random-walk noise into white noise. Similarly, by integrating a random process once in time (the inverse of differentiating), one multiplies its spectral density by $(2\pi f)^{-2}$. If instead one wants to multiply by f^{-1} , one can achieve that using the filter whose kernel is

$$K(\tau) = 0 \text{ for } \tau < 0, \quad K(\tau) = \sqrt{\frac{2}{\tau}} \text{ for } \tau > 0; \quad (6.52a)$$

FIGURE 6.12 The kernel (6.52a), whose filter multiplies the spectral density by a factor $1/f$, thereby converts white noise into flicker noise and flicker noise into random-walk noise.

see Fig. 6.12. Specifically, it is easy to show, by sending a sinusoid through this filter, that

$$w(t) \equiv \int_{-\infty}^t \sqrt{\frac{2}{t-t'}} y(t') dt' \quad (6.52b)$$

has spectral density

$$S_w(f) = \frac{1}{f} S_y(f). \quad (6.52c)$$

Thus by filtering in this way, one can convert white noise into flicker noise and flicker noise into random-walk noise.

Exercise 6.9 *Derivations and Practice: Examples of Filters*

- (a) Show that the kernels $K(\tau)$ in Eq. (6.47) produce the indicated outputs $w(t)$. Deduce the ratio $S_w(f)/S_y(f) = |\tilde{K}(f)|^2$ in two ways: (i) by Fourier transforming each $K(\tau)$; (ii) by setting $y = e^{i2\pi ft}$, deducing the corresponding filtered output w directly from the expression for w in terms of y , and then squaring to get $|\tilde{K}(f)|^2$.
- (b) Derive Eqs. (6.52b) and (6.52c) for the kernel (6.52a).
-

EXERCISES

6.7.2 Brownian Motion and Random Walks

As an example of the uses of filtering, consider the motion of an organelle derived from pollen (henceforth “dust particle”) being buffeted by thermalized air molecules—the phenomenon of Brownian motion, named for the Scottish botanist Robert Brown (1828), one of the first to observe it in careful experiments. As we discussed in Sec. 6.3.1 and in greater detail at the end of Sec. 6.3.3, any Cartesian component $v(t)$ of the particle’s velocity is a Gaussian-Markov process, whose statistical properties are all determined by its equilibrium mean $\bar{v} = 0$ and standard deviation $\sigma_v = \sqrt{k_B T/m}$, and its relaxation time τ_r (which we compute in Sec. 6.8.1). Here m is the particle’s

6.7.2

Brownian motion

mass, and T is the temperature of the air molecules that buffet it. The conditional probability distribution P_2 for v is given by Doob's theorem:

$$P_2(v_2, t|v_1) = \frac{e^{-(v_2 - \bar{v}_t)^2 / (2\sigma_{v_t}^2)}}{[2\pi\sigma_{v_t}^2]^{\frac{1}{2}}}, \quad \bar{v}_t = v_1 e^{-t/\tau_r},$$

$$\sigma_{v_t}^2 = (1 - e^{-2t/\tau_r})\sigma_v^2, \quad \sigma_v = \sqrt{\frac{k_B T}{m}} \quad (6.53a)$$

[Eqs. (6.18)], and its corresponding correlation function and spectral density have the standard forms (6.20) and (6.32) for a Gaussian-Markov process:

$$C_v(\tau) = \sigma_v^2 e^{-\tau/\tau_r}, \quad S_v(f) = \frac{4\sigma_v^2/\tau_r}{(2\pi f)^2 + (1/\tau_r)^2}. \quad (6.53b)$$

The Cartesian coordinate (position) of the dust particle, $x(t) = \int v dt$, is of special interest. Its spectral density can be deduced by applying the time-integral filter $|\tilde{K}(f)|^2 = 1/(2\pi f)^2$ to $S_v(f)$. The result, using Eq. (6.53b), is

$$S_x(f) = \frac{4\tau_r\sigma_v^2}{(2\pi f)^2[1 + (2\pi f\tau_r)^2]}. \quad (6.53c)$$

Notice that at frequencies $f \ll 1/\tau_r$ (corresponding to times long compared to the relaxation time), our result (6.53c) reduces to the random-walk spectrum $S_x = 4\sigma_v^2\tau_r/(2\pi f)^2$. From this spectrum, we can compute the rms distance $\sigma_{\Delta x}$ in the x direction that the dust particle travels in a time interval $\Delta\tau \gg \tau_r$. That $\sigma_{\Delta x}$ is the standard deviation of the random process $\Delta x(t) \equiv x(t + \Delta\tau) - x(t)$. The filter that takes $x(t)$ into $\Delta x(t)$ has

$$|\tilde{K}(f)|^2 = |e^{i2\pi f(t+\Delta\tau)} - e^{i2\pi ft}|^2 = 4 \sin^2(\pi f \Delta\tau). \quad (6.54a)$$

Correspondingly, $\Delta x(t)$ has spectral density

$$S_{\Delta x}(f) = |\tilde{K}(f)|^2 S_x(f) = 4\sigma_v^2\tau_r(\Delta\tau)^2 \text{sinc}^2(\pi f \Delta\tau) \quad (6.54b)$$

(where, again, $\text{sinc } u \equiv \sin u/u$), so the variance of Δx (i.e., the square of the rms distance traveled) is

$$(\sigma_{\Delta x})^2 = \int_0^\infty S_{\Delta x}(f) df = 2(\sigma_v\tau_r)^2 \frac{\Delta\tau}{\tau_r}. \quad (6.54c)$$

This equation has a simple physical interpretation. The damping time τ_r is the time required for collisions to change substantially the dust particle's momentum, so we can think of it as the duration of a single step in the particle's random walk. The particle's mean speed is roughly $\sqrt{2}\sigma_v$, so the distance traveled during each step (the particle's mean free path) is roughly $\sqrt{2}\sigma_v\tau_r$. (The $\sqrt{2}$ comes from our analysis; this physical argument could not have predicted it.) Therefore, during a time interval $\Delta\tau$ long compared to a single step τ_r , the rms distance traveled in the x direction by the

correlation function and spectral densities for Brownian motion

random-walking dust particle is about one mean-free path $\sqrt{2}\sigma_v\tau_r$, multiplied by the square root of the mean number of steps taken, $\sqrt{\Delta\tau/\tau_r}$:

$$\sigma_{\Delta x} = \sqrt{2}\sigma_v\tau_r\sqrt{\Delta\tau/\tau_r}. \quad (6.55)$$

rms distance traveled in
Brownian motion

This “square root of the number of steps taken” behavior is a universal rule of thumb for random walks; one meets it time and again in science, engineering, and mathematics. We have met it previously in our studies of diffusion (Exs. 3.17 and 6.3) and of the elementary “unit step” random walk problem that we studied using the central limit theorem in Ex. 6.4. We could have guessed Eq. (6.55) from this rule of thumb, up to an unknown multiplicative factor of order unity. Our analysis has told us that factor: $\sqrt{2}$.

Exercise 6.10 Example: Position, Viewed on Timescales $\Delta\tau \gg \tau_r$, as a Markov Process

EXERCISES

- (a) Explain why, physically, when the Brownian motion of a particle (which starts at $x = 0$ at time $t = 0$) is observed only on timescales $\Delta\tau \gg \tau_r$, corresponding to frequencies $f \ll 1/\tau_r$, its position $x(t)$ must be a Gaussian-Markov process with $\bar{x} = 0$. What are the spectral density of $x(t)$ and its relaxation time in this case?
- (b) Use Doob’s theorem to compute the conditional probability $P_2(x_2, \tau|x_1)$. Your answer should agree with the result deduced in Ex. 6.3 from the diffusion equation, and in Ex. 6.4 from the central limit theorem for a random walk.

6.7.3 Extracting a Weak Signal from Noise: Band-Pass Filter, Wiener’s Optimal Filter, Signal-to-Noise Ratio, and Allan Variance of Clock Noise

6.7.3

In experimental physics and engineering, one often meets a random process $Y(t)$ that consists of a sinusoidal signal on which is superposed noise $y(t)$:

$$Y(t) = \sqrt{2}Y_s \cos(2\pi f_o t + \delta_o) + y(t). \quad (6.56a)$$

[The factor $\sqrt{2}$ is included in Eq. (6.56a) because the time average of the square of the cosine is 1/2; correspondingly, with the factor $\sqrt{2}$ present, Y_s is the rms signal amplitude.] We assume that the frequency f_o and phase δ_o of the signal are known, and we want to determine the signal’s rms amplitude Y_s . The noise $y(t)$ is an impediment to the determination of Y_s . To reduce that impediment, we can send $Y(t)$ through a *band-pass filter* centered on the signal frequency f_o (i.e., a filter with a shape like that of Fig. 6.13).

band-pass filter

For such a filter, with central frequency f_o and with bandwidth $\Delta f \ll f_o$, the bandwidth is defined by

bandwidth

$$\Delta f \equiv \frac{\int_0^\infty |\tilde{K}(f)|^2 df}{|\tilde{K}(f_o)|^2}. \quad (6.56b)$$

FIGURE 6.13 A band-pass filter centered on frequency f_o with bandwidth Δf .

The output $W(t)$ of such a filter, when the input is $Y(t)$, has the form

$$W(t) = |\tilde{K}(f_o)|\sqrt{2}Y_s \cos(2\pi f_o t + \delta_1) + w(t), \quad (6.56c)$$

where the first term is the filtered signal and the second is the filtered noise. The output signal's phase δ_1 may be different from the input signal's phase δ_o , but that difference can be evaluated in advance for one's filter and can be taken into account in the measurement of Y_s ; thus it is of no interest to us. Assuming (as we shall) that the input noise $y(t)$ has spectral density S_y that varies negligibly over the small bandwidth of the filter, the filtered noise $w(t)$ will have spectral density

spectral density of
band-pass filter's output

$$S_w(f) = |\tilde{K}(f)|^2 S_y(f_o). \quad (6.56d)$$

This means that $w(t)$ consists of a random superposition of sinusoids all with nearly—but not quite—the same frequency f_o ; their frequency spread is Δf . Now, when one superposes two sinusoids with frequencies that differ by $\Delta f \ll f_o$, the two beat against each other, producing a modulation with period $1/\Delta f$. Correspondingly, with its random superposition of many such sinusoids, the noise $w(t)$ will have the form

$$w(t) = w_o(t) \cos[2\pi f_o t + \phi(t)], \quad (6.56e)$$

with amplitude $w_o(t)$ and phase $\phi(t)$ that fluctuate randomly on timescales

$$\Delta t \sim 1/\Delta f, \quad (6.56f)$$

but that are nearly constant on timescales $\Delta t \ll 1/\Delta f$.

band-pass filter's output in
time domain

The filter's net output $W(t)$ thus consists of a precisely sinusoidal signal at frequency f_o , with known phase δ_1 and with an amplitude that we wish to determine, plus noise $w(t)$ that is also sinusoidal at frequency f_o but with amplitude and phase that wander randomly on timescales $\Delta t \sim 1/\Delta f$. The rms output signal is

$$S \equiv |\tilde{K}(f_o)|Y_s \quad (6.56g)$$

[Eq. (6.56c)], while the rms output noise is

$$N \equiv \sigma_w = \left[\int_0^\infty S_w(f) df \right]^{\frac{1}{2}}$$

$$= \sqrt{S_y(f_o)} \left[\int_0^\infty |\tilde{K}(f)|^2 df \right]^{\frac{1}{2}} = |\tilde{K}(f_o)| \sqrt{S_y(f_o) \Delta f}, \quad (6.56h)$$

where the first integral follows from Eq. (6.26), the second from Eq. (6.56d), and the third from the definition (6.56b) of the bandwidth Δf . The ratio of the rms signal (6.56g) to the rms noise (6.56h) after filtering is

$$\boxed{\frac{S}{N} = \frac{Y_s}{\sqrt{S_y(f_o) \Delta f}}}. \quad (6.57)$$

signal-to-noise ratio for
band-pass filter

Thus, the rms output $S + N$ of the filter is the signal amplitude to within an rms fractional error N/S given by the reciprocal of (6.57). Notice that the narrower the filter's bandwidth, the more accurate will be the measurement of the signal. In practice, of course, one does not know the signal frequency with complete precision in advance; correspondingly, one does not want to make one's filter so narrow that the signal might be lost from it.

A simple example of a band-pass filter is the following *finite Fourier transform filter*:

$$w(t) = \int_{t-\Delta t}^t \cos[2\pi f_o(t-t')] y(t') dt', \quad \text{where } \Delta t \gg 1/f_o. \quad (6.58a)$$

In Ex. 6.11 it is shown that this is indeed a band-pass filter, and that the integration time Δt used in the Fourier transform is related to the filter's bandwidth by

$$\Delta f = 1/\Delta t. \quad (6.58b)$$

Often the signal one seeks amidst noise is not sinusoidal but has some other known form $s(t)$. In this case, the optimal way to search for it is with a so-called *Wiener filter* (an alternative to the band-pass filter); see the very important Ex. 6.12.

Exercise 6.11 *Derivation and Example: Bandwidths of a Finite-Fourier-Transform Filter and an Averaging Filter*

EXERCISES

- (a) If y is a random process with spectral density $S_y(f)$, and $w(t)$ is the output of the finite-Fourier-transform filter (6.58a), what is $S_w(f)$?
- (b) Sketch the filter function $|\tilde{K}(f)|^2$ for this finite-Fourier-transform filter, and show that its bandwidth is given by Eq. (6.58b).
- (c) An "averaging filter" is one that averages its input over some fixed time interval Δt :

$$w(t) \equiv \frac{1}{\Delta t} \int_{t-\Delta t}^t y(t') dt'. \quad (6.59a)$$

What is $|\tilde{K}(f)|^2$ for this filter? Draw a sketch of this $|\tilde{K}(f)|^2$.

- (d) Suppose that $y(t)$ has a spectral density that is very nearly constant at all frequencies, $f \lesssim 1/\Delta t$, and that this y is put through the averaging filter (6.59a). Show that the rms fluctuations in the averaged output $w(t)$ are

$$\sigma_w = \sqrt{S_y(0)\Delta f}, \quad (6.59b)$$

where Δf , interpretable as the bandwidth of the averaging filter, is

$$\Delta f = \frac{1}{2\Delta t}. \quad (6.59c)$$

(Recall that in our formalism we insist that f be nonnegative.) Why is there a factor 1/2 here and not one in the equation for an averaging filter [Eq. (6.58b)]? Because here, with f restricted to positive frequencies and the filter centered on zero frequency, we see only the right half of the filter: $f \geq f_o = 0$ in Fig. 6.13.

Exercise 6.12 ***Example: Wiener's Optimal Filter*

Suppose that you have a noisy receiver of weak signals (e.g., a communications receiver). You are expecting a signal $s(t)$ with finite duration and known form to come in, beginning at a predetermined time $t = 0$, but you are not sure whether it is present. If it is present, then your receiver's output will be

$$Y(t) = s(t) + y(t), \quad (6.60a)$$

where $y(t)$ is the receiver's noise, a random process with spectral density $S_y(f)$ and with zero mean, $\bar{y} = 0$. If it is absent, then $Y(t) = y(t)$. A powerful way to find out whether the signal is present is by passing $Y(t)$ through a filter with a carefully chosen kernel $K(t)$. More specifically, compute the quantity

$$W \equiv \int_{-\infty}^{+\infty} K(t)Y(t)dt. \quad (6.60b)$$

If $K(t)$ is chosen optimally, then W will be maximally sensitive to the signal $s(t)$ in the presence of the noise $y(t)$. Correspondingly, if W is large, you infer that the signal was present; if it is small, you infer that the signal was either absent or so weak as not to be detectable. This exercise derives the form of the *optimal filter*, $K(t)$ (i.e., the filter that will most effectively discern whether the signal is present). As tools in the derivation, we use the quantities S and N defined by

$$S \equiv \int_{-\infty}^{+\infty} K(t)s(t)dt, \quad N \equiv \int_{-\infty}^{+\infty} K(t)y(t)dt. \quad (6.60c)$$

Note that S is the filtered signal, N is the filtered noise, and $W = S + N$. Since $K(t)$ and $s(t)$ are precisely defined functions, S is a number. But since $y(t)$ is a random process, the value of N is not predictable, and instead is given by some probability distribution $p_1(N)$. We shall also need the Fourier transform $\tilde{K}(f)$ of the kernel $K(t)$.

- (a) In the measurement being done one is not filtering a function of time to get a new function of time; rather, one is just computing a number, $W = S + N$.

Nevertheless, as an aid in deriving the optimal filter it is helpful to consider the time-dependent output of the filter that results when noise $y(t)$ is fed continuously into it:

$$N(t) \equiv \int_{-\infty}^{+\infty} K(t-t')y(t')dt'. \quad (6.61a)$$

Show that this random process has a mean squared value

$$\overline{N^2} = \int_0^\infty |\tilde{K}(f)|^2 S_y(f) df. \quad (6.61b)$$

Explain why this quantity is equal to the average of the number N^2 computed using (6.60c) in an ensemble of many experiments:

$$\overline{N^2} = \langle N^2 \rangle \equiv \int p_1(N) N^2 dN = \int_0^\infty |\tilde{K}(f)|^2 S_y(f) df. \quad (6.61c)$$

(b) Show that of all choices of the kernel $K(t)$, the one that will give the largest value of

$$\frac{S}{\langle N^2 \rangle^{1/2}} \quad (6.61d)$$

is Norbert Wiener's (1949) *optimal filter*, whose kernel has the Fourier transform

$$\tilde{K}(f) = \text{const} \times \frac{\tilde{s}(f)}{S_y(f)}, \quad (6.62a)$$

where $\tilde{s}(f)$ is the Fourier transform of the signal $s(t)$, and $S_y(f)$ is the spectral density of the noise. Note that when the noise is white, so $S_y(f)$ is independent of f , this optimal kernel is just $K(t) = \text{const} \times s(t)$ (i.e., one should simply multiply the known signal form into the receiver's output and integrate). By contrast, when the noise is not white, the optimal kernel (6.62a) is a distortion of $\text{const} \times s(t)$ in which frequency components at which the noise is large are suppressed, while frequency components at which the noise is small are enhanced.

(c) Show that when the optimal kernel (6.62a) is used, the square of the signal-to-noise ratio is

$$\frac{S^2}{\langle N^2 \rangle} = 4 \int_0^\infty \frac{|\tilde{s}(f)|^2}{S_y(f)} df. \quad (6.62b)$$

(d) As an example, suppose the signal consists of n cycles of some complicated waveform with frequencies spread out over the range $f_o/2$ to $2f_o$ with amplitude $\sim A$ for its entire duration. Also suppose that S_y is approximately constant (near white noise) over this frequency band. Show that $S/\langle N^2 \rangle^{1/2} \sim 2nA/\sqrt{f_o S_y(f_o)}$, so the amplitude signal to noise increases linearly with the number of cycles in the signal.

Wiener's optimal filter

signal-to-noise ratio for Wiener's optimal filter

- (e) Suppose (as an idealization of searches for gravitational waves in noisy LIGO data) that (i) we do not know the signal $s(t)$ in advance, but we do know that it is from a set of N distinct signals, all of which have frequency content concentrated around some f_o ; (ii) we do not know when the signal will arrive, but we search for it for a long time τ_s (say, a year); and (iii) the noise superposed on the signal is Gaussian. Show that, in order to have 99% confidence that any signal found is real, it must have amplitude signal-to-noise ratio of $S/\langle N^2 \rangle^{1/2} \gtrsim [2 \ln(H/\sqrt{2 \ln H})]^{1/2}$, where $H = 100Nf_o\tau_s$. For $N \sim 10^4$, $f_o \sim 100$ Hz, $\tau_s \sim 1$ yr, this says $S/\langle N^2 \rangle^{1/2} \gtrsim 8.2$. This is so small because the Gaussian probability distribution falls off so rapidly. If the noise is non-Gaussian, then the minimum detectable signal will be larger than this, possibly much larger.

Exercise 6.13 ***Example: Allan Variance of Clocks*

Highly stable clocks (e.g., cesium clocks, hydrogen maser clocks, or quartz crystal oscillators) have angular frequencies ω of ticking that tend to wander so much over very long timescales that their variances diverge. For example, a cesium clock has random-walk noise on very long timescales (low frequencies)

$$S_\omega(f) \propto 1/f^2 \quad \text{at low } f; \quad (6.63a)$$

and correspondingly,

$$\sigma_\omega^2 = \int_0^\infty S_\omega(f) df = \infty \quad (6.63b)$$

(cf. Fig. 6.11 and associated discussion). For this reason, clock makers have introduced a special technique for quantifying the frequency fluctuations of their clocks. Using the phase

$$\phi(t) = \int_0^t \omega(t') dt', \quad (6.64a)$$

they define the quantity

$$\Phi_\tau(t) = \frac{[\phi(t+2\tau) - \phi(t+\tau)] - [\phi(t+\tau) - \phi(t)]}{\sqrt{2}\bar{\omega}\tau}, \quad (6.64b)$$

where $\bar{\omega}$ is the mean frequency. Aside from the $\sqrt{2}$, this $\Phi_\tau(t)$ is the fractional difference of clock readings for two successive intervals of duration τ . (In practice the measurement of t is made by a clock more accurate than the one being studied; or, if a more accurate clock is not available, by a clock or ensemble of clocks of the same type as is being studied.)

- (a) Show that the spectral density of $\Phi_\tau(t)$ is related to that of $\omega(t)$ by

$$\begin{aligned} S_{\Phi_\tau}(f) &= \frac{2}{\bar{\omega}^2} \left[\frac{\cos 2\pi f \tau - 1}{2\pi f \tau} \right]^2 S_\omega(f) \\ &\propto f^2 S_\omega(f) \text{ at } f \ll 1/(2\pi\tau) \\ &\propto f^{-2} S_\omega(f) \text{ at } f \gg 1/(2\pi\tau). \end{aligned} \quad (6.65)$$

Note that $S_{\Phi_\tau}(f)$ is much better behaved (more strongly convergent when integrated) than $S_\omega(f)$ is, both at low frequencies and at high.

(b) The *Allan variance* of the clock is defined as

$$\sigma_\tau^2 \equiv [\text{variance of } \Phi_\tau(t)] = \int_0^\infty S_{\Phi_\tau}(f) df. \quad (6.66)$$

Show that

$$\sigma_\tau = \left[\alpha \frac{S_\omega(1/(2\tau))}{\bar{\omega}^2} \frac{1}{2\tau} \right]^{\frac{1}{2}}, \quad (6.67)$$

where α is a constant of order unity that depends on the spectral shape of $S_\omega(f)$ near $f = 1/(2\tau)$. Explain why, aside from the factor α , the right-hand side of Eq. (6.67) is the rms fractional fluctuation of ω at frequency $1/(2\tau)$ in bandwidth $1/(2\tau)$.

(c) Show that, if ω has a white-noise spectrum, then the clock stability is better for long averaging times than for short; if ω has a flicker-noise spectrum, then the clock stability is independent of averaging time; and if ω has a random-walk spectrum, then the clock stability is better for short averaging times than for long. (See Fig. 6.11.)

6.7.4 Shot Noise

A specific kind of noise that one frequently meets and frequently wants to filter is *shot noise*. A random process $y(t)$ is said to consist of shot noise if it is a random superposition of a large number of finite-duration pulses. In this chapter, we restrict attention to a simple version of shot noise in which the pulses all have the same shape, $F(\tau)$ (e.g., Fig. 6.14a), but their arrival times t_i are random

$$y(t) = \sum_i F(t - t_i), \quad (6.68a)$$

as may be the case for individual photons arriving at a photodetector. We denote by \mathcal{R} the mean rate of pulse arrivals (the mean number per second). From the definition (6.25) of spectral density, it is straightforward to see that the spectral density of y is

$$S_y(f) = 2\mathcal{R}|\tilde{F}(f)|^2, \quad (6.68b)$$

where $\tilde{F}(f)$ is the Fourier transform of $F(\tau)$ (Fig. 6.14). See Ex. 6.14 for proof. If the pulses are broadband bursts without much substructure in them (as in Fig. 6.14a), then the duration τ_p of the pulse is related to the frequency f_{\max} at which the spectral density starts to cut off by $f_{\max} \sim 1/\tau_p$. Since the correlation function is the cosine transform of the spectral density, the correlation's relaxation time is $\tau_r \sim 1/f_{\max} \sim \tau_p$ (Ex. 6.14).

6.7.4

shot noise

spectral density of shot noise

FIGURE 6.14 (a) A broadband pulse that produces shot noise by arriving at random times. (b) The spectral density of the shot noise produced by that pulse.

In the common (but not universal) case that many pulses are on at once on average ($\mathcal{R}\tau_p \gg 1$), then at any moment of time $y(t)$ is the sum of many random processes. Correspondingly, the central limit theorem guarantees that y is a Gaussian random process. Over time intervals smaller than $\tau_p \sim \tau_r$, the process will not generally be Markov, because a knowledge of both $y(t_1)$ and $y(t_2)$ gives some rough indication of how many pulses happen to be on and how many new ones have turned on during the time interval between t_1 and t_2 and thus are still in their early stages at time t_3 ; this knowledge helps one predict $y(t_3)$ with greater confidence than if one knew only $y(t_2)$. In other words, $P_3(y_3, t_3|y_2, t_2; y_1, t_1)$ is not equal to $P_2(y_3, t_3|y_2, t_2)$, which implies non-Markov behavior.

By contrast, if many pulses are on at once, and if one takes a coarse-grained view of time, never examining time intervals as short as τ_p or shorter, then a knowledge of $y(t_1)$ is of no help in predicting $y(t_2)$. All correlations between different times are lost, so the process is Markov, and (because it is a random superposition of many independent influences) it is also Gaussian—an example of the central limit theorem at work. Thus it must have the standard Gaussian-Markov spectral density (6.32) with vanishing correlation time τ_r (i.e., it must be white). Indeed, it is: For $f \ll 1/\tau_p$, the limit of Eq. (6.68b) for S_y and the corresponding correlation function are

$$S_y(f) = 2\mathcal{R}|\tilde{F}(0)|^2, \quad C_y(\tau) = \mathcal{R}|\tilde{F}(0)|^2\delta(\tau). \quad (6.68c)$$

This formula remains true if the pulses have different shapes, so long as their Fourier transforms at zero frequency, $\tilde{F}_j(0) = \int_{-\infty}^{\infty} F_j dt$, are all the same; see Ex. 6.14b.

As an important example, consider a (nearly) monochromatic beam of light with angular frequency $\omega_o \sim 10^{15} \text{ s}^{-1}$ and with power (energy per unit time) $W(t)$ that is being measured by a photodetector. The arriving light consists of discrete photons, each with its own pulse shape $W_j(t - t_j)$,¹⁰ which lasts for a time τ_p long compared to the light's period ($\sim 3 \times 10^{-15} \text{ s}$) but short compared to the inverse frequency f^{-1} at which we measure the photon shot noise. The Fourier transform of W_j at zero

10. For a single photon, $W_j(t)$ is the probability per unit time for the photon's arrival, times the photon's energy $\hbar\omega_o$.

frequency is just $\tilde{W}_j(0) = \int_0^\infty W_j dt = \hbar\omega$ (the total energy carried by the photon), which is the same for all pulses; the rate of arrival of photons is $\mathcal{R} = \overline{W}/\hbar\omega_o$. Therefore the spectral density of the intensity measured by the photodetector is

$$S_W(f) = 2\overline{W} \hbar\omega. \quad (6.69)$$

In the LIGO interferometer, whose noise power spectrum is shown in Fig. 6.7, this photon shot noise dominates in the frequency band $f \gtrsim 200$ Hz. (Although S_W for the laser light has white noise, when passed through the interferometer as a filter, it produces $S_x \propto f^2$.)

EXERCISES

Exercise 6.14 *Derivation: Shot Noise*

- Show that for shot noise, $y(t) = \sum_i F(t - t_i)$, the spectral density $S_y(f)$ is given by Eq. (6.68b). Show that the relaxation time appearing in the correlation function is approximately the duration τ_p of $F(t)$.
- Suppose the shapes of $F_j(t - t_j)$ are all different instead of being identical but all last for times $\lesssim \tau_p$, and all have the same Fourier transform at zero frequency, $\tilde{F}_j(0) = \int_{-\infty}^\infty F_j dt = \tilde{F}(0)$. Show that the shot noise at frequencies $f \ll 1/\tau_p$ is still given by Eq. (6.68c).

Exercise 6.15 *Example: Shot Noise with Flicker Spectrum*

- Show that for shot noise with identical pulses that have the infinitely sharply peaked shape of Eq. (6.45), the power spectrum has the flicker form $S_y \propto 1/f$ for all f .
- Construct realizations of shot noise with flicker spectrum [Eq. (6.68a) with pulse shape (6.45)] that range from a few large pulses in the time interval observed to many small pulses, and describe the visual differences; cf. Fig. 6.10 and the discussion in Sec. 6.6.2.

6.8 Fluctuation-Dissipation Theorem

6.8

6.8.1 Elementary Version of the Fluctuation-Dissipation Theorem; Langevin Equation, Johnson Noise in a Resistor, and Relaxation Time for Brownian Motion

6.8.1

Friction is generally caused by interaction with the huge number of degrees of freedom of some sort of bath (e.g., the molecules of air against which a moving ball or dust particle pushes). Those degrees of freedom also produce fluctuating forces. In this section, we study the relationship between the friction and the fluctuating forces when the bath is thermalized at some temperature T (so it is a heat bath).

For simplicity, we restrict ourselves to a specific generalized coordinate q of the system that will interact with a bath (e.g., the x coordinate of the ball or dust particle).

We require just one special property for q : its time derivative $\dot{q} = dq/dt$ must appear in the system's lagrangian as a kinetic energy,

$$E_{\text{kinetic}} = \frac{1}{2}m\dot{q}^2, \quad (6.70)$$

and in no other way. Here m is a (generalized) mass associated with q . Then the equation of motion for q will have the simple form of Newton's second law, $m\ddot{q} = F$, where F includes contributions \mathcal{F} from the system itself (e.g., a restoring force in the case of a normal mode), plus a force F_{bath} due to the heat bath (i.e., due to all the degrees of freedom in the bath). This F_{bath} is a random process whose time average is a frictional (damping) force proportional to \dot{q} :

$$\bar{F}_{\text{bath}} = -R\dot{q}, \quad F_{\text{bath}} \equiv \bar{F}_{\text{bath}} + F'. \quad (6.71)$$

Here R is the coefficient of friction. The fluctuating part F' of F_{bath} is responsible for driving q toward statistical equilibrium.

examples:

dust particle

electric circuit

Three specific examples, to which we shall return below, are as follows.

1. The system might be a dust particle with q its x coordinate and m its mass. The heat bath might be air molecules at temperature T , which buffet the dust particle, producing Brownian motion.
2. The system might be an L - C - R circuit (i.e., an electric circuit containing an inductance L , a capacitance C , and a resistance R) with q the total electric charge on the top plate of the capacitor. The bath in this case would be the many mechanical degrees of freedom in the resistor. For such a circuit, the "equation of motion" is

$$L\ddot{q} + C^{-1}q = F_{\text{bath}}(t) = -R\dot{q} + F', \quad (6.72)$$

so the effective mass is the inductance L ; the coefficient of friction is the resistance (both denoted R); $-R\dot{q} + F'$ is the total voltage across the resistor; and F' is the fluctuating voltage produced by the resistor's internal degrees of freedom (the bath) and so might better be denoted V' .

normal mode of crystal

3. The system might be the fundamental mode of a 10-kg sapphire crystal with q its generalized coordinate (cf. Sec. 4.2.1). The heat bath might be all the other normal modes of vibration of the crystal, with which the fundamental mode interacts weakly.

LANGEVIN EQUATION

In general, the equation of motion for the generalized coordinate $q(t)$ under the joint action of (i) the bath's damping force $-R\dot{q}$, (ii) the bath's fluctuating forces F' , and (iii) the system's internal force \mathcal{F} will take the form [cf. Eq. (6.71)]

$$m\ddot{q} + R\dot{q} = \mathcal{F} + F'(t). \quad (6.73)$$

The internal force \mathcal{F} is derived from the system's hamiltonian or lagrangian in the absence of the heat bath. For the L - C - R circuit of Eq. (6.72) that force is $\mathcal{F} = -C^{-1}q$; for the dust particle, if the particle were endowed with a charge Q and were in an external electric field with potential $\Phi(t, x, y, z)$, it would be $\mathcal{F} = -Q\partial\Phi/\partial x$; for the normal mode of a crystal, it is $\mathcal{F} = -m\omega^2q$, where ω is the mode's eigenfrequency.

Because the equation of motion (6.73) involves a driving force $F'(t)$ that is a random process, one cannot solve it to obtain $q(t)$. Instead, one must solve it in a statistical way to obtain the evolution of q 's probability distributions $p_n(q_1, t_1; \dots; q_n, t_n)$. This and other evolution equations involving random-process driving terms are called by modern mathematicians *stochastic differential equations*, and there is an extensive body of mathematical formalism for solving them. In statistical physics the specific stochastic differential equation (6.73) is known as the *Langevin equation*.

stochastic differential equation

Langevin equation

ELEMENTARY FLUCTUATION-DISSIPATION THEOREM

Because the damping force $-R\dot{q}$ and the fluctuating force F' both arise from interaction with the same heat bath, there is an intimate connection between them. For example, the stronger the coupling to the bath, the stronger will be the coefficient of friction R and the stronger will be F' . The precise relationship between the dissipation embodied in R and the fluctuations embodied in F' is given by the following *fluctuation-dissipation theorem*: At frequencies

$$f \ll 1/\tau_r, \quad (6.74a)$$

where τ_r is the (very short) relaxation time for the fluctuating force F' , the fluctuating force has the spectral density

$$S_{F'}(f) = 4R \left(\frac{1}{2}hf + \frac{hf}{e^{hf/(k_B T)} - 1} \right) \quad \text{in general,} \quad (6.74b)$$

$$S_{F'}(f) = 4Rk_B T \quad \text{in the classical domain, } k_B T \gg hf. \quad (6.74c)$$

elementary fluctuation-dissipation theorem

Here T is the temperature of the bath, and h is Planck's constant.

Notice that in the classical domain, $k_B T \gg hf$, the spectral density has a white-noise spectrum. In fact, since we are restricting attention to frequencies at which F' has no self-correlations ($f^{-1} \gg \tau_r$), F' is Markov; and since it is produced by interaction with the huge number of degrees of freedom of the bath, F' is also Gaussian. Thus, in the classical domain F' is a Gaussian-Markov, white-noise process.

classical fluctuations accompanying $-R\dot{q}$ damping are Gaussian, Markov, white-noise processes

At frequencies $f \gg k_B T/h$ (quantum domain), in Eq. (6.74b) the term $S_{F'} = 4R\frac{1}{2}hf$ is associated with vacuum fluctuations of the degrees of freedom that make up the heat bath (one-half quantum of fluctuations per mode as for any quantum mechanical simple harmonic oscillator). In addition, the second term, $S_{F'}(f) = 4Rhf e^{-hf/(k_B T)}$, associated with thermal excitations of the bath's degrees of freedom, is exponentially suppressed because at these high frequencies, the bath's modes have exponentially small probabilities of containing any quanta at all. Since in this quantum

domain $S_{F'}(f)$ does not have the standard Gaussian-Markov frequency dependence (6.32), in the quantum domain F' is not a Gaussian-Markov process.

Proof of the Fluctuation-Dissipation Theorem.

proof of elementary
fluctuation-dissipation
theorem

In principle, we can alter the system's internal restoring force \mathcal{F} without altering its interactions with the heat bath [i.e., without altering R or $S_{F'}(f)$]. For simplicity, we set \mathcal{F} to zero so q becomes the coordinate of a free mass. The basic idea of our proof is to choose a frequency f_o at which to evaluate the spectral density of F' , and then, in an idealized thought experiment, very weakly couple a harmonic oscillator with eigenfrequency f_o to q . Through that coupling, the oscillator is indirectly damped by the resistance R of q and is indirectly driven by R 's associated fluctuating force F' , which arises from a bath with temperature T . After a long time, the oscillator will reach thermal equilibrium with that bath and will then have the standard thermalized mean kinetic energy ($\bar{E} = k_B T$ in the classical regime). We shall compute that mean energy in terms of $S_{F'}(f_o)$ and thereby deduce $S_{F'}(f_o)$.

The Langevin equation (6.73) and equation of motion for the coupled free mass and harmonic oscillator are

$$m\ddot{q} + R\dot{q} = -\kappa Q + F'(t), \quad M\ddot{Q} + M\omega_o^2 Q = -\kappa q. \quad (6.75a)$$

Here M , Q , and $\omega_o = 2\pi f_o$ are the oscillator's mass, coordinate, and angular eigenfrequency, and κ is the arbitrarily small coupling constant. (The form of the coupling terms $-\kappa Q$ and $-\kappa q$ in the two equations can be deduced from the coupling's interaction hamiltonian $H_I = \kappa q Q$.) Equations (6.75a) can be regarded as a filter to produce from the fluctuating-force input $F'(t)$ a resulting motion of the oscillator, $Q(t) = \int_{-\infty}^{+\infty} K(t-t')F'(t')dt'$. The squared Fourier transform $|\tilde{K}(f)|^2$ of this filter's kernel $K(t-t')$ is readily computed by the standard method [Eq. (6.51) and associated discussion] of inserting a sinusoid $e^{-i\omega t}$ (with $\omega = 2\pi f$) into the filter [i.e., into the differential equations (6.75a)] in place of F' , then solving for the sinusoidal output Q , and then setting $|\tilde{K}|^2 = |Q|^2$. The resulting $|\tilde{K}|^2$ is the ratio of the spectral densities of input and output. We carefully manipulate the resulting $|\tilde{K}|^2$ so as to bring it into the following standard resonant form:

$$S_q(f) = |\tilde{K}(f)|^2 S_{F'}(f) = \frac{|B|^2}{(\omega - \omega'_o)^2 + (2M\omega_o^2 R|B|^2)^2} S_{F'}(f). \quad (6.75b)$$

Here $B = \kappa/[2M\omega_o(m\omega_o^2 + iR\omega_o)]$ is arbitrarily small because κ is arbitrarily small; and $\omega'_o{}^2 = \omega_o^2 + 4mM\omega_o^4|B|^2$ is the oscillator's squared angular eigenfrequency after coupling to q , and is arbitrarily close to ω_o^2 because $|B|^2$ is arbitrarily small. In these equations we have replaced ω by ω_o everywhere except in the resonance term $(\omega - \omega'_o)^2$ because $|\tilde{K}|^2$ is negligibly small everywhere except near resonance, $\omega \cong \omega_o$.

The mean energy of the oscillator, averaged over an arbitrarily long timescale, can be computed in either of two ways.

1. Because the oscillator is a mode of some boson field and is in statistical equilibrium with a heat bath, its mean occupation number must have the standard Bose-Einstein value $\eta = 1/[e^{\hbar\omega_o/(k_B T)} - 1]$, and since each quantum carries an energy $\hbar\omega_o$, the mean energy is

$$\bar{E} = \frac{\hbar\omega_o}{e^{\hbar\omega_o/(k_B T)} - 1} + \frac{1}{2}\hbar\omega_o. \quad (6.75c)$$

Here we have included the half-quantum of energy associated with the mode's vacuum fluctuations.

2. Because on average the energy is half potential and half kinetic, and the mean potential energy is $\frac{1}{2}m\omega_o^2\overline{Q^2}$, and because the ergodic hypothesis tells us that time averages are the same as ensemble averages, it must be that

$$\bar{E} = 2\frac{1}{2}M\omega_o^2\omega^2\langle Q^2 \rangle = M\omega_o^2 \int_0^\infty S_Q(f) df. \quad (6.75d)$$

By inserting the spectral density (6.75b) and performing the frequency integral with the help of the narrowness of the resonance, we obtain

$$\bar{E} = \frac{S_{F'}(f_o)}{4R}. \quad (6.75e)$$

Equating this to our statistical-equilibrium expression (6.75c) for the mean energy, we see that at the frequency $f_o = \omega_o/(2\pi)$ the spectral density $S_{F'}(f_o)$ has the form (6.74b) claimed in the fluctuation-dissipation theorem. Moreover, since f_o can be chosen to be any frequency in the range (6.74a), the spectral density $S_{F'}(f)$ has the claimed form anywhere in this range. ■

Let us discuss two examples of the elementary fluctuation-dissipation theorem (6.74):

JOHNSON NOISE IN A RESISTOR

For the L - C - R circuit of Eq. (6.72), $R\dot{q}$ is the dissipative voltage across the resistor, and $F'(t)$ is the fluctuating voltage [more normally denoted $V'(t)$] across the resistor. The fluctuating voltage is called *Johnson noise*, and the fluctuation-dissipation relationship $S_V(f) = 4Rk_B T$ (classical regime) is called *Nyquist's theorem*, because John Johnson (1928) discovered the voltage fluctuations $V'(t)$ experimentally, and Harry Nyquist (1928) derived the fluctuation-dissipation relationship for a resistor to explain them. The fluctuation-dissipation theorem as formulated here is a generalization of Nyquist's original theorem to any system with kinetic energy $\frac{1}{2}m\dot{q}^2$ associated with a generalized coordinate q and with frictional dissipation produced by a heat bath.

BROWNIAN MOTION

In Secs. 6.3.3 and 6.7.2, we have studied the Brownian motion of a dust particle being buffeted by air molecules, but until now we omitted any attempt to deduce the motion's relaxation time τ_r . We now apply the fluctuation-dissipation theorem to deduce τ_r ,

Nyquist's theorem for Johnson noise

using a model in which the particle is idealized as a sphere with mass m and radius a that, of course, is far larger than the air molecules.

The equation of motion for the dust particle, when we ignore the molecules' fluctuating forces, is $mdv/dt = -Rv$. Here the resistance (friction) R due to interaction with the molecules has a form that depends on whether the molecules' mean free path λ is small or large compared to the particle. From the kinetic-theory formula $\lambda = 1/(n\sigma_{\text{mol}})$, where n is the number density of molecules and σ_{mol} is their cross section to scatter off each other (roughly their cross sectional area), we can deduce that for air $\lambda \sim 0.1 \mu\text{m}$. This is tiny compared to a dust particle's radius $a \sim 10$ to $1,000 \mu\text{m}$. This means that, when interacting with the dust particle, the air molecules will behave like a fluid. As we shall learn in Chap. 15, the friction for a fluid depends on whether a quantity called the Reynolds number, $\text{Re} = va/\nu$, is small or large compared to unity; here $\nu \sim 10^{-5} \text{m}^2 \text{s}^{-1}$ is the kinematic viscosity of air. Inserting numbers, we see that $\text{Re} \sim (v/0.1 \text{m s}^{-1})(a/100 \mu\text{m})$. The speeds v of dust particles being buffeted by air are far smaller than 0.1m s^{-1} as anyone who has watched them in a sunbeam knows, or as you can estimate from Eq. (6.53a). Therefore, the Reynolds number is small. From an analysis carried out in Sec. 14.3.2, we learn that in this low- Re fluid regime, the resistance (friction) on our spherical particle with radius a is [Eq. (14.34)]

$$R = 6\pi\rho va, \quad (6.76)$$

where $\rho \sim 1 \text{kg m}^{-3}$ is the density of air. (Notice that this resistance is proportional to the sphere's radius a or circumference; if λ were $\gg a$, then R would be proportional to the sphere's cross sectional area, i.e., to a^2 .)

When we turn on the molecules' fluctuating force F' , the particle's equation of motion becomes $mdv/dt + Rv = F'$. Feeding $e^{i2\pi ft}$ through this equation in place of F' , we get the output $v = 1/(R + i2\pi fm)$, whose modulus squared then is the ratio of S_v to $S_{F'}$. In this obviously classical regime, the fluctuation-dissipation theorem states that $S_{F'} = 4Rk_B T$. Therefore, we have

$$S_v = \frac{S_{F'}}{R^2 + (2\pi fm)^2} = \frac{4Rk_B T}{R^2 + (2\pi fm)^2} = \frac{4Rk_B T/m^2}{(2\pi f)^2 + (R/m)^2}. \quad (6.77)$$

relaxation time for
Brownian motion

By comparing with the S_v that we derived from Doob's theorem, Eq. (6.53b), we can read off the particle's rms velocity (in one dimension, x or y or z), $\sigma_v = \sqrt{k_B T/m}$ —which agrees with Eq. (6.53a) as it must—and we can also read off the particle's relaxation time (not to be confused with the bath's relaxation time),

$$\tau_r = m/R = m/(6\pi\rho va). \quad (6.78)$$

If we had tried to derive this relaxation time by analyzing the buffeting of the particle directly, we would have had great difficulty. The fluctuation-dissipation theorem,

FIGURE 6.15 An L - C - R circuit. See Ex. 6.16.

Doob's theorem, and the fluid-mechanics analysis of friction on a sphere have made the task straightforward.

EXERCISES

Exercise 6.16 *Practice: Noise in an L - C - R Circuit*

Consider an L - C - R circuit as shown in Fig. 6.15. This circuit is governed by the differential equation (6.72), where F' is the fluctuating voltage produced by the resistor's microscopic degrees of freedom (so we shall rename it V'), and $F \equiv V$ vanishes, since there is no driving voltage in the circuit. Assume that the resistor has temperature $T \gg \hbar\omega_o/k$, where $\omega_o = (LC)^{-1/2}$ is the circuit's resonant angular frequency, $\omega_o = 2\pi f_o$, and also assume that the circuit has a large quality factor (weak damping) so $R \ll 1/(\omega_o C) \simeq \omega_o L$.

- Initially consider the resistor R decoupled from the rest of the circuit, so current cannot flow across it. What is the spectral density $V_{\alpha\beta}$ of the voltage across this resistor?
- Now place the resistor into the circuit as shown in Fig. 6.15. The fluctuating voltage V' will produce a fluctuating current $I = \dot{q}$ in the circuit (where q is the charge on the capacitor). What is the spectral density of I ? And what, now, is the spectral density $V_{\alpha\beta}$ across the resistor?
- What is the spectral density of the voltage $V_{\alpha\gamma}$ between points α and γ ? and of $V_{\beta\gamma}$?
- The voltage $V_{\alpha\beta}$ is averaged from time $t = t_0$ to $t = t_0 + \tau$ (with $\tau \gg 1/f_o$), giving some average value U_0 . The average is measured once again from t_1 to $t_1 + \tau$, giving U_1 . A long sequence of such measurements gives an ensemble of numbers $\{U_0, U_1, \dots, U_n\}$. What are the mean \bar{U} and rms deviation $\Delta U \equiv \langle (U - \bar{U})^2 \rangle^{1/2}$ of this ensemble?

Exercise 6.17 ***Example: Detectability of a Sinusoidal Force that Acts on an Oscillator with Thermal Noise*

To measure a very weak sinusoidal force, let the force act on a simple harmonic oscillator with eigenfrequency at or near the force's frequency, and measure the oscillator's

response. Examples range in physical scale from nanomechanical oscillators ($\sim 1 \mu\text{m}$ in size) with eigenfrequency $\sim 1 \text{ GHz}$ that might play a role in future quantum information technology (e.g., Chan et al., 2011), to the fundamental mode of a $\sim 10\text{-kg}$ sapphire crystal, to a $\sim 40\text{-kg}$ LIGO mirror on which light pressure produces a restoring force, so its center of mass oscillates mechanically at frequency $\sim 100 \text{ Hz}$ (e.g., Abbott et al., 2009a). The oscillator need not be mechanical; for example, it could be an $L\text{-}C\text{-}R$ circuit, or a mode of an optical (Fabry-Perot) cavity.

The displacement $x(t)$ of any such oscillator is governed by the driven-harmonic-oscillator equation

$$m\left(\ddot{x} + \frac{2}{\tau_*}\dot{x} + \omega^2 x\right) = F(t) + F'(t). \quad (6.79)$$

Here m , ω , and τ_* are respectively the effective mass, angular frequency, and amplitude damping time associated with the oscillator; $F(t)$ is an external driving force; and $F'(t)$ is the fluctuating force associated with the dissipation that gives rise to τ_* . Assume that $\omega\tau_* \gg 1$ (weak damping).

- (a) Weak coupling to other modes is responsible for the damping. If the other modes are thermalized at temperature T , what is the spectral density $S_{F'}(f)$ of the fluctuating force F' ? What is the spectral density $S_x(f)$ of x ?
- (b) A very weak sinusoidal force drives the fundamental mode precisely on resonance:

$$F = \sqrt{2}F_s \cos \omega t. \quad (6.80)$$

Here F_s is the rms signal. What is the $x(t)$ produced by this signal force?

- (c) A sensor with negligible noise monitors this $x(t)$ and feeds it through a narrow-band filter with central frequency $f = \omega/(2\pi)$ and bandwidth $\Delta f = 1/\hat{\tau}$ (where $\hat{\tau}$ is the averaging time used by the filter). Assume that $\hat{\tau} \gg \tau_*$. What is the rms thermal noise σ_x after filtering? Show that the strength F_s of the signal force that produces a signal $x(t) = \sqrt{2}x_s \cos(\omega t + \delta)$ with rms amplitude x_s equal to σ_x and phase δ is

$$F_s = \sqrt{\frac{8mk_B T}{\hat{\tau}\tau_*}}. \quad (6.81)$$

This is the minimum detectable force at the “one- σ level.”

- (d) Suppose that the force acts at a frequency ω_o that differs from the oscillator’s eigenfrequency ω by an amount $|\omega - \omega_o| \lesssim 1/\tau_*$. What, then, is the minimum detectable force strength F_s ? What might be the advantages and disadvantages of operating off resonance in this way, versus on resonance?

Not all generalized coordinates q have kinetic energy $\frac{1}{2}m\dot{q}^2$. An important example (Levin, 1998) arises when one measures the location of the front of a mirror by bouncing a laser beam perpendicularly off of it—a common and powerful tool in modern technology. If the mirror moves along the beam's optic axis by Δz , the distance of the bouncing light's travel changes by $2\Delta z$, and the light acquires a phase shift $(2\pi/\lambda)2\Delta z$ (with λ the light's wavelength) that can be read out via interferometry (Chap. 9). Because the front of the mirror can deform, Δz is actually the change in a spatial average of the mirror front's location $z(r, \phi; t)$, an average weighted by the number of photons that hit a given region. In other words, the (time varying) mirror position monitored by the light is

$$q(t) = \int z(r, \phi; t) \frac{e^{-(r/r_o)^2}}{\pi r_o^2} r d\phi dr. \quad (6.82)$$

Here (r, ϕ) are cylindrical coordinates centered on the laser beam's optic axis, and $e^{-(r/r_o)^2}$ is the Gaussian distribution of the beam's energy flux, so

$$\left[e^{-(r/r_o)^2} / (\pi r_o^2) \right] r d\phi dr$$

is the probability that a photon of laser light will hit the mirror at (r, ϕ) in the range $(dr, d\phi)$.

Because the mirror front's deformations $z(r, \phi; t)$ can be expanded in normal modes, this q is a linear superposition of the generalized coordinates $q_j(t)$ of the mirror's normal modes of oscillation and its center-of-mass displacement $q_0(t)$: $q(t) = q_0(t) + \sum_j Q_j(r, \phi) q_j(t)$, where $Q_j(r, \phi)$ is mode j 's displacement eigenfunction evaluated at the mirror's face. Each of the generalized coordinates q_0 and q_j has a kinetic energy proportional to \dot{q}_j^2 , but this q does not. Therefore, the elementary version of the fluctuation-dissipation theorem, treated in the previous section, is not valid for this q .

Fortunately, there is a remarkably powerful generalized fluctuation-dissipation theorem due to Callen and Welton (1951) that works for this q and all other generalized coordinates that are coupled to a heat bath. To formulate this theorem, we must first introduce the *complex impedance* $Z(\omega)$ for a generalized coordinate.

Let a sinusoidal external force $F = F_o e^{-i\omega t}$ act on the generalized coordinate q [so q 's canonically conjugate momentum p is being driven as $(dp/dt)_{\text{drive}} = F_o e^{-i\omega t}$]. Then the velocity of the resulting sinusoidal motion will be

$$\dot{q} \equiv \frac{dq}{dt} = -i\omega q = \frac{1}{Z(\omega)} F_o e^{-i\omega t}, \quad (6.83a)$$

complex impedance for a generalized coordinate

where the real part of each expression is to be taken. This equation can be regarded as the definition of q 's complex impedance $Z(\omega)$ (ratio of force to velocity); it is determined by the system's details. If the system were completely conservative, then the impedance would be perfectly imaginary, $Z = iI$, where I is real. For example, for a freely moving dust particle in vacuum, driven by a sinusoidal force, the momentum is $p = m\dot{q}$ (where m is the particle's mass), the equation of motion is $F_o e^{-i\omega t} = dp/dt = m(d/dt)\dot{q} = m(-i\omega)\dot{q}$, and so the impedance is $Z = -im\omega$, which is purely imaginary.

The bath prevents the system from being conservative—energy can be fed back and forth between the generalized coordinate q and the bath's many degrees of freedom. This energy coupling influences the generalized coordinate q in two important ways. First, it changes the impedance $Z(\omega)$ from purely imaginary to complex,

$$Z(\omega) = iI(\omega) + R(\omega), \quad (6.83b)$$

where R is the *resistance* experienced by q . Correspondingly, when the sinusoidal force $F = F_o e^{-i\omega t}$ is applied, the resulting motions of q feed energy into the bath, dissipating power at a rate $W_{\text{diss}} = \langle \Re(F)\Re(\dot{q}) \rangle = \langle \Re(F_o e^{-i\omega t})\Re(F_o e^{-i\omega t}/Z) \rangle = \langle F_o \cos \omega t \Re(1/Z) F_o \cos \omega t \rangle$; that is,

$$W_{\text{diss}} = \frac{1}{2} \frac{R}{|Z|^2} F_o^2. \quad (6.84)$$

power dissipation rate

Second, the thermal motions of the bath exert a randomly fluctuating force $F'(t)$ on q , driving its generalized momentum as $(dp/dt)_{\text{drive}} = F'$.

As an example, consider the L - C - R circuit of Eq. (6.72). We can identify the generalized momentum by shutting off the bath (the resistor and its fluctuating voltage); writing down the lagrangian for the resulting L - C circuit, $\mathcal{L} = \frac{1}{2}L\dot{q}^2 - \frac{1}{2}q^2/C$; and computing $p = \partial\mathcal{L}/\partial\dot{q} = L\dot{q}$. [Equally well, we can identify p from one of Hamilton's equations for the hamiltonian $H = p^2/(2L) + q^2/(2C)$.] We evaluate the impedance $Z(\omega)$ from the equation of motion for this lagrangian with the bath's resistance restored (but not its fluctuating voltage) and with a sinusoidal voltage $V = V_o e^{-i\omega t}$ imposed:

$$L \frac{d\dot{q}}{dt} - \frac{q}{C} + R\dot{q} = \left(-i\omega L + \frac{1}{-i\omega C} + R \right) \dot{q} = V_o e^{-i\omega t}. \quad (6.85a)$$

Evidently, $V = V_o e^{-i\omega t}$ is the external force F that drives the generalized momentum $p = L\dot{q}$, and the complex impedance (ratio of force to velocity) is

$$Z(\omega) = \frac{V}{\dot{q}} = -i\omega L + \frac{1}{-i\omega C} + R. \quad (6.85b)$$

This is identical to the impedance as defined in the standard theory of electrical circuits (which is what motivates our $Z = F/\dot{q}$ definition of impedance), and as expected, the real part of this impedance is the circuit's resistance R .

Returning to our general q , the fluctuating force F' (equal to fluctuating voltage V' in the case of the circuit) and the resistance R to an external force both arise from interaction with the same heat bath. Therefore, it should not be surprising that they are connected by the generalized fluctuation-dissipation theorem:

$$S_{F'}(f) = 4R(f) \left(\frac{1}{2}hf + \frac{hf}{e^{hf/(k_B T)} - 1} \right) \quad \text{in general,} \quad (6.86a)$$

$$S_{F'}(f) = 4R(f)k_B T \quad \text{in the classical domain, } k_B T \gg hf, \quad (6.86b)$$

which is valid at all frequencies

$$f \ll 1/\tau_r, \quad (6.87)$$

where τ_r is the (very short) relaxation time for the bath's fluctuating forces F' . Here T is the temperature of the bath, h is Planck's constant, and we have written the resistance as $R(f)$ to emphasize that it can depend on frequency $f = \omega/(2\pi)$.

A derivation of this generalized fluctuation-dissipation theorem is sketched in Ex. 6.18.

One is usually less interested in the spectral density of the bath's force F' than in that of the generalized coordinate q . The definition (6.83a) of impedance implies $-i\omega\tilde{q} = \tilde{F}'/Z(\omega)$ for Fourier transforms, whence $S_q = S_{F'}/[(2\pi f)^2|Z|^2]$. When combined with Eqs. (6.86) and (6.84), this implies

$$S_q(f) = \frac{8W_{\text{diss}}}{(2\pi f)^2 F_o^2} \left(\frac{1}{2}hf + \frac{hf}{e^{hf/(k_B T)} - 1} \right) \quad \text{in general,} \quad (6.88a)$$

$$S_q(f) = \frac{8W_{\text{diss}}k_B T}{(2\pi f)^2 F_o^2} \quad \text{in the classical domain, } k_B T \gg hf. \quad (6.88b)$$

Therefore, to evaluate $S_q(f)$, one does not need to know the complex impedance $Z(\omega)$. Rather, one only needs the power dissipation W_{diss} that results when a sinusoidal force F_o is applied to the generalized momentum p that is conjugate to the coordinate q of interest.

The light beam bouncing off a mirror (beginning of this section) is a good example. To couple the sinusoidal force $F(t) = F_o e^{-i\omega t}$ to the mirror's generalized coordinate q , we add an interaction term $H_I = -F(t)q$ to the mirror's hamiltonian H_{mirror} . Hamilton's equation for the evolution of the momentum conjugate to q then becomes $dp/dt = -\partial[H_{\text{mirror}} - F(t)q]/\partial q = \partial H_{\text{mirror}}/\partial t + F(t)$. Thus, $F(t)$ drives p as desired. The form of the interaction term is, by Eq. (6.82) for q ,

$$H_I = -F(t)q = - \int z(r, \phi) \frac{F(t)e^{-(r/r_o)^2}}{\pi r_o^2} r d\phi dr. \quad (6.89)$$

generalized fluctuation-dissipation theorem

spectral density for generalized coordinate

This is the mathematical description of a time varying *pressure*

$$P = F_o e^{-i\omega t} e^{-(r/r_o)^2} / (\pi r_o^2)$$

applied to the mirror face, which has coordinate location $z(r, \phi)$. Therefore, to compute the spectral density of the mirror's light-beam-averaged displacement q , at frequency $f = \omega/(2\pi)$, we can

Levin's method for computing spectral density of mirror's light-averaged displacement

1. apply to the mirror's front face a pressure with spatial shape the same as that of the light beam's energy flux (a Gaussian in our example) and with total force $F_o e^{-i\omega t}$;
2. evaluate the power dissipation W_{diss} produced by this sinusoidally oscillating pressure; and then
3. insert the ratio W_{diss}/F_o^2 into Eq. (6.88a) or Eq. (6.88b). This is called Levin's (1998) method.

In practice, in this thought experiment the power can be dissipated at many locations: in the mirror coating (which makes the mirror reflective), in the substrate on which the coating is placed (usually glass, i.e., fused silica), in the attachment of the mirror to whatever supports it (usually a wire or glass fiber), and in the supporting structure (the wire or fiber and the solid object to which it is attached). The dissipations W_{diss} at each of these locations add together, and therefore the fluctuating noises from the various dissipation locations are additive. Correspondingly, one speaks of "coating thermal noise," "substrate thermal noise," and so forth; physicists making delicate optical measurements deduce each through a careful computation of its corresponding dissipation W_{diss} .

In the LIGO interferometer, whose noise power spectrum is shown in Fig. 6.7, these thermal noises dominate in the intermediate frequency band $40 \text{ Hz} \lesssim f \lesssim 150 \text{ Hz}$.

EXERCISES

Exercise 6.18 *Derivation: Generalized Fluctuation-Dissipation Theorem* T2

By a method analogous to that used for the elementary fluctuation-dissipation theorem (Sec. 6.8.1), derive the generalized fluctuation-dissipation theorem [Eqs. (6.86)].

Hints: Consider a thought experiment in which the system's generalized coordinate q is very weakly coupled to an external oscillator that has a mass M and an angular eigenfrequency ω_o , near which we wish to derive the fluctuation-dissipation formulas (6.86). Denote by Q and P the external oscillator's generalized coordinate and momentum and by κ the arbitrarily weak coupling constant between the oscillator and q , so the hamiltonian of system plus oscillator plus fluctuating force F' acting on q is

$$H = H_{\text{system}}(q, p, \dots) + \frac{P^2}{2M} + \frac{1}{2} M \omega_o^2 Q^2 + \kappa Qq - F'(t) q. \quad (6.90)$$

Here the “. . .” refers to the other degrees of freedom of the system, some of which might be strongly coupled to q and p (as is the case, e.g., for the laser-measured mirror discussed in the text).

- (a) By combining Hamilton's equations for q and its conjugate momentum p [which give Eq. (6.83a) with the appropriate driving force] with those for the external oscillator (Q, P), derive an equation that shows quantitatively how the force F' , acting through q , influences the oscillator's coordinate Q :

$$\left[M(-\omega^2 + \omega_o'^2) - \frac{i\kappa^2 R}{\omega|Z|^2} \right] \tilde{Q} = \frac{\kappa}{i\omega Z} \tilde{F}'. \quad (6.91)$$

Here the tildes denote Fourier transforms; $\omega = 2\pi f$ is the angular frequency at which the Fourier transforms are evaluated; and $\omega_o'^2 = \omega_o^2 - \kappa^2 I / (\omega|Z|^2)$, with $Z = R + iI$, is the impedance of q at angular frequency ω .

- (b) Show that

$$S_Q = \frac{(\kappa/\omega|Z|)^2 S_{F'}}{M^2(-\omega^2 + \omega_o'^2)^2 + \kappa^4 R^2 / (\omega|Z|^2)^2}. \quad (6.92)$$

- (c) Make the resonance in this equation arbitrarily sharp by choosing the coupling constant κ arbitrarily small. Then show that the mean energy in the oscillator is

$$\bar{E} = M\omega_o^2 \int_0^\infty S_Q(f) df = \frac{S_{F'}(f = \omega_o/(2\pi))}{4R}. \quad (6.93)$$

- (d) By equating this to expression (6.75c) for the mean energy of any oscillator coupled to a heat bath, deduce the desired generalized fluctuation-dissipation equations (6.86).

6.9 Fokker-Planck Equation

6.9

In statistical physics, we often want to know the collective influence of many degrees of freedom (a bath) on a single (possibly vectorial) degree of freedom q . The bath might or might not be thermalized. The forces it exerts on q might have short range (as in molecular collisions buffeting an air molecule or dust particle) or long range (as in Coulomb forces from many charged particles in a plasma pushing stochastically on an electron that interests us, or gravitational forces from many stars pulling on a single star of interest). There might also be long-range, macroscopic forces that produce anisotropies and/or inhomogeneities (e.g., applied electric or magnetic fields). We might want to compute how the bath's many degrees of freedom influence, for example, the diffusion of a particle as embodied in its degree of freedom q . Or we might want to compute the statistical properties of q for a representative electron in a plasma and from them deduce the plasma's transport coefficients (diffusivity, heat

conductivity, and thermal conductivity). Or we might want to know how the gravitational pulls of many stars in the vicinity of a black hole drive the collective evolution of the stars' distribution function.

The Fokker-Planck equation is a powerful tool in such situations. To apply it, we must identify a (possibly vectorial) degree of freedom q to analyze that is Markov. For the types of problems described here, this is typically the velocity (or a component of velocity) of a representative particle or star. The Fokker-Planck equation is then a differential equation for the evolution of the conditional probability distribution P_2 [Eq. (6.6b)], or other distribution function, for that Markov degree of freedom. In Sec. 6.9.1, we present the simplest, 1-dimensional example. Then in Sec. 6.9.3, we generalize to several dimensions.

crucial assumption of a Markov Process

6.9.1 Fokker-Planck for a 1-Dimensional Markov Process

For a 1-dimensional Markov process $y(t)$ (e.g., the x component of the velocity of a particle) being driven by a bath (not necessarily thermalized!) with many degrees of freedom, the *Fokker-Planck equation*¹¹ states

1-dimensional Fokker-Planck equation

$$\frac{\partial}{\partial t} P_2 = -\frac{\partial}{\partial y} [A(y)P_2] + \frac{1}{2} \frac{\partial^2}{\partial y^2} [B(y)P_2]. \quad (6.94)$$

Here $P_2 = P_2(y, t|y_o)$ is to be regarded as a function of the variables y and t with y_o fixed; that is, Eq. (6.94) is to be solved subject to the initial condition

$$P_2(y, 0|y_o) = \delta(y - y_o). \quad (6.95)$$

As we shall see later, this Fokker-Planck equation is a generalized diffusion equation for the probability P_2 : as time passes, the probability diffuses away from its initial location, $y = y_o$, spreading gradually out over a wide range of values of y .

In the Fokker-Planck equation (6.94) the function $A(y)$ produces a motion of the mean away from its initial location, while the function $B(y)$ produces a diffusion of the probability. If one can deduce the evolution of P_2 for very short times by some other method [e.g., in the case of a dust particle being buffeted by air molecules, by solving statistically the Langevin equation $mdv/dt + Rv = F'(t)$], then from that short-time evolution one can compute the functions $A(y)$ and $B(y)$:

$$A(y) = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \int_{-\infty}^{+\infty} (y' - y) P_2(y', \Delta t|y) dy', \quad (6.96a)$$

$$B(y) = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \int_{-\infty}^{+\infty} (y' - y)^2 P_2(y', \Delta t|y) dy'. \quad (6.96b)$$

11. A very important generalization of this equation is to replace the probability P_2 by a particle distribution function and the Markov process $y(t)$ by the 3-dimensional velocity or momentum of the particles. The foundations for this generalization are laid in the Track-Two Sec. 6.9.3, and an application is in Ex. 20.8.

(These equations can be deduced by reexpressing the limit as an integral of the time derivative $\partial P_2/\partial t$ and then inserting the Fokker-Planck equation and integrating by parts; Ex. 6.19.) Note that the integral (6.96a) for $A(y)$ is the mean change $\overline{\Delta y}$ in the value of y that occurs in time Δt , if at the beginning of Δt (at $t = 0$) the value of the process is precisely y ; moreover (since the integral of yP_2 is just equal to y , which is a constant), $A(y)$ is also the rate of change of the mean, $d\bar{y}/dt$. Correspondingly we can write Eq. (6.96a) in the more suggestive form

$$A(y) = \lim_{\Delta t \rightarrow 0} \left(\frac{\overline{\Delta y}}{\Delta t} \right) = \left(\frac{d\bar{y}}{dt} \right)_{t=0}. \quad (6.97a)$$

Similarly, the integral (6.96b) for $B(y)$ is the mean-squared change in y , $\overline{(\Delta y)^2}$, if at the beginning of Δt the value of the process is precisely y ; and (as one can fairly easily show; Ex. 6.19) it is also the rate of change of the variance $\sigma_y^2 = \int (y' - \bar{y})^2 P_2 dy'$. Correspondingly, Eq. (6.96b) can be written as

$$B(y) = \lim_{\Delta t \rightarrow 0} \left(\frac{\overline{(\Delta y)^2}}{\Delta t} \right) = \left(\frac{d\sigma_y^2}{dt} \right)_{t=0}. \quad (6.97b)$$

It may seem surprising that $\overline{\Delta y}$ and $\overline{(\Delta y)^2}$ can both increase linearly in time for small times [cf. the Δt in the denominators of both Eq. (6.97a) and Eq. (6.97b)], thereby both giving rise to finite functions $A(y)$ and $B(y)$. In fact, this is so: the linear evolution of $\overline{\Delta y}$ at small t corresponds to the motion of the mean (i.e., of the peak of the probability distribution), while the linear evolution of $\overline{(\Delta y)^2}$ corresponds to the diffusive broadening of the probability distribution.

DERIVATION OF THE FOKKER-PLANCK EQUATION (6.94)

Because y is Markov, it satisfies the Smoluchowski equation (6.11), which we rewrite here with a slight change of notation:

$$P_2(y, t + \tau | y_0) = \int_{-\infty}^{+\infty} P_2(y - \xi, t | y_0) P_2(y - \xi + \xi, \tau | y - \xi) d\xi. \quad (6.98a)$$

Take τ to be small so only small ξ will contribute to the integral, and expand in a Taylor series in τ on the left-hand side of (6.98a) and in the ξ of $y - \xi$ on the right-hand side:

$$\begin{aligned} P_2(y, t | y_0) + \sum_{n=1}^{\infty} \frac{1}{n!} \left[\frac{\partial^n}{\partial t^n} P_2(y, t | y_0) \right] \tau^n \\ = \int_{-\infty}^{+\infty} P_2(y, t | y_0) P_2(y + \xi, \tau | y) d\xi \\ + \sum_{n=1}^{\infty} \frac{1}{n!} \int_{-\infty}^{+\infty} (-\xi)^n \frac{\partial^n}{\partial y^n} [P_2(y, t | y_0) P_2(y + \xi, \tau | y)] d\xi. \quad (6.98b) \end{aligned}$$

In the first integral on the right-hand side the first term is independent of ξ and can be pulled out from under the integral, and the second term then integrates to one; thereby the first integral on the right reduces to $P_2(y, t|y_o)$, which cancels the first term on the left. The result is then

$$\begin{aligned} & \sum_{n=1}^{\infty} \frac{1}{n!} \left[\frac{\partial^n}{\partial t^n} P_2(y, t|y_o) \right] \tau^n \\ &= \sum_{n=1}^{\infty} \frac{(-1)^n}{n!} \frac{\partial^n}{\partial y^n} \left[P_2(y, t|y_o) \int_{-\infty}^{+\infty} \xi^n P_2(y + \xi, \tau|y) d\xi \right]. \end{aligned} \quad (6.98c)$$

Divide by τ , take the limit $\tau \rightarrow 0$, and set $\xi \equiv y' - y$ to obtain

$$\frac{\partial}{\partial t} P_2(y, t|y_o) = \sum_{n=1}^{\infty} \frac{(-1)^n}{n!} \frac{\partial^n}{\partial y^n} [M_n(y) P_2(y, t|y_o)], \quad (6.99a)$$

where

$$M_n(y) \equiv \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \int_{-\infty}^{+\infty} (y' - y)^n P_2(y', \Delta t|y) dy' \quad (6.99b)$$

is the n th moment of the probability distribution P_2 after time Δt . This is a form of the Fokker-Planck equation that has slightly wider validity than Eq. (6.94). Almost always, however, the only nonvanishing functions $M_n(y)$ are $M_1 \equiv A$, which describes the linear motion of the mean, and $M_2 \equiv B$, which describes the linear growth of the variance. Other moments of P_2 grow as higher powers of Δt than the first power, and correspondingly, their M_n s vanish. Thus, almost always¹² (and always, so far as we are concerned), Eq. (6.99a) reduces to the simpler version (6.94) of the Fokker-Planck equation.

TIME-INDEPENDENT FOKKER-PLANCK EQUATION

If, as we assume in this chapter, y is ergodic, then $p_1(y)$ can be deduced as the limit of $P_2(y, t|y_o)$ for arbitrarily large times t . Then (and in general) p_1 can be deduced from the time-independent Fokker-Planck equation:

time-independent Fokker-Planck equation

$$\boxed{-\frac{\partial}{\partial y} [A(y)p_1(y)] + \frac{1}{2} \frac{\partial^2}{\partial y^2} [B(y)p_1(y)] = 0.} \quad (6.100)$$

GAUSSIAN-MARKOV PROCESS

For a Gaussian-Markov process, the mathematical form of $P_2(y_2, t|y_1)$ is known from Doob's theorem: Eqs. (6.18). In the notation of those equations, the Fokker-Planck functions A and B are

$$A(y_1) = (d\bar{y}_t/dt)_{t=0} = -(y_1 - \bar{y})/\tau_r, \quad \text{and} \quad B(y_1) = (d\sigma_y^2/dt)_{t=0} = 2\sigma_y^2/\tau_r.$$

12. In practice, when there are important effects not captured by A and B (e.g., in the mathematical theory of finance; Hull, 2014), they are usually handled by adding other terms to Eq. (6.94), including sometimes integrals.

Translating back to the notation of this section, we have

$$A(y) = -(y - \bar{y})/\tau_r, \quad B(y) = 2\sigma_y^2/\tau_r. \quad (6.101)$$

Thus, if we can compute $A(y)$ and $B(y)$ explicitly for a Gaussian-Markov process, then from them we can read off the process's relaxation time τ_r , long-time mean \bar{y} , and long-time variance σ_y^2 . As examples, in Ex. 6.22 we revisit Brownian motion of a dust particle in air and in the next section, we analyze laser cooling of atoms. A rather different example is the evolution of a photon distribution function under Compton scattering (Sec. 28.6.3).

EXERCISES

Exercise 6.19 *Derivation: Equations for A and B*

Derive Eqs. (6.96) for A and B from the Fokker-Planck equation (6.94), and then from Eqs. (6.96) derive Eqs. (6.97).

Exercise 6.20 *Problem: Fokker-Planck Equation as Conservation Law for Probability*

Show that the Fokker-Planck equation can be interpreted as a conservation law for probability. What is the probability flux in this conservation law? What is the interpretation of each of its two terms?

Exercise 6.21 *Example: Fokker-Planck Coefficients When There Is Direct Detailed Balance*

Consider an electron that can transition between two levels by emitting or absorbing a photon; and recall (as discussed in Ex. 3.6) that we have argued that the stimulated transitions should be microscopically reversible. This is an example of a general principle introduced by Boltzmann called *detailed balance*. In the context of classical physics, it is usually considered in the context of the time reversibility of the underlying physical equations. For example, if two molecules collide elastically and exchange energy, the time-reversed process happens with the same probability per unit time when the colliding particles are in the time-reversed initial states. However, this does not necessarily imply that the probability of a single molecule changing its velocity from \mathbf{v} to \mathbf{v}' is the same as that of the reverse change. (A high-energy molecule is more likely to lose energy when one averages over all collisions.)

An important simplification happens when the probability of a change in y is equal to the probability of the opposite change. An example might be a light particle colliding with a heavy particle for which the recoil can be ignored. Under this more restrictive condition, we can write that $P_2(y', \Delta t|y) = P_2(y, \Delta t|y')$. Show that the Fokker-Planck equation then simplifies (under the usual assumptions) to a standard diffusion equation:

$$\frac{\partial}{\partial t} P_2 = \frac{1}{2} \frac{\partial}{\partial y} B(y) \frac{\partial}{\partial y} P_2. \quad (6.102)$$

Of course, there can be other contributions to the total Fokker-Planck coefficients that do not satisfy this condition, but this simplification can be very instructive. An example described in Sec. 23.3.3 is the quasilinear interaction between waves and particles in a plasma.

Exercise 6.22 *Example: Solution of Fokker-Planck Equation for Brownian Motion of a Dust Particle*

- (a) Write down the explicit form of the Langevin equation for the x component of velocity $v(t)$ of a dust particle interacting with thermalized air molecules.
- (b) Suppose that the dust particle has velocity v at time t . By integrating the Langevin equation, show that its velocity at time $t + \Delta t$ is $v + \Delta v$, where

$$m\Delta v + Rv\Delta t + O[(\Delta t)^2] = \int_t^{t+\Delta t} F'(t')dt', \quad (6.103a)$$

with R the frictional resistance and m the particle's mass. Take an ensemble average of this and use $\overline{F'} = 0$ to conclude that the function $A(v)$ appearing in the Fokker-Planck equation (6.94) has the form

$$A(v) \equiv \lim_{\Delta t \rightarrow 0} \frac{\overline{\Delta v}}{\Delta t} = -\frac{Rv}{m}. \quad (6.103b)$$

Compare this expression with the first of Eqs. (6.101) to conclude that the mean and relaxation time are $\bar{v} = 0$ and $\tau_r = m/R$, respectively, in agreement with the second of Eqs. (6.53a) in the limit $\tau \rightarrow \infty$ and with Eq. (6.78).

- (c) From Eq. (6.103a) show that

$$(\Delta v)^2 = \left[-\frac{v}{\tau_r}\Delta t + O[(\Delta t)^2] + \frac{1}{m} \int_t^{t+\Delta t} F'(t')dt' \right]^2. \quad (6.103c)$$

Take an ensemble average of this expression, and use $\overline{F'(t_1)F'(t_2)} = C_{F'}(t_2 - t_1)$ —together with the Wiener-Khintchine theorem—to evaluate the terms involving F' in terms of $S_{F'}$, which in turn is known from the fluctuation-dissipation theorem. Thereby obtain

$$B(v) = \lim_{\Delta t \rightarrow 0} \frac{\overline{(\Delta v)^2}}{\Delta t} = \frac{2Rk_B T}{m^2}. \quad (6.103d)$$

Combine with Eq. (6.101) and $\tau_r = m/R$ [from part (b)], to conclude that $\sigma_v^2 = k_B T/m$, in accord with the last of Eqs. (6.53a).

The 1997 Nobel Prize was awarded to Steven Chu, Claude Cohen-Tannoudji, and William D. Phillips for the “development of methods to cool and trap atoms with laser light” (Chu et al., 1998). In this section, we use the Fokker-Planck equation to analyze

FIGURE 6.16 Doppler cooling of an atom in a Fabry-Perot cavity. (a) The cavity formed by two mirrors with laser light bouncing back and forth between them, and the sodium atom at the center. (b) The cross section $\sigma' = d\sigma/d\omega$ for the atom in its ground state to absorb a photon of laser light. The laser angular frequency ω is tuned to the off-resonance inflection point (steepest slope) of σ' , indicated by the dot.

one of the most important methods they developed: *Doppler cooling*, also called *laser cooling* or *optical molasses*.

A neutral sodium atom is placed near the center (waist) of a Fabry-Perot optical cavity (Sec. 9.4.2), so it is bathed by laser light traveling in both the $+z$ and $-z$ directions (Fig. 6.16a). The atom absorbs and reemits photons and their momenta, resulting in a stochastic evolution of its z component of velocity, v . Using the Fokker-Planck equation to analyze this evolution, we shall discover that, if the light frequency and power are tuned appropriately, there is a strong resisting force (“optical molasses”) on the atom as well as a randomizing force. The net effect, after the atom relaxes into equilibrium with the photon field, is a very low effective temperature ($\sim 100 \mu\text{K}$) for the atom’s motion in the z direction.

The atom has a large cross section $\sigma' \equiv d\sigma/d\omega$ to absorb a photon with angular frequency $\omega \simeq 3.20 \times 10^{15} \text{ s}^{-1}$ (yellow light), thereby getting excited into a state with energy $\hbar\omega \simeq 2.11 \text{ eV}$. The absorption cross section $\sigma'(\omega)$ has a narrow resonance (Lorentzian line shape $\propto [1 + (\omega - \omega_0)^2/\Gamma^2]^{-1}$; Fig. 6.16b) with half-width $\Gamma \simeq 10 \text{ MHz}$; and, correspondingly, the excited atom has a half-life $1/\Gamma$ to reemit a photon and return to its ground state. The laser power is adjusted to make the excitation rate \mathcal{R} equal to Γ ,

$$\mathcal{R} = \Gamma \simeq 10^7 \text{ s}^{-1}, \quad (6.104a)$$

thereby maximizing the rate of excitations. (At a higher power, the excitation rate will saturate at $1/\Gamma$, because the atom spends most of its time excited and waiting to reemit.)

The laser frequency is tuned to the resonance’s inflection point (point of greatest slope $d\sigma'/d\omega$ on one side of the line), so that, when an atom is moving rightward with velocity v , the Doppler shift $\delta\omega/\omega = v/c$ produces a maximal fractional increase in the cross section and rate for absorbing leftward-moving photons and decrease in those for rightward-moving photons:

$$\frac{\delta\mathcal{R}}{\mathcal{R}} = \frac{\delta\sigma'}{\sigma'} = \frac{1}{\sigma'} \frac{d\sigma'}{d\omega} \left(\omega \frac{v}{c} \right) \sim \frac{\omega v}{\Gamma c}. \quad (6.104b)$$

(Here and henceforth “ \sim ” means accurate to within a factor of order unity.) This results in a net resisting force $F \sim \delta R \hbar k$ on the atom, due to the imbalance in absorption rates for leftward and rightward photons; here $k = \omega/c = 10.7 \mu\text{m}^{-1}$ is the photons’ wave number, and $\hbar k$ is the momentum absorbed from each photon. This slow-down force produces a rate of change of the atom’s mean velocity

$$A = \frac{d\bar{v}}{dt} \sim -\frac{\delta R \hbar k}{m} \sim -\frac{\hbar k^2}{m} v. \quad (6.104c)$$

Here we have used Eqs. (6.104b) and (6.104a), and $\omega/c = k$; and we have set the slow-down rate equal to the coefficient A in the Fokker-Planck equation for v [Eq. (6.97a)].

There are two sources of randomness in the atom’s velocity, both of the same magnitude: statistical randomness (\sqrt{N}) in the number of photons absorbed from the two directions, and randomness in the direction of reemission of photons and thence in the recoil direction. During a short time interval Δt , the mean number of absorptions and reemissions is $\sim \mathcal{R} \Delta t$, so the rms fluctuation in the momentum transfer to the atom (along the z direction) is $\sim \hbar k \sqrt{\mathcal{R} \Delta t}$, whence the change of the variance of the velocity is $(\Delta v)^2 \sim (\hbar k)^2 \mathcal{R} \Delta t / m^2$. (Here $m \simeq 3.82 \times 10^{-26}$ kg is the sodium atom’s mass.) Correspondingly, the B coefficient (6.103d) in the Fokker-Planck equation for v is

$$B = \frac{(\Delta v)^2}{\Delta t} \sim \left(\frac{\hbar k}{m}\right)^2 \mathcal{R} = \left(\frac{\hbar k}{m}\right)^2 \Gamma. \quad (6.104d)$$

From the A and B coefficients [Eqs. (6.104c) and (6.104d)] we infer, with the aid of Eqs. (6.101), the relaxation time, long-term mean, and long-term variance of the atom’s velocity along the z direction, and also an effective temperature associated with the variance:¹³

$$\tau_r \sim \frac{m}{(\hbar k^2)} = 3 \mu\text{s}, \quad \bar{v} = 0, \quad \sigma_v^2 \sim \frac{\hbar \Gamma}{m} = (0.17 \text{ ms}^{-1})^2, \\ T_{\text{eff}} = \frac{m \sigma_v^2}{k_B} \sim \frac{\hbar \Gamma}{k_B} \sim 8 \mu\text{K}. \quad (6.105)$$

It is remarkable how effective this optical molasses can be!

If one wants to cool all components of velocity, one can either impose counter-propagating laser beams along all three Cartesian axes, or put the atom into a potential well (inside the Fabry Perot cavity) that deflects its direction of motion on a timescale much less than τ_r .

This optical molasses technique is widely used today in atomic physics, for example, when cooling ensembles of atoms to produce Bose-Einstein condensates

13. The atom’s long-term, ergodically wandering velocity distribution is Gaussian rather than Maxwellian, so it is not truly thermalized. However, it has the same velocity variance as a thermal distribution with temperature $\sim \hbar \Gamma / k_B$, so we call this its “effective temperature.”

(Sec. 4.9), and for cooling atoms to be used as the ticking mechanisms of atomic clocks (Fig. 6.11, footnote 9 in Sec. 6.6.1, Ex. 6.13, and associated discussions).

6.9.3 Fokker-Planck for a Multidimensional Markov Process; Thermal Noise in an Oscillator T2

6.9.3

Few 1-dimensional random processes are Markov, so only a few can be treated using the 1-dimensional Fokker-Planck equation. However, it is frequently the case that, if one augments additional variables into the random process, it becomes Markov. An important example is a harmonic oscillator driven by a Gaussian random force (Ex. 6.23). Neither the oscillator's position $x(t)$ nor its velocity $v(t)$ is Markov, but the pair $\{x, v\}$ is a 2-dimensional Markov process.

For such a process, and more generally for any n -dimensional Gaussian-Markov process $\{y_1(t), y_2(t), \dots, y_n(t)\} \equiv \{\mathbf{y}(t)\}$, the conditional probability distribution $P_2(\mathbf{y}, t | \mathbf{y}_0)$ satisfies the following Fokker-Planck equation [the obvious generalization of Eq. (6.94)]:

$$\frac{\partial}{\partial t} P_2 = - \frac{\partial}{\partial y_j} [A_j(\mathbf{y}) P_2] + \frac{1}{2} \frac{\partial^2}{\partial y_j \partial y_k} [B_{jk}(\mathbf{y}) P_2]. \quad (6.106a)$$

multidimensional Fokker-Planck equation

Here the functions A_j and B_{jk} , by analogy with Eqs. (6.96) and (6.97), are

$$A_j(\mathbf{y}) = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \int (y'_j - y_j) P_2(\mathbf{y}', \Delta t | \mathbf{y}) d^n \mathbf{y}' = \lim_{\Delta t \rightarrow 0} \left(\frac{\overline{\Delta y_j}}{\Delta t} \right), \quad (6.106b)$$

$$B_{jk}(\mathbf{y}) = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \int (y'_j - y_j)(y'_k - y_k) P_2(\mathbf{y}', \Delta t | \mathbf{y}) d^n \mathbf{y}' = \lim_{\Delta t \rightarrow 0} \left(\frac{\overline{\Delta y_j \Delta y_k}}{\Delta t} \right). \quad (6.106c)$$

In Ex. 6.23 we use this Fokker-Planck equation to explore how a harmonic oscillator settles into equilibrium with a dissipative heat bath. In Ex. 20.8 we apply it to Coulomb collisions in an ionized plasma.

The multidimensional Fokker-Planck equation can be used to solve the Boltzmann transport equation (3.66) for the kinetic-theory distribution function $\mathcal{N}(\mathbf{p}, t)$ or (in the conventions of plasma physics) for the velocity distribution $f(\mathbf{v}, t)$ (Chap. 20). The reasons are (i) $\mathcal{N}(\mathbf{p}, t)$ and $f(\mathbf{v}, t)$ are the same kind of probability distribution as P_2 —probabilities for a Markov momentum or velocity—with the exception that $\mathcal{N}(\mathbf{p}, t)$ and $f(\mathbf{v}, t)$ usually have different initial conditions at time $t = 0$ than P_2 's delta function [in fact, P_2 can be regarded as a Green's function for $\mathcal{N}(\mathbf{p}, t)$ and $f(\mathbf{v}, t)$] and (ii) the initial conditions played no role in our derivation of the Fokker-Planck equation. In Sec. 20.4.3, we discuss the use of the Fokker-Planck equation to deduce how long-range Coulomb interactions drive the equilibration of the distribution functions $f(\mathbf{v}, t)$ for the velocities of electrons and ions in a plasma. In Sec. 23.3.3, we use the Fokker-Planck equation to study the interaction of electrons and ions with plasma waves (plasmons).

Exercise 6.23 ***Example: Solution of Fokker-Planck Equation for Thermal Noise in an Oscillator* T2

Consider a classical simple harmonic oscillator (e.g., the nanomechanical oscillator, LIGO mass on an optical spring, L - C - R circuit, or optical resonator briefly discussed in Ex. 6.17). Let the oscillator be coupled weakly to a dissipative heat bath with temperature T . The Langevin equation for the oscillator's generalized coordinate x is Eq. (6.79). The oscillator's coordinate $x(t)$ and momentum $p(t) \equiv m\dot{x}$ together form a 2-dimensional Gaussian-Markov process and thus obey the 2-dimensional Fokker-Planck equation (6.106a). As an aid to solving this Fokker-Planck equation, change variables from $\{x, p\}$ to the real and imaginary parts X_1 and X_2 of the oscillator's complex amplitude:

$$x = \Re[(X_1 + iX_2)e^{-i\omega t}] = X_1(t) \cos \omega t + X_2(t) \sin \omega t. \quad (6.107)$$

Then $\{X_1, X_2\}$ is a Gaussian-Markov process that evolves on a timescale $\sim \tau_r$.

(a) Show that X_1 and X_2 obey the Langevin equation

$$-2\omega(\dot{X}_1 + X_1/\tau_r) \sin \omega t + 2\omega(\dot{X}_2 + X_2/\tau_r) \cos \omega t = F'/m. \quad (6.108a)$$

(b) To compute the functions $A_j(\mathbf{X})$ and $B_{jk}(\mathbf{X})$ that appear in the Fokker-Planck equation (6.106a), choose the timescale Δt to be short compared to the oscillator's damping time τ_r but long compared to its period $2\pi/\omega$. By multiplying the Langevin equation successively by $\sin \omega t$ and $\cos \omega t$ and integrating from $t = 0$ to $t = \Delta t$, derive equations for the changes ΔX_1 and ΔX_2 produced during Δt by the fluctuating force $F'(t)$ and its associated dissipation. [Neglect fractional corrections of order $1/(\omega\Delta t)$ and of order $\Delta t/\tau_r$]. Your equations should be analogous to Eq. (6.103a).

(c) By the same technique as was used in Ex. 6.22, obtain from the equations derived in part (b) the following forms of the Fokker-Planck functions:

$$A_j = \frac{-X_j}{\tau_r}, \quad B_{jk} = \frac{2k_B T}{m\omega^2 \tau_r} \delta_{jk}. \quad (6.108b)$$

(d) Show that the Fokker-Planck equation, obtained by inserting functions (6.108b) into Eq. (6.106a), has the following Gaussian solution:

$$P_2(X_1, X_2, t | X_1^{(o)}, X_2^{(o)}) = \frac{1}{2\pi\sigma^2} \exp \left[-\frac{(X_1 - \bar{X}_1)^2 + (X_2 - \bar{X}_2)^2}{2\sigma^2} \right], \quad (6.109a)$$

where the means and variance of the distribution are

$$\bar{X}_j = X_j^{(o)} e^{-t/\tau_r}, \quad \sigma^2 = \frac{k_B T}{m\omega^2} \left(1 - e^{-2t/\tau_r} \right) \simeq \begin{cases} \frac{k_B T}{m\omega^2} \frac{2t}{\tau_r} & \text{for } t \ll \tau_r \\ \frac{k_B T}{m\omega^2} & \text{for } t \gg \tau_r. \end{cases} \quad (6.109b)$$

- (e) Discuss the physical meaning of the conditional probability (6.109a). Discuss its implications for the physics experiment described in Ex. 6.17, when the signal force acts for a time short compared to τ_r , rather than long.
-

Bibliographic Note

Random processes are treated in many standard textbooks on statistical physics, typically under the rubric of fluctuations or nonequilibrium statistical mechanics (and sometimes not even using the phrase “random process”). We like Kittel (2004), Sethna (2006), Reif (2008), and Pathria and Beale (2011). A treatise on signal processing that we recommend, despite its age, is Wainstein and Zubakov (1962). There are a number of textbooks on random processes (also called “stochastic processes” in book titles), usually aimed at mathematicians, engineers, or finance folks (who use the theory of random processes to try to make lots of money, and often succeed). But we do not like any of those books as well as the relevant sections in the above statistical mechanics texts. Nevertheless, you might want to peruse Lax et al. (2006), Van Kampen (2007), and Paul and Baschnagel (2010).

OPTICS

Prior to the twentieth century's quantum mechanics and opening of the electromagnetic spectrum observationally, the study of optics was concerned solely with visible light.

Reflection and refraction of light were first described by the Greeks and Arabs and further studied by such medieval scholastics as Roger Bacon (thirteenth century), who explained the rainbow and used refraction in the design of crude magnifying lenses and spectacles. However, it was not until the seventeenth century that there arose a strong commercial interest in manipulating light, particularly via the telescope and compound microscope, improved and famously used by Galileo and Newton.

The discovery of Snell's law in 1621 and observations of diffractive phenomena by Grimaldi in 1665 stimulated serious speculation about the physical nature of light. The wave and corpuscular theories were propounded by Huygens in 1678 and Newton in 1704, respectively. The corpuscular theory initially held sway, for 100 years. However, observational studies of interference by Young in 1803 and the derivation of a wave equation for electromagnetic disturbances by Maxwell in 1865 then seemed to settle the matter in favor of the undulatory theory, only for the debate to be resurrected in 1887 with the discovery of the photoelectric effect by Hertz. After quantum mechanics was developed in the 1920s, the dispute was abandoned, the wave and particle descriptions of light became "complementary," and Hamilton's optics-inspired formulation of classical mechanics was modified to produce the Schrödinger equation.

Many physics students are all too familiar with this potted history and may consequently regard optics as an ancient precursor to modern physics, one that has been completely subsumed by quantum mechanics. Not so! Optics has developed dramatically and independently from quantum mechanics in recent decades and is now a major branch of classical physics. And it is no longer concerned primarily with light. The principles of optics are routinely applied to all types of wave propagation: for example, all parts of the electromagnetic spectrum, quantum mechanical waves (e.g., of

electrons and neutrinos), waves in elastic solids (Part IV of this book), fluids (Part V), plasmas (Part VI), and the geometry of spacetime (Part VII). There is a commonality, for instance, to seismology, oceanography, and radio physics that allows ideas to be freely interchanged among these different disciplines. Even the study of visible light has seen major developments: the invention of the laser has led to the modern theory of coherence and has begotten the new field of nonlinear optics.

An even greater revolution has occurred in optical technology. From the credit card and white-light hologram to the laser scanner at a supermarket checkout, from laser printers to CDs, DVDs, and BDs, from radio telescopes capable of nanoradian angular resolution to Fabry-Perot systems that detect displacements smaller than the size of an elementary particle, we are surrounded by sophisticated optical devices in our everyday and scientific lives. Many of these devices turn out to be clever and direct applications of the fundamental optical principles that we discuss in this part of the book.

Our treatment of optics in this part differs from that found in traditional texts, in that we assume familiarity with basic classical mechanics and quantum mechanics and, consequently, fluency in the language of Fourier transforms. This inversion of the historical development reflects contemporary priorities and allows us to emphasize those aspects of the subject that involve fresh concepts and modern applications.

In Chap. 7, we discuss optical (wave-propagation) phenomena in the geometric optics approximation. This approximation is accurate when the wavelength and the wave period are short compared with the lengthscales and timescales on which the wave amplitude and the waves' environment vary. We show how a wave equation can be solved approximately, with optical rays becoming the classical trajectories of quantum particles (photons, phonons, plasmons, and gravitons) and the wave field propagating along these trajectories. We also show how, in general, these trajectories develop singularities or caustics where the geometric optics approximation breaks down, and we must revert to the wave description.

In Chap. 8, we develop the theory of diffraction that arises when the geometric optics approximation fails, and the waves' energy spreads in a non-particle-like way. We analyze diffraction in two limiting regimes, called "Fresnel" and "Fraunhofer" (after the physicists who discovered them), in which the wavefronts are approximately planar or spherical, respectively. As we are working with a linear theory of wave propagation, we make heavy use of Fourier methods and show how elementary applications of Fourier transforms can be used to design powerful optics instruments.

Most elementary diffractive phenomena involve the superposition of an infinite number of waves. However, in many optical applications, only a small number of waves from a common source are combined. This is known as interference and is the subject of Chap. 9. In this chapter, we also introduce the notion of coherence, which is a quantitative measure of the distributions of the combining waves and their capacity to interfere constructively.

The final chapter on optics, Chap. 10, is concerned with nonlinear phenomena that arise when waves, propagating through a medium, become sufficiently strong to couple to one another. These nonlinear phenomena can occur for all types of waves (we meet them for fluid waves in Sec. 16.3 and plasma waves in Chap. 23). For light (the focus of Chap. 10), nonlinearities have become especially important in recent years; the nonlinear effects that arise when laser light is shone through certain crystals are having a strong impact on technology and on fundamental scientific research. We explore several examples.

Geometric Optics

Solar rays parallel to OB and passing through this solid are refracted at the hyperbolic surface, and the refracted rays converge at A .

IBN SAHL (984)

7.1 Overview

7.1

Geometric optics, the study of “rays,” is the oldest approach to optics. It is an accurate description of wave propagation when the wavelengths and periods of the waves are far smaller than the lengthscales and timescales on which the wave amplitude and the medium supporting the waves vary.

After reviewing wave propagation in a homogeneous medium (Sec. 7.2), we begin our study of geometric optics in Sec. 7.3. There we derive the geometric-optics propagation equations with the aid of the eikonal approximation, and we elucidate the connection to Hamilton-Jacobi theory (which we assume the reader has already encountered). This connection is made more explicit by demonstrating that a classical, geometric-optics wave can be interpreted as a flux of quanta. In Sec. 7.4, we specialize the geometric-optics formalism to any situation where a bundle of nearly parallel rays is being guided and manipulated by some sort of apparatus. This is the paraxial approximation, and we illustrate it with a magnetically focused beam of charged particles and show how matrix methods can be used to describe the particle (i.e., ray) trajectories. In Sec. 7.5, we explore how imperfect optics can produce multiple images of a distant source, and that as one moves from one location to another, the images appear and disappear in pairs. Locations where this happens are called “caustics” and are governed by catastrophe theory, a topic we explore briefly. In Sec. 7.6, we describe gravitational lenses, remarkable astronomical phenomena that illustrate the formation of multiple images and caustics. Finally, in Sec. 7.7, we turn from scalar waves to the vector waves of electromagnetic radiation. We deduce the geometric-optics propagation law for the waves’ polarization vector and explore the classical version of a phenomenon called geometric phase.

BOX 7.1. READERS' GUIDE

- This chapter does not depend substantially on any previous chapter, but it does assume familiarity with classical mechanics, quantum mechanics, and classical electromagnetism.
- Secs. 7.1–7.4 are foundations for the remaining optics chapters, 8, 9, and 10.
- The discussion of caustics in Sec. 7.5 is a foundation for Sec. 8.6 on diffraction at a caustic.
- Secs. 7.2 and 7.3 (monochromatic plane waves and wave packets in a homogeneous, time-independent medium; the dispersion relation; and the geometric-optics equations) are used extensively in subsequent parts of this book, including
 - Chap. 12 for elastodynamic waves,
 - Chap. 16 for waves in fluids,
 - Sec. 19.7 and Chaps. 21–23 for waves in plasmas, and
 - Chap. 27 for gravitational waves.
 - Sec. 28.6.2 for weak gravitational lensing.

7.2 Waves in a Homogeneous Medium

7.2.1 Monochromatic Plane Waves; Dispersion Relation

Consider a monochromatic plane wave propagating through a homogeneous medium. Independently of the physical nature of the wave, it can be described mathematically by

$$\psi = Ae^{i(\mathbf{k}\cdot\mathbf{x}-\omega t)} \equiv Ae^{i\varphi}, \quad (7.1)$$

where ψ is any oscillatory physical quantity associated with the wave, for example, the y component of the magnetic field associated with an electromagnetic wave. If, as is usually the case, the physical quantity is real (not complex), then we must take the real part of Eq. (7.1). In Eq. (7.1), A is the wave's *complex amplitude*; $\varphi = \mathbf{k} \cdot \mathbf{x} - \omega t$ is the wave's *phase*; t and \mathbf{x} are time and location in space; $\omega = 2\pi f$ is the wave's *angular frequency*; and \mathbf{k} is its *wave vector* (with $k \equiv |\mathbf{k}|$ its *wave number*, $\lambda = 2\pi/k$ its *wavelength*, $\hat{\lambda} = \lambda/(2\pi)$ its *reduced wavelength*, and $\hat{\mathbf{k}} \equiv \mathbf{k}/k$ its *propagation direction*). Surfaces of constant phase φ are orthogonal to the propagation direction $\hat{\mathbf{k}}$ and move in the $\hat{\mathbf{k}}$ direction with the *phase velocity*

$$\mathbf{V}_{\text{ph}} \equiv \left(\frac{\partial \mathbf{x}}{\partial t} \right)_{\varphi} = \frac{\omega}{k} \hat{\mathbf{k}} \quad (7.2)$$

(cf. Fig. 7.1). The frequency ω is determined by the wave vector \mathbf{k} in a manner that depends on the wave's physical nature; the functional relationship

plane wave: complex amplitude, phase, angular frequency, wave vector, wavelength, and propagation direction

phase velocity

(7.3)

dispersion relation

is called the wave's *dispersion relation*, because (as we shall see in Ex. 7.2) it governs the dispersion (spreading) of a wave packet that is constructed by superposing plane waves.

Some examples of plane waves that we study in this book are:

1. Electromagnetic waves propagating through an isotropic dielectric medium with index of refraction n [Eq. 10.20], for which ψ could be any Cartesian component of the electric or magnetic field or vector potential and the dispersion relation is

$$\omega = \Omega(\mathbf{k}) = Ck \equiv C|\mathbf{k}|, \quad (7.4)$$

with $C = c/n$ the phase speed and c the speed of light in vacuum.

2. Sound waves propagating through a solid (Sec. 12.2.3) or fluid (liquid or vapor; Secs. 7.3.1 and 16.5), for which ψ could be the pressure or density perturbation produced by the sound wave (or it could be a potential whose gradient is the velocity perturbation), and the dispersion relation is the same as for electromagnetic waves, Eq. (7.4), but with C now the sound speed.
3. Waves on the surface of a deep body of water (depth $\gg \lambda$; Sec. 16.2.1), for which ψ could be the height of the water above equilibrium, and the dispersion relation is [Eq. (16.9)]:

$$\omega = \Omega(\mathbf{k}) = \sqrt{gk} = \sqrt{g|\mathbf{k}|}, \quad (7.5)$$

with g the acceleration of gravity.

4. Flexural waves on a stiff beam or rod (Sec. 12.3.4), for which ψ could be the transverse displacement of the beam from equilibrium, and the dispersion relation is

$$\omega = \Omega(\mathbf{k}) = \sqrt{\frac{D}{\Lambda}} k^2 = \sqrt{\frac{D}{\Lambda}} \mathbf{k} \cdot \mathbf{k}, \quad (7.6)$$

examples:

electromagnetic waves

sound waves

water waves

flexural waves

with Λ the rod's mass per unit length and D its "flexural rigidity" [Eq. (12.33)].

Alfvén waves

5. Alfvén waves in a magnetized, nonrelativistic plasma (bending waves of the plasma-laden magnetic field lines; Sec. 19.7.2), for which ψ could be the transverse displacement of the field and plasma, and the dispersion relation is [Eq. (19.75)]

$$\omega = \Omega(\mathbf{k}) = \mathbf{a} \cdot \mathbf{k}, \quad (7.7)$$

with $\mathbf{a} = \mathbf{B}/\sqrt{\mu_o\rho}$, $[= \mathbf{B}/\sqrt{4\pi\rho}]^1$ the Alfvén speed, \mathbf{B} the (homogeneous) magnetic field, μ_o the magnetic permittivity of the vacuum, and ρ the plasma mass density.

gravitational waves

6. Gravitational waves propagating across the universe, for which ψ can be a component of the waves' metric perturbation which describes the waves' stretching and squeezing of space; these waves propagate nondispersively at the speed of light, so their dispersion relation is Eq. (7.4) with C replaced by the vacuum light speed c .

In general, one can derive the dispersion relation $\omega = \Omega(\mathbf{k})$ by inserting the plane-wave ansatz (7.1) into the dynamical equations that govern one's physical system [e.g., Maxwell's equations, the equations of elastodynamics (Chap. 12), or the equations for a magnetized plasma (Part VI)]. We shall do so time and again in this book.

7.2.2

7.2.2 Wave Packets

Waves in the real world are not precisely monochromatic and planar. Instead, they occupy wave packets that are somewhat localized in space and time. Such wave packets can be constructed as superpositions of plane waves:

wave packet

$$\psi(\mathbf{x}, t) = \int \mathbf{A}(\mathbf{k}) e^{i\alpha(\mathbf{k})} e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)} \frac{d^3k}{(2\pi)^3}, \quad (7.8a)$$

where $\mathbf{A}(\mathbf{k})$ is concentrated around some $\mathbf{k} = \mathbf{k}_o$.

Here A and α (both real) are the modulus and phase of the complex amplitude $Ae^{i\alpha}$, and the integration element is $d^3k \equiv dV_k \equiv dk_x dk_y dk_z$ in terms of components of \mathbf{k} along Cartesian axes x , y , and z . In the integral (7.8a), the contributions from adjacent \mathbf{k} s will tend to cancel each other except in that region of space and time where the oscillatory phase factor changes little with changing \mathbf{k} (when \mathbf{k} is near \mathbf{k}_o). This is the spacetime region in which the wave packet is concentrated, and its center is where $\nabla_{\mathbf{k}}(\text{phase factor}) = 0$:

$$\left(\frac{\partial\alpha}{\partial k_j} + \frac{\partial}{\partial k_j}(\mathbf{k} \cdot \mathbf{x} - \omega t) \right)_{\mathbf{k}=\mathbf{k}_o} = 0. \quad (7.8b)$$

1. Gaussian unit equivalents will be given with square brackets.

FIGURE 7.2 (a) A wave packet of waves on a deep body of water. The packet is localized in the spatial region bounded by the ellipse. The packet's (ellipse's) center moves with the group velocity \mathbf{V}_g . The ellipse expands slowly due to wave-packet dispersion (spreading; Ex. 7.2). The surfaces of constant phase (the wave's oscillations) move twice as fast as the ellipse and in the same direction, $\mathbf{V}_{ph} = 2\mathbf{V}_g$ [Eq. (7.11)]. This means that the wave's oscillations arise at the back of the packet and move forward through the packet, disappearing at the front. The wavelength of these oscillations is $\lambda = 2\pi/k_o$, where $k_o = |\mathbf{k}_o|$ is the wave number about which the wave packet is concentrated [Eq. (7.8a) and associated discussion]. (b) A flexural wave packet on a beam, for which $\mathbf{V}_{ph} = \frac{1}{2}\mathbf{V}_g$ [Eq. (7.12)], so the wave's oscillations arise at the packet's front and, traveling more slowly than the packet, disappear at its back. (c) An Alfvén wave packet. Its center moves with a group velocity \mathbf{V}_g that points along the direction of the background magnetic field [Eq. (7.13)], and its surfaces of constant phase (the wave's oscillations) move with a phase velocity \mathbf{V}_{ph} that can be in any direction $\hat{\mathbf{k}}$. The phase speed is the projection of the group velocity onto the phase propagation direction, $|\mathbf{V}_{ph}| = \mathbf{V}_g \cdot \hat{\mathbf{k}}$ [Eq. (7.13)], which implies that the wave's oscillations remain fixed inside the packet as the packet moves; their pattern inside the ellipse does not change. (An even more striking example is provided by the Rossby wave, discussed in Sec. 16.4, in which the group velocity is equal and oppositely directed to the phase velocity.)

Evaluating the derivative with the aid of the wave's dispersion relation $\omega = \Omega(\mathbf{k})$, we obtain for the location of the wave packet's center

$$x_j - \left(\frac{\partial \Omega}{\partial k_j} \right)_{\mathbf{k}=\mathbf{k}_o} t = - \left(\frac{\partial \alpha}{\partial k_j} \right)_{\mathbf{k}=\mathbf{k}_o} = \text{const.} \quad (7.8c)$$

This tells us that the *wave packet* moves with the *group velocity*

$$\mathbf{V}_g = \nabla_{\mathbf{k}} \Omega, \quad \text{i.e.,} \quad V_{g,j} = \left(\frac{\partial \Omega}{\partial k_j} \right)_{\mathbf{k}=\mathbf{k}_o}. \quad (7.9)$$

group velocity

When, as for electromagnetic waves in a dielectric medium or sound waves in a solid or fluid, the dispersion relation has the simple form of Eq. (7.4), $\omega = \Omega(\mathbf{k}) = Ck$ with $k \equiv |\mathbf{k}|$, then the group and phase velocities are the same,

$$\mathbf{V}_g = \mathbf{V}_{ph} = C\hat{\mathbf{k}}, \quad (7.10)$$

and the waves are said to be *dispersionless*. If the dispersion relation has any other form, then the group and phase velocities are different, and the wave is said to exhibit

dispersion; cf. Ex. 7.2. Examples are (see Fig. 7.2 and the list in Sec. 7.2.1, from which our numbering is taken):

3. Waves on a deep body of water [dispersion relation (7.5); Fig. 7.2a], for which

$$\mathbf{V}_g = \frac{1}{2}\mathbf{V}_{ph} = \frac{1}{2}\sqrt{\frac{g}{k}}\hat{\mathbf{k}}; \quad (7.11)$$

4. Flexural waves on a stiff beam or rod [dispersion relation (7.6); Fig. 7.2b], for which

$$\mathbf{V}_g = 2\mathbf{V}_{ph} = 2\sqrt{\frac{D}{\Lambda}}k\hat{\mathbf{k}}; \quad (7.12)$$

5. Alfvén waves in a magnetized and nonrelativistic plasma [dispersion relation (7.7); Fig. 7.2c], for which

$$\mathbf{V}_g = \mathbf{a}, \quad \mathbf{V}_{ph} = (\mathbf{a} \cdot \hat{\mathbf{k}})\hat{\mathbf{k}}. \quad (7.13)$$

Notice that, depending on the dispersion relation, the group speed $|\mathbf{V}_g|$ can be less than or greater than the phase speed, and if the homogeneous medium is anisotropic (e.g., for a magnetized plasma), the group velocity can point in a different direction than the phase velocity.

Physically, it should be obvious that the energy contained in a wave packet must remain always with the packet and cannot move into the region outside the packet where the wave amplitude vanishes. Correspondingly, the wave packet's energy must propagate with the group velocity \mathbf{V}_g and not with the phase velocity \mathbf{V}_{ph} . When one examines the wave packet from a quantum mechanical viewpoint, its quanta must move with the group velocity \mathbf{V}_g . Since we have required that the wave packet have its wave vectors concentrated around \mathbf{k}_o , the energy and momentum of each of the packet's quanta are given by the standard quantum mechanical relations:

$$\boxed{\mathcal{E} = \hbar\Omega(\mathbf{k}_o), \quad \text{and} \quad \mathbf{p} = \hbar\mathbf{k}_o.} \quad (7.14)$$

EXERCISES

Exercise 7.1 *Practice: Group and Phase Velocities*

Derive the group and phase velocities (7.10)–(7.13) from the dispersion relations (7.4)–(7.7).

Exercise 7.2 ***Example: Gaussian Wave Packet and Its Dispersion*

Consider a 1-dimensional wave packet, $\psi(x, t) = \int A(k)e^{i\alpha(k)}e^{i(kx-\omega t)}dk/(2\pi)$, with dispersion relation $\omega = \Omega(k)$. For concreteness, let $A(k)$ be a narrow Gaussian peaked around k_o : $A \propto \exp[-\kappa^2/(2(\Delta k)^2)]$, where $\kappa = k - k_o$.

- (a) Expand α as $\alpha(k) = \alpha_o - x_o\kappa$ with x_o a constant, and assume for simplicity that higher order terms are negligible. Similarly, expand $\omega \equiv \Omega(k)$ to quadratic order,

and explain why the coefficients are related to the group velocity V_g at $k = k_o$ by $\Omega = \omega_o + V_g \kappa + (dV_g/dk)\kappa^2/2$.

(b) Show that the wave packet is given by

$$\psi \propto \exp[i(\alpha_o + k_o x - \omega_o t)] \int_{-\infty}^{+\infty} \exp[i\kappa(x - x_o - V_g t)] \times \exp\left[-\frac{\kappa^2}{2} \left(\frac{1}{(\Delta k)^2} + i \frac{dV_g}{dk} t\right)\right] d\kappa. \quad (7.15a)$$

The term in front of the integral describes the phase evolution of the waves inside the packet; cf. Fig. 7.2.

(c) Evaluate the integral analytically (with the help of a computer, if you wish). From your answer, show that the modulus of ψ satisfies

$$|\psi| \propto \frac{1}{L^{1/2}} \exp\left[-\frac{(x - x_o - V_g t)^2}{2L^2}\right], \quad \text{where } L = \frac{1}{\Delta k} \sqrt{1 + \left(\frac{dV_g}{dk} (\Delta k)^2 t\right)^2} \quad (7.15b)$$

is the packet's half-width.

- (d) Discuss the relationship of this result at time $t = 0$ to the uncertainty principle for the localization of the packet's quanta.
- (e) Equation (7.15b) shows that the wave packet spreads (i.e., disperses) due to its containing a range of group velocities [Eq. (7.11)]. How long does it take for the packet to enlarge by a factor 2? For what range of initial half-widths can a water wave on the ocean spread by less than a factor 2 while traveling from Hawaii to California?

7.3 Waves in an Inhomogeneous, Time-Varying Medium: The Eikonal Approximation and Geometric Optics

7.3

Suppose that the medium in which the waves propagate is spatially inhomogeneous and varies with time. If the lengthscale \mathcal{L} and timescale \mathcal{T} for substantial variations are long compared to the waves' reduced wavelength and period,

$$\mathcal{L} \gg \lambda = 1/k, \quad \mathcal{T} \gg 1/\omega, \quad (7.16)$$

then the waves can be regarded locally as planar and monochromatic. The medium's inhomogeneities and time variations may produce variations in the wave vector \mathbf{k} and frequency ω , but those variations should be substantial only on scales $\gtrsim \mathcal{L} \gg 1/k$ and $\gtrsim \mathcal{T} \gg 1/\omega$. This intuitively obvious fact can be proved rigorously using a two-lengthscale expansion (i.e., an expansion of the wave equation in powers of $\lambda/\mathcal{L} = 1/k\mathcal{L}$ and $1/\omega\mathcal{T}$). Such an expansion, in this context of wave propagation, is called

two-lengthscale expansion

eikonal approximation

WKB approximation

the *geometric-optics approximation* or the *eikonal approximation* (after the Greek word $\epsilon\iota\kappa\omega\nu$, meaning image). When the waves are those of elementary quantum mechanics, it is called the *WKB approximation*.² The eikonal approximation converts the laws of wave propagation into a remarkably simple form, in which the waves' amplitude is transported along trajectories in spacetime called *rays*. In the language of quantum mechanics, these rays are the world lines of the wave's quanta (photons for light, phonons for sound, plasmons for Alfvén waves, and gravitons for gravitational waves), and the law by which the wave amplitude is transported along the rays is one that conserves quanta. These ray-based propagation laws are called the laws of *geometric optics*.

In this section we develop and study the eikonal approximation and its resulting laws of geometric optics. We begin in Sec. 7.3.1 with a full development of the eikonal approximation and its geometric-optics consequences for a prototypical dispersion-free wave equation that represents, for example, sound waves in a weakly inhomogeneous fluid. In Sec. 7.3.3, we extend our analysis to cover all other types of waves. In Sec. 7.3.4 and a number of exercises we explore examples of geometric-optics waves, and in Sec. 7.3.5 we discuss conditions under which the eikonal approximation breaks down and some non-geometric-optics phenomena that result from the breakdown. Finally, in Sec. 7.3.6 we return to nondispersive light and sound waves, deduce Fermat's principle, and explore some of its consequences.

7.3.1

7.3.1 Geometric Optics for a Prototypical Wave Equation

Our prototypical wave equation is

prototypical wave equation in a slowly varying medium

$$\frac{\partial}{\partial t} \left(W \frac{\partial \psi}{\partial t} \right) - \nabla \cdot (W C^2 \nabla \psi) = 0. \quad (7.17)$$

Here $\psi(\mathbf{x}, t)$ is the quantity that oscillates (the *wave field*), $C(\mathbf{x}, t)$ will turn out to be the wave's slowly varying *propagation speed*, and $W(\mathbf{x}, t)$ is a slowly varying *weighting function* that depends on the properties of the medium through which the wave propagates. As we shall see, W has no influence on the wave's dispersion relation or on its geometric-optics rays, but it does influence the law of transport for the waves' amplitude.

The wave equation (7.17) describes sound waves propagating through a static, isentropic, inhomogeneous fluid (Ex. 16.13), in which case ψ is the wave's pressure perturbation δP , $C(\mathbf{x}) = \sqrt{(\partial P / \partial \rho)_s}$ is the adiabatic sound speed, and the weighting function is $W(\mathbf{x}) = 1/(\rho C^2)$, with ρ the fluid's unperturbed density. This wave equation also describes waves on the surface of a lake or pond or the ocean, in the limit that the slowly varying depth of the undisturbed water $h_o(\mathbf{x})$ is small compared

2. Sometimes called "JWKB," adding Jeffreys to the attribution, though Carlini, Liouville, and Green used it a century earlier.

to the wavelength (shallow-water waves; e.g., tsunamis); see Ex. 16.3. In this case ψ is the perturbation of the water's depth, $W = 1$, and $C = \sqrt{gh_0}$ with g the acceleration of gravity. In both cases—sound waves in a fluid and shallow-water waves—if we turn on a slow time dependence in the unperturbed fluid, then additional terms enter the wave equation (7.17). For pedagogical simplicity we leave those terms out, but in the analysis below we do allow W and C to be slowly varying in time, as well as in space: $W = W(\mathbf{x}, t)$ and $C = C(\mathbf{x}, t)$.

Associated with the wave equation (7.17) are an energy density $U(\mathbf{x}, t)$ and energy flux $\mathbf{F}(\mathbf{x}, t)$ given by

$$U = W \left[\frac{1}{2} \left(\frac{\partial \psi}{\partial t} \right)^2 + \frac{1}{2} C^2 (\nabla \psi)^2 \right], \quad \mathbf{F} = -WC^2 \frac{\partial \psi}{\partial t} \nabla \psi; \quad (7.18)$$

energy density and flux

see Ex. 7.4. It is straightforward to verify that, if C and W are independent of time t , then the scalar wave equation (7.17) guarantees that the U and \mathbf{F} of Eq. (7.18) satisfy the law of energy conservation:

$$\frac{\partial U}{\partial t} + \nabla \cdot \mathbf{F} = 0; \quad (7.19)$$

cf. Ex. 7.4.³

We now specialize to a weakly inhomogeneous and slowly time-varying fluid and to nearly plane waves, and we seek a solution of the wave equation (7.17) that locally has approximately the plane-wave form $\psi \simeq A e^{i\mathbf{k} \cdot \mathbf{x} - \omega t}$. Motivated by this plane-wave form, (i) we express the waves in the eikonal approximation as the product of a real amplitude $A(\mathbf{x}, t)$ that varies slowly on the length- and timescales \mathcal{L} and \mathcal{T} , and the exponential of a complex phase $\varphi(\mathbf{x}, t)$ that varies rapidly on the timescale $1/\omega$ and lengthscale λ :

eikonal approximated wave: amplitude, phase, wave vector, and angular frequency

$$\psi(\mathbf{x}, t) = A(\mathbf{x}, t) e^{i\varphi(\mathbf{x}, t)}; \quad (7.20)$$

and (ii) we define the wave vector (field) and angular frequency (field) by

$$\mathbf{k}(\mathbf{x}, t) \equiv \nabla \varphi, \quad \omega(\mathbf{x}, t) \equiv -\partial \varphi / \partial t. \quad (7.21)$$

In addition to our two-lengthscale requirement, $\mathcal{L} \gg 1/k$ and $\mathcal{T} \gg 1/\omega$, we also require that A , \mathbf{k} , and ω vary slowly (i.e., vary on lengthscales \mathcal{R} and timescales \mathcal{T}' long compared to $\lambda = 1/k$ and $1/\omega$).⁴ This requirement guarantees that the waves are locally planar, $\varphi \simeq \mathbf{k} \cdot \mathbf{x} - \omega t + \text{constant}$.

3. Alternatively, one can observe that a stationary medium will not perform work.

4. Note that these variations can arise both (i) from the influence of the medium's inhomogeneity (which puts limits $\mathcal{R} \lesssim \mathcal{L}$ and $\mathcal{T}' \lesssim \mathcal{T}$ on the wave's variations) and (ii) from the chosen form of the wave. For example, the wave might be traveling outward from a source and so have nearly spherical phase fronts with radii of curvature $r \simeq$ (distance from source); then $\mathcal{R} = \min(r, \mathcal{L})$.

BOX 7.2. BOOKKEEPING PARAMETER IN TWO-LENGTHSCALE EXPANSIONS

When developing a two-lengthscale expansion, it is sometimes helpful to introduce a bookkeeping parameter σ and rewrite the ansatz (7.20) in a fleshed-out form:

$$\psi = (A + \sigma B + \dots)e^{i\varphi/\sigma}. \quad (1)$$

The numerical value of σ is unity, so it can be dropped when the analysis is finished. We use σ to tell us how various terms scale when λ is reduced at fixed \mathcal{L} and \mathcal{R} . The amplitude A has no attached σ and so scales as λ^0 , B is multiplied by σ and so scales proportional to λ , and φ is multiplied by σ^{-1} and so scales as λ^{-1} . When one uses these factors of σ in the evaluation of the wave equation, the first term on the right-hand side of Eq. (7.22) gets multiplied by σ^{-2} , the second term by σ^{-1} , and the omitted terms by σ^0 . These factors of σ help us to quickly group together all terms that scale in a similar manner and to identify which of the groupings is leading order, and which subleading, in the two-lengthscale expansion. In Eq. (7.22) the omitted σ^0 terms are the first ones in which B appears; they produce a propagation law for B , which can be regarded as a post-geometric-optics correction.

Occasionally the wave equation itself will contain terms that scale with λ differently from one another (e.g., Ex. 7.9). One should always look out for this possibility.

We now insert the eikonal-approximated wave field (7.20) into the wave equation (7.17), perform the differentiations with the aid of Eqs. (7.21), and collect terms in a manner dictated by a two-lengthscale expansion (see Box 7.2):

$$\begin{aligned} 0 &= \frac{\partial}{\partial t} \left(W \frac{\partial \psi}{\partial t} \right) - \nabla \cdot (W C^2 \nabla \psi) \\ &= \left(-\omega^2 + C^2 k^2 \right) W \psi \\ &\quad + i \left[-2 \left(\omega \frac{\partial A}{\partial t} + C^2 k_j A_{,j} \right) W - \frac{\partial (W \omega)}{\partial t} A - (W C^2 k_j)_{,j} A \right] e^{i\varphi} + \dots \end{aligned} \quad (7.22)$$

The first term on the right-hand side, $(-\omega^2 + C^2 k^2)W\psi$, scales as λ^{-2} when we make the reduced wavelength λ shorter and shorter while holding the macroscopic lengthscales \mathcal{L} and \mathcal{R} fixed; the second term (in square brackets) scales as λ^{-1} ; and the omitted terms scale as λ^0 . This is what we mean by “collecting terms in a manner dictated by a two-lengthscale expansion.” Because of their different scaling, the first,

second, and omitted terms must vanish separately; they cannot possibly cancel one another.

The vanishing of the first term in the eikonal-approximated wave equation (7.22) implies that the waves' frequency field $\omega(\mathbf{x}, t) \equiv -\partial\varphi/\partial t$ and wave-vector field $\mathbf{k} \equiv \nabla\varphi$ satisfy the dispersionless dispersion relation,

$$\omega = \Omega(\mathbf{k}, \mathbf{x}, t) \equiv C(\mathbf{x}, t)k, \quad (7.23)$$

where (as throughout this chapter) $k \equiv |\mathbf{k}|$. Notice that, as promised, this dispersion relation is independent of the weighting function W in the wave equation. Notice further that this dispersion relation is identical to that for a precisely plane wave in a homogeneous medium, Eq. (7.4), except that the propagation speed C is now a slowly varying function of space and time. This will always be so.

One can always deduce the geometric-optics dispersion relation by (i) considering a precisely plane, monochromatic wave in a precisely homogeneous, time-independent medium and deducing $\omega = \Omega(\mathbf{k})$ in a functional form that involves the medium's properties (e.g., density) and then (ii) allowing the properties to be slowly varying functions of \mathbf{x} and t . The resulting dispersion relation [e.g., Eq. (7.23)] then acquires its \mathbf{x} and t dependence from the properties of the medium.

The vanishing of the second term in the eikonal-approximated wave equation (7.22) dictates that the wave's real amplitude A is transported with the group velocity $\mathbf{V}_g = C\hat{\mathbf{k}}$ in the following manner:

$$\frac{dA}{dt} \equiv \left(\frac{\partial}{\partial t} + \mathbf{V}_g \cdot \nabla \right) A = -\frac{1}{2W\omega} \left[\frac{\partial(W\omega)}{\partial t} + \nabla \cdot (WC^2\mathbf{k}) \right] A. \quad (7.24)$$

This propagation law, by contrast with the dispersion relation, does depend on the weighting function W . We return to this propagation law shortly and shall understand more deeply its dependence on W , but first we must investigate in detail the directions along which A is transported.

The time derivative $d/dt = \partial/\partial t + \mathbf{V}_g \cdot \nabla$ appearing in the propagation law (7.24) is similar to the derivative with respect to proper time along a world line in special relativity, $d/d\tau = u^0\partial/\partial t + \mathbf{u} \cdot \nabla$ (with u^α the world line's 4-velocity). This analogy tells us that the waves' amplitude A is being propagated along some sort of world lines (trajectories). Those world lines (the waves' rays), in fact, are governed by Hamilton's equations of particle mechanics with the dispersion relation $\Omega(\mathbf{x}, t, \mathbf{k})$ playing the role of the hamiltonian and \mathbf{k} playing the role of momentum:

$$\boxed{\frac{dx_j}{dt} = \left(\frac{\partial\Omega}{\partial k_j} \right)_{\mathbf{x},t} \equiv V_{g,j}}, \quad \boxed{\frac{dk_j}{dt} = - \left(\frac{\partial\Omega}{\partial x_j} \right)_{\mathbf{k},t}}, \quad \boxed{\frac{d\omega}{dt} = \left(\frac{\partial\Omega}{\partial t} \right)_{\mathbf{x},\mathbf{k}}}. \quad (7.25)$$

The first of these Hamilton equations is just our definition of the group velocity, with which [according to Eq. (7.24)] the amplitude is transported. The second tells us how

dispersion relation

propagation law for amplitude

rays

Hamilton's equations for rays

the wave vector \mathbf{k} changes along a ray, and together with our knowledge of $C(\mathbf{x}, t)$, it tells us how the group velocity $\mathbf{V}_g = C\hat{\mathbf{k}}$ for our dispersionless waves changes along a ray, and thence defines the ray itself. The third tells us how the waves' frequency changes along a ray.

To deduce the second and third of these Hamilton equations, we begin by inserting the definitions $\omega = -\partial\varphi/\partial t$ and $\mathbf{k} = \nabla\varphi$ [Eqs. (7.21)] into the dispersion relation $\omega = \Omega(\mathbf{x}, t; \mathbf{k})$ for an arbitrary wave, thereby obtaining

$$\boxed{\frac{\partial\varphi}{\partial t} + \Omega(\mathbf{x}, t; \nabla\varphi) = 0.} \quad (7.26a)$$

eikonal equation and Hamilton-Jacobi equation

This equation is known in optics as the *eikonal equation*. It is formally the same as the Hamilton-Jacobi equation of classical mechanics (see, e.g., Goldstein, Poole, and Safko, 2002), if we identify Ω with the hamiltonian and φ with Hamilton's principal function (cf. Ex. 7.9). This suggests that, to derive the second and third of Eqs. (7.25), we can follow the same procedure as is used to derive Hamilton's equations of motion. We take the gradient of Eq. (7.26a) to obtain

$$\frac{\partial^2\varphi}{\partial t\partial x_j} + \frac{\partial\Omega}{\partial k_l} \frac{\partial^2\varphi}{\partial x_l\partial x_j} + \frac{\partial\Omega}{\partial x_j} = 0, \quad (7.26b)$$

where the partial derivatives of Ω are with respect to its arguments $(\mathbf{x}, t; \mathbf{k})$; we then use $\partial\varphi/\partial x_j = k_j$ and $\partial\Omega/\partial k_l = V_{g_l}$ to write Eq. (7.26b) as $dk_j/dt = -\partial\Omega/\partial x_j$. This is the second of Hamilton's equations (7.25), and it tells us how the wave vector changes along a ray. The third Hamilton equation, $d\omega/dt = \partial\Omega/\partial t$ [Eq. (7.25)], is obtained by taking the time derivative of the eikonal equation (7.26a).

Not only is the waves' amplitude A propagated along the rays, so also is their phase:

propagation equation for phase

$$\frac{d\varphi}{dt} = \frac{\partial\varphi}{\partial t} + \mathbf{V}_g \cdot \nabla\varphi = -\omega + \mathbf{V}_g \cdot \mathbf{k}. \quad (7.27)$$

Since our dispersionless waves have $\omega = Ck$ and $\mathbf{V}_g = C\hat{\mathbf{k}}$, this vanishes. Therefore, for the special case of dispersionless waves (e.g., sound waves in a fluid and electromagnetic waves in an isotropic dielectric medium), the phase is constant along each ray:

$$\boxed{d\varphi/dt = 0.} \quad (7.28)$$

7.3.2 Connection of Geometric Optics to Quantum Theory

Although the waves $\psi = Ae^{i\varphi}$ are classical and our analysis is classical, their propagation laws in the eikonal approximation can be described most nicely in quantum mechanical language.⁵ Quantum mechanics insists that, associated with any wave in

5. This is intimately related to the fact that quantum mechanics underlies classical mechanics; the classical world is an approximation to the quantum world, often a very good approximation.

the geometric-optics regime, there are real quanta: the wave's quantum mechanical particles. If the wave is electromagnetic, the quanta are photons; if it is gravitational, they are gravitons; if it is sound, they are phonons; if it is a plasma wave (e.g., Alfvén), they are plasmons. When we multiply the wave's \mathbf{k} and ω by \hbar , we obtain the particles' momentum and energy:

$$\boxed{\mathbf{p} = \hbar\mathbf{k}, \quad \mathcal{E} = \hbar\omega.} \quad (7.29)$$

quanta

momentum and energy of quanta

Although the originators of the nineteenth-century theory of classical waves were unaware of these quanta, once quantum mechanics had been formulated, the quanta became a powerful conceptual tool for thinking about classical waves.

In particular, we can regard the rays as the world lines of the quanta, and by multiplying the dispersion relation by \hbar , we can obtain the hamiltonian for the quanta's world lines:

$$\boxed{H(\mathbf{x}, t; \mathbf{p}) = \hbar\Omega(\mathbf{x}, t; \mathbf{k} = \mathbf{p}/\hbar).} \quad (7.30)$$

hamiltonian for quanta

Hamilton's equations (7.25) for the rays then immediately become Hamilton's equations for the quanta: $dx_j/dt = \partial H/\partial p_j$, $dp_j/dt = -\partial H/\partial x_j$, and $d\mathcal{E}/dt = \partial H/\partial t$.

Return now to the propagation law (7.24) for the waves' amplitude, and examine its consequences for the waves' energy. By inserting the ansatz $\psi = \Re(Ae^{i\varphi}) = A \cos(\varphi)$ into Eqs. (7.18) for the energy density U and energy flux \mathbf{F} and averaging over a wavelength and wave period (so $\overline{\cos^2 \varphi} = \overline{\sin^2 \varphi} = 1/2$), we find that

$$U = \frac{1}{2}WC^2k^2A^2 = \frac{1}{2}W\omega^2A^2, \quad \mathbf{F} = U(C\hat{\mathbf{k}}) = U\mathbf{V}_g. \quad (7.31)$$

Inserting these into the expression $\partial U/\partial t + \nabla \cdot \mathbf{F}$ for the rate at which energy (per unit volume) fails to be conserved and using the propagation law (7.24) for A , we obtain

$$\frac{\partial U}{\partial t} + \nabla \cdot \mathbf{F} = U \frac{\partial \ln C}{\partial t}. \quad (7.32)$$

Thus, as the propagation speed C slowly changes at a fixed location in space due to a slow change in the medium's properties, the medium slowly pumps energy into the waves or removes it from them at a rate per unit volume of $U \partial \ln C/\partial t$.

This slow energy change can be understood more deeply using quantum concepts. The number density and number flux of quanta are

$$\boxed{n = \frac{U}{\hbar\omega}, \quad \mathbf{S} = \frac{\mathbf{F}}{\hbar\omega} = n\mathbf{V}_g.} \quad (7.33)$$

number density and flux of quanta

By combining these equations with the energy (non)conservation equation (7.32), we obtain

$$\frac{\partial n}{\partial t} + \nabla \cdot \mathbf{S} = n \left[\frac{\partial \ln C}{\partial t} - \frac{d \ln \omega}{dt} \right]. \quad (7.34)$$

The third Hamilton equation (7.25) tells us that

$$d\omega/dt = (\partial\Omega/\partial t)_{x,k} = [\partial(Ck)/\partial t]_{x,k} = k\partial C/\partial t,$$

whence $d \ln \omega/dt = \partial \ln C/\partial t$, which, when inserted into Eq. (7.34), implies that the quanta are conserved:

conservation of quanta

$$\frac{\partial n}{\partial t} + \nabla \cdot \mathbf{S} = 0. \quad (7.35a)$$

Since $\mathbf{S} = n\mathbf{V}_g$ and $d/dt = \partial/\partial t + \mathbf{V}_g \cdot \nabla$, we can rewrite this conservation law as a propagation law for the number density of quanta:

$$\frac{dn}{dt} + n\nabla \cdot \mathbf{V}_g = 0. \quad (7.35b)$$

The propagation law for the waves' amplitude, Eq. (7.24), can now be understood much more deeply: *The amplitude propagation law is nothing but the law of conservation of quanta in a slowly varying medium, rewritten in terms of the amplitude. This is true quite generally, for any kind of wave (Sec. 7.3.3); and the quickest route to the amplitude propagation law is often to express the wave's energy density U in terms of the amplitude and then invoke conservation of quanta, Eq. (7.35b).*

In Ex. 7.3 we show that the conservation law (7.35b) is equivalent to

$$\frac{d(nCA)}{dt} = 0, \quad \text{i.e., } nCA \text{ is a constant along each ray.} \quad (7.35c)$$

Here \mathcal{A} is the cross sectional area of a bundle of rays surrounding the ray along which the wave is propagating. Equivalently, by virtue of Eqs. (7.33) and (7.31) for the number density of quanta in terms of the wave amplitude A , we have

$$\frac{d}{dt} A\sqrt{CW\omega\mathcal{A}} = 0, \quad \text{i.e., } A\sqrt{CW\omega\mathcal{A}} \text{ is a constant along each ray.} \quad (7.35d)$$

In Eqs. (7.33) and (7.35), we have boxed those equations that are completely general (because they embody conservation of quanta) and have not boxed those that are specialized to our prototypical wave equation.

EXERCISES

Exercise 7.3 ** Derivation and Example: Amplitude Propagation for Dispersionless Waves Expressed as Constancy of Something along a Ray

- In connection with Eq. (7.35b), explain why $\nabla \cdot \mathbf{V}_g = d \ln \mathcal{V}/dt$, where \mathcal{V} is the tiny volume occupied by a collection of the wave's quanta.
- Choose for the collection of quanta those that occupy a cross sectional area \mathcal{A} orthogonal to a chosen ray, and a longitudinal length Δs along the ray, so $\mathcal{V} = \mathcal{A}\Delta s$. Show that $d \ln \Delta s/dt = d \ln C/dt$ and correspondingly, $d \ln \mathcal{V}/dt = d \ln(C\mathcal{A})/dt$.

- (c) Given part (b), show that the conservation law (7.35b) is equivalent to the constancy of nCA along a ray, Eq. (7.35c).
- (d) From the results of part (c), derive the constancy of $A\sqrt{CW\omega A}$ along a ray (where A is the wave's amplitude), Eq. (7.35d).

Exercise 7.4 ***Example: Energy Density and Flux, and Adiabatic Invariant, for a Dispersionless Wave*

- (a) Show that the prototypical scalar wave equation (7.17) follows from the variational principle

$$\delta \int \mathcal{L} dt d^3x = 0, \quad (7.36a)$$

where \mathcal{L} is the lagrangian density

$$\mathcal{L} = W \left[\frac{1}{2} \left(\frac{\partial \psi}{\partial t} \right)^2 - \frac{1}{2} C^2 (\nabla \psi)^2 \right] \quad (7.36b)$$

(not to be confused with the lengthscale \mathcal{L} of inhomogeneities in the medium).

- (b) For any scalar-field lagrangian density $\mathcal{L}(\psi, \partial\psi/\partial t, \nabla\psi, \mathbf{x}, t)$, the energy density and energy flux can be expressed in terms of the lagrangian, in Cartesian coordinates, as

$$U(\mathbf{x}, t) = \frac{\partial \psi}{\partial t} \frac{\partial \mathcal{L}}{\partial \psi / \partial t} - \mathcal{L}, \quad F_j = \frac{\partial \psi}{\partial t} \frac{\partial \mathcal{L}}{\partial \psi / \partial x_j} \quad (7.36c)$$

(Goldstein, Poole, and Safko, 2002, Sec. 13.3). Show, from the Euler-Lagrange equations for \mathcal{L} , that these expressions satisfy energy conservation, $\partial U / \partial t + \nabla \cdot \mathbf{F} = 0$, if \mathcal{L} has no explicit time dependence [e.g., for the lagrangian (7.36b) if $C = C(\mathbf{x})$ and $W = W(\mathbf{x})$ do not depend on time t].

- (c) Show that expression (7.36c) for the field's energy density U and its energy flux F_j agree with Eqs. (7.18).
- (d) Now, regard the wave amplitude ψ as a generalized (field) coordinate. Use the lagrangian $L = \int \mathcal{L} d^3x$ to define a field momentum Π conjugate to this ψ , and then compute a *wave action*,

$$J \equiv \int_0^{2\pi/\omega} \int \Pi(\partial\psi/\partial t) d^3x dt, \quad (7.36d)$$

which is the continuum analog of Eq. (7.43) in Sec. 7.3.6. The temporal integral is over one wave period. Show that this J is proportional to the wave energy divided by the frequency and thence to the number of quanta in the wave.

It is shown in standard texts on classical mechanics that, for approximately periodic oscillations, the particle action (7.43), with the integral limited to one period of oscillation of q , is an *adiabatic invariant*. By the extension of that proof to continuum physics, the wave action (7.36d) is also an adiabatic invariant. This

means that the wave action and hence the number of quanta in the waves are conserved when the medium [in our case the index of refraction $n(\mathbf{x})$] changes very slowly in time—a result asserted in the text, and one that also follows from quantum mechanics. We study the particle version (7.43) of this adiabatic invariant in detail when we analyze charged-particle motion in a slowly varying magnetic field in Sec. 20.7.4.

Exercise 7.5 *Problem: Propagation of Sound Waves in a Wind*

Consider sound waves propagating in an atmosphere with a horizontal wind. Assume that the sound speed C , as measured in the air's local rest frame, is constant. Let the wind velocity $\mathbf{u} = u_x \mathbf{e}_x$ increase linearly with height z above the ground: $u_x = Sz$, where S is the constant shearing rate. Consider only rays in the x - z plane.

- (a) Give an expression for the dispersion relation $\omega = \Omega(\mathbf{x}, t; \mathbf{k})$. [Hint: In the local rest frame of the air, Ω should have its standard sound-wave form.]
- (b) Show that k_x is constant along a ray path, and then demonstrate that sound waves will not propagate when

$$\left| \frac{\omega}{k_x} - u_x(z) \right| < C. \tag{7.37}$$

- (c) Consider sound rays generated on the ground that make an angle θ to the horizontal initially. Derive the equations describing the rays, and use them to sketch the rays, distinguishing values of θ both less than and greater than $\pi/2$. (You might like to perform this exercise numerically.)

7.3.3

7.3.3 Geometric Optics for a General Wave

With the simple case of nondispersive sound waves (Secs. 7.3.1 and 7.3.2) as our model, we now study an arbitrary kind of wave in a weakly inhomogeneous and slowly time varying medium (e.g., any of the examples in Sec. 7.2.1: light waves in a dielectric medium, deep water waves, flexural waves on a stiff beam, or Alfvén waves). Whatever the wave may be, we seek a solution to its wave equation using the eikonal approximation $\psi = Ae^{i\varphi}$ with slowly varying amplitude A and rapidly varying phase φ . Depending on the nature of the wave, ψ and A might be a scalar (e.g., sound waves), a vector (e.g., light waves), or a tensor (e.g., gravitational waves).

When we insert the ansatz $\psi = Ae^{i\varphi}$ into the wave equation and collect terms in the manner dictated by our two-lengthscale expansion [as in Eq. (7.22) and Box 7.2], the leading-order term will arise from letting every temporal or spatial derivative act on the $e^{i\varphi}$. This is precisely where the derivatives would operate in the case of a plane wave in a homogeneous medium, and here, as there, the result of each differentiation is $\partial e^{i\varphi} / \partial t = -i\omega e^{i\varphi}$ or $\partial e^{i\varphi} / \partial x_j = ik_j e^{i\varphi}$. Correspondingly, the leading-order terms in the wave equation here will be identical to those in the homogeneous plane wave

case: they will be the dispersion relation multiplied by something times the wave,

$$[-\omega^2 + \Omega^2(\mathbf{x}, t; \mathbf{k})] \times (\text{something}) A e^{i\varphi} = 0, \quad (7.38a)$$

with the spatial and temporal dependence of Ω^2 entering through the medium's properties. This guarantees that (as we claimed in Sec. 7.3.1) the dispersion relation can be obtained by analyzing a plane, monochromatic wave in a homogeneous, time-independent medium and then letting the medium's properties, in the dispersion relation, vary slowly with \mathbf{x} and t .

dispersion relation for general wave

Each next-order (“subleading”) term in the wave equation will entail just one of the wave operator’s derivatives acting on a slowly varying quantity (A , a medium property, ω , or \mathbf{k}) and all the other derivatives acting on $e^{i\varphi}$. The subleading terms that interest us, for the moment, are those in which the one derivative acts on A , thereby propagating it. Therefore, the subleading terms can be deduced from the leading-order terms (7.38a) by replacing just one $i\omega A e^{i\varphi} = -A(e^{i\varphi})_{,t}$ by $-A_{,t} e^{i\varphi}$, and replacing just one $ik_j A e^{i\varphi} = A(e^{i\varphi})_{,j}$ by $A_{,j} e^{i\varphi}$ (where the subscript commas denote partial derivatives in Cartesian coordinates). A little thought then reveals that the equation for the vanishing of the subleading terms must take the form [deducible from the leading terms (7.38a)]:

$$-2i\omega \frac{\partial A}{\partial t} - 2i\Omega(\mathbf{k}, \mathbf{x}, t) \frac{\partial \Omega(\mathbf{k}, \mathbf{x}, t)}{\partial k_j} \frac{\partial A}{\partial x_j} = \text{terms proportional to } A. \quad (7.38b)$$

Using the dispersion relation $\omega = \Omega(\mathbf{x}, t; \mathbf{k})$ and the group velocity (first Hamilton equation) $\partial \Omega / \partial k_j = V_{g j}$, we bring this into the “propagate A along a ray” form:

$$\frac{dA}{dt} \equiv \frac{\partial A}{\partial t} + \mathbf{V}_g \cdot \nabla A = \text{terms proportional to } A. \quad (7.38c)$$

Let us return to the leading-order terms (7.38a) in the wave equation [i.e., to the dispersion relation $\omega = \Omega(\mathbf{x}, t; k)$]. For our general wave, as for the prototypical dispersionless wave of the previous two sections, the argument embodied in Eqs. (7.26) shows that the rays are determined by Hamilton’s equations (7.25),

$$\boxed{\frac{dx_j}{dt} = \left(\frac{\partial \Omega}{\partial k_j} \right)_{\mathbf{x}, t} \equiv V_{g j}, \quad \frac{dk_j}{dt} = - \left(\frac{\partial \Omega}{\partial x_j} \right)_{\mathbf{k}, t}, \quad \frac{d\omega}{dt} = \left(\frac{\partial \Omega}{\partial t} \right)_{\mathbf{x}, \mathbf{k}}} \quad (7.39)$$

Hamilton’s equations for general wave

but using the general wave’s dispersion relation $\Omega(\mathbf{k}, \mathbf{x}, t)$ rather than $\Omega = C(\mathbf{x}, t)k$. These Hamilton equations include propagation laws for $\omega = -\partial \varphi / \partial t$ and $k_j = \partial \varphi / \partial x_j$, from which we can deduce the propagation law (7.27) for φ along the rays:

$$\boxed{\frac{d\varphi}{dt} = -\omega + \mathbf{V}_g \cdot \mathbf{k}.} \quad (7.40)$$

propagation law for phase of general wave

For waves with dispersion, by contrast with sound in a fluid and other waves that have $\Omega = Ck$, φ will not be constant along a ray.

conservation of quanta and propagation of amplitude for general wave

For our general wave, as for dispersionless waves, the Hamilton equations for the rays can be reinterpreted as Hamilton's equations for the world lines of the waves' quanta [Eq. (7.30) and associated discussion]. And for our general wave, as for dispersionless waves, the medium's slow variations are incapable of creating or destroying wave quanta.⁶ Correspondingly, if one knows the relationship between the waves' energy density U and their amplitude A , and thence the relationship between the waves' quantum number density $n = U/\hbar\omega$ and A , then *from the quantum conservation law* [boxed Eqs. (7.35)]

$$\frac{\partial n}{\partial t} + \nabla \cdot (n\mathbf{V}_g) = 0, \quad \frac{dn}{dt} + n\nabla \cdot \mathbf{V}_g = 0, \quad \text{or} \quad \frac{d(nCA)}{dt} = 0, \quad (7.41)$$

one can deduce the propagation law for A —and the result must be the same propagation law as one obtains from the subleading terms in the eikonal approximation.

7.3.4

7.3.4 Examples of Geometric-Optics Wave Propagation

SPHERICAL SOUND WAVES

As a simple example of these geometric-optics propagation laws, consider a sound wave propagating radially outward through a homogeneous fluid from a spherical source (e.g., a radially oscillating ball; cf. Sec. 16.5.3). The dispersion relation is Eq. (7.4): $\Omega = Ck$. It is straightforward (Ex. 7.6) to integrate Hamilton's equations and learn that the rays have the simple form $\{r = Ct + \text{constant}, \theta = \text{constant}, \phi = \text{constant}, \mathbf{k} = (\omega/C)\mathbf{e}_r\}$ in spherical polar coordinates, with \mathbf{e}_r the unit radial vector. Because the wave is dispersionless, its phase φ must be conserved along a ray [Eq. (7.28)], so φ must be a function of $Ct - r$, θ , and ϕ . For the waves to propagate radially, it is essential that $\mathbf{k} = \nabla\varphi$ point very nearly radially, which implies that φ must be a rapidly varying function of $Ct - r$ and a slowly varying one of θ and ϕ . The law of conservation of quanta in this case reduces to the propagation law $d(rA)/dt = 0$ (Ex. 7.6), so rA is also a constant along the ray; we call it \mathcal{B} . Putting this all together, we conclude that the sound waves' pressure perturbation $\psi = \delta P$ has the form

$$\psi = \frac{\mathcal{B}(Ct - r, \theta, \phi)}{r} e^{i\varphi(Ct - r, \theta, \phi)}, \quad (7.42)$$

where the phase φ is rapidly varying in $Ct - r$ and slowly varying in the angles, and the amplitude \mathcal{B} is slowly varying in $Ct - r$ and the angles.

FLEXURAL WAVES

As another example of the geometric-optics propagation laws, consider flexural waves on a spacecraft's tapering antenna. The dispersion relation is $\Omega = k^2\sqrt{D/\Lambda}$ [Eq. (7.6)] with $D/\Lambda \propto h^2$, where h is the antenna's thickness in its direction of bend (or the

6. This is a general feature of quantum theory; creation and destruction of quanta require imposed oscillations at the high frequency and short wavelength of the waves themselves, or at some submultiple of them (in the case of nonlinear creation and annihilation processes; Chap. 10).

antenna's diameter, if it has a circular cross section); cf. Eq. (12.33). Since Ω is independent of t , as the waves propagate from the spacecraft to the antenna's tip, their frequency ω is conserved [third of Eqs. (7.39)], which implies by the dispersion relation that $k = (D/\Lambda)^{-1/4}\omega^{1/2} \propto h^{-1/2}$; hence the wavelength decreases as $h^{1/2}$. The group velocity is $V_g = 2(D/\Lambda)^{1/4}\omega^{1/2} \propto h^{1/2}$. Since the energy per quantum $\hbar\omega$ is constant, particle conservation implies that the waves' energy must be conserved, which in this 1-dimensional problem means that the energy flowing through a segment of the antenna per unit time must be constant along the antenna. On physical grounds this constant energy flow rate must be proportional to $A^2V_g h^2$, which means that the amplitude A must increase $\propto h^{-5/4}$ as the flexural waves approach the antenna's end. A qualitatively similar phenomenon is seen in the cracking of a bullwhip (where the speed of the end can become supersonic).

LIGHT THROUGH A LENS AND ALFVÉN WAVES

Figure 7.3 sketches two other examples: light propagating through a lens and Alfvén waves propagating in the magnetosphere of a planet. In Sec. 7.3.6 and the exercises we explore a variety of other applications, but first we describe how the geometric-optics propagation laws can fail (Sec. 7.3.5).

Exercise 7.6 *Derivation and Practice: Quasi-Spherical Solution to Vacuum Scalar Wave Equation*

Derive the quasi-spherical solution (7.42) of the vacuum scalar wave equation $-\partial^2\psi/\partial t^2 + \nabla^2\psi = 0$ from the geometric-optics laws by the procedure sketched in the text.

EXERCISES

7.3.5 Relation to Wave Packets; Limitations of the Eikonal Approximation and Geometric Optics

7.3.5

The form $\psi = Ae^{i\varphi}$ of the waves in the eikonal approximation is remarkably general. At some initial moment of time, A and φ can have any form whatsoever, so long as the two-lengthscale constraints are satisfied [$A, \omega \equiv -\partial\varphi/\partial t$, $\mathbf{k} \equiv \nabla\varphi$, and dispersion relation $\Omega(\mathbf{k}; \mathbf{x}, t)$ all vary on lengthscales long compared to $\lambda = 1/k$ and on timescales long compared to $1/\omega$]. For example, ψ could be as nearly planar as is allowed by the inhomogeneities of the dispersion relation. At the other extreme, ψ could be a moderately narrow wave packet, confined initially to a small region of space (though not too small; its size must be large compared to its mean reduced wavelength). In either case, the evolution will be governed by the above propagation laws.

Of course, the eikonal approximation is an approximation. Its propagation laws make errors, though when the two-lengthscale constraints are well satisfied, the errors will be small for sufficiently short propagation times. Wave packets provide an important example. Dispersion (different group velocities for different wave vectors) causes wave packets to spread (disperse) as they propagate; see Ex. 7.2. This spreading

phenomena missed by geometric optics

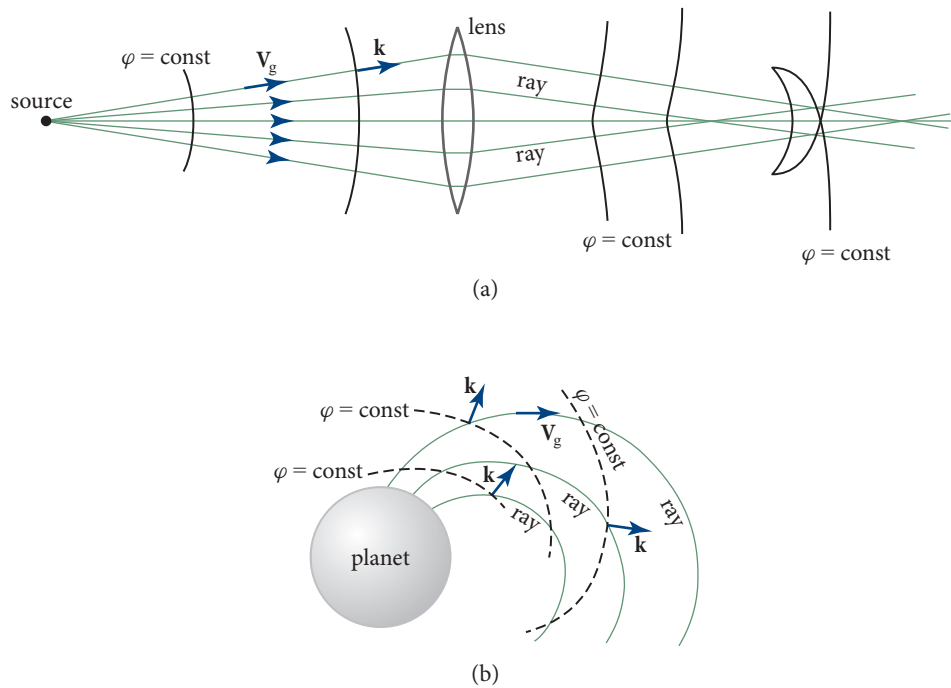

FIGURE 7.3 (a) The rays and the surfaces of constant phase φ at a fixed time for light passing through a converging lens [dispersion relation $\Omega = ck/n(\mathbf{x})$, where n is the index of refraction]. In this case the rays (which always point along \mathbf{V}_g) are parallel to the wave vector $\mathbf{k} = \nabla\varphi$ and thus are also parallel to the phase velocity \mathbf{V}_{ph} , and the waves propagate along the rays with a speed $V_g = V_{ph} = c/n$ that is independent of wavelength. The strange self-intersecting shape of the last phase front is due to caustics; see Sec. 7.5. (b) The rays and surfaces of constant phase for Alfvén waves in the magnetosphere of a planet [dispersion relation $\Omega = \mathbf{a}(\mathbf{x}) \cdot \mathbf{k}$]. In this case, because $\mathbf{V}_g = \mathbf{a} \equiv \mathbf{B}/\sqrt{\mu_0\rho}$, the rays are parallel to the magnetic field lines and are not parallel to the wave vector, and the waves propagate along the field lines with speeds V_g that are independent of wavelength; cf. Fig. 7.2c. As a consequence, if some electric discharge excites Alfvén waves on the planetary surface, then they will be observable by a spacecraft when it passes magnetic field lines on which the discharge occurred. As the waves propagate, because \mathbf{B} and ρ are time independent and hence $\partial\Omega/\partial t = 0$, the frequency ω and energy $\hbar\omega$ of each quantum is conserved, and conservation of quanta implies conservation of wave energy. Because the Alfvén speed generally diminishes with increasing distance from the planet, conservation of wave energy typically requires the waves' energy density and amplitude to increase as they climb upward.

is not included in the geometric-optics propagation laws; it is a fundamentally wave-based phenomenon and is lost when one goes to the particle-motion regime. In the limit that the wave packet becomes very large compared to its wavelength or that the packet propagates for only a short time, the spreading is small (Ex. 7.2). This is the geometric-optics regime, and geometric optics ignores the spreading.

Many other wave phenomena are missed by geometric optics. Examples are diffraction (e.g., at a geometric-optics caustic; Secs. 7.5 and 8.6), nonlinear wave-wave coupling (Chaps. 10 and 23, and Sec. 16.3), and parametric amplification of waves by

rapid time variations of the medium (Sec. 10.7.3)—which shows up in quantum mechanics as particle production (i.e., a breakdown of the law of conservation of quanta). In Sec. 28.7.1, we will encounter such particle production in inflationary models of the early universe.

7.3.6 Fermat's Principle

7.3.6

Hamilton's equations of optics allow us to solve for the paths of rays in media that vary both spatially and temporally. When the medium is time independent, the rays $\mathbf{x}(t)$ can be computed from a variational principle due to Fermat. This is the optical analog of the classical dynamics principle of least action,⁷ which states that, when a particle moves from one point to another through a time-independent potential (so its energy, the hamiltonian, is conserved), then the path $\mathbf{q}(t)$ that it follows is one that extremizes the action

principle of least action

$$J = \int \mathbf{p} \cdot d\mathbf{q} \quad (7.43)$$

(where \mathbf{q} and \mathbf{p} are the particle's generalized coordinates and momentum), subject to the constraint that the paths have a fixed starting point, a fixed endpoint, and constant energy. The proof (e.g., Goldstein, Poole, and Safko, 2002, Sec. 8.6) carries over directly to optics when we replace the hamiltonian by Ω , \mathbf{q} by \mathbf{x} , and \mathbf{p} by \mathbf{k} . The resulting Fermat principle, stated with some care, has the following form.

Consider waves whose hamiltonian $\Omega(\mathbf{k}, \mathbf{x})$ is independent of time. Choose an initial location $\mathbf{x}_{\text{initial}}$ and a final location $\mathbf{x}_{\text{final}}$ in space, and consider the rays $\mathbf{x}(t)$ that connect these two points. The rays (usually only one) are those paths that satisfy the variational principle

Fermat's principle

$$\delta \int \mathbf{k} \cdot d\mathbf{x} = 0. \quad (7.44)$$

In this variational principle, \mathbf{k} must be expressed in terms of the trial path $\mathbf{x}(t)$ using Hamilton's equation $dx^j/dt = -\partial\Omega/\partial k_j$; the rate that the trial path is traversed (i.e., the magnitude of the group velocity) must be adjusted to keep Ω constant along the trial path (which means that the total time taken to go from $\mathbf{x}_{\text{initial}}$ to $\mathbf{x}_{\text{final}}$ can differ from one trial path to another). And of course, the trial paths must all begin at $\mathbf{x}_{\text{initial}}$ and end at $\mathbf{x}_{\text{final}}$.

PATH INTEGRALS

Notice that, once a ray has been identified by this action principle, it has $\mathbf{k} = \nabla\varphi$, and therefore the extremal value of the action $\int \mathbf{k} \cdot d\mathbf{x}$ along the ray is equal to the waves'

7. This is commonly attributed to Maupertuis, though others, including Leibniz and Euler, understood it earlier or better. This "action" and the rules for its variation are different from those in play in Hamilton's principle.

phase difference $\Delta\varphi$ between $\mathbf{x}_{\text{initial}}$ and $\mathbf{x}_{\text{final}}$. Correspondingly, for any trial path, we can think of the action as a phase difference along that path,

$$\Delta\varphi = \int \mathbf{k} \cdot d\mathbf{x}, \quad (7.45a)$$

and we can think of Fermat's principle as saying that the particle travels along a path of extremal phase difference $\Delta\varphi$. This can be reexpressed in a form closely related to *Feynman's path-integral formulation of quantum mechanics* (Feynman, 1966). We can regard all the trial paths as being followed with equal probability. For each path, we are to construct a probability amplitude $e^{i\Delta\varphi}$, and we must then add together these amplitudes,

$$\sum_{\text{all paths}} e^{i\Delta\varphi}, \quad (7.45b)$$

to get the net complex amplitude for quanta associated with the waves to travel from $\mathbf{x}_{\text{initial}}$ to $\mathbf{x}_{\text{final}}$. The contributions from almost all neighboring paths will interfere destructively. The only exceptions are those paths whose neighbors have the same values of $\Delta\varphi$, to first order in the path difference. These are the paths that extremize the action (7.44): they are the wave's rays, the actual paths of the quanta.

SPECIALIZATION TO $\Omega = C(\mathbf{x})k$

Fermat's principle takes on an especially simple form when not only is the hamiltonian $\Omega(\mathbf{k}, \mathbf{x})$ time independent, but it also has the simple dispersion-free form $\Omega = C(\mathbf{x})k$ —a form valid for the propagation of light through a time-independent dielectric, and sound waves through a time-independent, inhomogeneous fluid, and electromagnetic or gravitational waves through a time-independent, Newtonian gravitational field (Sec. 7.6). In this $\Omega = C(\mathbf{x})k$ case, the hamiltonian dictates that for each trial path, \mathbf{k} is parallel to $d\mathbf{x}$, and therefore $\mathbf{k} \cdot d\mathbf{x} = kds$, where s is distance along the path. Using the dispersion relation $k = \Omega/C$ and noting that Hamilton's equation $dx^j/dt = \partial\Omega/\partial k_j$ implies $ds/dt = C$ for the rate of traversal of the trial path, we see that $\mathbf{k} \cdot d\mathbf{x} = kds = \Omega dt$. Since the trial paths are constrained to have Ω constant, Fermat's principle (7.44) becomes a principle of extremal time: The rays between $\mathbf{x}_{\text{initial}}$ and $\mathbf{x}_{\text{final}}$ are those paths along which

$$\int dt = \int \frac{ds}{C(\mathbf{x})} = \int \frac{n(\mathbf{x})}{c} ds \quad (7.46)$$

is extremal. In the last expression we have adopted the convention used for light in a dielectric medium, that $C(\mathbf{x}) = c/n(\mathbf{x})$, where c is the speed of light in vacuum, and n is the medium's index of refraction. Since c is constant, the rays are paths of extremal optical path length $\int n(\mathbf{x})ds$.

We can use Fermat's principle to demonstrate that, if the medium contains no opaque objects, then there will always be at least one ray connecting any two

principle of extreme time for dispersionless wave

index of refraction

points. This is because there is a lower bound on the optical path between any two points, given by $n_{\min}L$, where n_{\min} is the lowest value of the refractive index anywhere in the medium, and L is the distance between the two points. This means that for some path the optical path length must be a minimum, and that path is then a ray connecting the two points.

From the principle of extremal time, we can derive the Euler-Lagrange differential equation for the ray. For ease of derivation, we write the action principle in the form

$$\delta \int n(\mathbf{x}) \sqrt{\frac{d\mathbf{x}}{ds} \cdot \frac{d\mathbf{x}}{ds}} ds, \quad (7.47)$$

where the quantity in the square root is identically one. Performing a variation in the usual manner then gives

$$\boxed{\frac{d}{ds} \left(n \frac{d\mathbf{x}}{ds} \right) = \nabla n, \quad \text{i.e.,} \quad \frac{d}{ds} \left(\frac{1}{C} \frac{d\mathbf{x}}{ds} \right) = \nabla \left(\frac{1}{C} \right)}. \quad (7.48)$$

ray equation for dispersionless wave

This is equivalent to Hamilton's equations for the ray, as one can readily verify using the hamiltonian $\Omega = kc/n$ (Ex. 7.7).

Equation (7.48) is a second-order differential equation requiring two boundary conditions to define a solution. We can either choose these to be the location of the start of the ray and its starting direction, or the start and end of the ray. A simple case arises when the medium is stratified [i.e., when $n = n(z)$, where (x, y, z) are Cartesian coordinates]. Projecting Eq. (7.48) perpendicular to \mathbf{e}_z , we discover that ndy/ds and ndx/ds are constant, which implies

$$\boxed{n \sin \theta = \text{constant}}, \quad (7.49)$$

Snell's law

where θ is the angle between the ray and \mathbf{e}_z . This is a variant of Snell's law of refraction. Snell's law is just a mathematical statement that the rays are normal to surfaces (wavefronts) on which the eikonal (phase) φ is constant (cf. Fig. 7.4).⁸ Snell's law is valid not only when $n(\mathbf{x})$ varies slowly but also when it jumps discontinuously, despite the assumptions underlying geometric optics failing at a discontinuity.

Exercise 7.7 *Derivation: Hamilton's Equations for Dispersionless Waves; Fermat's Principle*

EXERCISES

Show that Hamilton's equations for the standard dispersionless dispersion relation (7.4) imply the same ray equation (7.48) as we derived using Fermat's principle.

8. Another important application of this general principle is to the design of optical instruments, where it is known as the *Abbé condition*. See, e.g., Born and Wolf (1999).

FIGURE 7.4 Illustration of Snell's law of refraction at the interface between two media, for which the refractive indices are n_1 and n_2 (assumed less than n_1). As the wavefronts must be continuous across the interface, simple geometry tells us that $\lambda_1/\sin\theta_1 = \lambda_2/\sin\theta_2$. This and the fact that the wavelengths are inversely proportional to the refractive index, $\lambda_j \propto 1/n_j$, imply that $n_1 \sin\theta_1 = n_2 \sin\theta_2$, in agreement with Eq. (7.49).

Exercise 7.8 *Example: Self-Focusing Optical Fibers*

Optical fibers in which the refractive index varies with radius are commonly used to transport optical signals. When the diameter of the fiber is many wavelengths, we can use geometric optics. Let the refractive index be

$$n = n_0(1 - \alpha^2 r^2)^{1/2}, \quad (7.50a)$$

where n_0 and α are constants, and r is radial distance from the fiber's axis.

- (a) Consider a ray that leaves the axis of the fiber along a direction that makes an angle β to the axis. Solve the ray-transport equation (7.48) to show that the radius of the ray is given by

$$r = \frac{\sin\beta}{\alpha} \left| \sin\left(\frac{\alpha z}{\cos\beta}\right) \right|, \quad (7.50b)$$

where z measures distance along the fiber.

- (b) Next consider the propagation time T for a light pulse propagating along the ray with $\beta \ll 1$, down a long length L of fiber. Show that

$$T = \frac{n_0 L}{C} [1 + O(\beta^4)], \quad (7.50c)$$

and comment on the implications of this result for the use of fiber optics for communication.

Exercise 7.9 ***Example: Geometric Optics for the Schrödinger Equation*

Consider the nonrelativistic Schrödinger equation for a particle moving in a time-dependent, 3-dimensional potential well:

$$-\frac{\hbar}{i} \frac{\partial \psi}{\partial t} = \left[\frac{1}{2m} \left(\frac{\hbar}{i} \nabla \right)^2 + V(\mathbf{x}, t) \right] \psi. \quad (7.51)$$

- (a) Seek a geometric-optics solution to this equation with the form $\psi = A e^{iS/\hbar}$, where A and V are assumed to vary on a lengthscale \mathcal{L} and timescale \mathcal{T} long compared to those, $1/k$ and $1/\omega$, on which S varies. Show that the leading-order terms in the two-lengthscale expansion of the Schrödinger equation give the Hamilton-Jacobi equation

$$\frac{\partial S}{\partial t} + \frac{1}{2m} (\nabla S)^2 + V = 0. \quad (7.52a)$$

Our notation $\varphi \equiv S/\hbar$ for the phase φ of the wave function ψ is motivated by the fact that the geometric-optics limit of quantum mechanics is classical mechanics, and the function $S = \hbar\varphi$ becomes, in that limit, “Hamilton’s principal function,” which obeys the Hamilton-Jacobi equation (see, e.g., Goldstein, Poole, and Safko, 2002, Chap. 10). [Hint: Use a formal parameter σ to keep track of orders (Box 7.2), and argue that terms proportional to \hbar^n are of order σ^n . This means there must be factors of σ in the Schrödinger equation (7.51) itself.]

- (b) From Eq. (7.52a) derive the equation of motion for the rays (which of course is identical to the equation of motion for a wave packet and therefore is also the equation of motion for a classical particle):

$$\frac{d\mathbf{x}}{dt} = \frac{\mathbf{p}}{m}, \quad \frac{d\mathbf{p}}{dt} = -\nabla V, \quad (7.52b)$$

where $\mathbf{p} = \nabla S$.

- (c) Derive the propagation equation for the wave amplitude A and show that it implies

$$\frac{d|A|^2}{dt} + |A|^2 \frac{\nabla \cdot \mathbf{p}}{m} = 0. \quad (7.52c)$$

Interpret this equation quantum mechanically.

7.4 Paraxial Optics**7.4**

It is quite common in optics to be concerned with a bundle of rays that are almost parallel (i.e., for which the angle the rays make with some reference ray can be treated as small). This approximation is called *paraxial optics*, and it permits one to linearize the geometric-optics equations and use matrix methods to trace their

FIGURE 7.5 A reference ray (the z -axis) and an adjacent ray identified by its transverse distances $x(z)$ and $y(z)$, from the reference ray.

rays. The resulting matrix formalism underlies the first-order theory of simple optical instruments (e.g., the telescope and the microscope).

We develop the paraxial optics formalism for waves whose dispersion relation has the simple, time-independent, nondispersive form $\Omega = kc/n(\mathbf{x})$. This applies to light in a dielectric medium—the usual application. As we shall see, it also applies to charged particles in a storage ring or electron microscope (Sec. 7.4.2) and to light being lensed by a weak gravitational field (Sec. 7.6).

We restrict ourselves to a situation where there exists a ray that is a straight line, except when it reflects off a mirror or other surface. We choose this as a *reference ray* (also called the *optic axis*) for our formalism, and we orient the z -axis of a Cartesian coordinate system along it (Fig. 7.5). Let the 2-dimensional vector $\mathbf{x}(z)$ be the transverse displacement of some other ray from this reference ray, and denote by $(x, y) = (x_1, x_2)$ the Cartesian components of \mathbf{x} .

Under paraxial conditions, $|\mathbf{x}|$ is small compared to the z lengthscales of the propagation, so we can Taylor expand the refractive index $n(\mathbf{x}, z)$ in (x_1, x_2) :

$$n(\mathbf{x}, z) = n(0, z) + x_i n_{,i}(0, z) + \frac{1}{2} x_i x_j n_{,ij}(0, z) + \dots \quad (7.53a)$$

Here the subscript commas denote partial derivatives with respect to the transverse coordinates, $n_{,i} \equiv \partial n / \partial x_i$. The linearized form of the ray-propagation equation (7.48) is then given by

$$\frac{d}{dz} \left(n(0, z) \frac{dx_i}{dz} \right) = n_{,i}(0, z) + x_j n_{,ij}(0, z). \quad (7.53b)$$

In order for the reference ray $x_i = 0$ to satisfy this equation, $n_{,i}(0, z)$ must vanish, so Eq. (7.53b) becomes a linear, homogeneous, second-order equation for the path of a nearby ray, $\mathbf{x}(z)$:

$$\boxed{\left(\frac{d}{dz} \right) \left(\frac{ndx_i}{dz} \right) = x_j n_{,ij}.} \quad (7.54)$$

Here n and $n_{,ij}$ are evaluated on the reference ray. It is helpful to regard z as “time” and think of Eq. (7.54) as an equation for the 2-dimensional motion of a particle (the

paraxial ray equation

ray) in a quadratic potential well. We can solve Eq. (7.54) given starting values $\mathbf{x}(z')$ and $\dot{\mathbf{x}}(z')$, where the dot denotes differentiation with respect to z , and z' is the starting location. The solution at some later point z is linearly related to the starting values. We can capitalize on this linearity by treating $\{\mathbf{x}(z), \dot{\mathbf{x}}(z)\}$ as a 4-dimensional vector $V_i(z)$, with

$$\boxed{V_1 = x, \quad V_2 = \dot{x}, \quad V_3 = y, \quad \text{and} \quad V_4 = \dot{y},} \quad (7.55a)$$

and embodying the linear transformation [linear solution of Eq. (7.54)] from location z' to location z in a *transfer matrix* $J_{ab}(z, z')$:

$$\boxed{V_a(z) = J_{ab}(z, z') \cdot V_b(z'),} \quad (7.55b)$$

paraxial transfer matrix

where there is an implied sum over the repeated index b . The transfer matrix contains full information about the change of position and direction of all rays that propagate from z' to z . As is always the case for linear systems, the transfer matrix for propagation over a large interval, from z' to z , can be written as the product of the matrices for two subintervals, from z' to z'' and from z'' to z :

$$\boxed{J_{ac}(z, z') = J_{ab}(z, z'') J_{bc}(z'', z').} \quad (7.55c)$$

7.4.1 Axisymmetric, Paraxial Systems: Lenses, Mirrors, Telescopes, Microscopes, and Optical Cavities

7.4.1

If the index of refraction is everywhere axisymmetric, so $n = n(\sqrt{x^2 + y^2}, z)$, then there is no coupling between the motions of rays along the x and y directions, and the equations of motion along x are identical to those along y . In other words, $J_{11} = J_{33}$, $J_{12} = J_{34}$, $J_{21} = J_{43}$, and $J_{22} = J_{44}$ are the only nonzero components of the transfer matrix. This reduces the dimensionality of the propagation problem from 4 dimensions to 2: V_a can be regarded as either $\{x(z), \dot{x}(z)\}$ or $\{y(z), \dot{y}(z)\}$, and in both cases the 2×2 transfer matrix J_{ab} is the same.

Let us illustrate the paraxial formalism by deriving the transfer matrices of a few simple, axisymmetric optical elements. In our derivations it is helpful conceptually to focus on rays that move in the x - z plane (i.e., that have $y = \dot{y} = 0$). We write the 2-dimensional V_i as a column vector:

$$\boxed{V_a = \begin{pmatrix} x \\ \dot{x} \end{pmatrix}.} \quad (7.56a)$$

axisymmetric transfer matrices

The simplest case is a straight section of length d extending from z' to $z = z' + d$. The components of V will change according to

$$\begin{aligned} x &= x' + \dot{x}'d, \\ \dot{x} &= \dot{x}', \end{aligned}$$

so

for straight section

$$J_{ab} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \text{ for a straight section of length } d, \quad (7.56b)$$

where $x' = x(z')$, and so forth. Next, consider a thin lens with focal length f . The usual convention in optics is to give f a positive sign when the lens is converging and a negative sign when diverging. A thin lens gives a deflection to the ray that is linearly proportional to its displacement from the optic axis, but does not change its transverse location. Correspondingly, the transfer matrix in crossing the lens (ignoring its thickness) is

for thin lens

$$J_{ab} = \begin{pmatrix} 1 & 0 \\ -f^{-1} & 1 \end{pmatrix} \text{ for a thin lens with focal length } f. \quad (7.56c)$$

Similarly, a spherical mirror with radius of curvature R (again adopting a positive sign for a converging mirror and a negative sign for a diverging mirror) has a transfer matrix

for spherical mirror

$$J_{ab} = \begin{pmatrix} 1 & 0 \\ -2R^{-1} & 1 \end{pmatrix} \text{ for a spherical mirror with radius of curvature } R. \quad (7.56d)$$

(Recall our convention that z always increases along a ray, even when the ray reflects off a mirror.)

As a simple illustration, we consider rays that leave a point source located a distance u in front of a converging lens of focal length f , and we solve for the ray positions a distance v behind the lens (Fig. 7.6). The total transfer matrix is the transfer matrix (7.56b) for a straight section, multiplied by the product of the lens transfer matrix (7.56c) and a second straight-section transfer matrix:

$$J_{ab} = \begin{pmatrix} 1 & v \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -f^{-1} & 1 \end{pmatrix} \begin{pmatrix} 1 & u \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 - vf^{-1} & u + v - uvf^{-1} \\ -f^{-1} & 1 - uf^{-1} \end{pmatrix}. \quad (7.57)$$

When the 1-2 element (upper right entry) of this transfer matrix vanishes, the position of the ray after traversing the optical system is independent of the starting direction. In other words, rays from the point source form a point image. When this happens, the planes containing the source and the image are said to be conjugate. The condition for this to occur is

conjugate planes

thin-lens equations

$$\frac{1}{u} + \frac{1}{v} = \frac{1}{f}. \quad (7.58)$$

FIGURE 7.6 Simple converging lens used to illustrate the use of transfer matrices. The total transfer matrix is formed by taking the product of the straight-section transfer matrix with the lens matrix and another straight-section matrix.

FIGURE 7.7 Simple refracting telescope. By convention $\theta > 0$ and $\mathcal{M}\theta < 0$, so the image is inverted.

This is the standard thin-lens equation. The linear magnification of the image is given by $\mathcal{M} = J_{11} = 1 - v/f$, that is,

$$\mathcal{M} = -\frac{v}{u}, \quad (7.59)$$

where the negative sign means that the image is inverted. Note that, if a ray is reversed in direction, it remains a ray, but with the source and image planes interchanged; u and v are exchanged, Eq. (7.58) is unaffected, and the magnification (7.59) is inverted: $\mathcal{M} \rightarrow 1/\mathcal{M}$.

Exercise 7.10 *Problem: Matrix Optics for a Simple Refracting Telescope*

Consider a simple refracting telescope (Fig. 7.7) that comprises two converging lenses, the *objective* and the *eyepiece*. This telescope takes parallel rays of light from distant stars, which make an angle $\theta \ll 1$ with the optic axis, and converts them into parallel rays making a much larger angle $\mathcal{M}\theta$. Here \mathcal{M} is the magnification with \mathcal{M} negative,

EXERCISES

FIGURE 7.8 Simple microscope.

$|\mathcal{M}| \gg 1$, and $|\mathcal{M}\theta| \ll 1$. (The parallel output rays are then focused by the lens of a human's eye, to a point on the eye's retina.)

- Use matrix methods to investigate how the output rays depend on the separation of the two lenses, and hence find the condition that the output rays are parallel when the input rays are parallel.
- How does the magnification \mathcal{M} depend on the ratio of the focal lengths of the two lenses?
- If, instead of looking through the telescope with one's eye, one wants to record the stars' image on a photographic plate or CCD, how should the optics be changed?

Exercise 7.11 *Problem: Matrix Optics for a Simple Microscope*

A microscope takes light rays from a point on a microscopic object, very near the optic axis, and transforms them into parallel light rays that will be focused by a human eye's lens onto the eye's retina (Fig. 7.8). Use matrix methods to explore the operation of such a microscope. A single lens (magnifying glass) could do the same job (rays from a point converted to parallel rays). Why does a microscope need two lenses? What focal lengths and lens separations are appropriate for the eye to resolve a bacterium $100 \mu\text{m}$ in size?

Exercise 7.12 *Example: Optical Cavity—Rays Bouncing between Two Mirrors*

Consider two spherical mirrors, each with radius of curvature R , separated by distance d so as to form an optical cavity (Fig. 7.9). A laser beam bounces back and forth between the two mirrors. The center of the beam travels along a geometric-optics ray. (We study such beams, including their diffractive behavior, in Sec. 8.5.5.)

- Show, using matrix methods, that the central ray hits one of the mirrors (either one) at successive locations $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \dots$ (where $\mathbf{x} \equiv (x, y)$ is a 2-dimensional vector in the plane perpendicular to the optic axis), which satisfy the difference equation

$$\mathbf{x}_{k+2} - 2b\mathbf{x}_{k+1} + \mathbf{x}_k = 0, \tag{7.60a}$$

FIGURE 7.9 An optical cavity formed by two mirrors, and a light beam bouncing back and forth inside it.

where

$$b = 1 - \frac{4d}{R} + \frac{2d^2}{R^2}. \quad (7.60b)$$

Explain why this is a difference-equation analog of the simple-harmonic-oscillator equation.

- (b) Show that this difference equation has the general solution

$$\mathbf{x}_k = \mathbf{A} \cos(k \cos^{-1} b) + \mathbf{B} \sin(k \cos^{-1} b). \quad (7.60c)$$

Obviously, \mathbf{A} is the transverse position \mathbf{x}_0 of the ray at its 0th bounce. The ray's 0th position \mathbf{x}_0 and its 0th direction of motion $\dot{\mathbf{x}}_0$ together determine \mathbf{B} .

- (c) Show that if $0 \leq d \leq 2R$, the mirror system is stable. In other words, all rays oscillate about the optic axis. Similarly, show that if $d > 2R$, the mirror system is unstable and the rays diverge from the optic axis.
- (d) For an appropriate choice of initial conditions \mathbf{x}_0 and $\dot{\mathbf{x}}_0$, the laser beam's successive spots on the mirror lie on a circle centered on the optic axis. When operated in this manner, the cavity is called a *Harriet delay line*. How must d/R be chosen so that the spots have an angular step size θ ? (There are two possible choices.)

7.4.2 Converging Magnetic Lens for Charged Particle Beam

7.4.2

Since geometric optics is the same as particle dynamics, matrix equations can be used to describe paraxial motions of electrons or ions in a storage ring. (Note, however, that the hamiltonian for such particles is dispersive, since it does not depend linearly on the particle momentum, and so for our simple matrix formalism to be valid, we must confine attention to a monoenergetic beam of particles.)

The simplest practical lens for charged particles is a quadrupolar magnet. Quadrupolar magnetic fields are used to guide particles around storage rings. If we orient our axes appropriately, the magnet's magnetic field can be expressed in the form

$$\mathbf{B} = \frac{B_0}{r_0}(y\mathbf{e}_x + x\mathbf{e}_y) \quad \text{independent of } z \text{ within the lens} \quad (7.61)$$

quadrupolar magnetic field

FIGURE 7.10 Quadrupolar magnetic lens. The magnetic field lines lie in a plane perpendicular to the optic axis. Positively charged particles moving along e_z converge when $y = 0$ and diverge when $x = 0$.

(Fig. 7.10). Particles traversing this magnetic field will be subjected to a Lorentz force that curves their trajectories. In the paraxial approximation, a particle's coordinates satisfy the two differential equations

$$\ddot{x} = -\frac{x}{\lambda^2}, \quad \ddot{y} = \frac{y}{\lambda^2}, \quad (7.62a)$$

where the dots (as above) mean $d/dz = v^{-1}d/dt$, and

$$\lambda = \left(\frac{pr_0}{qB_0} \right)^{1/2} \quad (7.62b)$$

[cf. Eq. (7.61)], with q the particle's charge (assumed positive) and p its momentum. The motions in the x and y directions are decoupled. It is convenient in this case to work with two 2-dimensional vectors, $\{V_{x1}, V_{x2}\} \equiv \{x, \dot{x}\}$ and $\{V_{y1}, V_{y2}\} = \{y, \dot{y}\}$. From the elementary solutions to the equations of motion (7.62a), we infer that the transfer matrices from the magnet's entrance to its exit are $J_{x ab}$, $J_{y ab}$, where

$$J_{x ab} = \begin{pmatrix} \cos \phi & \lambda \sin \phi \\ -\lambda^{-1} \sin \phi & \cos \phi \end{pmatrix}, \quad (7.63a)$$

$$J_{y ab} = \begin{pmatrix} \cosh \phi & \lambda \sinh \phi \\ \lambda^{-1} \sinh \phi & \cosh \phi \end{pmatrix}, \quad (7.63b)$$

and

$$\phi = L/\lambda, \quad (7.63c)$$

with L the distance from entrance to exit (i.e., the lens thickness).

transfer matrices for quadrupolar magnetic lens

The matrices J_{xab} and J_{yab} can be decomposed as follows:

$$J_{xab} = \begin{pmatrix} 1 & \lambda \tan \phi/2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\lambda^{-1} \sin \phi & 1 \end{pmatrix} \begin{pmatrix} 1 & \lambda \tan \phi/2 \\ 0 & 1 \end{pmatrix} \quad (7.63d)$$

$$J_{yab} = \begin{pmatrix} 1 & \lambda \tanh \phi/2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ \lambda^{-1} \sinh \phi & 1 \end{pmatrix} \begin{pmatrix} 1 & \lambda \tanh \phi/2 \\ 0 & 1 \end{pmatrix} \quad (7.63e)$$

Comparing with Eqs. (7.56b) and (7.56c), we see that the action of a single magnet is equivalent to the action of a straight section, followed by a thin lens, followed by another straight section. Unfortunately, if the lens is focusing in the x direction, it must be defocusing in the y direction and vice versa. However, we can construct a lens that is focusing along both directions by combining two magnets that have opposite polarity but the same focusing strength $\phi = L/\lambda$.

Consider first the particles' motion in the x direction. Let

$$f_+ = \lambda / \sin \phi \quad \text{and} \quad f_- = -\lambda / \sinh \phi \quad (7.64)$$

be the equivalent focal lengths of the first converging lens and the second diverging lens. If we separate the magnets by a distance s , this must be added to the two effective lengths of the two magnets to give an equivalent separation of $d = \lambda \tan(\phi/2) + s + \lambda \tanh(\phi/2)$ for the two equivalent thin lenses. The combined transfer matrix for the two thin lenses separated by this distance d is then

$$\begin{pmatrix} 1 & 0 \\ -f_-^{-1} & 1 \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -f_+^{-1} & 1 \end{pmatrix} = \begin{pmatrix} 1 - df_+^{-1} & d \\ -f_*^{-1} & 1 - df_-^{-1} \end{pmatrix}, \quad (7.65a)$$

where

$$\frac{1}{f_*} = \frac{1}{f_-} + \frac{1}{f_+} - \frac{d}{f_- f_+} = \frac{\sin \phi}{\lambda} - \frac{\sinh \phi}{\lambda} + \frac{d \sin \phi \sinh \phi}{\lambda^2}. \quad (7.65b)$$

If we assume that $\phi \ll 1$ and $s \ll L$, then we can expand as a Taylor series in ϕ to obtain

$$f_* \simeq \frac{3\lambda}{2\phi^3} = \frac{3\lambda^4}{2L^3}. \quad (7.66)$$

The effective focal length f_* of the combined magnets is positive, and so the lens has a net focusing effect. From the symmetry of Eq. (7.65b) under interchange of f_+ and f_- , it should be clear that f_* is independent of the order in which the magnets are encountered. Therefore, if we were to repeat the calculation for the motion in the y direction, we would get the same focusing effect. (The diagonal elements of the transfer matrix are interchanged, but as they are both close to unity, this difference is rather small.)

The combination of two quadrupole lenses of opposite polarity can therefore imitate the action of a converging lens. Combinations of magnets like this are used to collimate particle beams in storage rings, particle accelerators, and electron microscopes.

combining two magnets to make a converging lens

transfer matrix for converging magnetic lens

caustic

CAUSTICS

Many simple optical instruments are carefully made to form point images from point sources. However, naturally occurring optical systems, and indeed precision optical instruments when examined in fine detail, bring light to a focus not at a point, but instead on a 2-dimensional surface—an envelope formed by the rays—called a *caustic*. Caustics are often seen in everyday life. For example, when bright sunlight is reflected by the inside of an empty coffee mug some of the rays are reflected *specularly* (angle of incidence equals angle of reflection) and some of the rays are reflected *diffusely* (in all directions due to surface irregularity and multiple reflections and refractions beneath the surface). The specular reflection by the walls—a cylindrical mirror—forms a caustic surface. The intersection of this surface with the bottom forms caustic lines that can be seen in diffuse reflection.⁹ These caustic lines are observed to meet in a point. When the optical surfaces are quite irregular (e.g., the water surface in a swimming pool¹⁰ or the type of glass used in bathrooms), then a *caustic network* forms. Caustic lines and points are seen, just the same as with the mug (Fig. 7.11).

catastrophes

What may be surprising is that caustics like these, formed under quite general conditions, can be classified into a rather small number of types, called *catastrophes*, possessing generic properties and scaling laws (Thom, 1994). The scaling laws are reminiscent of the renormalization group discussed in Sec. 5.8.3. Although we focus on catastrophes in the context of optics (e.g., Berry and Upstill, 1980), where they are caustics, the phenomenon is quite general and crops up in other subfields of physics, especially dynamics (e.g., Arnold, 1992) and thermodynamics (e.g., Ex. 7.16). It has also been invoked, often quite controversially, in fields outside physics (e.g., Poston and Stewart, 2012). Catastrophes can be found whenever we have a physical system whose states are determined by extremizing a function, such as energy. Our treatment will be quite heuristic, but the subject does have a formal mathematical foundation that connects it to bifurcations and *Morse theory* (see Sec. 11.6; see also, e.g., Petters et al., 2001).

STATE VARIABLES AND CONTROL PARAMETERS

Let us start with a specific, simple example. Suppose that there is a distant *source* S and a *detector* D separated by free space. If we consider all the paths from S to

9. The curve that is formed is called a “nephroid.”

10. The optics is quite complicated. Some rays from the Sun are reflected specularly by the surface of the water, creating multiple images of the Sun. As the Sun is half a degree in diameter, these produce thickened caustic lines. Some rays are refracted by the water, forming caustic surfaces that are intersected by the bottom of the pool to form a caustic pattern. Some light from this pattern is reflected diffusely before being refracted a second time on the surface of the water and ultimately detected by a retina or a CCD. Other rays are reflected multiple times.

FIGURE 7.11 Photographs of caustics. (a) Simple caustic pattern formed by a coffee mug. (b) Caustic network formed in a swimming pool. The generic structure of these patterns comprises *fold* lines meeting at *cusp* points.

FIGURE 7.12 (a) Alternative paths make up a sequence of straight segments from a source S to a detector D . The path $S\text{-}\mathcal{P}_1\text{-}\mathcal{P}_2\text{-}\mathcal{P}_3\text{-}D$ can be simplified to a shorter path $S\text{-}\mathcal{P}_1\text{-}\mathcal{P}_3\text{-}D$, and this process can be continued until we have the minimum number of segments needed to exhibit the catastrophe. The (true) ray, with the smallest phase difference, is the axis $S\text{-}D$. (b) A single path from a distant source intersecting a screen at $\{a, b\}$ and ending at detector D with coordinates $\{x, y, z\}$.

D there is a single extremum—a minimum—in the phase difference, $\Delta\varphi = \omega t = \int \mathbf{k} \cdot d\mathbf{x}$. By Fermat's principle, this is the (true) ray—the *axis*—connecting the two points. There are an infinite number of alternative paths that could be defined by an infinite set of parameters, but wherever else the rays go, the phase difference is larger. Take one of these alternative paths connecting S and D and break it down into a sequence of connected segments (Fig. 7.12a). We can imagine replacing two successive segments with a single segment connecting their endpoints. This will reduce the phase difference. The operation can be repeated until we are left with the minimum number of segments, specified by the minimum number of necessary variables that we need to exhibit the catastrophe. The order in which we do this does not matter, and the final variables characterizing the path can be chosen for convenience. These variables are known as *state variables*.

state variables

Next, introduce a screen perpendicular to the S - D axis and close to D (Fig. 7.12b). Consider a path from S , nearly parallel to the axis and intersecting the screen at a point with Cartesian coordinates $\{a, b\}$ measured from the axis. There let it be deflected toward D . In this section and the next, introduce the *delay* $t \equiv \Delta\varphi/\omega$, subtracting off the constant travel time along the axis in the absence of the screen, to measure the phase. The additional geometric delay associated with this ray is given approximately by

$$t_{\text{geo}} = \frac{a^2 + b^2}{2zc}, \quad (7.67)$$

control parameters

where $z \gg \{a, b\}$ measures the distance from the screen to D , parallel to the axis, and c is the speed of light. The coordinates $\{a, b\}$ act as state variables, and the true ray is determined by differentiating with respect to them. Next, move D off the axis and give it Cartesian coordinates $\{x, y, z\}$ with the x - y plane parallel to the a - b plane, and the transverse coordinates measured from the original axis. As these coordinates specify one of the endpoints, they do not enter into the variation that determines the true ray, but they do change t_{geo} to $[(a-x)^2 + (b-y)^2]/(2zc)$. These $\{x, y, z\}$ parameters are examples of *control parameters*. In general, the number of control parameters that we use is also the minimum needed to exhibit the catastrophe, and the choice is usually determined by algebraic convenience.

FOLD CATASTROPHE

Now replace the screen with a thin lens of refractive index n and thickness $w(a, b)$. This introduces an additional contribution to the delay, $t_{\text{lens}} = (n-1)w/c$. The true ray will be fixed by the variation of the sum of the geometric and lens delays with respect to a and b plus any additional state variables that are needed. Suppose that the lens is cylindrical so rays are bent only in the x direction and one state variable, a , suffices. Let us use an analytically tractable example, $t_{\text{lens}} = s^2(1 - 2a^2/s^2 + a^4/s^4)/(4fc)$, for $|a| < s$, where $f \gg s$ is the focal length (Fig. 7.13). Place the detector D on the axis with $z < f$. The delay along a path is:

$$t \equiv t_{\text{geo}} + t_{\text{lens}} = \frac{a^2}{2fzc} \left(f - z + \frac{a^2z}{2s^2} \right), \quad (7.68)$$

dropping a constant. This leaves the single minimum and the true ray at $a = 0$.

Now displace D perpendicular to the axis a distance x with z fixed. t_{geo} becomes $(a-x)^2/(2zc)$, and the true ray will be parameterized by the single real value of a that minimizes t and therefore solves

$$x = \frac{a}{f} \left(f - z + z \frac{a^2}{s^2} \right). \quad (7.69)$$

The first two terms, $f - z$, represent a perfect thin lens [cf. J_{11} in Eq. (7.57)]; the third represents an imperfection.

A human eye at D [coordinates (x, y, z)] focuses the ray through D and adjacent rays onto its retina, producing there a point image of the point source at S . The

FIGURE 7.13 Light from a distant source is normally incident on a thin, phase-changing lens. The phase change depends solely on the distance a from the axis. The delay t along paths encountering a detector D located at (x, z) can be calculated using an equation such as Eq. (7.68). The true rays are located where t is extremized. The envelope created by these rays comprises two fold caustic curves (red) that meet at a cusp point. When D lies outside the caustic, for example at A , there is only one true ray (cyan) where t has its single minimum. When D lies inside the caustic, for example at point B , there are three true rays associated with two minima (orange, cyan) and one maximum (purple) of t . When D lies on the caustic, for example at C , there is one minimum (cyan) and a point of inflection (green). The magnification is formally infinite on the caustic. The cusp at the end of the caustic is the focus, a distance f from the screen.

power $P = d\mathcal{E}/dt$ in that image is the energy flux at D times the area inside the eye's iris, so the image power is proportional to the energy flux. Since the energy flux is proportional to the square of the field amplitude A^2 and $A \propto 1/\sqrt{\mathcal{A}}$, where \mathcal{A} is the area of a bundle of rays [Eq. (7.35d)], the image power is $P \propto 1/\mathcal{A}$.

Consider a rectangular ray bundle that passes through $\{a, b\}$ on the screen with edges da and db , and area $\mathcal{A}_{\text{screen}} = dadb$. The bundle's area when it arrives at D is $\mathcal{A}_D = dx dy$. Because the lens is cylindrical, $dy = db$, so the ratio of power seen by an eye at D to that seen by an eye at the screen (i.e., the lens's *magnification*) is $\mathcal{M} = dP_D/dP_{\text{screen}} = \mathcal{A}_{\text{screen}}/\mathcal{A}_D = da/dx$. Using Eq. (7.69), we find

$$\mathcal{H} \equiv \mathcal{M}^{-1} = \frac{dx}{da} = zc \left(\frac{d^2t}{da^2} \right) = \left(\frac{f-z}{f} + 3 \frac{a^2z}{s^2f} \right). \quad (7.70)$$

If the curvature \mathcal{H} of the delay in the vicinity of a true ray is decreased, the magnification is increased. When $z < f$, the curvature is positive. When $z > f$ the curvature for $a = x = 0$ is negative, and the magnification is $\mathcal{M} = -f/(z-f)$, corresponding to an inverted image. However, there are now two additional images with $a = \pm z^{-1/2}(z-f)^{1/2}s$ at minima with associated magnifications $\mathcal{M} = \frac{1}{2}f(z-f)^{-1}$.

Next move the detector D farther away from the axis. A maximum and a minimum in t will become a point of inflection and, equivalently, two of the images will merge when $a = a_f = \pm 3^{-1/2}z^{-1/2}(z-f)^{1/2}s$ or

$$x = x_f \equiv \mp 2f^{-1}z^{-1/2}(z-f)^{3/2}s. \quad (7.71)$$

This is the location of the caustic; in 3-dimensional space it is the surface shown in the first panel of Fig. 7.15 below.

The magnification of the two images will diverge at the caustic and, expanding \mathcal{H} to linear order about zero, we find that $\mathcal{M} = \pm 2^{-1} 3^{-1/4} f^{1/2} s^{1/2} z^{-1/4} (z - f)^{-1/4} |x - x_f|^{-1/2}$ for each image. However, when $|x| > x_f$, the two images vanish. This abrupt change in the optics—two point images becoming infinitely magnified and then vanishing as the detector is moved—is an example of a *fold catastrophe* occurring at a caustic. (Note that the algebraic sum of the two magnifications is zero in the limit.)

It should be pointed out that the divergence of the magnification does not happen in practice for two reasons. The first is that a point source is only an idealization, and if we allow the source to have finite size, different parts will produce caustics at slightly different locations. The second is that geometric optics, on which our analysis is based, pretends that the wavelength of light is vanishingly small. In actuality, the wavelength is always nonzero, and near a caustic its finiteness leads to diffraction effects, which also limit the magnification to a finite value (Sec. 8.6).

Although we have examined one specific and stylized example, the algebraic details can be worked out for any configuration governed by geometric optics. However, they are less important than the scaling laws—for example, $\mathcal{M} \propto |x - x_f|^{-1/2}$ —that become increasingly accurate as the catastrophe (caustic) is approached. For this reason, catastrophes are commonly given a *standard form* chosen to exhibit these features and only valid very close to the catastrophe. We discuss this here just in the context of geometrical optics, but the basic scalings are useful in other physics applications (see, e.g., Ex. 7.16).

First we measure the state variables a, b, \dots in units of some appropriate scale. Next we do likewise for the control parameters, x, y, \dots . We call the new state variables and control parameters $\tilde{a}, \tilde{b}, \dots$ and $\tilde{x}, \tilde{y}, \dots$, respectively. We then Taylor expand the delay about the catastrophe. In the case of the fold, we want to be able to find up to two extrema. This requires a cubic equation in \tilde{a} . The constant is clearly irrelevant, and an overall multiplying factor will not change the scalings. We are also free to change the origin of \tilde{a} , allowing us to drop either the linear or the quadratic term (we choose the latter, so that the coefficient is linearly related to x). If we adjust the scaled delay in the vicinity of a fold catastrophe, Eq. (7.68) can be written in the standard form:

$$\tilde{t}_{\text{fold}} = \frac{1}{3} \tilde{a}^3 - \tilde{x} \tilde{a}, \quad (7.72)$$

where the coefficients are chosen for algebraic convenience. The maximum number of rays involved in the catastrophe is two, and the number of control parameters required is one, which we can think of as being used to adjust the difference in \tilde{t} between two stationary points. The scaled magnifications are now given by $\tilde{\mathcal{M}} \equiv (d\tilde{x}/d\tilde{a})^{-1} = \pm \frac{1}{2} \tilde{x}^{-1/2}$, and the combined, scaled magnification is $\tilde{\mathcal{M}} = \tilde{x}^{-1/2}$ for $\tilde{x} > 0$.

CUSP CATASTROPHE

So far, we have only allowed D to move perpendicular to the axis along x . Now move it along the axis toward the screen. We find that x_f decreases with decreasing z until it vanishes at $z = f$. At this point, the central maximum in t merges simultaneously with both minima, leaving a single image. This is an example of a *cusp catastrophe*. Working in 1-dimensional state-variable space with two control parameters and applying the same arguments as we just used with the fold, the standard form for the cusp can be written as

$$\tilde{t}_{\text{cusp}} = \frac{1}{4}\tilde{a}^4 - \frac{1}{2}\tilde{z}\tilde{a}^2 - \tilde{x}\tilde{a}. \quad (7.73)$$

for cusp catastrophe

The parameter \tilde{x} is still associated with a transverse displacement of D , and we can quickly persuade ourselves that $\tilde{z} \propto z - f$ by inspecting the quadratic term in Eq. (7.68).

The cusp then describes a transition between one and three images, one of which must be inverted with respect to the other two. The location of the image for a given \tilde{a} and \tilde{z} is

$$\tilde{x} = \tilde{a}^3 - \tilde{z}\tilde{a}. \quad (7.74)$$

Conversely, for a given \tilde{x} and \tilde{z} , there are one or three real solutions for $\tilde{a}(\tilde{x}, \tilde{z})$ and one or three images. The equation satisfied by the fold lines where the transition occurs is

$$\tilde{x} = \pm \frac{2}{3^{3/2}}\tilde{z}^{3/2}. \quad (7.75)$$

These are the two branches of a semi-cubical parabola (the caustic surface in 3 dimensions depicted in the second panel of Fig. 7.15 below), and they meet at the cusp catastrophe where $\tilde{x} = \tilde{z} = 0$.

The scaled magnification at the cusp is

$$\tilde{\mathcal{M}}(\tilde{x}, \tilde{z}) = \left(\frac{\partial \tilde{x}}{\partial \tilde{a}} \right)_{\tilde{z}}^{-1} = [3\tilde{a}(\tilde{x}, \tilde{z})^2 - z]^{-1}. \quad (7.76)$$

SWALLOWTAIL CATASTROPHE

Now let the rays propagate in 3 dimensions, so that there are three control variables, x , y , and z , where the y -axis is perpendicular to the x - and z -axes. The fold, which was a point in 1 dimension and a line in 2, becomes a surface in 3 dimensions, and the point cusp in 2 dimensions becomes a line in 3 (see Fig. 7.15 below). If there is still only one state variable, then \tilde{t} should be a quintic with up to four extrema. (In general, a catastrophe involving as many as N images requires $N - 1$ control parameters for its full description. These parameters can be thought of as independently changing the relative values of \tilde{t} at the extrema.) The resulting, four-image catastrophe is called a *swallowtail*. (In practice, this catastrophe only arises when there are two state variables, and additional images are always present. However, these are not involved in the

catastrophe.) Again following our procedure, we can write the standard form of the swallowtail catastrophe as

for swallowtail catastrophe

$$\tilde{t}_{\text{swallowtail}} = \frac{1}{5}\tilde{a}^5 - \frac{1}{3}\tilde{z}\tilde{a}^3 - \frac{1}{2}\tilde{y}\tilde{a}^2 - \tilde{x}\tilde{a}. \quad (7.77)$$

There are two cusp lines in the half-space $\tilde{z} > 0$, and these meet at the catastrophe where $\tilde{x} = \tilde{y} = \tilde{z} = 0$ (see Fig. 7.15 below). The relationship between \tilde{x} , \tilde{y} , and \tilde{z} and x , y , and z in this or any other example is not simple, and so the variation of the magnification in the vicinity of the swallowtail catastrophe depends on the details.

HYPERBOLIC UMBILIC CATASTROPHE

Next increase the number of essential state variables to two. We can choose these to be \tilde{a} and \tilde{b} . To see what is possible, sketch contours of Δt in the \tilde{a} - \tilde{b} plane for fixed values of the control variables. The true rays will be associated with maxima, minima, or saddle points, and each distinct catastrophe corresponds to a different way to nest the contours (Fig. 7.14). The properties of the fold, cusp, and swallowtail are essentially unchanged by the extra dimension. We say that they are *structurally stable*. However, a little geometric experimentation uncovers a genuinely 2-dimensional nesting. The *hyperbolic umbilic* catastrophe has two saddles, one maximum and one minimum. Further algebraic experiment produces a standard form:

for hyperbolic umbilic catastrophe

$$\tilde{t} = \frac{1}{3}(\tilde{a}^3 + \tilde{b}^3) - \tilde{z}\tilde{a}\tilde{b} - \tilde{x}\tilde{a} - \tilde{y}\tilde{b}. \quad (7.78)$$

This catastrophe can be exhibited by a simple generalization of our example. We replace the cylindrical lens described by Eq. (7.68) with a nearly circular lens where the focal length f_a for rays in the a - z plane differs from the focal length f_b for rays in the b - z plane.

$$t = \frac{a^2}{2f_a z c} \left(f_a - z + \frac{a^2 z}{2s_a^2} \right) + \frac{b^2}{2f_b z c} \left(f_b - z + \frac{b^2 z}{2s_b^2} \right). \quad (7.79)$$

astigmatism

This is an example of *astigmatism*. A pair of fold surfaces is associated with each of these foci. These surfaces can cross, and when this happens a cusp line associated with one fold surface can transfer onto the other fold surface. The point where this happens is the hyperbolic umbilic catastrophe.

This example also allows us to illustrate a simple feature of magnification. When the source and the detector are both treated as 2-dimensional, then we generalize the curvature to the *Hessian* matrix

magnification matrix

$$\tilde{\mathcal{H}} = \tilde{\mathcal{M}}^{-1} = \begin{pmatrix} \frac{\partial \tilde{x}}{\partial \tilde{a}} & \frac{\partial \tilde{y}}{\partial \tilde{a}} \\ \frac{\partial \tilde{x}}{\partial \tilde{b}} & \frac{\partial \tilde{y}}{\partial \tilde{b}} \end{pmatrix}. \quad (7.80)$$

The magnification matrix $\tilde{\mathcal{M}}$, which describes the mapping from the source plane to the image plane, is simply the inverse of $\tilde{\mathcal{H}}$. The four matrix elements also describe the deformation of the image. As we describe in more detail when discussing elastostatics (Sec. 11.2.2), the antisymmetric part of $\tilde{\mathcal{M}}$ describes the rotation of the image, and

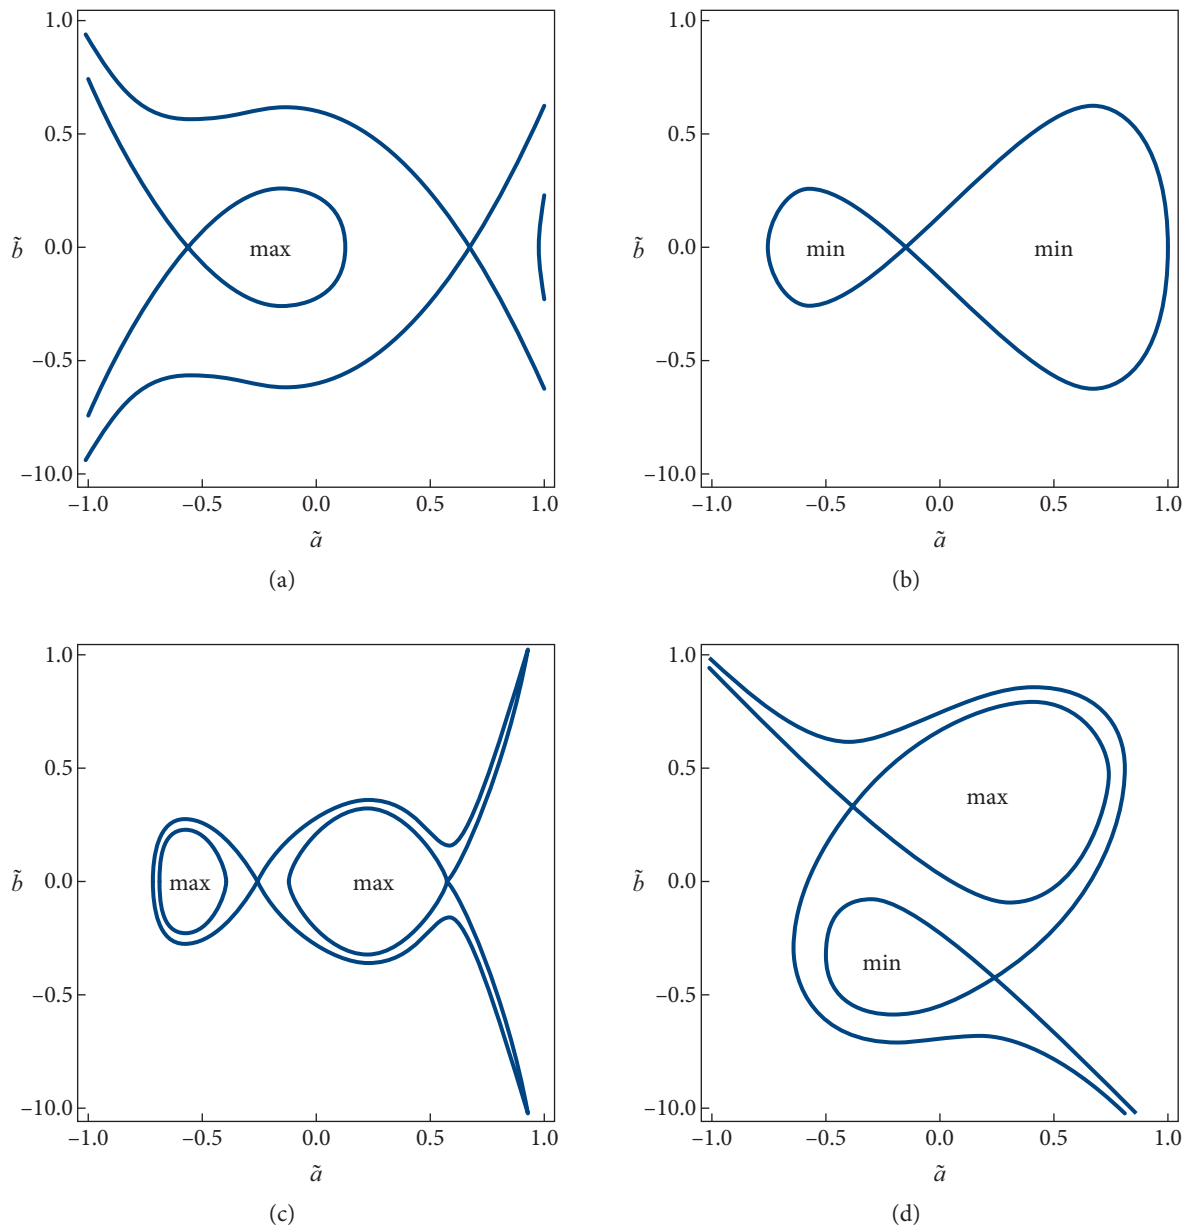

FIGURE 7.14 Distinct nestings of contours of \tilde{t} in state-variable space. (a) A 1-dimensional arrangement of two saddle points and a maximum in the vicinity of a cusp. The locations of the extrema and their curvatures change as the control parameters change. (b) A cusp formed by two minima and a saddle. Although the nestings look different in 2 dimensions, this is essentially the same catastrophe when considered in 1 dimension, which is all that is necessary to determine its salient properties. These are the only contour nestings possible with two state variables and three extrema (or rays). (c) When we increase the number of extrema to four, two more nestings are possible. The swallowtail catastrophe is essentially a cusp with an additional extremum added to the end, requiring three control parameters to express. It, too, is essentially 1-dimensional. (d) The hyperbolic umbilic catastrophe is essentially 2-dimensional and is associated with a maximum, a minimum, and two saddles. A distinct nesting of contours with three saddle points and one extremum occurs in the elliptic umbilic catastrophe (Ex. 7.13).

T2

the symmetric part its magnification and stretching or *shear*. Both eigenvalues of $\tilde{\mathcal{M}}$ are positive at a minimum, and the image is a distorted version of the source. At a saddle, one eigenvalue is positive, the other negative, and the image is inverted; at a maximum, they are both negative, and the image is doubly inverted so that it appears to have been rotated through a half-turn.

ELLIPTIC UMBILIC CATASTROPHE

There is a second standard form that can describe the nesting of contours just discussed—a distinct catastrophe called the *elliptic umbilic catastrophe* (Ex. 7.13b):

$$\tilde{t} = \frac{1}{3}\tilde{a}^3 - \tilde{a}\tilde{b}^2 - \tilde{z}(\tilde{a}^2 + \tilde{b}^2) - \tilde{x}\tilde{a} - \tilde{y}\tilde{b}. \quad (7.81)$$

standard form for elliptic umbilic catastrophe

The caustic surfaces in three dimensions (\tilde{x} , \tilde{y} , \tilde{z}) for the five elementary catastrophes discussed here are shown in Fig. 7.15. Additional types of catastrophe are found with more control parameters, for example, time (e.g., Poston and Stewart, 2012). This is relevant, for example, to the twinkling of starlight in the geometric-optics limit.

EXERCISES

Exercise 7.13 Derivation and Problem: Cusps and Elliptic Umbilics T2

- Work through the derivation of Eq. (7.73) for the scaled time delay in the vicinity of the cusp caustic for our simple example [Eq. (7.68)], with the aid of a suitable change of variables (Goodman, Romani, Blandford, and Narayan, 1987, Appendix B).
- Sketch the nesting of the contours for the elliptic umbilic catastrophe as shown for the other four catastrophes in Fig. 7.14. Verify that Eq. (7.81) describes this catastrophe.

Exercise 7.14 Problem: Cusp Scaling Relations T2

Consider a cusp catastrophe created by a screen as in the example and described by a standard cusp potential, Eq. (7.73). Suppose that a detector lies between the folds, so that there are three images of a single point source with state variables \tilde{a}_i .

- Explain how, in principle, it is possible to determine \tilde{a} for a single image by measurements at D .
- Make a 3-dimensional plot of the location of the image(s) in \tilde{a} - \tilde{x} - \tilde{y} space and explain why the names “fold” and “cusp” were chosen.
- Prove as many as you can of the following scaling relations, valid in the limit as the cusp catastrophe is approached:

$$\begin{aligned} \sum_{i=1}^3 \tilde{a}_i &= 0, & \sum_{i=1}^3 \frac{1}{\tilde{a}_i} &= -\frac{\tilde{z}}{\tilde{x}}, & \sum_{i=1}^3 \tilde{\mathcal{M}}_i &= 0, & \sum_{i=1}^3 \tilde{a}_i \tilde{\mathcal{M}}_i &= 0, \\ \sum_{i=1}^3 \tilde{a}_i^2 \tilde{\mathcal{M}}_i &= 1, & \sum_{i=1}^3 \tilde{a}_i^3 \tilde{\mathcal{M}}_i &= 0 & \text{and} & \sum_{i=1}^3 \tilde{a}_i^4 \tilde{\mathcal{M}}_i &= \tilde{z}. \end{aligned} \quad (7.82)$$

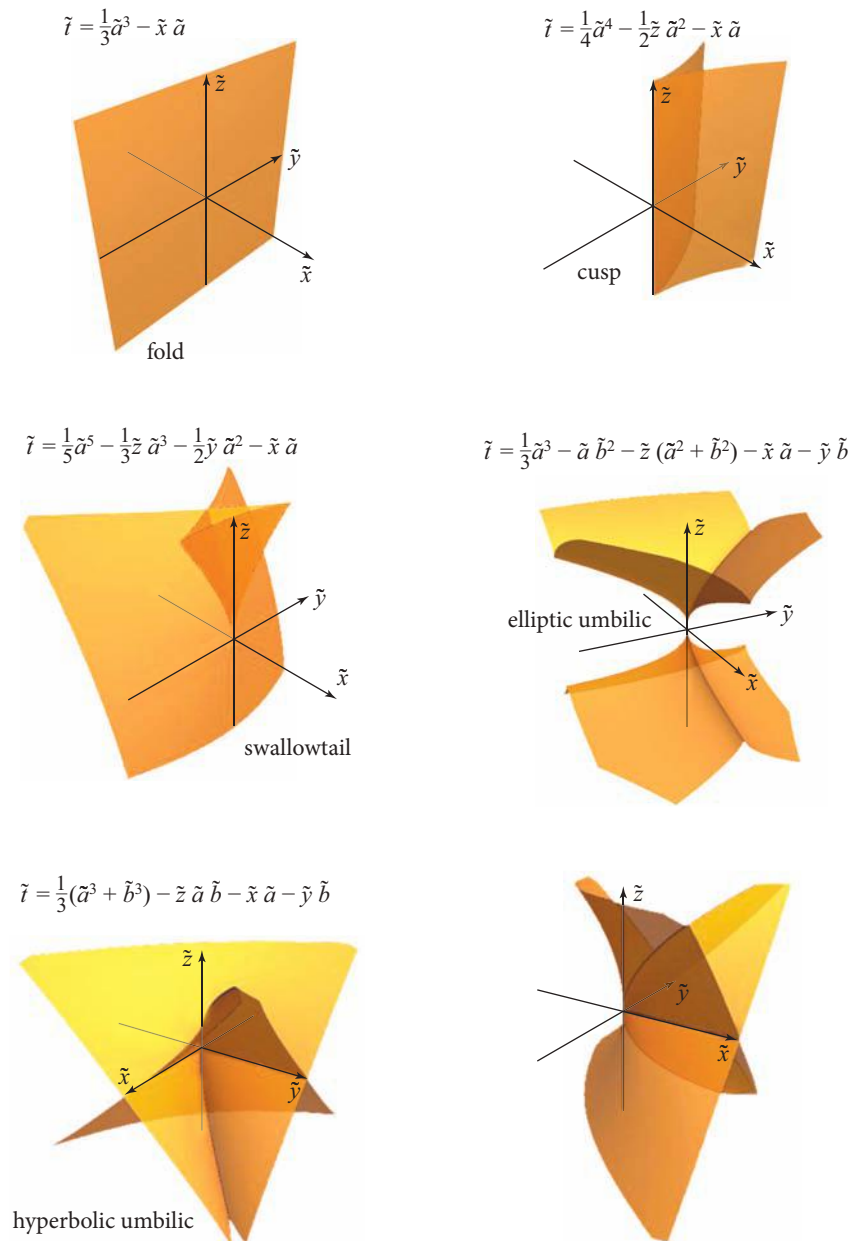

FIGURE 7.15 The five elementary catastrophes (caustic structures) that are possible for a set of light rays specified by one or two state variables $\{\tilde{a}, \tilde{b}\}$ in 3-dimensional space with coordinates (control parameters) $\{\tilde{x}, \tilde{y}, \tilde{z}\}$. The surfaces represent the loci of points of infinite magnification assuming a point source and geometric optics. The actual caustic surfaces will be deformed versions of these basic shapes. The hyperbolic umbilic surfaces are shown from two different viewpoints.

T2

[Hint: You must retain the sign of the magnification.] Of course, not all of these are useful. However, relations like these exist for all catastrophes and are increasingly accurate as the separation of the images becomes much smaller than the scale of variation of \tilde{l} .

Exercise 7.15 *Problem: Wavefronts* T2

As we have emphasized, representing light using wavefronts is complementary to treating it in terms of rays. Sketch the evolution of the wavefronts after they propagate through a phase-changing screen and eventually form caustics. Do this for a 2-dimensional cusp, and then consider the formation of a hyperbolic umbilic catastrophe by an astigmatic lens.

Exercise 7.16 ***Example: Van der Waals Catastrophe* T2

The van der Waals equation of state $(P + a/v^2)(v - b) = k_B T$ for H_2O relates the pressure P and specific volume (volume per molecule) v to the temperature T ; see Sec. 5.7. Figure 5.8 makes it clear that, at some temperatures T and pressures P , there are three allowed volumes $v(T, P)$, one describing liquid water, one water vapor, and the third an unstable phase that cannot exist in Nature. At other values of T and P , there is only one allowed v . The transition between three allowed v values and one occurs along some curve in the T - P plane—a catastrophe curve.

- This curve must correspond to one of the elementary catastrophes explored in the previous exercise. Based on the number of solutions for $v(T, P)$, which catastrophe must it be?
- Change variables in the van der Waals equation of state to $p = P/P_c - 1$, $\tau = T/T_c - 1$, and $\rho = v_c/v - 1$, where $T_c = 8a/(27bk_B)$, $P_c = a/(27b^2)$, and $v_c = 3b$ are the temperature, pressure, and specific volume at the critical point C of Fig. 5.8. Show that this change of variables brings the van der Waals equation of state into the form

$$\rho^3 - z\rho - x = 0, \quad (7.83)$$

where $z = -(p/3 + 8\tau/3)$ and $x = 2p/3 - 8\tau/3$.

- This equation $\rho^3 - z\rho - x$ is the equilibrium surface associated with the catastrophe-theory potential $t(\rho; x, z) = \frac{1}{4}\rho^4 - \frac{1}{2}z\rho^2 - x\rho$ [Eq. (7.73)]. Correspondingly, the catastrophe [the boundary between three solutions $v(T, P)$ and one] has the universal cusp form $x = \pm 2(z/3)^{2/3}$ [Eq. (7.75)]. Plot this curve in the temperature-pressure plane.

Note that we were guaranteed by catastrophe theory that the catastrophe curve would have this form near its cusp point. However, it is a surprise and quite unusual that, for

the van der Waals case, the cusp shape $x = \pm 2(z/3)^{2/3}$ is not confined to the vicinity of the cusp point but remains accurate far from that point.

7.5.2 Aberrations of Optical Instruments 7.5.2

Much computational effort is expended in the design of expensive optical instruments prior to prototyping and fabrication. This is conventionally discussed in terms of *aberrations*, which provide a perturbative description of rays that complements the singularity-based approach of catastrophe theory. While it is possible to design instruments that take all the rays from a point source S and focus them geometrically onto a point detector D ,¹¹ this is not what is demanded of them in practice. Typically, they have to map an extended image onto an extended surface, for example, a CCD detector. Sometimes the source is large, and the instrument must achieve a large *field of view*; sometimes it is small, and image fidelity close to the axis matters. Sometimes light levels are low, and transmission losses must be minimized. Sometimes the bandwidth of the light is large, and the variation of the imaging with frequency must be minimized. Sometimes diffractive effects are important. The residual imperfections of an instrument are known as *aberrations*.

As we have shown, any (geometric-optics) instrument will map, one to many, source points onto detector points. This mapping is usually expanded in terms of a set of basis functions, and several choices are in use, for example, those due to Seidel and Zernike (e.g., Born and Wolf, 1999, Secs. 5.3, 9.2). If we set aside effects caused by the variation of the refractive index with wavelength, known as *chromatic aberration*, there are five common types of geometrical aberration. *Spherical aberration* is the failure to bring a point on the optic axis to a single focus. Instead, an axisymmetric cusp/fold caustic is created. We have already exhibited *astigmatism* in our discussion of the hyperbolic umbilic catastrophe with a non-axisymmetric lens and an axial source (Sec. 7.5.1). It is not hard to make axisymmetric lenses and mirrors, so this does not happen much in practice. However, as soon as we consider off-axis surfaces, we break the symmetry, and astigmatism is unavoidable. *Curvature* arises when the surface on which the rays from point sources are best brought to a focus lies on a curved surface, not on a plane. It is sometimes advantageous to accept this aberration and to curve the detector surface.¹² To understand *coma*, consider a small pencil of rays from an off-axis source that passes through the center of an instrument and is brought to a focus. Now consider a cone of rays about this pencil that passes through the periphery of the lens. When there is coma, these rays will on average be displaced

aberrations

chromatic aberration

spherical aberration

curvature

coma

11. A simple example is to make the interior of a prolate ellipsoidal detector perfectly reflecting and to place S and D at the two foci, as crudely implemented in whispering galleries.

12. For example, in a traditional Schmidt telescope.

T2

distortion

radially. Coma can be ameliorated by reducing the aperture. Finally, there is *distortion*, in which the sides of a square in the source plane are pushed in (*pin cushion*) or out (*barrel*) in the image plane.

7.6

7.6 Gravitational Lenses T2

7.6.1

7.6.1 Gravitational Deflection of Light T2

Albert Einstein's general relativity theory predicts that light rays should be deflected by the gravitational field of the Sun (Ex. 27.3; Sec. 27.2.3). Newton's law of gravity combined with his corpuscular theory of light also predicts this deflection, but through an angle half as great as relativity predicts. A famous measurement, during a 1919 solar eclipse, confirmed the relativistic prediction, thereby making Einstein world famous.

The deflection of light by gravitational fields allows a cosmologically distant galaxy to behave like a crude lens and, in particular, to produce multiple images of a more distant quasar. Many examples of this phenomenon have been observed. The optics of these gravitational lenses provides an excellent illustration of the use of Fermat's principle (e.g., Blandford and Narayan, 1992; Schneider, Ehlers, and Falco, 1992). We explore these issues in this section.

The action of a gravitational lens can only be understood properly using general relativity. However, when the gravitational field is weak, there exists an equivalent Newtonian model, due to Eddington (1919), that is adequate for our purposes. In this model, curved spacetime behaves as if it were spatially flat and endowed with a refractive index given by

refractive index model for gravitational lensing

$$n = 1 - \frac{2\Phi}{c^2}, \quad (7.84)$$

where Φ is the Newtonian gravitational potential, normalized to vanish far from the source of the gravitational field and chosen to have a negative sign (so, e.g., the field at a distance r from a point mass M is $\Phi = -GM/r$). Time is treated in the Newtonian manner in this model. In Sec. 27.2.3, we use a general relativistic version of Fermat's principle to show that for static gravitational fields this index-of-refraction model gives the same predictions as general relativity, up to fractional corrections of order $|\Phi|/c^2$, which are $\lesssim 10^{-5}$ for the lensing examples in this chapter.

second refractive index model

A second Newtonian model gives the same predictions as this index-of-refraction model to within its errors, $\sim |\Phi|/c^2$. We deduce it by rewriting the ray equation (7.48) in terms of Newtonian time t using $ds/dt = C = c/n$. The resulting equation is $(n^3/c^2)d^2\mathbf{x}/dt^2 = \nabla n - 2(n/c)^2(dn/dt)d\mathbf{x}/dt$. The second term changes the length of the velocity vector $d\mathbf{x}/dt$ by a fractional amount of order $|\Phi|/c^2 \lesssim 10^{-5}$ (so as to keep the length of $d\mathbf{x}/ds$ unity). This is of no significance for our Newtonian model, so we drop this term. The factor $n^3 \simeq 1 - 6\Phi/c^2$ produces a fractional correction to $d^2\mathbf{x}/dt^2$ that is of the same magnitude as the fractional errors in our index of refraction

model, so we replace this factor by one. The resulting equation of motion for the ray is

$$\frac{d^2\mathbf{x}}{dt^2} = c^2\nabla\mathbf{n} = -2\nabla\Phi. \quad (7.85)$$

Equation (7.85) says that the photons that travel along rays feel a Newtonian gravitational potential that is twice as large as the potential felt by low-speed particles; the photons, moving at speed c (aside from fractional changes of order $|\Phi|/c^2$), respond to that doubled Newtonian field in the same way as any Newtonian particle would. The extra deflection is attributable to the geometry of the spatial part of the metric being non-Euclidean (Sec. 27.2.3).

7.6.2 Optical Configuration T2

7.6.2

To understand how gravitational lenses work, we adopt some key features from our discussion of optical catastrophes formed by an intervening screen. However, there are some essential differences.

- The source is not assumed to be distant from the screen (which we now call a lens, L).
- Instead of tracing rays emanating from a point source S , we consider a *congruence* of rays emanating from the observer O (i.e., us) and propagating backward in time past the lens to the sources. This is because there are many stars and galaxies whose images will be distorted by the lens. The caustics envelop the sources.
- The universe is expanding, which makes the optics formally time-dependent. However, as we discuss in Sec. 28.6.2, we can work in comoving coordinates and still use Fermat's principle. For the moment, we introduce three distances: d_{OL} for distance from the observer to the lens, d_{OS} for the distance from the observer to the source, and d_{LS} for the distance from the lens to the source. We evaluate these quantities cosmologically in Sec. 28.6.2.
- Instead of treating a and b as the state variables that describe rays (Sec. 7.5.1), we use a 2-dimensional (small) angular vector $\boldsymbol{\theta}$ measuring the image position on the sky. We also replace the control parameters x and y with the 2-dimensional angle $\boldsymbol{\beta}$, which measures the location that the image of the source would have in the absence of the lens. We can also treat the distance d_{OS} as a third control parameter replacing z .

The Hessian matrix, replacing Eq. (7.80), is now the Jacobian of the vectorial angles that a small, finite source would subtend in the absence and in the presence of the lens:

$$\mathcal{H} = \mathcal{M}^{-1} = \frac{\partial\boldsymbol{\beta}}{\partial\boldsymbol{\theta}}. \quad (7.86)$$

As the specific intensity $I_\nu = dE/dAdtd\nu d\Omega$ is conserved along a ray (see Sec. 3.6), the determinant of \mathcal{H} is just the ratio of the flux of energy per unit frequency without the lens to the flux with the lens, and correspondingly the determinant of \mathcal{M} (the scalar magnification) is the ratio of flux with the lens to that without the lens.

7.6.3

7.6.3 Microlensing T2

Our first example of a gravitational lens is a point mass—specifically, a star. This phenomenon is known as *microlensing*, because the angles of deflection are typically microarcseconds.¹³ The source is also usually another star, which we also treat as a point.

We first compute the deflection of a Newtonian particle with speed v passing by a mass M with impact parameter b . By computing the perpendicular impulse, it is straightforward to show that the deflection angle is $2GM/v^2$. Replacing v by c and doubling the answer gives the small deflection angle for light:

microlensing deflection angle

$$\alpha = \frac{4GM}{bc^2} = 1.75 \left(\frac{M}{M_\odot} \right) \left(\frac{b}{R_\odot} \right)^{-1} \hat{\mathbf{b}} \text{ arcsec}, \quad (7.87)$$

where $\hat{\mathbf{b}}$ is a unit vector along the impact parameter, which allows us to treat the deflection as a 2-dimensional vector like $\boldsymbol{\theta}$ and $\boldsymbol{\beta}$. M_\odot and R_\odot are the solar mass and radius, respectively.

microlensing lens equation

The imaging geometry can be expressed as a simple vector equation called the *lens equation* (Fig. 7.16):

$$\boldsymbol{\theta} = \boldsymbol{\beta} + \frac{d_{LS}}{d_{OS}} \boldsymbol{\alpha}. \quad (7.88)$$

A point mass exhibits circular symmetry, so we can treat this equation as a scalar equation and rewrite it in the form

$$\theta = \beta + \frac{\theta_E^2}{\theta}, \quad (7.89)$$

where

$$\theta_E = \left(\frac{4GM}{d_{\text{eff}} c^2} \right)^{1/2} = 903 \left(\frac{M}{M_\odot} \right)^{1/2} \left(\frac{d_{\text{eff}}}{10 \text{ kpc}} \right)^{-1/2} \mu \text{ arcsec} \quad (7.90)$$

is the *Einstein radius*, and

$$d_{\text{eff}} = \frac{d_{OL} d_{OS}}{d_{LS}} \quad (7.91)$$

is the *effective distance*. (Here 10 kpc means 10 kiloparsecs, about 30,000 light years.)

13. Interestingly, Newton speculated that light rays could be deflected by gravity, and the underlying theory of microlensing was worked out correctly by Einstein in 1912, before he realized that the deflection was twice the Newtonian value.

FIGURE 7.16 Geometry for microlensing of a stellar source S by a stellar lens L observed at O .

The solutions to this quadratic equation are

$$\theta_{\pm} = \frac{\beta}{2} \pm \sqrt{\theta_E^2 + \left(\frac{\beta}{2}\right)^2}. \quad (7.92)$$

image locations

The magnification of the two images can be computed directly by evaluating the reciprocal of the determinant of \mathcal{H} from Eq. (7.86). However, it is quicker to exploit the circular symmetry and note that the element of source solid angle in polar coordinates is $\beta d\beta d\phi$, while the element of image solid angle is $\theta d\theta d\phi$, so that

$$\mathcal{M} = \frac{\theta d\theta}{\beta d\beta} = \frac{1}{1 - (\theta_E/\theta)^4}. \quad (7.93)$$

image magnifications

The eigenvalues of the magnification matrix are $[1 + (\theta_E/\theta)^2]^{-1}$ and $[1 - (\theta_E/\theta)^2]^{-1}$. The former describes the radial magnification, the latter the tangential magnification. As $\beta \rightarrow 0$, $\theta \rightarrow \theta_E$ for both images. If we consider a source of finite angular size, when β approaches this size then the tangential stretching is pronounced and two nearly circular arcs are formed on opposite sides of the lens, one with $\theta > \theta_E$; the other, inverted, with $\theta < \theta_E$. When β is reduced even more, the arcs join up to form an *Einstein ring* (Fig. 7.17).

Einstein ring

Astronomers routinely observe microlensing events when stellar sources pass behind stellar lenses. They are unable to distinguish the two images and so measure a combined magnification $\mathcal{M} = |\mathcal{M}_+| + |\mathcal{M}_-|$. If we substitute β for θ , then we have

$$\mathcal{M} = \frac{(\theta_E^2 + \frac{1}{2}\beta^2)}{(\theta_E^2 + \frac{1}{4}\beta^2)^{1/2}\beta}. \quad (7.94)$$

Note that in the limit of large magnifications, $\mathcal{M} \sim \theta_E/\beta$, and the probability that the magnification exceeds \mathcal{M} is proportional to the cross sectional area $\pi\beta^2 \propto \mathcal{M}^{-2}$ (cf. Fig. 7.16).

If the speed of the source relative to the continuation of the O - L line is v , and the closest approach to this line is h , which happens at time $t = 0$, then $\beta = (h^2 + v^2t^2)^{1/2}/d_{OS}$, and then there is a one-parameter family of magnification curves (shown in Fig. 7.18). The characteristic variation of the magnification can be used to distinguish this phenomenon from intrinsic stellar variation. This behavior is very

FIGURE 7.17 The source LRG 3-757, as imaged by the Hubble Space Telescope. The blue Einstein ring is the image of two background galaxies formed by the gravitational field associated with the intervening central (yellow) lens galaxy. The accurate alignment of the lens and source galaxies is quite unusual. (ESA/Hubble and NASA.)

FIGURE 7.18 Variation of the combined magnifications of a stellar source as it passes behind a lens star. The time t is measured in units of $d_{OS}\theta_E/v$, and the parameter that labels the curves is $h/(d_{OS}\theta_E)$.

different from that at a generic caustic (Sec. 7.5.1) and is not structurally stable: if the axisymmetry is broken, then the behavior will change significantly. Nevertheless, for finite-sized sources of light and stars or nearly circular galaxies, stable Einstein rings are commonly formed.

Exercise 7.17 *Example: Microlensing Time Delay* T2

An alternative derivation of the lens equation for a point-mass lens, Eq. (7.88), evaluates the time delay along a path from the source to the observer and finds the true ray by extremizing it with respect to variations of θ [cf. Eq. (7.68)].

(a) Show that the geometric time delay is given by

$$t_{\text{geo}} = \frac{1}{2c} d_{\text{eff}} (\theta - \beta)^2. \quad (7.95)$$

(b) Next show that the lens time delay can be expressed as

$$t_{\text{lens}} = -(4GM/c^3) \ln b + \text{const},$$

where b is the impact parameter. (It will be helpful to evaluate the difference in delays between two rays with differing impact parameters.) This is known as the *Shapiro delay* and is discussed further in Sec. 27.2.4.

(c) Show that the lens delay can also be written as

$$t_{\text{lens}} = -\frac{2}{c^3} \int dz \Phi = -\frac{2}{c^3} \Phi_2, \quad (7.96)$$

where Φ_2 is the surface gravitational potential obtained by integrating the 3-dimensional potential Φ along the path. The surface potential is only determined up to an unimportant, divergent constant, which is acceptable because we are only interested in dt_{lens}/db which is finite.

(d) By minimizing $t_{\text{geo}} + t_{\text{lens}}$, derive the lens equation (7.88).

Exercise 7.18 *Derivation: Microlensing Variation* T2

Derive Eq. (7.94).

Exercise 7.19 *Problem: Magnification by a Massive Black Hole* T2

Suppose that a large black hole forms two images of a background source separated by an angle θ . Let the fluxes of the two images be F_+ and $F_- < F_+$. Show that the flux from the source would be $F_+ - F_-$ if there were no lens and that the black hole should be located an angular distance $[1 + (F_-/F_+)^{-1/2}]^{-1}\theta$ along the line from the brighter image to the fainter one. (Only consider small angle deflections.)

7.6.4 Lensing by Galaxies T2

7.6.4

Most observed gravitational lenses are galaxies. Observing these systems brings out new features of the optics and proves useful for learning about galaxies and the universe. Galaxies comprise dark matter and stars, and the dispersion $\langle v_{\parallel}^2 \rangle$ in the

stars' velocities along the line of sight can be measured using spectroscopy. The virial theorem (Goldstein, Poole, and Saffko, 2002) tells us that the kinetic energy of the matter in the galaxy is half the magnitude of its gravitational potential energy Φ . We can therefore make an order of magnitude estimate of the ray deflection angle caused by a galaxy by using Eq. (7.87):

$$\alpha \sim \frac{4GM}{bc^2} \sim \frac{4|\Phi|}{c^2} \sim 4 \times 2 \times \frac{3}{2} \times \frac{\langle v_{\parallel}^2 \rangle}{c^2} \sim \frac{12\langle v_{\parallel}^2 \rangle}{c^2}. \quad (7.97)$$

This evaluates to $\alpha \sim 2$ arcsec for a typical galaxy velocity dispersion of ~ 300 km s^{-1} . The images can typically be resolved using radio and optical telescopes, but their separations are much less than the full angular sizes of distant galaxies and so the imaging is sensitive to the lens galaxy's structure. As the lens is typically far more complicated than a point mass, it is now convenient to measure the angle θ relative to the reference ray that connects us to the source.

We can describe the optics of a galaxy gravitational lens by adapting the formalism that we developed for a point-mass lens in Ex. 7.17. We assume that there is a point source at β and consider paths designated by θ . The geometrical time delay is unchanged. In Ex. 7.17, we showed that the lens time delay for a point mass was proportional to the surface gravitational potential Φ_2 . A distributed lens is handled by adding the potentials associated with all the point masses out of which it can be considered as being composed. In other words, we simply use the surface potential for the distributed mass in the galaxy,

$$t = t_{\text{geo}} + t_{\text{lens}} = \frac{d_{\text{eff}}}{2c} (\theta - \beta)^2 - \frac{2}{c^3} \Phi_2 = \frac{d_{\text{eff}} \tilde{t}}{c}, \quad (7.98)$$

scaled time delay for
lensing by galaxies

where the *scaled time delay* t is defined by $\tilde{t}(\theta; \beta) = \frac{1}{2}(\theta - \beta)^2 - \Psi(\theta)$, and $\Psi = 2\Phi_2/(c^2 d_{\text{eff}})$. The quantity Ψ satisfies the 2-dimensional Poisson equation:

$$\nabla_{2,\theta}^2 \Psi = \frac{8\pi G \Sigma}{d_{\text{eff}} c^2}, \quad (7.99)$$

where Σ is the density of matter per unit solid angle, and the 2-dimensional laplacian describes differentiation with respect to the components of θ .¹⁴

As written, Eq. (7.98) describes all paths for a given source position, only a small number of which correspond to true rays. However, if, instead, we set $\beta = 0$ and choose any convenient origin for θ so that

14. The minimum surface density (expressed as mass per area) of a cosmologically distant lens needed to produce multiple images of a background source turns out to be ~ 1 g cm^{-2} . It is remarkable that such a seemingly small surface density operating on these scales can make such a large difference to our view of the universe. It is tempting to call this a "rule of thumb," because it is roughly the column density associated with one's thumb!

$$\tilde{t}(\boldsymbol{\theta}) = \frac{1}{2}\theta^2 - \Psi(\boldsymbol{\theta}), \quad (7.100)$$

T2

then three useful features of \tilde{t} emerge:

uses of scaled time delay

- if there is an image at $\boldsymbol{\theta}$, then the source position is simply $\boldsymbol{\beta} = \nabla_{\boldsymbol{\theta}}\tilde{t}$ [cf. Eq. (7.88)];
- the magnification tensor associated with this image can be calculated by taking the inverse of the Hessian matrix $\mathcal{H} = \nabla_{\boldsymbol{\theta}}\nabla_{\boldsymbol{\theta}}\tilde{t}$ [cf. Eq. (7.86)]; and
- the measured differences in the times of variation observed in multiple images of the same source are just the differences in $d_{\text{eff}}\tilde{t}/c$ evaluated at the image positions.¹⁵

Computing \tilde{t} for a model of a putative lens galaxy allows one to assess whether background sources are being multiply imaged and, if so, to learn about the lens as well as the source.

Exercise 7.20 *Problem: Catastrophe Optics of an Elliptical Gravitational Lens* T2

EXERCISES

Consider an elliptical gravitational lens where the potential Ψ is modeled by

$$\Psi(\boldsymbol{\theta}) = (1 + A\theta_x^2 + 2B\theta_x\theta_y + C\theta_y^2)^q; \quad 0 < q < 1/2. \quad (7.101)$$

Determine the generic form of the caustic surfaces, the types of catastrophe encountered, and the change in the number of images formed when a point source crosses these surfaces. Note that it is in the spirit of catastrophe theory *not* to compute exact expressions but to determine scaling laws and to understand the qualitative features of the images.

Exercise 7.21 *Challenge: Microlensing in a Galaxy* T2

Our discussion of microlensing assumed a single star and a circularly symmetric potential about it. This is usually a good approximation for stars in our galaxy. However, when the star is in another galaxy and the source is a background quasar (Figs. 7.19, 7.20), it is necessary to include the gravitational effects of the galaxy's other stars and its dark matter. Recast the microlensing analysis (Sec. 7.6.3) in the potential formulation of Eq. (7.98) and add *external magnification* and *external shear* contributions to

15. These differences can be used to measure the size and age of the universe. To order of magnitude, the relative delays are the times it takes light to cross the universe (or equivalently, the age of the universe, roughly 10 Gyr) times the square of the scattering angle (roughly 2 arcsec or $\sim 10^{-5}$ radians), which is roughly 1 year. This is very convenient for astronomers (see Fig. 7.20).

FIGURE 7.19 Geometry for gravitational lensing of a quasar source S by a galaxy lens L observed at O .

FIGURE 7.20 Gravitational lens in which a distant quasar, Q2237+0305, is quadruply imaged by an intervening galaxy. The four quasar images are denoted A, B, C, and D. The galaxy is much larger than the separation of the images (1–1.5 arcsec) but its bright central core is labeled. There is also a fifth, faint image coincident with this core. There are many examples of gravitational lenses like this, where the source region is very compact and variable so that the delay in the variation seen in the individual images can be used to measure the distance of the source and the size and age of the universe. In addition, microlensing-like variations in the images are induced by individual stars in the lens galaxy moving in front of the quasar. Analyzing these changes can be used to measure the proportion of stars and dark matter in galaxies. Adapted from image by Hubble Space Telescope. (NASA, ESA, STScI.)

Ψ that are proportional to $\theta_x^2 + \theta_y^2$ and $\theta_x^2 - \theta_y^2$, respectively. The latter will break the circular symmetry, and structurally stable caustics will be formed. Explore the behavior of these caustics as you vary the strength and sign of the magnification and shear contributions. Plot a few flux variations that might be observed.

7.7 Polarization

7.7

In our geometric-optics analyses thus far, we have either dealt with a scalar wave (e.g., a sound wave) or simply supposed that individual components of vector or tensor waves can be treated as scalars. For most purposes, this is indeed the case, and we continue to use this simplification in the following chapters. However, there are some important wave properties that are unique to vector (or tensor) waves. Most of these come under the heading of *polarization* effects. In Secs. 27.3, 27.4, and 27.5, we study polarization effects for (tensorial) gravitational waves. Here and in Secs. 10.5 and 28.6.1, we examine them for electromagnetic waves.

An electromagnetic wave's two polarizations are powerful tools for technology, engineering, and experimental physics. However, we forgo any discussion of this in the present chapter. Instead we focus solely on the geometric-optics propagation law for polarization (Sec. 7.7.1) and an intriguing aspect of it—the geometric phase (Sec. 7.7.2).

7.7.1 Polarization Vector and Its Geometric-Optics Propagation Law

7.7.1

A plane electromagnetic wave in a vacuum has its electric and magnetic fields \mathbf{E} and \mathbf{B} perpendicular to its propagation direction $\hat{\mathbf{k}}$ and perpendicular to each other. In a medium, \mathbf{E} and \mathbf{B} may or may not remain perpendicular to $\hat{\mathbf{k}}$, depending on the medium's properties. For example, an Alfvén wave has its vibrating magnetic field perpendicular to the background magnetic field, which can make an arbitrary angle with respect to $\hat{\mathbf{k}}$. By contrast, in the simplest case of an isotropic dielectric medium, where the dispersion relation has our standard dispersion-free form $\Omega = (c/n)k$, the group and phase velocities are parallel to $\hat{\mathbf{k}}$, and \mathbf{E} and \mathbf{B} turn out to be perpendicular to $\hat{\mathbf{k}}$ and to each other—as in a vacuum. In this section, we confine attention to this simple situation and to linearly polarized waves, for which \mathbf{E} oscillates linearly along a unit polarization vector $\hat{\mathbf{f}}$ that is perpendicular to $\hat{\mathbf{k}}$:

polarization vector

$$\mathbf{E} = Ae^{i\varphi} \hat{\mathbf{f}}, \quad \hat{\mathbf{f}} \cdot \hat{\mathbf{k}} \equiv \hat{\mathbf{f}} \cdot \nabla\varphi = 0. \quad (7.102)$$

In the eikonal approximation, $Ae^{i\varphi} \equiv \psi$ satisfies the geometric-optics propagation laws of Sec. 7.3, and the polarization vector $\hat{\mathbf{f}}$, like the amplitude A , will propagate along the rays. The propagation law for $\hat{\mathbf{f}}$ can be derived by applying the eikonal approximation to Maxwell's equations, but it is easier to infer that law by simple physical reasoning:

1. Since $\hat{\mathbf{f}}$ is orthogonal to $\hat{\mathbf{k}}$ for a plane wave, it must also be orthogonal to $\hat{\mathbf{k}}$ in the eikonal approximation (which, after all, treats the wave as planar on lengthscales long compared to the wavelength).
2. If the ray is straight, then the medium, being isotropic, is unable to distinguish a slow right-handed rotation of $\hat{\mathbf{f}}$ from a slow left-handed rotation, so there will be no rotation at all: $\hat{\mathbf{f}}$ will continue always to point in the same direction (i.e., $\hat{\mathbf{f}}$ will be kept parallel to itself during transport along the ray).

3. If the ray bends, so $d\hat{\mathbf{k}}/ds \neq 0$ (where s is distance along the ray), then $\hat{\mathbf{f}}$ will have to change as well, so as always to remain perpendicular to $\hat{\mathbf{k}}$. The direction of $\hat{\mathbf{f}}$'s change must be $\hat{\mathbf{k}}$, since the medium, being isotropic, cannot provide any other preferred direction for the change. The magnitude of the change is determined by the requirement that $\hat{\mathbf{f}} \cdot \hat{\mathbf{k}}$ remain zero all along the ray and that $\hat{\mathbf{k}} \cdot \hat{\mathbf{k}} = 1$. This immediately implies that the propagation law for $\hat{\mathbf{f}}$ is

$$\frac{d\hat{\mathbf{f}}}{ds} = -\hat{\mathbf{k}} \left(\hat{\mathbf{f}} \cdot \frac{d\hat{\mathbf{k}}}{ds} \right). \quad (7.103)$$

This equation states that the vector $\hat{\mathbf{f}}$ is parallel-transported along the ray (cf. Fig. 7.5 in Sec. 24.3.3). Here “parallel transport” means: (i) Carry $\hat{\mathbf{f}}$ a short distance along the ray, keeping it parallel to itself in 3-dimensional space. Because of the bending of the ray and its tangent vector $\hat{\mathbf{k}}$, this will cause $\hat{\mathbf{f}}$ to no longer be perpendicular to $\hat{\mathbf{k}}$. (ii) Project $\hat{\mathbf{f}}$ perpendicular to $\hat{\mathbf{k}}$ by adding onto it the appropriate multiple of $\hat{\mathbf{k}}$. (The techniques of differential geometry for curved lines and surfaces, which we develop in Chaps. 24 and 25 in preparation for studying general relativity, give powerful mathematical tools for analyzing this parallel transport.)

7.7.2 Geometric Phase T2

We use the polarization propagation law (7.103) to illustrate a quite general phenomenon known as the *geometric phase*, or sometimes as the *Berry phase*, after Michael Berry who elucidated it. For further details and some history of this concept, see Berry (1990).

As a simple context for the geometric phase, consider a linearly polarized, monochromatic light beam that propagates in an optical fiber. Focus on the evolution of the polarization vector along the fiber's optic axis. We can imagine bending the fiber into any desired shape, thereby controlling the shape of the ray. The ray's shape in turn will control the propagation of the polarization via Eq. (7.103).

If the fiber and ray are straight, then the propagation law (7.103) keeps $\hat{\mathbf{f}}$ constant. If the fiber and ray are circular, then Eq. (7.103) causes $\hat{\mathbf{f}}$ to rotate in such a way as to always point along the generator of a cone, as shown in Fig. 7.21a. This polarization behavior, and that for any other ray shape, can be deduced with the aid of a unit sphere on which we plot the ray direction $\hat{\mathbf{k}}$ (Fig. 7.21b). For example, the ray directions at ray locations C and H of panel a are as shown in panel b of the figure. Notice that the trajectory of $\hat{\mathbf{k}}$ around the unit sphere is a great circle.

On the unit sphere we also plot the polarization vector $\hat{\mathbf{f}}$ —one vector at each point corresponding to a ray direction. Because $\hat{\mathbf{f}} \cdot \hat{\mathbf{k}} = 0$, the polarization vectors are always tangent to the unit sphere. Notice that each $\hat{\mathbf{f}}$ on the unit sphere is identical in length and direction to the corresponding one in the physical space of Fig. 7.21a.

The parallel-transport law (7.103) keeps constant the angle α between $\hat{\mathbf{f}}$ and the trajectory of $\hat{\mathbf{k}}$ (i.e., the great circle in panel b of the figure). Translated back to

FIGURE 7.21 (a) The ray along the optic axis of a circular loop of optical fiber, and the polarization vector $\hat{\mathbf{f}}$ that is transported along the ray by the geometric-optics transport law $d\hat{\mathbf{f}}/ds = -\hat{\mathbf{k}}(\hat{\mathbf{f}} \cdot d\hat{\mathbf{k}}/ds)$. (b) The polarization vector $\hat{\mathbf{f}}$ drawn on the unit sphere. The vector from the center of the sphere to each of the points A, B, \dots, H is the ray's propagation direction $\hat{\mathbf{k}}$, and the polarization vector (which is orthogonal to $\hat{\mathbf{k}}$ and thus tangent to the sphere) is identical to that in the physical space of the ray (panel a).

panel a, this constancy of α implies that the polarization vector points always along the generators of the cone, whose opening angle is $\pi/2 - \alpha$, as shown.

Next let the fiber and its central axis (the ray) be helical as shown in Fig. 7.22a. In this case, the propagation direction $\hat{\mathbf{k}}$ rotates, always maintaining the same angle θ to the vertical direction, and correspondingly its trajectory on the unit sphere of Fig. 7.22b is a circle of constant polar angle θ . Therefore (as one can see, e.g., with the aid of a large globe of Earth and a pencil transported around a circle of latitude $90^\circ - \theta$), the parallel-transport law dictates that the angle α between $\hat{\mathbf{f}}$ and the circle *not* remain constant, but instead rotate at the rate

$$d\alpha/d\phi = \cos \theta. \quad (7.104)$$

Here ϕ is the angle (longitude on the globe) around the circle. This is the same propagation law as for the direction of swing of a Foucault pendulum as Earth turns (cf. Box 14.5), and for the same reason: the gyroscopic action of the Foucault pendulum is described by parallel transport of its plane along Earth's spherical surface.

In the case where θ is arbitrarily small (a nearly straight ray), Eq. (7.104) says $d\alpha/d\phi = 1$. This is easily understood: although $\hat{\mathbf{f}}$ remains arbitrarily close to constant, the trajectory of $\hat{\mathbf{k}}$ turns rapidly around a tiny circle about the pole of the unit sphere, so α changes rapidly—by a total amount $\Delta\alpha = 2\pi$ after one trip around the pole, $\Delta\phi = 2\pi$; whence $d\alpha/d\phi = \Delta\alpha/\Delta\phi = 1$. For any other helical pitch angle θ , Eq. (7.104) says that during one round trip, α will change by an amount $2\pi \cos \theta$ that lags behind its change for a tiny circle (nearly straight ray) by the lag angle $\alpha_{\text{lag}} = 2\pi(1 - \cos \theta)$, which is also the solid angle $\Delta\Omega$ enclosed by the path of $\hat{\mathbf{k}}$ on the unit sphere:

$$\alpha_{\text{lag}} = \Delta\Omega. \quad (7.105)$$

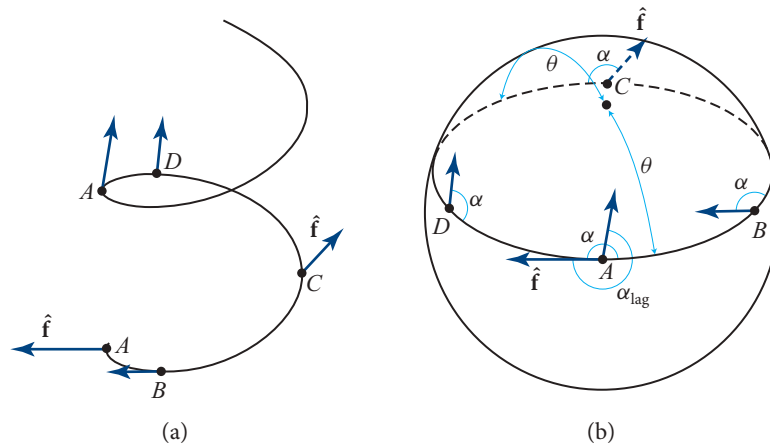

FIGURE 7.22 (a) The ray along the optic axis of a helical loop of optical fiber, and the polarization vector \hat{f} that is transported along this ray by the geometric-optics transport law $d\hat{f}/ds = -\hat{k}(\hat{f} \cdot d\hat{k}/ds)$. The ray's propagation direction \hat{k} makes an angle $\theta = 73^\circ$ to the vertical direction. (b) The trajectory of \hat{k} on the unit sphere (a circle with polar angle $\theta = 73^\circ$), and the polarization vector \hat{f} that is parallel transported along that trajectory. The polarization vectors in panel a are deduced from the parallel-transport law demonstrated in panel b. The lag angle $\alpha_{\text{lag}} = 2\pi(1 - \cos \theta) = 1.42\pi$ is equal to the solid angle contained inside the trajectory of \hat{k} (the $\theta = 73^\circ$ circle).

(For the circular ray of Fig. 7.21, the enclosed solid angle is $\Delta\Omega = 2\pi$ steradians, so the lag angle is 2π radians, which means that \hat{f} returns to its original value after one trip around the optical fiber, in accord with the drawings in the figure.)

lag angle for polarization vector in an optical fiber

Remarkably, Eq. (7.105) is true for light propagation along an optical fiber of any shape: if the light travels from one point on the fiber to another at which the tangent vector \hat{k} has returned to its original value, then the lag angle is given by the enclosed solid angle on the unit sphere, Eq. (7.105).

By itself, the relationship $\alpha_{\text{lag}} = \Delta\Omega$ is merely a cute phenomenon. However, it turns out to be just one example of a very general property of both classical and quantum mechanical systems when they are forced to make slow, *adiabatic* changes described by circuits in the space of parameters that characterize them. In the more general case, one focuses on a phase lag rather than a direction-angle lag. We can easily translate our example into such a phase lag.

geometric phase change

The apparent rotation of \hat{f} by the lag angle $\alpha_{\text{lag}} = \Delta\Omega$ can be regarded as an advance of the phase of one circularly polarized component of the wave by $\Delta\Omega$ and a phase retardation of the other circular polarization by the same amount. Thus the phase of a circularly polarized wave will change, after one circuit around the fiber's helix, by an amount equal to the usual phase advance $\Delta\varphi = \int \mathbf{k} \cdot d\mathbf{x}$ (where $d\mathbf{x}$ is displacement along the fiber) plus an extra *geometric* phase change $\pm\Delta\Omega$, where the sign is given by the sense of circular polarization. This type of geometric phase change is found quite generally, when classical vector or tensor waves propagate through

backgrounds that change slowly, either temporally or spatially. The phases of the wave functions of quantum mechanical particles with spin behave similarly.

EXERCISES

Exercise 7.22 *Derivation: Parallel Transport* T2

Use the parallel-transport law (7.103) to derive the relation (7.104).

Exercise 7.23 *Problem: Martian Rover* T2

A Martian Rover is equipped with a single gyroscope that is free to pivot about the direction perpendicular to the plane containing its wheels. To climb a steep hill on Mars without straining its motor, it must circle the summit in a decreasing spiral trajectory. Explain why there will be an error in its measurement of North after it has reached the summit. Could it be programmed to navigate correctly? Will a stochastic error build up as it traverses a rocky terrain?

Bibliographic Note

Modern textbooks on optics deal with the geometric-optics approximation only for electromagnetic waves propagating through a dispersion-free medium. Accordingly, they typically begin with Fermat's principle and then treat in considerable detail the paraxial approximation, applications to optical instruments, and sometimes the human eye. There is rarely any mention of the eikonal approximation or of multiple images and caustics. Examples of texts of this sort that we like are Bennett (2008), Ghatak (2010), and Hecht (2017). For a far more thorough treatise on geometric optics of scalar and electromagnetic waves in isotropic and anisotropic dielectric media, see Kravtsov (2005). A good engineering-oriented text with many contemporary applications is Iizuka (1987).

We do not know of textbooks that treat the eikonal approximation to the degree of generality used in this chapter, though some should, since it has applications to all types of waves (many of which are explored later in this book). For the eikonal approximation specialized to Maxwell's equations, see Kravtsov (2005) and the classic treatise on optics by Born and Wolf (1999), which in this new edition has modern updates by a number of other authors. For the eikonal approximation specialized to the Schrödinger equation and its connection to Hamilton-Jacobi theory, see most any quantum mechanics textbook (e.g., Griffiths, 2004).

Multiple-image formation and caustics are omitted from most standard optics textbooks, except for a nice but out-of-date treatment in Born and Wolf (1999). Much better are the beautiful review by Berry and Upstill (1980) and the much more thorough treatments in Kravtsov (2005) and Nye (1999). For an elementary mathematical treatment of catastrophe theory, we like Saunders (1980). For a pedagogical treatise on gravitational lenses, see Schneider, Ehlers, and Falco (1992). Finally, for some history and details of the geometric phase, see Berry (1990).

Diffraction

I have seen—without any illusion—three broad stripes in the spectrum of Sirius,
which seem to have no similarity to those of sunlight.

JOSEPH VON FRAUNHOFER (1814-1815)

8.1 Overview

8.1

The previous chapter was devoted to the classical mechanics of wave propagation. We showed how a classical wave equation can be solved in the short-wavelength (eikonal) approximation to yield Hamilton's dynamical equations for its rays. When the medium is time independent (as we require in this chapter), we showed that the frequency of a wave packet is constant, and we imported a result from classical mechanics—the principle of stationary action—to show that the true geometric-optics rays coincide with paths along which the action (the phase) is stationary [Eqs. (7.44) and (7.45a) and associated discussion]. Our physical interpretation of this result was that the waves do indeed travel along every path, from some source to a point of observation, where they are added together, but they only give a significant net contribution when they can add coherently in phase—along the true rays [Eq. (7.45b)]. Essentially, this is Huygens' model of wave propagation, or, in modern language, a *path integral*.

Huygens' principle asserts that every point on a wavefront acts as a source of secondary waves that combine so their envelope constitutes the advancing wavefront. This principle must be supplemented by two ancillary conditions: that the secondary waves are only formed in the forward direction, not backward, and that a $\pi/2$ phase shift be introduced into the secondary wave. The reason for the former condition is obvious, that for the latter, less so. We discuss both together with the formal justification of Huygens' construction in Sec. 8.2.

We begin our exploration of the “wave mechanics” of optics in this chapter and continue it in Chaps. 9 and 10. Wave mechanics differs increasingly from geometric optics as the reduced wavelength λ increases relative to the lengthscales \mathcal{R} of the phase fronts and \mathcal{L} of the medium's inhomogeneities. The number of paths that can combine constructively increases, and the rays that connect two points become blurred. In quantum mechanics, we recognize this phenomenon as the uncertainty principle, and it is just as applicable to photons as to electrons.

BOX 8.1. READERS' GUIDE

- This chapter depends substantially on Secs. 7.1–7.4 (geometric optics).
- In addition, Sec. 8.6 of this chapter (on diffraction at a caustic) depends on Sec. 7.5.
- Chapters 9 and 10 depend substantially on Secs. 8.1–8.5 of this chapter.
- Nothing else in this book relies on this chapter.

Solving the wave equation exactly is very hard, except in simple circumstances. Geometric optics is one approximate method of solving it—a method that works well in the short-wavelength limit. In this chapter and the next two, we develop approximate techniques that work when the wavelength becomes longer and geometric optics fails.

In this book, we make a somewhat artificial distinction between phenomena that arise when an effectively infinite number of propagation paths are involved (which we call *diffraction* and describe in this chapter) and those when a few paths, or, more correctly, a few tight bundles of rays are combined (which we term *interference*, and whose discussion we defer to the next chapter).

In Sec. 8.2, we present the Fresnel-Helmholtz-Kirchhoff theory that underlies most elementary discussions of diffraction. We then distinguish between Fraunhofer diffraction (the limiting case when spreading of the wavefront mandated by the uncertainty principle is important) and Fresnel diffraction (where wavefront spreading is a modest effect, and geometric optics is beginning to work, at least roughly). In Sec. 8.3, we illustrate Fraunhofer diffraction by computing the angular resolution of the Hubble Space Telescope, and in Sec. 8.4, we analyze Fresnel diffraction and illustrate it using zone plates and lunar occultation of radio waves.

Many contemporary optical devices can be regarded as linear systems that take an input wave signal and transform it into a linearly related output. Their operation, particularly as image-processing devices, can be considerably enhanced by processing the signal in the spatial Fourier domain, a procedure known as spatial filtering. In Sec. 8.5 we introduce a tool for analyzing such devices: paraxial Fourier optics—a close analog of the paraxial geometric optics of Sec. 7.4. Using paraxial Fourier optics, we develop the theory of image processing by spatial filters and use it to discuss various types of filters and the phase-contrast microscope. We also use Fourier optics to develop the theory of Gaussian beams—the kind of light beam produced by lasers when (as is usual) their optically resonating cavities have spherical mirrors. Finally, in Sec. 8.6 we analyze diffraction near a caustic of a wave's phase field, a location where

geometric optics predicts a divergent magnification of the wave (Sec. 7.5). As we shall see, diffraction keeps the magnification finite and produces an oscillating energy-flux pattern (interference fringes).

8.2 Helmholtz-Kirchhoff Integral

8.2

In this section, we derive a formalism for describing diffraction. We restrict attention to the simplest (and, fortunately, the most widely useful) case: a monochromatic scalar wave,

$$\Psi = \psi(\mathbf{x})e^{-i\omega t}, \quad (8.1a)$$

with field variable ψ that satisfies the Helmholtz equation

$$\nabla^2\psi + k^2\psi = 0, \quad \text{with } k = \omega/c, \quad (8.1b)$$

Helmholtz equation

except at boundaries. Generally, Ψ will represent a real-valued physical quantity, but for mathematical convenience we give it a complex representation and take the real part of Ψ when making contact with physical measurements. This is in contrast to a quantum mechanical wave function satisfying the Schrödinger equation, which is an intrinsically complex function. We assume that the wave in Eqs. (8.1) is monochromatic (constant ω) and nondispersive, and that the medium is isotropic and homogeneous (phase speed equal to group speed, and both with a constant value C , so k is also constant). Each of these assumptions can be relaxed, but with some technical penalty.

applications of scalar diffraction formalism

The scalar formalism that we develop based on Eq. (8.1b) is fully valid for weak sound waves in a homogeneous fluid or solid (e.g., air; Secs. 12.2 and 16.5). It is also quite accurate, but not precisely so, for the most widely used application of diffraction theory: electromagnetic waves in a vacuum or in a medium with a homogeneous dielectric constant. In this case ψ can be regarded as one of the Cartesian components of the electric field vector, such as E_x (or equally well, a Cartesian component of the vector potential or the magnetic field vector). In a vacuum or in a homogeneous dielectric medium, Maxwell's equations imply that this $\psi = E_x$ satisfies the scalar wave equation exactly and hence, for fixed frequency, the Helmholtz equation (8.1b). However, when the wave hits a boundary of the medium (e.g., the edge of an aperture, or the surface of a mirror or lens), its interaction with the boundary can couple the various components of \mathbf{E} , thereby invalidating the simple scalar theory we develop in this chapter. Fortunately, this polarizational coupling is usually weak in the paraxial (small angle) limit, and also under a variety of other circumstances, thereby making our simple scalar formalism quite accurate.¹

1. For a formulation of diffraction that takes account of these polarization effects, see, e.g., Born and Wolf (1999, Chap. 11).

The Helmholtz equation (8.1b) is an elliptic, linear, partial differential equation, and we can thus express the value $\psi_{\mathcal{P}}$ of ψ at any point \mathcal{P} inside some closed surface \mathcal{S} as an integral over \mathcal{S} of some linear combination of ψ and its normal derivative; see Fig. 8.1. To derive such an expression, we proceed as follows. First, we introduce in the interior of \mathcal{S} a second solution of the Helmholtz equation:

spherical wave

$$\psi_0 = \frac{e^{ikr}}{r}. \quad (8.2)$$

This is a spherical wave originating from the point \mathcal{P} , and r is the distance from \mathcal{P} to the point where ψ_0 is evaluated. Next we apply Gauss's theorem, Eq. (1.28a), to the vector field $\psi \nabla \psi_0 - \psi_0 \nabla \psi$ and invoke Eq. (8.1b), thereby obtaining

$$\begin{aligned} \int_{\mathcal{S} \cup \mathcal{S}_o} (\psi \nabla \psi_0 - \psi_0 \nabla \psi) \cdot d\mathbf{\Sigma} &= - \int_{\mathcal{V}} (\psi \nabla^2 \psi_0 - \psi_0 \nabla^2 \psi) dV \\ &= 0. \end{aligned} \quad (8.3)$$

Here we have introduced a small sphere \mathcal{S}_o of radius r_o surrounding \mathcal{P} (Fig. 8.1); \mathcal{V} is the volume between the two surfaces \mathcal{S}_o and \mathcal{S} (so $\mathcal{S} \cup \mathcal{S}_o$ is the boundary $\partial\mathcal{V}$ of \mathcal{V}). For future convenience we have made an unconventional choice of direction for the integration element $d\mathbf{\Sigma}$: it points into \mathcal{V} instead of outward, thereby producing the minus sign in the second expression in Eq. (8.3). As we let the radius r_o decrease to zero, we find that $\psi \nabla \psi_0 - \psi_0 \nabla \psi \rightarrow -\psi_{\mathcal{P}}/r_o^2 \mathbf{e}_r + \mathcal{O}(1/r_o)$, and so the integral over \mathcal{S}_o becomes $-4\pi \psi_{\mathcal{P}}$ (where $\psi_{\mathcal{P}}$ is the value of ψ at \mathcal{P}). Rearranging, we obtain

Helmholtz-Kirchhoff
integral

$$\psi_{\mathcal{P}} = \frac{1}{4\pi} \int_{\mathcal{S}} \left(\psi \nabla \frac{e^{ikr}}{r} - \frac{e^{ikr}}{r} \nabla \psi \right) \cdot d\mathbf{\Sigma}. \quad (8.4)$$

Equation (8.4), known as the *Helmholtz-Kirchhoff integral*, is the promised expression for the field ψ at some point \mathcal{P} in terms of a linear combination of its value and normal derivative on a surrounding surface. The specific combination of ψ and $d\mathbf{\Sigma} \cdot \nabla \psi$ that appears in this formula is perfectly immune to contributions from any wave that might originate at \mathcal{P} and pass outward through \mathcal{S} (any outgoing wave). The integral thus is influenced only by waves that enter \mathcal{V} through \mathcal{S} , propagate through \mathcal{V} , and then leave through \mathcal{S} . (There cannot be sources inside \mathcal{S} , except conceivably at \mathcal{P} , because we assumed ψ satisfies the source-free Helmholtz equation throughout \mathcal{V} .) If \mathcal{P} is many wavelengths away from the boundary \mathcal{S} , then to high accuracy, the integral is influenced by the waves ψ only when they are entering through \mathcal{S} (when they are incoming) and not when they are leaving (outgoing). This fact is important for applications, as we shall see.

8.2.1 Diffraction by an Aperture

Now let us suppose that some aperture \mathcal{Q} , with size much larger than a wavelength but much smaller than the distance to \mathcal{P} , is illuminated by a distant wave source (left side

FIGURE 8.1 Geometry for the Helmholtz-Kirchhoff integral (8.4), which expresses the field $\psi_{\mathcal{P}}$ at the point \mathcal{P} in terms of an integral of the field and its normal derivative over the surrounding surface \mathcal{S} . The small sphere \mathcal{S}_o is centered on the observation point \mathcal{P} , and \mathcal{V} is the volume bounded by \mathcal{S} and \mathcal{S}_o . (The aperture \mathcal{Q} , the vectors \mathbf{n} and \mathbf{n}' at the aperture, the incoming wave ψ' , and the point \mathcal{P}' are irrelevant to the formulation of the Helmholtz-Kirchhoff integral, but appear in applications later in this chapter—initially in Sec. 8.2.1.)

of Fig. 8.1).² Let the surface \mathcal{S} pass through the aperture \mathcal{Q} , and denote by ψ' the wave incident on \mathcal{Q} . We assume that the diffracting aperture has a local and linear effect on ψ' . More specifically, we suppose that the wave transmitted through the aperture is given by

$$\psi_{\mathcal{Q}} = t \psi', \quad (8.5)$$

where t is a complex transmission function that varies over the aperture. In practice, t is usually zero (completely opaque region) or unity (completely transparent region). However, t can also represent a variable phase factor when, for example, the aperture consists of a medium (lens) of variable thickness and of different refractive index from that of the homogeneous medium outside the aperture—as is the case in microscopes, telescopes, eyes, and other optical devices.

What this formalism does not allow is that $\psi_{\mathcal{Q}}$ at any point on the aperture be influenced by the wave's interaction with other parts of the aperture. For this reason, not only the aperture, but also any structure that it contains must be many wavelengths across. To give a specific example of what might go wrong, suppose that electromagnetic radiation is normally incident on a wire grid. A surface current will

complex transmission function t

limitations of this scalar diffraction formalism

2. If the aperture were comparable to a wavelength in size, or if part of it were only a few wavelengths from \mathcal{P} , then polarizational coupling effects at the aperture would be large (Born and Wolf, 1999). Our assumption avoids this complication.

FIGURE 8.2 Geometry for deriving Eq. (8.6) for diffraction by an aperture.

be induced in each wire by the wave's electric field, and that current will produce a secondary wave that cancels the primary wave immediately behind the wire, thereby "eclipsing" the wave. If the wire separation is not large compared to a wavelength, then the secondary wave from the current flowing in one wire will drive currents in adjacent wires, thereby modifying their secondary waves and disturbing the eclipse in a complex, polarization-dependent manner. Such modifications are negligible if the wires are many wavelengths apart.

Let us now use the Helmholtz-Kirchhoff integral (8.4) to compute the field at \mathcal{P} due to the wave $\psi_Q = t \psi'$ transmitted through the aperture. Let the (imaginary) surface S in Fig. 8.1 comprise the aperture \mathcal{Q} , a sphere of radius $R \gg r$ centered on \mathcal{P} , and an extension of the aperture to meet the sphere as sketched in Fig. 8.2. Assume that the only incoming waves are those passing through the aperture. Then, for the reason discussed in the paragraph following Eq. (8.4), when the incoming waves subsequently pass on outward through the spherical part of S , they contribute negligibly to the integral (8.4). Also, with the extension from aperture to sphere swinging back as drawn (Fig. 8.2), the contribution from the extension will also be negligible. Therefore, the only contribution is from the aperture itself.³

Because $kr \gg 1$, we can write $\nabla(e^{ikr}/r) \simeq -ik\mathbf{n}e^{ikr}/r$ on the aperture. Here \mathbf{n} is a unit vector pointing toward \mathcal{P} (Fig. 8.1). Similarly, we write $\nabla\psi \simeq ikt \mathbf{n}'\psi'$, where \mathbf{n}' is a unit vector along the direction of propagation of the incident wave (and where our assumption that anything in the aperture varies on scales long compared to $\lambda = 1/k$ permits us to ignore the gradient of t). Inserting these gradients into the Helmholtz-Kirchhoff integral, we obtain

3. Actually, the incoming waves will diffract around the edge of the aperture onto the back side of the screen that bounds the aperture (i.e., the side facing \mathcal{P}), and this diffracted wave will contribute to the Helmholtz-Kirchhoff integral in a polarization-dependent way (see Born and Wolf, 1999, Chap. 11). However, because the diffracted wave decays along the screen with an e -folding length of order a wavelength, its contribution will be negligible if the aperture is many wavelengths across and \mathcal{P} is many wavelengths away from the edge of the aperture, as we have assumed.

$$\psi_{\mathcal{P}} = -\frac{ik}{2\pi} \int_{\mathcal{Q}} d\mathbf{\Sigma} \cdot \left(\frac{\mathbf{n} + \mathbf{n}'}{2} \right) \frac{e^{ikr}}{r} t \psi' \quad (8.6)$$

wave field behind an aperture

Equation (8.6) can be used to compute the wave from a small aperture \mathcal{Q} at any point \mathcal{P} in the far field. It has the form of an integral transform of the incident field variable ψ' , where the integral is over the area of the aperture. The kernel of the transform is the product of several factors. The factor $1/r$ guarantees that the wave's energy flux falls off as the inverse square of the distance to the aperture, as we might have expected. The phase factor $-ie^{ikr}$ advances the phase of the wave by an amount equal to the optical path length between the element $d\mathbf{\Sigma}$ of the aperture and \mathcal{P} , minus $\pi/2$ (the phase of $-i$). The amplitude and phase of the wave ψ' can also be changed by the transmission function t . Finally there is the geometric factor $d\hat{\mathbf{\Sigma}} \cdot (\mathbf{n} + \mathbf{n}')/2$ (with $d\hat{\mathbf{\Sigma}}$ the unit vector normal to the aperture). This is known as the *obliquity factor*, and it ensures that the waves from the aperture propagate only forward with respect to the original wave and not backward (i.e., not in the direction $\mathbf{n} = -\mathbf{n}'$). More specifically, this factor prevents the backward-propagating secondary wavelets in a Huygens construction from reinforcing one another to produce a back-scattered wave. When dealing with paraxial Fourier optics (Sec. 8.5), we can usually set the obliquity factor to unity.

obliquity factor

It is instructive to specialize to a point source seen through a small diffracting aperture. If we suppose that the source has unit strength and is located at \mathcal{P}' , a distance r' before \mathcal{Q} (Fig. 8.1), then $\psi' = -e^{ikr'}/(4\pi r')$ (our definition of unit strength), and $\psi_{\mathcal{P}}$ can be written in the symmetric form

$$\psi_{\mathcal{P}} = \int_{\mathcal{Q}} \left(\frac{e^{ikr}}{4\pi r} \right) it (\mathbf{k} + \mathbf{k}') \cdot d\mathbf{\Sigma} \left(\frac{e^{ikr'}}{4\pi r'} \right) \quad (8.7)$$

propagator through an aperture

We can think of this expression as the Green's function response at \mathcal{P} to a delta function source at \mathcal{P}' . Alternatively, we can regard it as a *propagator* from \mathcal{P}' to \mathcal{P} by way of the aperture (co-opting a concept that was first utilized in quantum mechanics but is also useful in classical optics).

8.2.2 Spreading of the Wavefront: Fresnel and Fraunhofer Regions

8.2.2

Equation (8.6) [or Eq. (8.7)] gives a general prescription for computing the diffraction pattern from an illuminated aperture. It is commonly used in two complementary limits, called "Fraunhofer" and "Fresnel."

Suppose that the aperture has linear size a (as in Fig. 8.3) and is roughly centered on the geometric ray from the source point \mathcal{P}' to the field point \mathcal{P} , so $\mathbf{n} \cdot d\hat{\mathbf{\Sigma}} = \mathbf{n}' \cdot d\hat{\mathbf{\Sigma}} \simeq 1$. Consider the variations of the phase φ of the contributions to $\psi_{\mathcal{P}}$ that come from various places in the aperture. Using elementary trigonometry, we can estimate that locations on the aperture's opposite edges produce phases at \mathcal{P} that differ by $\Delta\varphi =$

FIGURE 8.3 Fraunhofer and Fresnel diffraction. The dashed line is an approximation to the edge of the aperture's shadow.

$k(\rho_2 - \rho_1) \sim ka^2/2\rho$, where ρ_1 and ρ_2 are the distances of \mathcal{P} from the two edges of the aperture, and ρ is the distance from the center of the aperture. There are two limiting regions for ρ , depending on whether \mathcal{P} 's so-called *Fresnel length*,

$$r_F \equiv \left(\frac{2\pi\rho}{k} \right)^{1/2} = (\lambda\rho)^{1/2} \quad (8.8)$$

Fresnel length

regions of Fraunhofer and Fresnel diffraction

(a surrogate for the distance ρ), is large or small compared to the aperture. Notice that $(a/r_F)^2 = ka^2/(2\pi\rho) \sim \Delta\varphi/\pi$. Therefore, when $r_F \gg a$ (field point far from the aperture), the phase variation $\Delta\varphi$ across the aperture is $\ll \pi$ and can be ignored, so the contributions at \mathcal{P} from different parts of the aperture are essentially in phase with one another. This is the *Fraunhofer* region. When $r_F \ll a$ (near the aperture), the phase variation is $\Delta\varphi \gg \pi$ and therefore is of utmost importance in determining the observed energy-flux pattern $F \propto |\psi_{\mathcal{P}}|^2$. This is the *Fresnel* region; see Fig. 8.3.

We can use an argument familiar, perhaps, from quantum mechanics to deduce the qualitative form of the flux patterns in these two regions. For simplicity, let the incoming wave be planar [r' huge in Eq. (8.7)]; let it propagate perpendicular to the aperture (as shown in Fig. 8.3); and let the aperture be empty, so $t = 1$ inside the aperture. Then geometric optics (photons treated like classical particles) would predict that the aperture's edge will cast a sharp shadow; the wave leaves the plane of the aperture as a beam with a sharp edge. However, wave optics insists that the transverse localization of the wave into a region of size $\Delta x \sim a$ must produce a spread in its transverse wave vector, $\Delta k_x \sim 1/a$ (a momentum uncertainty $\Delta p_x = \hbar\Delta k_x \sim \hbar/a$ in the language of the Heisenberg uncertainty principle). This uncertain transverse

wave vector produces, after propagating a distance ρ , a corresponding uncertainty $(\Delta k_x/k)\rho \sim r_F^2/a$ in the beam's transverse size. This uncertainty superposes incoherently on the aperture-induced size a of the beam to produce a net transverse beam size of

$$\Delta x \sim \sqrt{a^2 + (r_F^2/a)^2} \sim \begin{cases} a & \text{if } r_F \ll a \text{ (i.e., } \rho \ll a^2/\lambda; \text{ Fresnel region),} \\ \left(\frac{\lambda}{a}\right) \rho & \text{if } r_F \gg a \text{ (i.e., } \rho \gg a^2/\lambda; \text{ Fraunhofer region).} \end{cases} \quad (8.9)$$

Therefore, in the nearby, Fresnel region, the aperture creates a beam whose edges have the same shape and size as the aperture itself, and are reasonably sharp (but with some oscillatory blurring, associated with wavepacket spreading, that we analyze below); see Fig. 8.4. Thus, in the Fresnel region the field behaves approximately as one would predict using geometric optics. By contrast, in the more distant, Fraunhofer region, wavefront spreading causes the transverse size of the entire beam to grow linearly with distance; as illustrated in Fig. 8.4, the flux pattern differs markedly from the aperture's shape. We analyze the distant (Fraunhofer) region in Sec. 8.3 and the near (Fresnel) region in Sec. 8.4.

Fresnel and Fraunhofer diffraction regions and patterns

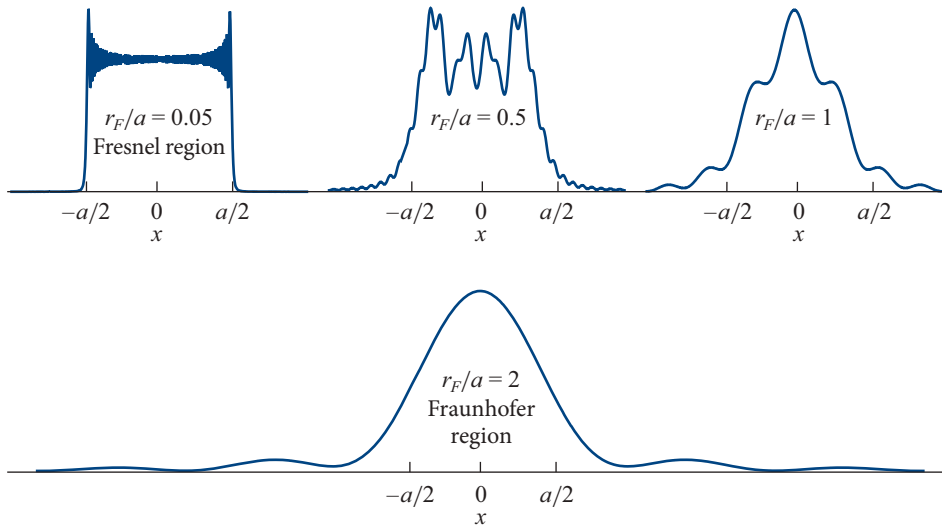

FIGURE 8.4 The 1-dimensional energy-flux diffraction pattern $|\psi|^2$ produced on a screen a distance z from a slit with $t(x) = 1$ for $|x| < a/2$ and $t(x) = 0$ for $|x| > a/2$. Four patterns are shown, each for a different value of $r_F/a = \sqrt{\lambda z}/a$. For $r_F/a = 0.05$ (very near the slit; extreme Fresnel region), the flux distribution resembles the slit itself: sharp edges at $x = \pm a/2$, but with damped oscillations (interference fringes) near the edges. For $r_F/a = 1$ (beginning of Fraunhofer region) there is a bright central peak and low-brightness, oscillatory side bands. As r_F/a increases from 0.05 to 2, the pattern transitions (quite rapidly between 0.5 and 2) from the Fresnel to the Fraunhofer pattern. These flux distributions are derived in Ex. 8.8.

8.3

8.3 Fraunhofer Diffraction

Consider the Fraunhofer region of strong wavefront spreading, $r_F \gg a$, and for simplicity specialize to the case of an incident plane wave with wave vector \mathbf{k} orthogonal to the aperture plane; see Fig. 8.5. Regard the line along \mathbf{k} through the center of the aperture \mathcal{Q} as the optic axis and identify points in the aperture by their transverse 2-dimensional vectorial separation \mathbf{x} from that axis. Identify \mathcal{P} by its distance ρ from the aperture center and its 2-dimensional transverse separation $\rho\boldsymbol{\theta}$ from the optic axis, and restrict attention to small-angle diffraction $|\boldsymbol{\theta}| \ll 1$. Then the geometric path length between \mathcal{P} and a point \mathbf{x} on \mathcal{Q} [the length denoted r in Eq. (8.6)] can be expanded as

$$\text{Path length} = r = (\rho^2 - 2\rho\mathbf{x} \cdot \boldsymbol{\theta} + x^2)^{1/2} \simeq \rho - \mathbf{x} \cdot \boldsymbol{\theta} + \frac{x^2}{2\rho} + \dots; \quad (8.10)$$

cf. Fig. 8.5. The first term in this expression, ρ , just contributes an \mathbf{x} -independent phase $e^{ik\rho}$ to the $\psi_{\mathcal{P}}$ of Eq. (8.6). The third term, $x^2/(2\rho)$, contributes a phase variation that is $\ll 1$ in the Fraunhofer region (but that will be important in the Fresnel region; Sec. 8.4). Therefore, in the Fraunhofer region we can retain just the second term, $-\mathbf{x} \cdot \boldsymbol{\theta}$, and write Eq. (8.6) in the form

Fraunhofer diffraction of a plane wave

$$\psi_{\mathcal{P}}(\boldsymbol{\theta}) \propto \int e^{-ik\mathbf{x} \cdot \boldsymbol{\theta}} t(\mathbf{x}) d\Sigma \equiv \tilde{t}(\boldsymbol{\theta}), \quad (8.11a)$$

where $d\Sigma$ is the surface-area element in the aperture plane, and we have dropped a constant phase factor and constant multiplicative factors. Thus, $\psi_{\mathcal{P}}(\boldsymbol{\theta})$ in the Fraunhofer region is given by the 2-dimensional Fourier transform, denoted $\tilde{t}(\boldsymbol{\theta})$, of the transmission function $t(\mathbf{x})$, with \mathbf{x} made dimensionless in the transform by multiplying by $k = 2\pi/\lambda$. [Note that with this optics convention for the Fourier transform, the inverse transform is

optics convention for Fourier transform

$$t(\mathbf{x}) = \left(\frac{k}{2\pi}\right)^2 \int e^{ik\mathbf{x} \cdot \boldsymbol{\theta}} \tilde{t}(\boldsymbol{\theta}) d\Omega, \quad (8.11b)$$

where $d\Omega = d\theta_x d\theta_y$ is the solid angle.]

The flux distribution of the diffracted wave [Eq. (8.11a)] is

Fraunhofer diffracted flux

$$F(\boldsymbol{\theta}) = \overline{(\Re[\psi_{\mathcal{P}}(\boldsymbol{\theta})e^{-i\omega t}])^2} = \frac{1}{2} |\psi_{\mathcal{P}}(\boldsymbol{\theta})|^2 \propto |\tilde{t}(\boldsymbol{\theta})|^2, \quad (8.12)$$

where \Re means take the real part, and the bar means average over time.

As an example, the bottom curve in Fig. 8.4 (the curve $r_F = 2a$) shows the flux distribution $F(\theta)$ from a slit

$$t(x) = H_1(x) \equiv \begin{cases} 1 & |x| < a/2 \\ 0 & |x| > a/2, \end{cases} \quad (8.13a)$$

FIGURE 8.5 Geometry for computing the path length between a point Q in the aperture and the point of observation \mathcal{P} . The transverse vector \mathbf{x} is used to identify Q in our Fraunhofer analysis (Sec. 8.3), and \mathbf{x}' is used in the Fresnel analysis (Sec. 8.4).

for which

$$\psi_{\mathcal{P}}(\theta) \propto \tilde{H}_1 \propto \int_{-a/2}^{a/2} e^{ikx\theta} dx \propto \text{sinc}\left(\frac{1}{2}ka\theta\right), \quad (8.13b)$$

$$F(\theta) \propto \text{sinc}^2\left(\frac{1}{2}ka\theta\right). \quad (8.13c)$$

Fraunhofer diffraction
from a slit with width a

Here $\text{sinc}(\xi) \equiv \sin(\xi)/\xi$. The bottom flux curve in Fig. 8.4 is almost—but not quite—described by Eq. (8.13c); the differences (e.g., the not-quite-zero value of the minimum between the central peak and the first side lobe) are due to the field point not being fully in the Fraunhofer region, $r_F/a = 2$ rather than $r_F/a \gg 1$.

It is usually uninteresting to normalize a Fraunhofer diffraction pattern. On those rare occasions when the absolute value of the observed flux is needed, rather than just the pattern's angular shape, it typically can be derived most easily from conservation of the total wave energy. This is why we have ignored the proportionality factors in the diffraction patterns.

All techniques for handling Fourier transforms (which should be familiar from quantum mechanics and elsewhere, though with different normalizations) can be applied to derive Fraunhofer diffraction patterns. In particular, the *convolution theorem* turns out to be very useful. It says that the Fourier transform of the convolution

$$f_2 \otimes f_1 \equiv \int_{-\infty}^{+\infty} f_2(\mathbf{x} - \mathbf{x}') f_1(\mathbf{x}') d\Sigma' \quad (8.14)$$

convolution

of two functions f_1 and f_2 is equal to the product $\tilde{f}_2(\boldsymbol{\theta})\tilde{f}_1(\boldsymbol{\theta})$ of their Fourier transforms, and conversely, the Fourier transform of a product is equal to the convolution. [Here and throughout this chapter, we use the optics version of a Fourier transform, in which 2-dimensional transverse position \mathbf{x} is made dimensionless via the wave number k ; Eq. (8.11a).]

As an example of the convolution theorem's power, we now compute the diffraction pattern produced by a diffraction grating.

8.3.1 Diffraction Grating

A diffraction grating⁴ can be modeled as a finite series of alternating transparent and opaque, long, parallel strips. Let there be N transparent and opaque strips each of width $a \gg \lambda$ (Fig. 8.6a), and idealize them as infinitely long, so their diffraction pattern is 1-dimensional. We outline how to use the convolution theorem to derive the grating's Fraunhofer diffraction pattern. The details are left as an exercise for the reader (Ex. 8.2).

using convolution to build transmission function

Our idealized N -slit grating can be regarded as an infinite series of delta functions with separation $2a$, convolved with the transmission function H_1 [Eq. (8.13a)] for a single slit of width a ,

$$\int_{-\infty}^{\infty} \left[\sum_{n=-\infty}^{+\infty} \delta(\xi - 2an) \right] H_1(x - \xi) d\xi, \quad (8.15a)$$

and then multiplied by an aperture function with width $2Na$:

$$H_{2N}(x) \equiv \begin{cases} 1 & |x| < Na \\ 0 & |x| > Na. \end{cases} \quad (8.15b)$$

More explicitly, we have

$$t(x) = \left(\int_{-\infty}^{\infty} \left[\sum_{n=-\infty}^{+\infty} \delta(\xi - 2an) \right] H_1(x - \xi) d\xi \right) H_{2N}(x), \quad (8.16)$$

which is shown graphically in Fig. 8.6b.

using the convolution theorem to compute Fraunhofer diffraction

Let us use the convolution theorem to evaluate the Fourier transform $\tilde{t}(\theta)$ of expression (8.16), thereby obtaining the diffraction pattern $\psi_{\mathcal{P}}(\theta) \propto \tilde{t}(\theta)$ for our transmission grating. The Fourier transform of the infinite series of delta functions with spacing $2a$ is itself an infinite series of delta functions with reciprocal spacing $2\pi/(2ka) = \lambda/(2a)$ (see the hint in Ex. 8.2). This must be multiplied by the Fourier transform $\tilde{H}_1(\theta) \propto \text{sinc}(\frac{1}{2}ka\theta)$ of the single narrow slit and then convolved with the Fourier transform $\tilde{H}_{2N}(\theta) \propto \text{sinc}(Nka\theta)$ of the aperture (wide slit). The result is shown schematically in Fig. 8.6c. (Each of the transforms is real, so the 1-dimensional functions shown in the figure fully embody them.)

The resulting diffracted energy flux, $F \propto |t(\theta)|^2$ (as computed in Ex. 8.2), is shown in Fig. 8.6d. The grating has channeled the incident radiation into a few equally spaced beams with directions $\theta = \pi p/(ka) = p\lambda/(2a)$, where p is an integer known as the *order* of the beam. Each of these beams has a shape given by $|\tilde{H}_{2N}(\theta)|^2$: a sharp central peak with half-width (distance from center of peak to first null of the flux) $\lambda/(2Na)$, followed by a set of *side lobes* whose intensities are $\propto N^{-1}$.

4. Diffraction gratings were first fabricated by David Rittenhouse in 1785 by winding hair around a pair of screws.

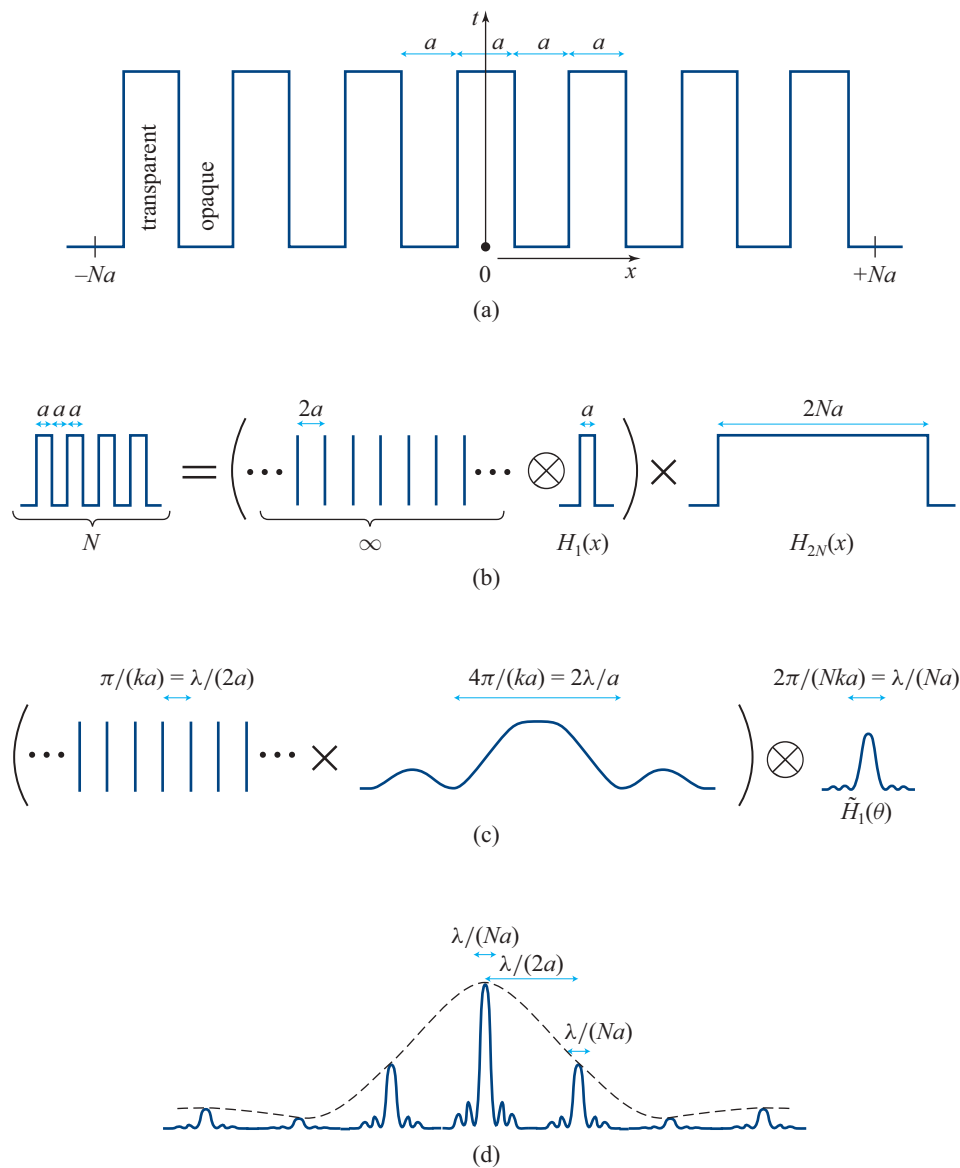

FIGURE 8.6 (a) Diffraction grating $t(x)$ formed by N alternating transparent and opaque strips each of width a . (b) Decomposition of this finite grating into an infinite series of equally spaced delta functions that are convolved (the symbol \otimes) with the shape of an individual transparent strip (i.e., a slit) and then multiplied (the symbol \times) by a large aperture function covering N such slits; Eq. (8.16). (c) The resulting Fraunhofer diffraction pattern $\tilde{t}(\theta)$ is shown schematically as the Fourier transform of a series of delta functions multiplied by the Fourier transform of a single slit and then convolved with the Fourier transform of the aperture. (d) The energy flux $F \propto |\tilde{t}(\theta)|^2$ of this diffraction pattern.

The deflection angles $\theta = p\lambda/(2a)$ of these beams are proportional to λ ; this underpins the use of diffraction gratings for spectroscopy (different wavelengths deflected into beams at different angles). It is of interest to ask what the wavelength resolution of such an idealized grating might be. If one focuses attention on the p th-order beams at two wavelengths λ and $\lambda + \delta\lambda$ [which are located at $\theta = p\lambda/(2a)$ and $p(\lambda + \delta\lambda)/(2a)$], then one can distinguish the beams from each other when their separation $\delta\theta = p\delta\lambda/(2a)$ is at least as large as the angular distance $\lambda/(2Na)$ between the maximum of each beam's diffraction pattern and its first minimum, that is, when

$$\frac{\lambda}{\delta\lambda} \lesssim \mathcal{R} \equiv Np. \quad (8.17)$$

diffraction grating's
chromatic resolving power

(Recall that N is the total number of slits in the grating, and p is the order of the diffracted beam.) This \mathcal{R} is called the grating's *chromatic resolving power*.

Real gratings are not this simple. First, they usually work not by modulating the amplitude of the incident radiation in this simple manner, but instead by modulating the phase. Second, the manner in which the phase is modulated is such as to channel most of the incident power into a particular order, a technique known as *blazing*. Third, gratings are often used in reflection rather than transmission. Despite these complications, the principles of a real grating's operation are essentially the same as our idealized grating. Manufactured gratings typically have $N \gtrsim 10,000$, giving a wavelength resolution for visual light that can be as small as $\lambda/10^5 \sim 10$ pm (i.e., 10^{-11} m).

EXERCISES

Exercise 8.1 Practice: Convolutions and Fourier Transforms

- Calculate the 1-dimensional Fourier transforms [Eq. (8.11a) reduced to 1 dimension] of the functions $f_1(x) \equiv e^{-x^2/2\sigma^2}$, and $f_2 \equiv 0$ for $x < 0$, $f_2 \equiv e^{-x/h}$ for $x \geq 0$.
- Take the inverse transforms of your answers to part (a) and recover the original functions.
- Convolve the exponential function f_2 with the Gaussian function f_1 , and then compute the Fourier transform of their convolution. Verify that the result is the same as the product of the Fourier transforms of f_1 and f_2 .

Exercise 8.2 Derivation: Diffraction Grating

Use the convolution theorem to carry out the calculation of the Fraunhofer diffraction pattern from the grating shown in Fig. 8.6. [Hint: To show that the Fourier transform of the infinite sequence of equally spaced delta functions is a similar sequence of delta functions, perform the Fourier transform to get $\sum_{n=-\infty}^{+\infty} e^{i2kan\theta}$ (aside from a multiplicative factor); then use the formulas for a Fourier *series* expansion, and its inverse, for any function that is periodic with period $\pi/(ka)$ to show that $\sum_{n=-\infty}^{+\infty} e^{i2kan\theta}$ is a sequence of delta functions.]

FIGURE 8.7 Diffraction grating formed from three groups of parallel lines.

Exercise 8.3 *Problem: Triangular Diffraction Grating*

Sketch the Fraunhofer diffraction pattern you would expect to see from a diffraction grating made from three groups of parallel lines aligned at angles of 120° to one another (Fig. 8.7).

8.3.2 Airy Pattern of a Circular Aperture: Hubble Space Telescope

8.3.2

The Hubble Space Telescope was launched in April 1990 to observe planets, stars, and galaxies above Earth's atmosphere. One reason for going into space is to avoid the irregular refractive-index variations in Earth's atmosphere, known, generically, as *seeing*, which degrade the quality of the images. (Another reason is to observe the ultraviolet part of the spectrum, which is absorbed in Earth's atmosphere.) Seeing typically limits the angular resolution of Earth-bound telescopes to $\sim 0.5''$ at visual wavelengths (see Box 9.2). We wish to compute how much the angular resolution improves by going into space. As we shall see, the computation is essentially an exercise in Fraunhofer diffraction theory.

The essence of the computation is to idealize the telescope as a circular aperture with diameter equal to that of the primary mirror. Light from this mirror is actually reflected onto a secondary mirror and then follows a complex optical path before being focused on a variety of detectors. However, this path is irrelevant to the angular resolution. The purposes of the optics are merely (i) to bring the Fraunhofer-region light to a focus close to the mirror [Eq. (8.31) and subsequent discussion], in order to produce an instrument that is compact enough to be launched, and (ii) to match the sizes of stars' images to the pixel size on the detector. In doing so, however, the optics leaves the angular resolution unchanged; the resolution is the same as if we were to observe the light, which passes through the primary mirror's circular aperture, far beyond the mirror, in the Fraunhofer region.

If the telescope aperture were very small, for example, a pin hole, then the light from a point source (a very distant star) would create a broad diffraction pattern, and the telescope's angular resolution would be correspondingly poor. As we increase the diameter of the aperture, we still see a diffraction pattern, but its angular width diminishes.

FIGURE 8.8 Airy diffraction pattern produced by a circular aperture.

Using these considerations, we can compute how well the telescope can distinguish neighboring stars. We do not expect it to resolve them fully if they are closer together on the sky than the angular width of the diffraction pattern. Of course, optical imperfections and pointing errors in a real telescope may degrade the image quality even further, but this is the best that can be done, limited only by the uncertainty principle.

The calculation of the Fraunhofer amplitude far from the aperture, via the Fourier transform (8.11a), is straightforward (Ex. 8.4):

$$\begin{aligned}\psi(\theta) &\propto \int_{\text{Disk with diameter } D} e^{-ik\mathbf{x}\cdot\boldsymbol{\theta}} d\Sigma \\ &\propto \text{jinc}\left(\frac{kD\theta}{2}\right),\end{aligned}\quad (8.18)$$

where D is the diameter of the aperture (i.e., of the telescope's primary mirror), $\theta \equiv |\boldsymbol{\theta}|$ is the angle from the optic axis, and $\text{jinc}(x) \equiv J_1(x)/x$, with J_1 the Bessel function of the first kind and of order one. The flux from the star observed at angle θ is therefore $\propto \text{jinc}^2(kD\theta/2)$. This energy-flux pattern, known as the *Airy pattern*, is shown in Fig. 8.8. The image appears as a central "Airy disk" surrounded by a circle where the flux vanishes, and then further surrounded by a series of concentric rings whose flux diminishes with radius. Only 16% of the total light falls outside the central Airy disk. The angular radius θ_A of the Airy disk (i.e., the radius of the dark circle surrounding it) is determined by the first zero of $J_1(kD\theta/2) = J_1(\theta \pi D/\lambda)$:

$$\boxed{\theta_A = 1.22\lambda/D.} \quad (8.19)$$

A conventional, though essentially arbitrary, criterion for angular resolution is to say that two point sources can be distinguished if they are separated in angle by more than θ_A . For the Hubble Space Telescope, $D = 2.4$ m and $\theta_A \sim 0.05''$ at visual wavelengths, which is more than 10 times better than is achievable on the ground with conventional (nonadaptive) optics.

Initially, there was a serious problem with Hubble's telescope optics. The hyperboloidal primary mirror was ground to the wrong shape, so rays parallel to the optic

Airy diffraction pattern
from circular aperture

axis did not pass through a common focus after reflection off a convex hyperboloidal secondary mirror. This defect, known as *spherical aberration* (Sec. 7.5.2), created blurred images. However, it was possible to correct this error in subsequent instruments in the optical train, and the Hubble Space Telescope became the most successful optical telescope of all time, transforming our view of the universe.

The Hubble Space Telescope should be succeeded in 2018 by the James Webb Space Telescope. Webb will have a diameter $D \simeq 6.5$ m (2.7 times larger than Hubble) but its wavelengths of observation are somewhat longer ($0.6 \mu\text{m}$ to $28.5 \mu\text{m}$), so its angular resolution will be, on average, roughly the same as Hubble's.

Exercise 8.4 *Derivation: Airy Pattern*

Derive and plot the Airy diffraction pattern [Eq. (8.18)] and show that 84% of the light is contained within the Airy disk.

EXERCISES

Exercise 8.5 *Problem: Pointillist Painting*

The neoimpressionist painter Georges Seurat was a member of the pointillist school. His paintings consisted of an enormous number of closely spaced dots of pure pigment (of size ranging from ~ 0.4 mm in his smaller paintings to ~ 4 mm in his largest paintings, such as *Gray Weather, Grande Jatte*, Fig. 8.9). The illusion of color mixing was produced only in the eye of the observer. How far from the painting should one stand to obtain the desired blending of color?

FIGURE 8.9 (a) Georges Seurat's painting *Gray Weather, Grande Jatte*. When viewed from a sufficient distance, adjacent dots of paint with different colors blend together in the eye to form another color. (b) Enlargement of the boat near the center of the painting. In this enlargement, one sees clearly the individual dots of paint. *Gray Weather, Grande Jatte* by Georges Seurat (ca. 1886–88); The Metropolitan Museum of Art (www.metmuseum.org); The Walter H. and Leonore Annenberg Collection, Gift of Walter H. and Leonore Annenberg, 2002, Bequest of Walter H. Annenberg, 2002.

FIGURE 8.10 Geometry for Babinet's principle. The beam produced by the large aperture D is confined between the long-dashed lines. Outside this beam, the energy-flux pattern $F(\theta) \propto |t(\theta)|^2$ produced by a small object (size a) and its complement are the same, Eqs. (8.20). This diffracted flux pattern is confined between the dotted lines.

8.3.3 Babinet's Principle

Suppose that monochromatic light falls normally onto a large circular aperture with diameter D . At distances $z \lesssim D^2/\lambda$ (i.e., $r_F \lesssim D$), the transmitted light will be collimated into a beam with diameter D , and at larger distances, the beam will become conical with opening angle λ/D (Fig. 8.3) and flux distribution given by the Airy diffraction pattern of Fig. 8.8.

Now place into this aperture a significantly smaller object (size $a \ll D$; Fig. 8.10) with transmissivity $t_1(\mathbf{x})$ —for example, an opaque star-shaped object. This object will produce a Fraunhofer diffraction pattern with opening angle $\lambda/a \gg \lambda/D$ that extends well beyond the large aperture's beam. Outside that beam, the diffraction pattern will be insensitive to the shape and size of the large aperture, because only the small object can diffract light to these large angles; so the diffracted flux will be $F_1(\theta) \propto |\tilde{t}_1(\theta)|^2$.

Next, suppose that we replace the small object by one with a *complementary transmissivity* t_2 , complementary in the sense that

$$t_1(\mathbf{x}) + t_2(\mathbf{x}) = 1. \quad (8.20a)$$

Babinet's principle

For example, we replace a small, opaque star-shaped object by an opaque screen that fills the original, large aperture except for a star-shaped hole. This complementary object will produce a diffraction pattern $F_2(\theta) \propto |\tilde{t}_2(\theta)|^2$. Outside the large aperture's beam, this pattern again is insensitive to the size and shape of the large aperture, that is, it is insensitive to the 1 in $t_2 = 1 - t_1$ (which sends light solely inside the large aperture's

beam); so at these large angles, $\tilde{t}_2(\boldsymbol{\theta}) = -\tilde{t}_1(\boldsymbol{\theta})$, which implies that the energy-flux diffraction pattern of the original object and the new, complementary object will be the same outside the large aperture's beam:

$$F_2(\boldsymbol{\theta}) \propto |\tilde{t}_2(\boldsymbol{\theta})|^2 = |\tilde{t}_1(\boldsymbol{\theta})|^2 \propto F_1(\boldsymbol{\theta}). \quad (8.20b)$$

This is called *Babinet's principle*.

EXERCISES

Exercise 8.6 *Problem: Light Scattering by a Large, Opaque Particle*

Consider the scattering of light by an opaque particle with size $a \gg 1/k$. Neglect any scattering via excitation of electrons in the particle. Then the scattering is solely due to diffraction of light around the particle. With the aid of Babinet's principle, do the following.

- Explain why the scattered light is confined to a cone with opening angle $\Delta\theta \sim \pi/(ka) \ll 1$.
- Show that the total power in the scattered light, at very large distances from the particle, is $P_S = FA$, where F is the incident energy flux, and A is the cross sectional area of the particle perpendicular to the incident wave.
- Explain why the total "extinction" (absorption plus scattering) cross section is equal to $2A$ independent of the shape of the opaque particle.

Exercise 8.7 *Problem: Thickness of a Human Hair*

Conceive and carry out an experiment using light diffraction to measure the thickness of a hair from your head, accurate to within a factor of ~ 2 . [Hint: Make sure the source of light that you use is small enough—e.g., a very narrow laser beam—that its finite size has negligible influence on your result.]

8.4 Fresnel Diffraction

8.4

We next turn to the Fresnel region of observation points \mathcal{P} with $r_F = \sqrt{\lambda\rho}$ much smaller than the aperture. In this region, the field at \mathcal{P} arriving from different parts of the aperture has significantly different phase $\Delta\varphi \gg 1$. We again specialize to incoming wave vectors that are approximately orthogonal to the aperture plane and to small diffraction angles, so we can ignore the obliquity factor $d\hat{\boldsymbol{\Sigma}} \cdot (\mathbf{n} + \mathbf{n}')/2$ in Eq. (8.6). By contrast with the Fraunhofer case, we now identify \mathcal{P} by its distance z from the aperture plane instead of its distance ρ from the aperture center, and we use as our integration variable in the aperture $\mathbf{x}' \equiv \mathbf{x} - \rho\boldsymbol{\theta}$ (Fig. 8.5), thereby writing the dependence of the phase at \mathcal{P} on \mathbf{x} in the form

$$\Delta\varphi \equiv k \times [(\text{path length from } \mathbf{x} \text{ to } \mathcal{P}) - z] = \frac{k\mathbf{x}'^2}{2z} + \mathcal{O}\left(\frac{kx'^4}{z^3}\right). \quad (8.21)$$

In the Fraunhofer region (Sec. 8.3) only the linear term $-k\mathbf{x} \cdot \boldsymbol{\theta}$ in $k\mathbf{x}'^2/(2z) \simeq k(\mathbf{x} - r\boldsymbol{\theta})^2/r$ was significant. In the Fresnel region the term quadratic in \mathbf{x} is also significant (and we have changed variables to \mathbf{x}' so as to simplify it), but the $O(x'^4)$ term is negligible. Therefore, in the Fresnel region the diffraction pattern (8.6) is

$$\psi_{\mathcal{P}} = \frac{-ik e^{ikz}}{2\pi z} \int e^{i\Delta\varphi} t \psi' d\Sigma' = \frac{-ik e^{ikz}}{2\pi z} \int e^{ik\mathbf{x}'^2/(2z)} t(\mathbf{x}') \psi'(\mathbf{x}') d\Sigma', \quad (8.22)$$

where in the denominator we have replaced r by z to excellent approximation.

Let us consider the Fresnel diffraction pattern formed by an empty ($t = 1$) simple aperture of arbitrary shape, illuminated by a normally incident plane wave. It is convenient to introduce transverse Cartesian coordinates $\mathbf{x}' = (x', y')$ and define

$$\sigma = \left(\frac{k}{\pi z}\right)^{1/2} x', \quad \tau = \left(\frac{k}{\pi z}\right)^{1/2} y'. \quad (8.23a)$$

[Notice that $(k/[\pi z])^{1/2}$ is $\sqrt{2}/r_F$; cf. Eq. (8.8).] We can thereby rewrite Eq. (8.22) in the form

$$\psi_{\mathcal{P}} = -\frac{i}{2} \int \int_{\mathcal{Q}} e^{i\pi\sigma^2/2} e^{i\pi\tau^2/2} \psi_{\mathcal{Q}} e^{ikz} d\sigma d\tau. \quad (8.23b)$$

Fresnel diffraction pattern from arbitrary empty aperture \mathcal{Q}

Here we have changed notation for the field ψ' impinging on the aperture \mathcal{Q} to $\psi_{\mathcal{Q}}$.

Equations (8.23) depend on the transverse location of the observation point \mathcal{P} through the origin used to define $\mathbf{x}' = (x', y')$; see Fig. 8.5. We use these rather general expressions in Sec. 8.5, when discussing paraxial Fourier optics, as well as in Secs. 8.4.1–8.4.4 on Fresnel diffraction.

8.4.1

8.4.1 Rectangular Aperture, Fresnel Integrals, and the Cornu Spiral

In this and the following three sections, we explore the details of the Fresnel diffraction pattern for an incoming plane wave that falls perpendicularly on the aperture, so $\psi_{\mathcal{Q}}$ is constant over the aperture.

For simplicity, we initially confine attention to a rectangular aperture with edges along the x' and y' directions. Then the two integrals have limits that are independent of each other, and the integrals can be expressed in the form $\mathcal{E}(\sigma_{\max}) - \mathcal{E}(\sigma_{\min})$ and $\mathcal{E}(\tau_{\max}) - \mathcal{E}(\tau_{\min})$, so

$$\psi_{\mathcal{P}} = \frac{-i}{2} [\mathcal{E}(\sigma_{\max}) - \mathcal{E}(\sigma_{\min})][\mathcal{E}(\tau_{\max}) - \mathcal{E}(\tau_{\min})] \psi_{\mathcal{Q}} e^{ikz} \equiv \frac{-i}{2} \Delta\mathcal{E}_{\sigma} \Delta\mathcal{E}_{\tau} \psi_{\mathcal{Q}} e^{ikz}, \quad (8.24a)$$

where the arguments are the limits of integration (the two edges of the aperture), and where

$$\mathcal{E}(\xi) \equiv \int_0^{\xi} e^{i\pi\sigma^2/2} d\sigma \equiv C(\xi) + iS(\xi). \quad (8.24b)$$

Fresnel diffraction by rectangular aperture

FIGURE 8.11 Cornu spiral in the complex plane; the real part of $\mathcal{E}(\xi) = C(\xi) + iS(\xi)$ is plotted horizontally, and the imaginary part vertically; the point $\xi = 0$ is at the origin, positive ξ is in the upper right quadrant, and negative ξ is in the lower left quadrant. The diffracted energy flux is proportional to the squared length of the arrow reaching from $\xi = \sigma_{\min}$ to $\xi = \sigma_{\max}$.

Here

$$C(\xi) \equiv \int_0^\xi d\sigma \cos(\pi\sigma^2/2), \quad S(\xi) \equiv \int_0^\xi d\sigma \sin(\pi\sigma^2/2) \quad (8.24c)$$

Fresnel integrals

are known as *Fresnel integrals* and are standard functions tabulated in many books and can be found in Mathematica, Matlab, and Maple. Notice that the energy-flux distribution is

$$F \propto |\psi_{\mathcal{P}}|^2 \propto |\Delta\mathcal{E}_\sigma|^2 |\Delta\mathcal{E}_\tau|^2. \quad (8.24d)$$

Cornu spiral

It is convenient to exhibit the Fresnel integrals graphically using a *Cornu spiral* (Fig. 8.11). This is a graph of the parametric equation $[C(\xi), S(\xi)]$, or equivalently, a graph of $\mathcal{E}(\xi) = C(\xi) + iS(\xi)$ in the complex plane. The two terms $\Delta\mathcal{E}_\sigma$ and $\Delta\mathcal{E}_\tau$ in Eq. (8.24a) can be represented in amplitude and phase by arrows in the C - S plane reaching from $\xi = \sigma_{\min}$ on the Cornu spiral to $\xi = \sigma_{\max}$ (Fig. 8.11), and from $\xi = \tau_{\min}$ to $\xi = \tau_{\max}$. Correspondingly, the flux F [Eq. (8.24d)] is proportional to the product of the squared lengths of these two vectors.

As the observation point \mathcal{P} moves around in the observation plane (Fig. 8.5), x'_{\min} and x'_{\max} change, and hence $\sigma_{\min} = [k/(\pi z)]^{1/2} x'_{\min}$ and $\sigma_{\max} = [k/(\pi z)]^{1/2} x'_{\max}$ change [i.e., the tail and tip of the arrow in Fig. 8.11 move along the Cornu spiral, thereby changing the diffracted flux, which is $\propto (\text{length of arrow})^2$].

The simplest illustration of Fresnel integrals is the totally unobscured plane wave. In this case, the limits of both integrations extend from $-\infty$ to $+\infty$, which, as we see in Fig. 8.11, is an arrow of length $2^{1/2}$ and phase $\pi/4$. Therefore, $\psi_{\mathcal{P}}$ is equal to $(2^{1/2}e^{i\pi/4})^2(-i/2)\psi_{\mathcal{Q}}e^{ikz} = \psi_{\mathcal{Q}}e^{ikz}$, as we could have deduced simply by solving the Helmholtz equation (8.1b) for a plane wave.

This unobscured-wavefront calculation elucidates three issues that we have already met. First, it illustrates our interpretation of Fermat's principle in geometric optics. In the limit of short wavelengths, the paths that contribute to the wave field are just those along which the phase is stationary to small variations. Our present calculation shows that, because of the tightening of the Cornu spiral as one moves toward a large argument, the paths that contribute significantly to $\psi_{\mathcal{P}}$ are those that are separated from the geometric-optics path by less than a few Fresnel lengths at \mathcal{Q} . (For a laboratory experiment with light and $z \sim 2$ m, the Fresnel length is $\sqrt{\lambda z} \sim 1$ mm.)

A second, and related, point is that, when computing the Fresnel diffraction pattern from a more complicated aperture, we need only perform the integral (8.6) in the immediate vicinity of the geometric-optics ray. We can ignore the contribution from the extension of the aperture \mathcal{Q} to meet the "sphere at infinity" (the surface \mathcal{S} in Fig. 8.2), even when the wave is unobstructed there. The rapid phase variation makes the contribution from that extension and from \mathcal{S} sum to zero.

Third, when integrating over the whole area of the wavefront at \mathcal{Q} , we have summed contributions with increasingly large phase differences that add in such a way that the total has a net extra phase of $\pi/2$ relative to the geometric-optics ray. This phase factor cancels exactly the prefactor $-i$ in the Helmholtz-Kirchhoff formula (8.6). (This phase factor is unimportant in the limit of geometric optics.)

The next-simplest case of Fresnel diffraction is the pattern formed by a straight edge. As a specific example, consider a cosmologically distant source of radio waves that is occulted by the Moon. If we treat the lunar limb as a straight edge, then the radio source will create a changing diffraction pattern as it passes behind the Moon, and the diffraction pattern can be measured by a radio telescope on Earth. We orient our coordinates so the Moon's edge is along the y' direction (τ direction). Then in Eq. (8.24a) $\Delta\mathcal{E}_{\tau} \equiv \mathcal{E}(\tau_{\max}) - \mathcal{E}(\tau_{\min}) = \sqrt{2i}$ is constant, and $\Delta\mathcal{E}_{\sigma} \equiv \mathcal{E}(\sigma_{\max}) - \mathcal{E}(\sigma_{\min})$ is described by the Cornu spiral of Fig. 8.12b.

Long before the occultation, we can approximate $\sigma_{\min} = -\infty$ and $\sigma_{\max} = +\infty$ (Fig. 8.12a), so $\Delta\mathcal{E}_{\sigma}$ is given by the arrow from $(-1/2, -1/2)$ to $(1/2, 1/2)$ in Fig. 8.12b (i.e., $\Delta\mathcal{E}_{\sigma} = \sqrt{2i}$). The observed wave amplitude, Eq. (8.24a), is therefore $\psi_{\mathcal{Q}}e^{ikz}$. When the Moon approaches occultation of the radio source, the upper bound on the Fresnel integral begins to diminish from $\sigma_{\max} = +\infty$, and the complex vector on the Cornu spiral begins to oscillate in length (e.g., from A to B in Fig. 8.12b,c) and in phase. The observed flux also oscillates, more and more strongly as geometric

for Fresnel diffraction dominant paths are near geometric optics path

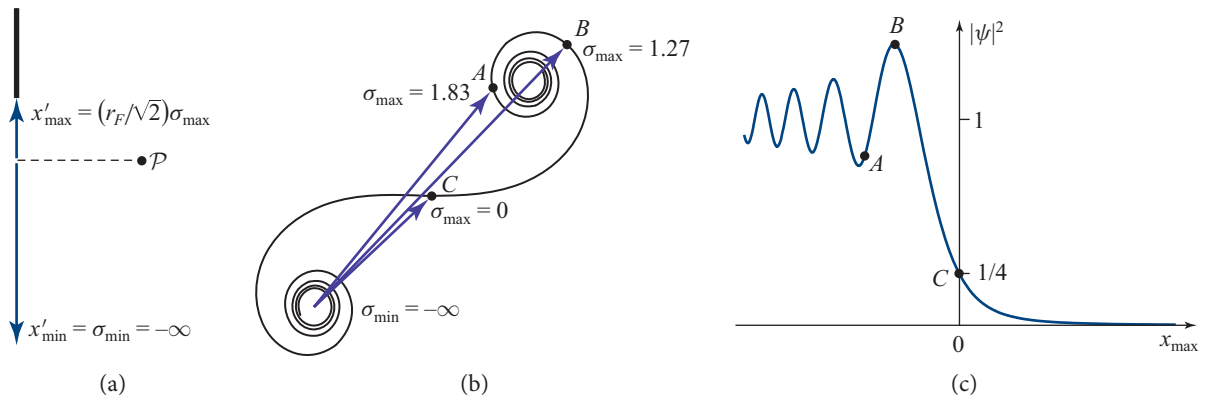

FIGURE 8.12 Diffraction from a straight edge. (a) The straight edge, onto which a plane wave impinges orthogonally, the observation point \mathcal{P} , and the vectors that reach to the lower and upper limits of integration, $x'_{\min} = -\infty$ and x'_{\max} for computation of the diffraction integral (8.23b). (b) The Cornu spiral, showing the arrows that represent the contribution $\Delta\mathcal{E}_\sigma$ to the diffracted field $\psi_{\mathcal{P}}$. (c) The energy-flux diffraction pattern formed by the straight edge. The flux $|\psi|^2 \propto |\Delta\mathcal{E}_\sigma|^2$ is proportional to the squared length of the arrow on the Cornu spiral in panel b.

occultation is approached. At the point of geometric occultation (point C in Fig. 8.12b,c), the complex vector extends from $(-1/2, -1/2)$ to $(0, 0)$, and so the observed wave amplitude is one-half the unocculted value, and the flux is reduced to one-fourth. As the occultation proceeds, the length of the complex vector and the observed flux decrease monotonically to zero, while the phase continues to oscillate.

Historically, diffraction of a radio source's waves by the Moon led to the discovery of quasars—the hyperactive nuclei of distant galaxies. In the early 1960s, a team of Australian and British radio observers led by Cyril Hazard knew that the Moon would occult the powerful radio source 3C273, so they set up their telescope to observe the development of the diffraction pattern as the occultation proceeded. From the pattern's observed times of ingress (passage into the Moon's shadow) and egress (emergence from the Moon's shadow), Hazard determined the coordinates of 3C273 on the sky and did so with remarkable accuracy, thanks to the oscillatory features in the diffraction pattern. These coordinates enabled Maarten Schmidt at the 200-inch telescope on Palomar Mountain to identify 3C273 optically and discover (from its optical redshift) that it was surprisingly distant and consequently had an unprecedented luminosity. It was the first example of a quasar—a previously unknown astrophysical object.

discovery of quasars

In Hazard's occultation measurements, the observing wavelength was $\lambda \sim 0.2$ m. Since the Moon is roughly $z \sim 400,000$ km distant, the Fresnel length was about $r_F = \sqrt{\lambda z} \sim 10$ km. The Moon's orbital speed is $v \sim 200$ m s $^{-1}$, so the diffraction pattern took a time $\sim 5r_F/v \sim 4$ min to pass through the telescope.

The straight-edge diffraction pattern of Fig. 8.12c occurs universally along the edge of the shadow of any object, so long as the source of light is sufficiently small

FIGURE 8.13 Fresnel diffraction pattern in the shadow of *Mary's Hand Holding a Dime*—a photograph by Eugene Hecht, from the first figure in Hecht (2017, Chap. 10).

and the shadow's edge bends on lengthscales long compared to the Fresnel length $r_F = \sqrt{\lambda z}$. Examples are the diffraction patterns on the two edges of a slit's shadow in the upper-left curve in Fig. 8.4 (cf. Ex. 8.8) and the diffraction pattern along the edge of a shadow cast by a person's hand in Fig. 8.13.

EXERCISES

Exercise 8.8 Example: Diffraction Pattern from a Slit

Derive a formula for the energy-flux diffraction pattern $F(x)$ of a slit with width a , as a function of distance x from the center of the slit, in terms of Fresnel integrals. Plot your formula for various distances z from the slit's plane (i.e., for various values of $r_F/a = \sqrt{\lambda z/a^2}$), and compare with Fig. 8.4.

8.4.4 8.4.4 Circular Apertures: Fresnel Zones and Zone Plates

We have seen how the Fresnel diffraction pattern for a plane wave can be thought of as formed by waves that derive from a patch in the diffracting object's plane a few Fresnel lengths in size. This notion can be made quantitatively useful by reanalyzing an unobstructed wavefront in circular polar coordinates. More specifically, consider a plane wave incident on an aperture \mathcal{Q} that is infinitely large (no obstruction), and define $\varpi \equiv |\mathbf{x}'|/r_F = \sqrt{\frac{1}{2}(\sigma^2 + \tau^2)}$. Then the phase factor in Eq. (8.23b) is $\Delta\varphi = \pi\varpi^2$, so the observed wave coming from the region inside a circle of radius $|\mathbf{x}'| = r_F\varpi$ will be given by

$$\begin{aligned}\psi_{\mathcal{P}} &= -i \int_0^{\varpi} 2\pi\varpi' d\varpi' e^{i\pi\varpi'^2} \psi_{\mathcal{Q}} e^{ikz} \\ &= (1 - e^{i\pi\varpi^2}) \psi_{\mathcal{Q}} e^{ikz}.\end{aligned}\tag{8.25}$$

Now, this integral does not appear to converge as $\varpi \rightarrow \infty$. We can see what is happening if we sketch an amplitude-and-phase diagram (Fig. 8.14).

FIGURE 8.14 Amplitude-and-phase diagram for an unobstructed plane wavefront, decomposed into Fresnel zones; Eq. (8.25).

As we integrate outward from $\varpi = 0$, the complex vector has the initial phase retardation of $\pi/2$ but then moves on a semi-circle, so that by the time we have integrated out to a radius of $|\mathbf{x}'| = r_F$ ($\varpi = 1$), the contribution to the observed wave is $\psi_P = 2\psi_Q$ in phase with the incident wave. When the integration has been extended to $\sqrt{2} r_F$, ($\varpi = \sqrt{2}$), the circle has been completed, and $\psi_P = 0$! The integral continues on around the same circle over and over again, as the upper-bound radius is further increased; see Fig. 8.14.

Of course, the field must actually have a well-defined value as $\varpi \rightarrow \infty$, despite this apparent failure of the integral to converge. To understand how the field becomes well defined, imagine splitting the aperture Q up into concentric annular rings, known as *Fresnel half-period zones*, with outer radii $\sqrt{n} r_F$, where $n = 1, 2, 3, \dots$. The integral fails to converge because the contribution from each odd-numbered ring cancels that from an adjacent even-numbered ring. However, the thickness of these rings decreases as $1/\sqrt{n}$, and eventually we must allow for the fact that the incoming wave is not exactly planar; or, equivalently and more usefully, we must allow for the fact that the wave's distant source has some finite angular size. The finite size causes different pieces of the source to have their Fresnel rings centered at slightly different points in the aperture plane, which causes our computation of ψ_P to begin averaging over rings. This averaging forces the tip of the complex vector ($\Re\psi$, $\Im\psi$), where \Re and \Im correspond to the real and imaginary parts, to asymptote to the center of the circle in Fig. 8.14. Correspondingly, due to the averaging, the observed energy flux asymptotes to $|\psi_Q|^2$ [Eq. (8.25) with the exponential $e^{i\pi\varpi^2}$ going to zero].

Although this may not seem to be a particularly wise way to decompose a plane wavefront, it does allow a striking experimental verification of our theory of diffraction. Suppose that we fabricate an aperture (called a *zone plate*) in which, for a chosen wavelength and observation point P on the optic axis, alternate half-period

half-period zones

zone plate

zones are obscured. Then the wave observed at \mathcal{P} will be the linear sum of several diameters of the circle in Fig. 8.14 and therefore will be far larger than ψ_Q . This strong amplification is confined to our chosen spot on the optic axis; most everywhere else the field's energy flux is reduced, thereby conserving energy. Thus the zone plate behaves like a lens. Because the common area of the half-period zones is $A = n\pi r_F^2 - (n-1)\pi r_F^2 = \pi r_F^2 = \pi \lambda z$, if we construct a zone plate with fixed area A for the zones, its focal length will be $f = z = A/(\pi \lambda)$. For $A =$ (a few square millimeters)—the typical choice—and $\lambda \sim 500$ nm (optical wavelengths), we have $f \sim$ a few meters.

Zone plates are only good lenses when the radiation is monochromatic, since the focal length is wavelength dependent, $f \propto \lambda^{-1}$. They have the further interesting property that they possess secondary foci, where the fields from 3 contiguous zones, or 5 or 7 or so forth, add up coherently (Ex. 8.9).

secondary foci

EXERCISES

Exercise 8.9 *Problem: Zone Plate*

- Use an amplitude-and-phase diagram to explain why a zone plate has secondary foci at distances of $f/3$, $f/5$, $f/7 \dots$
- An opaque, perfectly circular disk of diameter D is placed perpendicular to an incoming plane wave. Show that, at distances r such that $r_F \ll D$, the disk casts a rather sharp shadow, but at the precise center of the shadow there must be a bright spot.⁵ How bright?

Exercise 8.10 *Problem: Spy Satellites*

Telescopes can also look down through the same atmospheric irregularities as those mentioned in Sec. 8.3.2 (see also Box 9.2). In what important respects will the optics differ from those for ground-based telescopes looking upward?

8.5 Paraxial Fourier Optics

We have developed a linear theory of wave optics that has allowed us to calculate diffraction patterns in the Fraunhofer and Fresnel limiting regions. That these calculations agree with laboratory measurements provides some vindication of the theory and the assumptions implicit in it. We now turn to practical applications of these ideas, specifically, to the acquisition and processing of images by instruments operating throughout the electromagnetic spectrum. As we shall see, these instruments rely

5. Siméon Poisson predicted the existence of this spot as a consequence of Fresnel's wave theory of light, in order to demonstrate that Fresnel's theory was wrong. However, François Arago (who was briefly, in 1848, premier of France) quickly demonstrated experimentally that the bright spot existed. It is now called the Poisson spot (despite Poisson's skepticism) or the Arago spot.

on an extension of paraxial geometric optics (Sec. 7.4) to situations where diffraction effects are important. Because of the central role played by Fourier transforms in diffraction [e.g., Eq. (8.11a)], the theory underlying these instruments is called *paraxial Fourier optics*, or just *Fourier optics*.

Although the conceptual framework and mathematical machinery for image processing by Fourier optics were developed in the nineteenth century, Fourier optics was not widely exploited until the second half of the twentieth century. Its maturation was driven in part by a growing recognition of similarities between optics and communication theory—for example, the realization that a microscope is simply an *image-processing system*. The development of electronic computation has also triggered enormous strides; computers are now seen as extensions of optical devices, and vice versa. It is a matter of convenience, accuracy, economics, and practicality to decide which parts of the image processing are carried out with mirrors, lenses, and the like, and which parts are performed numerically.

One conceptually simple example of optical image processing is an improvement in one's ability to identify a faint star in the Fraunhofer diffraction rings ("fringes") of a much brighter star. As we shall see [Eq. (8.31) and subsequent discussion], the bright image of a source in a telescope's or microscope's focal plane has the same Airy diffraction pattern as we met in Eq. (8.18) and Fig. 8.8. If the shape of that image could be changed from the ring-endowed Airy pattern to a Gaussian, then it would be far easier to identify a nearby feature or faint star. One way to achieve this would be to attenuate the incident radiation at the telescope aperture in such a way that, immediately after passing through the aperture, it has a Gaussian profile instead of a sharp-edged profile. Its Fourier transform (the diffraction pattern in the focal plane) would then also be Gaussian. Such a Gaussian-shaped attenuation is difficult to achieve in practice, but it turns out—as we shall see—that there are easier options.

Before exploring these options, we must lay some foundations, beginning with the concept of coherent illumination in Sec. 8.5.1, and then moving on to point-spread functions in Sec. 8.5.2.

8.5.1 Coherent Illumination

If the radiation arriving at the input of an optical system derives from a single source (e.g., a point source that has been collimated into a parallel beam by a converging lens), then the radiation is best described by its complex amplitude ψ (as we are doing in this chapter). An example might be a biological specimen on a microscope slide, illuminated by an external point source, for which the phases of the waves leaving different parts of the slide are strongly correlated with one another. This is called *coherent illumination*. If, by contrast, the source is self-luminous and of nonnegligible size, with the atoms or molecules in its different parts radiating independently—for example, a cluster of stars—then the phases of the radiation from different parts are uncorrelated, and it may be the radiation's energy flux, not its complex amplitude, that obeys well-defined (nonprobabilistic) evolution laws. This is called *incoherent*

image processing with mirrors, lenses, etc. plus computing

Gaussian aperture

8.5.1

illumination. In this chapter we develop Fourier optics for a coherently illuminating source (the kind of illumination tacitly assumed in previous sections of the chapter). A parallel theory with a similar vocabulary can be developed for incoherent illumination, and some of the foundations for it are laid in Chap. 9. In Chap. 9, we also develop a more precise formulation of the concept of *coherence*.

8.5.2 Point-Spread Functions

In our treatment of paraxial geometric optics (Sec. 7.4), we showed how it is possible to regard a group of optical elements as a sequence of linear devices and relate the output rays to the input by linear operators (i.e., matrices). This chapter's theory of diffraction is also linear, and so a similar approach can be followed. As in Sec. 7.4, we restrict attention to small angles relative to some optic axis ("paraxial Fourier optics"). We describe the wave field at some distance z_j along the optic axis by the function $\psi_j(\mathbf{x})$, where \mathbf{x} is a 2-dimensional vector perpendicular to the optic axis (as in Fig. 8.5). If we consider a single linear optical device, then we can relate the output field ψ_2 at z_2 to the input ψ_1 at z_1 using a Green's function denoted $P_{21}(\mathbf{x}_2, \mathbf{x}_1)$.⁶

Green's function,
point-spread function,
propagator

$$\psi_2(\mathbf{x}_2) = \int P_{21}(\mathbf{x}_2, \mathbf{x}_1) d\Sigma_1 \psi_1. \quad (8.26)$$

If ψ_1 were a delta function, then the output would be simply given by the function P_{21} , up to normalization. For this reason, P_{21} is usually known as the *point-spread function*. Alternatively, we can think of it as a *propagator*. If we now combine two optical devices sequentially, so the output ψ_2 of the first device is the input to the second, then the point-spread functions combine in the natural manner of any linear propagator to give a total point-spread function

combining point-spread
functions

$$P_{31}(\mathbf{x}_3, \mathbf{x}_1) = \int P_{32}(\mathbf{x}_3, \mathbf{x}_2) d\Sigma_2 P_{21}(\mathbf{x}_2, \mathbf{x}_1). \quad (8.27)$$

Just as the simplest matrix for paraxial, geometric-optics propagation is that for free propagation through some distance d , so also the simplest point-spread function is that for free propagation. From Eq. (8.22) we see that it is given by

free-propagation point-
spread function

$$P_{21} = \frac{-ik}{2\pi d} e^{ikd} \exp\left(\frac{ik(\mathbf{x}_2 - \mathbf{x}_1)^2}{2d}\right) \quad (8.28)$$

for free propagation through a distance $d = z_2 - z_1$.

6. The approach followed here has an interesting history. It originated in the treatment of Markov processes by Norbert Wiener and others (see Sec 6.3). It was then cleverly adopted for use in quantum mechanics and quantum field theory by Paul Dirac, Richard Feynman, and others, where it constitutes the path integral formulation. This, in turn, suggested the simpler adaptation to problems in classical optics laid out here.

FIGURE 8.15 Wave theory of a single converging lens. The focal plane is a distance f (lens focal length) from the lens plane; and the image plane is a distance $v = fu/(u - f)$ from the lens plane.

Note that this P_{21} depends only on $\mathbf{x}_2 - \mathbf{x}_1$ as it should, and not on \mathbf{x}_2 or \mathbf{x}_1 individually, because there is joint translational invariance in the transverse $\mathbf{x}_1, \mathbf{x}_2$ planes.

A thin lens adds or subtracts an extra phase $\Delta\varphi$ to the wave, and $\Delta\varphi$ depends quadratically on distance $|\mathbf{x}|$ from the optic axis, so the angle of deflection, which is proportional to the gradient of the extra phase, will depend linearly on \mathbf{x} . Correspondingly, the point-spread function for a thin lens with focal length f is

$$P_{21} = \exp\left(\frac{-ik|\mathbf{x}_1|^2}{2f}\right) \delta(\mathbf{x}_2 - \mathbf{x}_1). \quad (8.29)$$

thin-lens point-spread function

For a converging lens, f is positive; for a diverging one, it is negative.

8.5.3 Abbé's Description of Image Formation by a Thin Lens

8.5.3

We can use the two point-spread functions (8.28) and (8.29) to give a wave description of the production of images by a single converging lens, in parallel to the geometric-optics description of Fig. 7.6. This description was formulated by Ernst Abbé in 1873. We develop Abbé's description in two stages. First, we propagate the wave from the source plane S a distance u in front of the lens, through the lens L , and to its focal plane F a distance f behind the lens (Fig. 8.15). Then we propagate the wave a further distance $v - f$ from the focal plane to the image plane. We know from geometric optics that $v = fu/(u - f)$ [Eq. (7.58)]. We restrict ourselves to $u > f$, so v is positive and the lens forms a real, inverted image.

Using Eqs. (8.27)–(8.29), we obtain the following expression for the propagator from the source plane S through the lens plane L to the focal plane F :

$$\begin{aligned}
 P_{FS} &= \int P_{FL} d\Sigma_L P_{LS} \\
 &= \int \frac{-ik}{2\pi f} e^{ikf} \exp\left(\frac{ik(\mathbf{x}_F - \mathbf{x}_L)^2}{2f}\right) d\Sigma_L \delta(\mathbf{x}_L - \mathbf{x}_S) \exp\left(\frac{-ik|\mathbf{x}_L|^2}{2f}\right) \\
 &\quad \times d\Sigma_L \frac{-ik}{2\pi u} e^{iku} \exp\left(\frac{ik(\mathbf{x}_L - \mathbf{x}_S)^2}{2u}\right) \\
 &= \frac{-ik}{2\pi f} e^{ik(f+u)} \exp\left(\frac{-ikx_F^2}{2(v-f)}\right) \exp\left(\frac{-ik\mathbf{x}_F \cdot \mathbf{x}_S}{f}\right). \tag{8.30}
 \end{aligned}$$

Here we have extended all integrations to $\pm\infty$ and have used the values of the Fresnel integrals at infinity, $\mathcal{E}(\pm\infty) = \pm(1+i)/2$, to get the expression on the last line. The wave in the focal plane is given by $\psi_F(\mathbf{x}_F) = \int P_{FS} d\Sigma_S \psi_S(\mathbf{x}_S)$, which integrates to

$$\psi_F(\mathbf{x}_F) = -\frac{ik}{2\pi f} e^{ik(f+u)} \exp\left(\frac{-ikx_F^2}{2(v-f)}\right) \tilde{\psi}_S(\mathbf{x}_F/f). \tag{8.31}$$

Here

$$\tilde{\psi}_S(\boldsymbol{\theta}) = \int d\Sigma_S \psi_S(\mathbf{x}_S) e^{-ik\boldsymbol{\theta} \cdot \mathbf{x}_S}. \tag{8.32}$$

Equation (8.31) states that the field in the focal plane is, apart from a phase factor, proportional to the Fourier transform of the field in the source plane [recall our optics convention Eq. (8.11a) for the Fourier transform]. In other words, *the focal-plane field is the Fraunhofer diffraction pattern of the input wave*. That this has to be the case can be understood from Fig. 8.15. The focal plane F is where the converging lens brings parallel rays from the source plane to a focus. By doing so, the lens in effect brings in from “infinity” the Fraunhofer diffraction pattern of the source [Eq. (8.11a)]⁷ and places it into the focal plane.

It now remains to propagate the final distance from the focal plane to the image plane. We do so with the free-propagation point-spread function (8.28): $\psi_I = \int P_{IF} d\Sigma_F \psi_F$, which integrates to

$$\psi_I(\mathbf{x}_I) = -\left(\frac{u}{v}\right) e^{ik(u+v)} \exp\left(\frac{ikx_I^2}{2(v-f)}\right) \psi_S(\mathbf{x}_S = -\mathbf{x}_I u/v). \tag{8.33}$$

7. In Eq. (8.11a), the input wave at the system’s entrance aperture is $\psi_S = \psi' \mathfrak{t}(\mathbf{x}) \propto \mathfrak{t}(\mathbf{x})$ [Eq. (8.6) and Fig. 8.2], the Fraunhofer diffraction pattern is $\psi_P \propto \mathfrak{t}(\boldsymbol{\theta})$, and the lens produces the focal-plane field $\psi_F \propto \mathfrak{t}(\mathbf{x}_F/f)$.

Thus (again ignoring a phase factor) the wave in the image plane is just a magnified and inverted version of the wave in the source plane, as we might have expected from geometric optics. In words, the lens acts by taking the Fourier transform of the source and then takes the Fourier transform again to recover the source structure.

8.5.4 Image Processing by a Spatial Filter in the Focal Plane of a Lens: High-Pass, Low-Pass, and Notch Filters; Phase-Contrast Microscopy

8.5.4

The focal plane of a lens is a convenient place to process an image by altering its Fourier transform. This process, known as *spatial filtering*, is a powerful technique. We shall gain insight into its power via several examples.

spatial filtering

In each of these examples, we assume for simplicity the one-lens system of Fig. 8.15, for which we worked out Abbé's description in the previous section. If the source wave has planar phase fronts parallel to the source plane so ψ_S is real, then the output wave in the image plane has spherical phase fronts, embodied in the phase factor $\exp[ikx_f^2/(2(v-f))]$. If, instead, one wants the output wave to have the same planar phase fronts as the input wave, one can achieve that by using a two-lens system with the lenses separated by the sum of the lenses' focal lengths and altering the Fourier transform occurring in the common focal plane between them (Ex. 8.11).

LOW-PASS FILTER: CLEANING A LASER BEAM

In low-pass filtering, a small circular aperture or "stop" is introduced into the focal plane, thereby allowing only the low-order spatial Fourier components (long-wavelength components) to be transmitted to the image plane. This produces a considerable smoothing of the wave. An application is to the output beam from a laser (Chap. 10), which ought to be smooth but in practice has high spatial frequency structure (high transverse wave numbers, short wavelengths) on account of noise and imperfections in the optics. A low-pass filter can be used to clean the beam. In the language of Fourier transforms, if we multiply the transform of the source, in the focal plane, by a small-diameter circular aperture function, we will thereby convolve the image with a broad Airy-disk smoothing function.

aperture stop to remove
high spatial-frequency
noise

HIGH-PASS FILTER: ACCENTUATING AN IMAGE'S FEATURES

Conversely, we can exclude the low spatial frequencies with a high-pass filter (e.g., by placing an opaque circular disk in the focal plane, centered on the optic axis). This accentuates boundaries and discontinuities in the source's image and can be used to highlight features where the gradient of the brightness is large.

high-pass filter to
accentuate edges

NOTCH FILTER: REMOVING PIXELATION FROM AN IMAGE

Another type of filter is used when the image is pixelated and thus has unwanted structure with wavelength equal to pixel size. A narrow range of frequencies centered around this spatial frequency is removed by putting an appropriate filter in the focal plane; this is sometimes called a "notch filter."

notch filter to remove
pixelations

FIGURE 8.16 Schematic phase-contrast microscope.

PHASE-CONTRAST MICROSCOPY

Phase-contrast microscopy (Fig. 8.16) is a useful technique for studying small objects, such as transparent biological specimens, that modify the phase of coherent illuminating light but not its amplitude. Suppose that the differential phase change in the object is small, $|\varphi| \ll 1$, as often is the case for biological specimens. We can then write the field just after it passes through the specimen as

$$\psi_S(\mathbf{x}) = H(\mathbf{x})e^{i\varphi(\mathbf{x})} \simeq H(\mathbf{x}) + i\varphi(\mathbf{x})H(\mathbf{x}). \quad (8.34)$$

Here H is the microscope's aperture function, unity for $|\mathbf{x}| < D/2$ and zero for $|\mathbf{x}| > D/2$, with D the aperture diameter. The energy flux is not modulated, and therefore the effect of the specimen on the wave is hard to observe unless one is clever.

Equation (8.34) and the linearity of the Fourier transform imply that the wave in the focal plane is the sum of (i) the Fourier transform of the aperture function [Eq. (8.18) and Ex. 8.4] and (ii) the transform of the phase function convolved with that of the aperture [in which the fine-scale variations of the phase function dominate and push $\tilde{\varphi}$ to large radii in the focal plane (Fig. 8.16), where the aperture has little influence]:

$$\psi_F \sim \text{jinc}\left(\frac{kD|\mathbf{x}_F|}{2f}\right) + i\tilde{\varphi}\left(\frac{\mathbf{x}_F}{f}\right), \quad \text{where } \text{jinc}(x) = J_1(x)/x. \quad (8.35)$$

If a high-pass filter is used to remove the Airy disk completely, then the remaining wave field in the image plane will be essentially φ magnified by v/u . However, the energy flux $F \propto (\varphi v/u)^2$ will be quadratic in the phase, and so the contrast in the image will still be small. A better technique is to phase shift the Airy disk in the focal plane by $\pi/2$ so that the two terms in Eq. (8.35) are in phase. The flux variations, $F \sim (1 \pm \varphi)^2 \simeq 1 \pm 2\varphi$, will now be linear in the phase φ . An even better procedure is

converting phase changes to amplitude changes

FIGURE 8.17 Two-lens system for spatial filtering.

to attenuate the Airy disk until its amplitude is comparable with the rms value of φ and also phase shift it by $\pi/2$ (as indicated by the “1/4-wave phase plate and attenuator” in Fig. 8.16). This will maximize the contrast in the final image. Analogous techniques are used in communications to interconvert amplitude-modulated and phase-modulated signals.

EXERCISES

Exercise 8.11 ***Example: Two-Lens Spatial Filter*

Figure 8.17 depicts a two-lens system for spatial filtering (also sometimes called a “ $4f$ system,” since it involves five special planes separated by four intervals with lengths equal to the common focal length f of the two lenses). Develop a description, patterned after Abbé’s, of image formation with this system. Most importantly, do the following.

- (a) Show that the field at the filter plane is

$$\psi_F(\mathbf{x}_F) = -\frac{ik}{2\pi f} e^{2ikf} \tilde{\psi}_S(\mathbf{x}_F/f). \quad (8.36a)$$

This is like Eq. (8.31) for the one-lens system but with the spatially dependent phase factor $\exp[-ikx_F^2/(2(v-f))]$ gone, so aside from a multiplicative constant, the filter-plane field is precisely the Fourier transform of the source-plane field.

- (b) In the filter plane we place a filter whose transmissivity we denote $\tilde{K}(-\mathbf{x}_F/f)$, so it is (proportional to) the filter-plane field that would be obtained from some source-plane field $K(-\mathbf{x}_S)$. Using the optics conventions (8.11) for the Fourier transform and its inverse, show that the image-plane field, with the filter present, is

$$\psi_I(\mathbf{x}_I) = -e^{4ikf} \Psi_S(\mathbf{x}_S = -\mathbf{x}_I). \quad (8.36b)$$

Here Ψ_S is the convolution of the source field and the filter function

$$\Psi_S(\mathbf{x}_S) = \int K(\mathbf{x}_S - \mathbf{x}') \psi_S(\mathbf{x}') d\Sigma'. \quad (8.36c)$$

In the absence of the filter, Ψ_S is equal to ψ_S , so Eq. (8.36b) is like the image-plane field (8.33) for the single-lens system, but with the spatially dependent phase factor $\exp[-ikx_F^2/(2(v-f))]$ gone. Thus ψ_I is precisely the same as the inverted ψ_S , aside from an overall phase.

Exercise 8.12 *Problem: Convolution via Fourier Optics*

- (a) Suppose that you have two thin sheets with transmission functions $t = g(x, y)$ and $t = h(x, y)$, and you wish to compute via Fourier optics the convolution

$$g \otimes h(x_o, y_o) \equiv \iint g(x, y) h(x_o - x, y_o - y) dx dy. \quad (8.37)$$

Devise a method for doing so using Fourier optics. [Hint: Use several lenses and a projection screen with a pinhole through which passes light whose energy flux is proportional to the convolution; place the two sheets at strategically chosen locations along the optic axis, and displace one of the two sheets transversely with respect to the other.]

- (b) Suppose you wish to convolve a large number of different pairs of 1-dimensional functions $\{g_1 h_1\}, \{g_2 h_2\}, \dots$ simultaneously; that is, you want to compute

$$g_j \otimes h_j(x_o) \equiv \int g_j(x) h_j(x_o - x) dx \quad (8.38)$$

for $j = 1, 2, \dots$. Devise a way to do this via Fourier optics using appropriately constructed transmissive sheets and cylindrical lenses.

Exercise 8.13 ***Example: Transmission Electron Microscope*

In a transmission electron microscope, electrons, behaving as waves, are prepared in near-plane-wave quantum wave-packet states with transverse sizes large compared to the object (“sample”) being imaged. The sample, placed in the source plane of Fig. 8.15, is sufficiently thin—with a transmission function $t(\mathbf{x})$ —that the electron waves can pass through it, being diffracted in the process. The diffracted waves travel through the lens shown in Fig. 8.15 (the *objective lens*), then onward to and through a second lens, called the *projector lens*, which focuses them onto a fluorescent screen that shines with an energy flux proportional to the arriving electron flux. At least two lenses are needed, as in the simplest of optical microscopes and telescopes (Figs. 7.7 and 7.8), and for the same reason: to make images far larger than could be achieved with a single lens.

- (a) The electrons all have the same kinetic energy $E \sim 200$ keV, to within an energy spread $\Delta E \sim 1$ eV. What is the wavelength λ of their nearly plane-wave quantum wave functions, and what is their fractional wavelength spread $\Delta\lambda/\lambda$? Your

answer for λ (\sim a few picometers) is so small that electron microscopy can be used to study atoms and molecules. Contrast this with light's million-fold longer wavelength $\sim 1 \mu\text{m}$, which constrains it to imaging objects a million times larger than atoms.

- (b) Explain why the paraxial Fourier-optics formalism that we developed in Sec. 8.5 can be used without change to analyze this electron microscope. This is true even though the photons of an ordinary microscope are in states with mean occupation numbers η huge compared to unity while the electrons have $\eta \ll 1$, and the photons have zero rest mass while the electrons have finite rest mass m with roughly the same magnitude as their kinetic energies, $E \sim mc^2$.
- (c) Suppose that each magnetic lens in the electron microscope is made of two transverse magnetic quadrupoles, as described in Sec. 7.4.2. Show that, although these quadrupoles are far from axisymmetric, their combined influence on each electron's wave function is given by the axisymmetric thin-lens point-spread function (8.29) with focal length (7.66), to within the accuracy of the analysis of Sec. 7.4.2. [In practice, higher-order corrections make the combined lens sufficiently nonaxisymmetric that electron microscopes do not use this type of magnetic lens. Instead they use a truly axisymmetric lens in which the magnetic field lines lie in planes of constant azimuthal angle ϕ , and the field lines first bend the electron trajectories into helices (give them motion in the ϕ direction), then bend them radially, and then undo the helical motion.]
- (d) By appropriate placement of the projector lens, the microscope can produce, in the fluorescing plane, either a vastly enlarged image of the source-plane sample, $|\mathbf{t}(\mathbf{x})|^2$, or a large image of the modulus of that object's Fourier transform (the object's diffraction pattern), $|\tilde{\mathbf{t}}(\mathbf{k})|^2$. Explain how each of these is achieved.

8.5.5 Gaussian Beams: Optical Cavities and Interferometric Gravitational-Wave Detectors

8.5.5

The mathematical techniques of Fourier optics enable us to analyze the structure and propagation of light beams that have Gaussian profiles. Such Gaussian beams are the natural output of ideal lasers; they are the real output of spatially filtered lasers; and they are widely used for optical communication, interferometry, and other practical applications. Moreover, they are the closest one can come in the real world of wave optics to the idealization of a geometric-optics pencil beam.

Consider a beam that is precisely plane-fronted, with a Gaussian profile, at location $z = 0$ on the optic axis:

$$\psi_0 = \exp\left(\frac{-\varpi^2}{\sigma_0^2}\right); \quad (8.39)$$

freely propagating
Gaussian beam

here $\varpi = |\mathbf{x}|$ is radial distance from the optic axis. The form of this same wave at a distance z farther down the optic axis can be computed by propagating this ψ_0 using the point-spread function (8.28) (with the distance d replaced by z). The result is

$$\psi_z = \frac{\sigma_0}{\sigma_z} \exp\left(\frac{-\varpi^2}{\sigma_z^2}\right) \exp\left[i\left(\frac{k\varpi^2}{2R_z} + kz - \arctan\frac{z}{z_0}\right)\right], \quad (8.40a)$$

where

$$z_0 = \frac{k\sigma_0^2}{2} = \frac{\pi\sigma_0^2}{\lambda}, \quad \sigma_z = \sigma_0(1 + z^2/z_0^2)^{1/2}, \quad R_z = z(1 + z_0^2/z^2), \quad (8.40b)$$

and a subscript z indicates that this quantity is a function of z . These equations for the freely propagating Gaussian beam are valid for negative z as well as positive.

From these equations we learn the following properties of the beam:

- The beam's cross sectional energy-flux distribution

$$F \propto |\psi_z|^2 \propto \exp(-\varpi^2/\sigma_z^2)$$

remains a Gaussian as the wave propagates, with a beam radius

beam radius

$$\sigma_z = \sigma_0 \sqrt{1 + z^2/z_0^2}$$

that is a minimum at $z = 0$ (the beam's *waist*) and grows away from the waist, both forward and backward, in just the manner to be expected from our uncertainty-principle discussion of wavefront spreading [Eq. (8.9)]. At distances $|z| \ll z_0$ from the waist location (corresponding to a Fresnel length $r_F = \sqrt{\lambda|z|} \ll \sqrt{\pi}\sigma_0$), the beam radius is nearly constant; this is the Fresnel region. At distances $z \gg z_0$ ($r_F \gg \sqrt{\pi}\sigma_0$), the beam radius increases linearly [i.e., the beam spreads with an opening angle $\theta = \sigma_0/z_0 = \lambda/(\pi\sigma_0)$]; this is the Fraunhofer region.

- The beam's wavefronts (surfaces of constant phase) have phase

$$\varphi = k\varpi^2/(2R_z) + kz - \arctan(z/z_0) = \text{constant}.$$

Gouy phase

The arctan term (called the wave's *Gouy phase*) varies far far more slowly with changing z than does the kz term, so the wavefronts are almost precisely $z = -\varpi^2/2R_z + \text{const}$, which is a segment of a sphere of radius R_z . Thus, the wavefronts are spherical, with radii of curvature $R_z = z(1 + z_0^2/z^2)$, which is infinite (flat phase fronts) at the waist $z = 0$, decreases to a minimum of $2z_0$ at $z = z_0$ (boundary between Fresnel and Fraunhofer regions and beginning of substantial wavefront spreading), and then increases as z (gradual flattening of spreading wavefronts) when one moves deep into the Fraunhofer region.

- The Gaussian beam's form [Eqs. (8.40)] at some arbitrary location is fully characterized by three parameters: the wavelength $\lambda = 2\pi/k$, the distance z to the waist, and the beam radius σ_0 at the waist [from which one can compute the local beam radius σ_z and the local wavefront radius of curvature R_z via Eqs. (8.40b)].

One can easily compute the effects of a thin lens on a Gaussian beam by folding the ψ_z at the lens's location into the lens point-spread function (8.29). The result is a phase change that preserves the general Gaussian form of the wave but alters the distance z to the waist and the radius σ_0 at the waist. Thus, by judicious placement of lenses or mirrors and with judicious choices of the lenses' and mirrors' focal lengths, one can tailor the parameters of a Gaussian beam to fit whatever optical device one is working with. For example, if one wants to send a Gaussian beam into a self-focusing optical fiber (Exs. 7.8 and 8.14), one should place its waist at the entrance to the fiber and adjust its waist size there to coincide with that of the fiber's Gaussian mode of propagation (the mode analyzed in Ex. 8.14). The beam will then enter the fiber smoothly and will propagate steadily along the fiber, with the effects of the transversely varying index of refraction continually compensating for the effects of diffraction so as to keep the phase fronts flat and the waist size constant.

tailoring the beam parameters

Gaussian beams are used (among many other places) in interferometric gravitational-wave detectors, such as LIGO (the Laser Interferometer Gravitational-Wave Observatory). We shall learn how these *GW interferometers* work in Sec. 9.5. For the present, all we need to know is that a GW interferometer entails an optical cavity formed by mirrors facing each other, as in Fig. 7.9. A Gaussian beam travels back and forth between the two mirrors, its light superposing on itself coherently after each round trip—the light *resonates* in the cavity formed by the two mirrors. Each mirror hangs from an overhead support, and when a gravitational wave passes, it pushes the hanging mirrors back and forth with respect to each other, causing the cavity to lengthen and shorten by a tiny fraction of a light wavelength. This puts a minuscule phase shift on the resonating light, which is measured by allowing some of the light to leak out of the cavity and interfere with light from another, similar cavity (see Sec. 9.5).

use of Gaussian beams in LIGO

For the light to resonate in the cavity, the mirrors' surfaces must coincide with the Gaussian beam's wavefronts. Suppose that the mirrors are identical, with radii of curvature R , and are separated by a distance $L = 4$ km, as in LIGO. Then the beam must be symmetric around the center of the cavity, so its waist must be halfway between the mirrors. What is the smallest that the beam radius can be at the mirrors' locations $z = \pm L/2 = \pm 2$ km? From $\sigma_z = \sigma_0(1 + z^2/z_0^2)^{1/2}$ together with $z_0 = \pi\sigma_0^2/\lambda$, we see that $\sigma_{L/2}$ is minimized when $z_0 = L/2 = 2$ km. If the wavelength is $\lambda = 1.064 \mu\text{m}$ (Nd:YAG—neodymium-doped yttrium aluminum garnet—laser light, as in LIGO), then the beam radii at the waist and at the mirrors are $\sigma_0 = \sqrt{\lambda z_0/\pi} = \sqrt{\lambda L/2\pi} = 2.6$ cm, and $\sigma_{L/2} = \sqrt{2}\sigma_0 = 3.7$ cm, respectively, and the mirrors' radii of curvature are $R_{L/2} = L = 4$ km. This was approximately the regime of parameters used for

LIGO's initial GW interferometers, which carried out a 2-year-long search for gravitational waves from autumn 2005 to autumn 2007 and then, after some sensitivity improvements, a second long search in 2009 and 2010.

A new generation of GW interferometers, called “Advanced LIGO” (LIGO Scientific Collaboration, 2015), began operating in summer 2015 and shortly thereafter discovered gravitational waves. In these GW interferometers, the spot sizes on the mirrors are enlarged, so as to reduce thermal noise by averaging over a much larger spatial sampling of thermal fluctuations of the mirror surfaces (cf. Secs. 6.8.2 and 11.9.2). How were the spot sizes enlarged? From Eqs. (8.40b) we see that, in the limit $z_0 = \pi\sigma_0^2/\lambda \rightarrow 0$, the mirrors' radii of curvature approach the cavity half-length, $R_{L/2} \rightarrow L/2$, and the beam radii on the mirrors diverge as $\sigma_{L/2} \rightarrow L\lambda/(2\pi\sigma_0) \rightarrow \infty$. This is the same instability as we discovered in the geometric-optics limit (Ex. 7.12). Advanced LIGO takes advantage of this instability by moving toward the near-unstable regime, causing the beams on the mirrors to enlarge. In Advanced LIGO's semifinal design, the mirrors' radii of curvature were set at $R_{L/2} = 2.076$ km, just 4% above the unstable point $R = L/2 = 2$ km; and Eqs. (8.40b) then tell us that $\sigma_0 = 1.15$ cm, $z_0 = 0.389$ km $\ll L/2 = 2$ km, and σ_z was pushed up by nearly a factor of two, to $\sigma_z = 6.01$ cm. The mirrors are deep into the Fraunhofer, wavefront-spreading region. In the final design the optical cavity was made slightly asymmetric with mirror radii of curvature a bit below and a bit above 2.076 km (Table 1 of LIGO Scientific Collaboration, 2015).

EXERCISES

Exercise 8.14 *Problem: Guided Gaussian Beams*

Consider a self-focusing optical fiber discussed in Ex. 7.8, in which the refractive index is

$$n(\mathbf{x}) = n_o(1 - \alpha^2 r^2)^{1/2}, \quad (8.41)$$

where $r = |\mathbf{x}|$.

- Write down the Helmholtz equation in cylindrical polar coordinates and seek an axisymmetric mode for which $\psi = R(r)Z(z)$, where R and Z are functions to be determined, and z measures distance along the fiber. In particular, show that there exist modes with a Gaussian radial profile that propagate along the fiber without spreading.
- Compute the group and phase velocities along the fiber for this mode.

Exercise 8.15 *Example: Noise Due to Scattered Light in LIGO*

In LIGO and other GW interferometers, one potential source of noise is scattered light. When the Gaussian beam in one of LIGO's cavities reflects off a mirror, a small portion of the light gets scattered toward the walls of the cavity's vacuum tube. Some of this scattered light can reflect or scatter off the tube wall and then propagate toward the distant mirror, where it scatters back into the Gaussian beam; see Fig. 8.18a (without

FIGURE 8.18 (a) Scattered light in LIGO’s beam tube. (b) Cross section of a baffle used to reduce the noise due to scattered light.

the baffles, which are shown dashed). This is troublesome because the tube wall vibrates from sound-wave excitations and seismic excitations, and those vibrations put a phase shift on the scattered light. Although the fraction of all the light that scatters in this way is tiny, the phase shift is huge compared to that produced in the Gaussian beam by gravitational waves. When the tiny amount of scattered light with its huge oscillating phase shift recombines into the Gaussian beam, it produces a net Gaussian-beam phase shift that can be large enough to mask a gravitational wave. This exercise explores some aspects of this scattered-light noise and its control.

- (a) The scattering of Gaussian-beam light off the mirror is caused by bumps in the mirror surface (imperfections). Denote by $h(\mathbf{x})$ the height of the mirror surface relative to the desired shape (a segment of a sphere with radius of curvature that matches the Gaussian beam’s wavefronts). Show that, if the Gaussian-beam field emerging from a perfect mirror is $\psi^G(\mathbf{x})$ [Eq. (8.40a)] at the mirror plane, then the beam emerging from the actual mirror is $\psi'(\mathbf{x}) = \psi^G(\mathbf{x}) \exp[-i2kh(\mathbf{x})]$. The magnitude of the mirror irregularities is very small compared to a wavelength, so $|2kh| \ll 1$, and the wave field emerging from the mirror is $\psi'(\mathbf{x}) = \psi^G(\mathbf{x})[1 - i2kh(\mathbf{x})]$. Explain why the factor 1 does not contribute at all to the scattered light (where does its light go?), so the scattered light field emerging from the mirror is

$$\psi^S(\mathbf{x}) = -i\psi^G(\mathbf{x})2kh(\mathbf{x}). \tag{8.42}$$

- (b) Assume that, when arriving at the vacuum-tube wall, the scattered light is in the Fraunhofer region. (You will justify this later in this example.) Then at the tube wall, the scattered light field is given by the Fraunhofer formula

$$\psi^S(\boldsymbol{\theta}) \propto \int \psi^G(\mathbf{x}) kh(\mathbf{x}) e^{ik\mathbf{x}\cdot\boldsymbol{\theta}} d\Sigma. \quad (8.43)$$

Show that the light that hits the tube wall at an angle $\theta = |\boldsymbol{\theta}|$ to the optic axis arises from irregularities in the mirror that have spatial wavelengths $\lambda_{\text{mirror}} \sim \lambda/\theta$. The radius of the beam tube is $\mathcal{R} = 60$ cm in LIGO, and the length of the tube (distance between cavity mirrors) is $L = 4$ km. What is the spatial wavelength of the mirror irregularities that scatter light to the tube wall at distances $z \sim L/2$ (which can then reflect or scatter off the wall toward the distant mirror and there scatter back into the Gaussian beam)? Show that for these irregularities, the tube wall is indeed in the Fraunhofer region. [Hint: The irregularities have a coherence length of only a few wavelengths λ_{mirror} .]

- (c) In the initial LIGO interferometers, the mirrors' scattered light consisted of two components: one peaked strongly toward small angles so it hit the distant tube wall (e.g., at $z \sim L/2$), and the other roughly isotropically distributed. What is the size of the irregularities that produced the isotropic component?
- (d) To reduce substantially the amount of scattered light reaching the distant mirror via reflection or scattering from the tube wall, a set of baffles was installed in the tube, in such a way as to hide the wall from scattered light (dashed lines in Fig. 8.18). The baffles have an angle of 35° to the tube wall, so when light hits a baffle, it reflects at a steep angle, $\sim 70^\circ$ toward the opposite tube wall, and after a few bounces gets absorbed. However, a small portion of the scattered light can now *diffract* off the top of each baffle and then propagate to the distant mirror and scatter back into the main beam. Especially troublesome is the case of a mirror in the center of the beam tube's cross section, because light that scatters off such a mirror travels nearly the same total distance from the mirror to the top of some baffle and then to the distant mirror, independent of the azimuthal angle ϕ on the baffle at which it diffracts. There is then a danger of *coherent superposition* of all scattered light that diffracts off all angular locations around any given baffle—and coherent superposition means a much enlarged net noise (a variant of the Poisson or Arago spot discussed in the footnote to Ex. 8.9). To protect against any such coherence, the baffles in the LIGO beam tubes are serrated (i.e., they have sawtooth edges), and the heights of the teeth are drawn from a random (Gaussian) probability distribution (Fig. 8.18b). The typical tooth heights are large enough to extend through about six Fresnel zones. How wide is each Fresnel zone at the baffle location, and correspondingly, how high must be the typical baffle tooth? By approximately how much do the random serrations reduce the light-scattering noise, relative to what it would be with no serrations and with coherent scattering? [Hint: See part e. There are two ways that the noise is reduced: (i) The breaking

of coherence of scattered light by the randomness of serrated tooth height, which causes the phase of the scattered light diffracting off different teeth to be randomly different. (ii) The reduction in energy flux of the scattered light due to the teeth reaching through six Fresnel zones, on average.]

- (e) To aid you in answering part d, show that the propagator (point-spread function) for light that begins at the center of one mirror, travels to the edge of a baffle, and then propagates to the center of the distant mirror is

$$P \propto \int_0^{2\pi} \exp\left(\frac{ikR^2(\phi)}{2\ell_{\text{red}}}\right) d\phi, \quad \text{where} \quad \frac{1}{\ell_{\text{red}}} = \frac{1}{\ell} + \frac{1}{L - \ell}. \quad (8.44)$$

Here $R(\phi)$ is the radial distance of the baffle edge from the beam tube axis at azimuthal angle ϕ around the beam tube, and at distance ℓ down the tube from the scattering mirror. Note that ℓ_{red} is the “reduced baffle distance” analogous to the reduced mass in a binary system. One can show that the time-varying part of the scattered-light amplitude (i.e., the part whose time dependence is produced by baffle vibrations) is proportional to this propagator. Explain why this is plausible. Then explain how the baffle serrations, embodied in the ϕ dependence of $R(\phi)$, produce the reduction of scattered-light amplitude in the manner described in part c.

8.6 Diffraction at a Caustic

In Sec. 7.5, we described how caustics can be formed in general in the geometric-optics limit (e.g., on the bottom of a swimming pool when the water’s surface is randomly rippled, or behind a gravitational lens). We chose as an example an imperfect lens illuminated by a point source (Fig. 7.13) and showed how a pair of images would merge as the transverse distance x of the observer from the caustic decreases to zero. That merging was controlled by maxima and minima of the scaled time delay \tilde{t} or equivalently, the phase φ of the light that originates at transverse location a just before the lens and arrives at transverse location x in the observation plane. We argued that for a fold caustic, this phase, when expressed as a Taylor series in a , has the standard form $\varphi(\tilde{a}, \tilde{x}) = \tilde{a}^3/3 - \tilde{x}\tilde{a}$, where \tilde{a} and \tilde{x} are rescaled a and x [Eq. (7.72)]. Using this φ , we showed that the magnification \mathcal{M} of the images diverged $\propto \tilde{x}^{-1/2}$ as the caustic was approached ($\tilde{x} \rightarrow 0$), and then \mathcal{M} crashed to zero just past the caustic (the two images disappeared). This singular behavior raised the question of what happens when we take into account the finite wavelength of the wave while still assuming the source has negligible size.

We are now in a position to answer this question. We simply use the Helmholtz-Kirchhoff formula (8.6) to write the expression for the amplitude measured at position \tilde{x} in the form (Ex. 8.17)

8.6

geometric optics
divergence at a fold
caustic

FIGURE 8.19 The Airy function $\text{Ai}(\xi)$ describing diffraction at a fold caustic. The argument is $\xi = -\tilde{x}$, where \tilde{x} is rescaled distance from the caustic.

$$\psi(\tilde{x}) \propto \int d\tilde{a} e^{i\varphi(\tilde{a}, \tilde{x})} = \int d\tilde{a} (\cos \varphi + i \sin \varphi), \quad \text{where } \varphi = \frac{\tilde{a}^3}{3} - \tilde{x}\tilde{a}. \quad (8.45)$$

The phase φ varies rapidly with location \tilde{a} in the lens at large $|\tilde{a}|$, so we can treat the limits of integration as $\pm\infty$. Because $\varphi(\tilde{a}, \tilde{x})$ is odd in \tilde{a} , the sine term integrates to zero, and the cosine integral turns out to be the Airy function

diffraction at a caustic:
Airy function

$$\psi \propto \int_{-\infty}^{\infty} d\tilde{a} \cos(\tilde{a}^3/3 - \tilde{x}\tilde{a}) = 2\pi \text{Ai}(-\tilde{x}). \quad (8.46)$$

The Airy function $\text{Ai}(\xi)$ is displayed in Fig. 8.19.

The asymptotic behavior of $\text{Ai}(\xi)$ is

$$\begin{aligned} \text{Ai}(\xi) &\sim \pi^{-1/2} |\xi|^{-1/4} \sin(2|\xi|^{3/2}/3 + \pi/4), \quad \text{for } \xi \rightarrow -\infty \\ &\sim \frac{e^{-2\xi^{3/2}/3}}{2\pi^{1/2}\xi^{1/4}}, \quad \text{for } \xi \rightarrow \infty. \end{aligned} \quad (8.47)$$

diffractive field structure
at a fold caustic

We see that the amplitude ψ remains finite as the caustic is approached (as $\tilde{x} = -\xi \rightarrow 0$) instead of diverging as in the geometric-optics limit, and it decreases smoothly toward zero when the caustic is passed, instead of crashing instantaneously to zero. For $\tilde{x} > 0$ ($\xi = -\tilde{x} < 0$; left part of Fig. 8.19), where an observer sees two geometric-optics images, the envelope of ψ diminishes $\propto \tilde{x}^{-1/4}$, so the energy flux $|\psi|^2$ decreases $\propto \tilde{x}^{-1/2}$ just as in the geometric-optics limit. What is actually seen is a series of bands of alternating dark and light with their spacing calculated by using $\Delta(2\tilde{x}^{3/2}/3) = \pi$ or $\Delta\tilde{x} \propto \tilde{x}^{-1/2}$. At sufficient distance from the caustic, it is not possible to resolve these bands, and a uniform illumination of average flux is observed, so we recover the geometric-optics limit.

These near-caustic scalings and others in Ex. 8.16, like the geometric-optics scalings (Sec. 7.5), are a universal property of this type of caustic (the simplest caustic of all, the “fold”).

There is a helpful analogy, familiar from quantum mechanics. Consider a particle in a harmonic potential well in a highly excited state. Its wave function is given in the usual way using Hermite polynomials of large order. Close to the classical turning point, these functions change from being oscillatory to having exponential decay, just like the Airy function (and if we were to expand about the turning point, we would recover Airy functions). Of course, what is happening is that the probability density of finding the particle close to its turning point diverges classically, because it is moving vanishingly slowly at the turning point; the oscillations stem from interference between waves associated with the particle moving in opposite directions at the turning point.

analogy with quantum wave function in harmonic oscillator potential

For light near a caustic, if we consider the transverse component of the photon motion, then we have essentially the same problem. The field’s oscillations stem from interference of the waves associated with the motions of the photons in two geometric-optics beams coming from slightly different directions and thus having slightly different transverse photon speeds.

This is our first illustration of the formation of large-contrast interference fringes when only a few beams are combined. We shall meet other examples of such interference in the next chapter.

Exercise 8.16 *Problem: Wavelength Scaling at a Fold Caustic*

EXERCISES

For the fold caustic discussed in the text, assume that the phase change introduced by the imperfect lens is nondispersive, so that the $\varphi(\tilde{a}, \tilde{x})$ in Eq. (8.45) satisfies $\varphi \propto \lambda^{-1}$. Show that the peak magnification of the interference fringes at the caustic scales with wavelength, $\propto \lambda^{-4/3}$. Also show that the spacing Δx of the fringes near a fixed observing position x is $\propto \lambda^{2/3}$. Discuss qualitatively how the fringes will be affected if the source has a finite size.

Exercise 8.17 *Problem: Diffraction at Generic Caustics*

In Sec. 7.5, we explored five elementary (generic) caustics that can occur in geometric optics. Each is described by its phase $\varphi(\tilde{a}, \tilde{b}; \tilde{x}, \tilde{y}, \tilde{z})$ for light arriving at an observation point with Cartesian coordinates $\{\tilde{x}, \tilde{y}, \tilde{z}\}$ along paths labeled by (\tilde{a}, \tilde{b}) .

- (a) Suppose the (monochromatic) wave field $\psi(\tilde{x}, \tilde{y}, \tilde{z})$ that exhibits one of these caustics is produced by plane-wave light that impinges orthogonally on a phase-shifting surface on which are laid out Cartesian coordinates (\tilde{a}, \tilde{b}) . Using the Helmholtz-Kirchhoff diffraction integral (8.6), show that the field near a caustic is given by

$$\psi(\tilde{x}, \tilde{y}, \tilde{z}) \propto \int \int d\tilde{a} d\tilde{b} e^{i\varphi(\tilde{a}, \tilde{b}; \tilde{x}, \tilde{y}, \tilde{z})}. \quad (8.48)$$

- (b) In the text we evaluated this near-caustic diffraction integral for a fold caustic, obtaining the Airy function. For the higher-order elementary caustics, the integral cannot be evaluated analytically in terms of standard functions. To get insight into the influence of finite wavelength, evaluate the integral numerically for the case of a cusp caustic, $\varphi = \frac{1}{4}\tilde{a}^4 - \frac{1}{2}\tilde{z}\tilde{a}^2 - \tilde{x}\tilde{a}$, and plot the real and imaginary parts of ψ ($\Re\psi$ and $\Im\psi$). Before doing so, though, guess what these parts will look like. As foundations for this guess, (i) pay attention to the shape $\tilde{x} = \pm 2(\tilde{z}/3)^{3/2}$ of the caustic in the geometric-optics approximation, (ii) notice that away from the cusp point, each branch of the caustic is a fold, whose ψ is the Airy function (Fig. 8.19), and (iii) note that the oscillating ψ associated with each branch interferes with that associated with the other branch. The numerical computation may take awhile, so make a wise decision from the outset as to the range of \tilde{z} and \tilde{x} to include in your computations and plots. If your computer is really slow, you may want to prove that the integral is symmetric in \tilde{x} and so restrict yourself to positive \tilde{x} , and argue that the qualitative behaviors of $\Re\psi$ and $\Im\psi$ must be the same, and so restrict yourself to $\Re\psi$.
-

Bibliographic Note

Hecht (2017) gives a pedagogically excellent treatment of diffraction at roughly the same level as this chapter, but in much more detail, with many illustrations and intuitive explanations. Other nice treatments at about our level will be found in standard optics textbooks, including Jenkins and White (1976), Brooker (2003), Sharma (2006), Bennett (2008), Ghatak (2010), and, from an earlier era, Longhurst (1973) and Welford (1988). The definitive treatment of diffraction at an advanced and thorough level is that of Born and Wolf (1999). For an excellent and thorough treatment of paraxial Fourier optics and spatial filtering, see Goodman (2005). The standard textbooks say little or nothing about diffraction at caustics, though they should; for this, we recommend the brief treatment by Berry and Upstill (1980) and the thorough treatment by Nye (1999).

Interference and Coherence

When two Undulations, from different Origins, coincide either perfectly or very nearly in Direction, their joint effect is a Combination of the Motions belonging to each.

THOMAS YOUNG (1802)

9.1 Overview

9.1

In the last chapter, we considered superpositions of waves that pass through a (typically large) aperture. The foundation for our analysis was the Helmholtz-Kirchhoff expression (8.4) for the field at a chosen point \mathcal{P} as a sum of contributions from all points on a closed surface surrounding \mathcal{P} . The spatially varying field pattern resulting from this superposition of many different contributions is known as diffraction.

In this chapter, we continue our study of superposition, but for the special case where only two (or at most, several) discrete beams are being superposed. For this special case one uses the term *interference* rather than diffraction. Interference is important in a wide variety of practical instruments designed to measure or use the spatial and temporal structures of electromagnetic radiation. However, interference is not just of practical importance. Attempting to understand it forces us to devise ways of describing the radiation field that are independent of the field's origin and of the means by which it is probed. Such descriptions lead us naturally to the fundamental concept of coherence (Sec. 9.2).

The light from a distant, monochromatic point source is effectively a plane wave; we call it “perfectly coherent” radiation. In fact, there are two different types of coherence present: *lateral or spatial coherence* (coherence in the angular structure of the radiation field), and *temporal or longitudinal coherence* (coherence in the field's temporal structure, which clearly must imply something also about its frequency structure). We shall see in Sec. 9.2 that for both types of coherence there is a measurable quantity, called the *degree of coherence*, that is the Fourier transform of either the radiation's angular intensity distribution $I(\boldsymbol{\alpha})$ (energy flux per unit angle or solid angle, as a function of direction $\boldsymbol{\alpha}$) or its spectral energy flux $F_\omega(\omega)$ (energy flux per unit angular frequency ω , as a function of angular frequency).

Interspersed with our development of the theory of coherence are two historical devices with modern applications: (i) the stellar interferometer (Sec. 9.2.5), by which Michelson measured the diameters of Jupiter's moons and several bright stars using

 - correlation functions, spectral densities, and the Wiener-Khinchine theorem for random processes (Sec. 6.4).
- The concept of coherence length or coherence time, as developed in this chapter, is used in Chaps. 10, 15, 16, and 23.
- Interferometry as developed in this chapter, especially in Sec. 9.5, is a foundation for the discussion of gravitational-wave detection in Sec. 27.6.
- Nothing else in this book relies substantially on this chapter.

spatial coherence; and (ii) the Michelson interferometer and its practical implementation in a Fourier-transform spectrometer (Sec. 9.2.7), which use temporal coherence to measure electromagnetic spectra (e.g., the spectral energy flux of the cosmic microwave background radiation). After developing our full formalism for coherence, we go on in Sec. 9.3 to apply it to the operation of radio telescope arrays, which function by measuring the spatial coherence of the radiation field.

In Sec. 9.4, we turn to multiple-beam interferometry, in which incident radiation is split many times into several different paths and then recombined. A simple example is an etalon, made from two parallel, reflecting surfaces. A Fabry-Perot cavity interferometer, in which light is trapped between two highly reflecting mirrors (e.g., in a laser), is essentially a large-scale etalon. In Secs. 9.4.3 and 9.5, we discuss a number of applications of Fabry-Perot interferometers, including lasers, their stabilization, manipulations of laser light, the optical frequency comb, and laser interferometer gravitational-wave detectors.

Finally, in Sec. 9.6, we turn to the intensity interferometer. This has not proved especially powerful in application but does illustrate some quite subtle issues of physics and, in particular, highlights the relationship between the classical and quantum theories of light.

9.2

9.2 Coherence

9.2.1

9.2.1 Young's Slits

Young's slits

The most elementary example of interference is provided by Young's slits. Suppose two long, narrow, parallel slits are illuminated coherently by monochromatic light from a distant source that lies on the perpendicular bisector of the line joining the slits (the

FIGURE 9.1 (a) Young's slits. (b) Interference fringes observed in a transverse plane [Eq. (9.1b)]. (c) The propagation direction of the incoming waves is rotated to make an angle α to the optic axis; as a result, the angular positions of the interference fringes in panel b are shifted by $\Delta\theta = \alpha$ [Eq. (9.3); not shown]. (d) Interference fringes observed from an extended source [Eq. (9.8)].

optic axis), so an incident wavefront reaches the slits simultaneously (Fig. 9.1a). This situation can be regarded as having only one lateral dimension because of translation invariance in the other. The waves from the slits (effectively, two 1-dimensional beams) fall onto a screen in the distant, Fraunhofer region, and there they interfere. The Fraunhofer interference pattern observed at a point \mathcal{P} , whose position is specified using the polar coordinates $\{r, \theta\}$ shown in Fig. 9.1, is proportional to the spatial Fourier transform of the transmission function [Eq. (8.11a)]. If the slits are very narrow, we can regard the transmission function as two delta functions, separated by the slit separation a , and its Fourier transform will be

$$\psi(\theta) \propto e^{-ika\theta/2} + e^{ika\theta/2} \propto \cos\left(\frac{ka\theta}{2}\right), \quad (9.1a)$$

where $k = 2\pi/\lambda$ is the light's wave number, and a is the slit's separation. (That we can sum the wave fields from the two slits in this manner is a direct consequence of

the linearity of the underlying wave equation.) The *energy flux* (energy per unit time crossing a unit area) at \mathcal{P} (at angle θ to the optic axis) will be

$$F(\theta) \propto |\psi|^2 \propto \cos^2(ka\theta/2); \quad (9.1b)$$

interference fringes from Young's slits

cf. Fig. 9.1b. The alternating regions of dark and bright illumination in this flux distribution are known as *interference fringes*. Notice that the flux falls to zero between the bright fringes. This will be very nearly so even if (as is always the case in practice) the field is slightly nonmonochromatic, that is, even if the field hitting the slits has the form $e^{i[\omega_o t + \delta\varphi(t)]}$, where $\omega_o = c/k$ is the light's average angular frequency, and $\delta\varphi(t)$ is a phase [not to be confused with the light's full phase $\varphi = \omega_o t + \delta\varphi(t)$], which varies randomly on a timescale extremely long compared to $1/\omega_o$.¹ Notice also that there are many fringes, symmetrically disposed with respect to the optic axis. [If we were to take account of the finite width $w \ll a$ of the two slits, then we would find, by contrast with Eq. (9.1b), that the actual number of fringes is finite, in fact of order a/w ; cf. Fig. 8.6 and associated discussion.] This type of interferometry is sometimes known as *interference by division of the wavefront*.

interference by division of the wavefront

Young's slits in quantum mechanics

Of course, this Young's slits experiment is familiar from quantum mechanics, where it is often used as a striking example of the nonparticulate behavior of electrons (e.g., Feynman, Leighton, and Sands, 2013, Vol. III, Chap. 1). Just as for electrons, so also for photons it is possible to produce interference fringes even if only one photon is in the apparatus at any time, as was demonstrated in a famous experiment performed by G. I. Taylor in 1909. However, our concerns in this chapter are with the classical limit, where many photons are present simultaneously and their fields can be described by Maxwell's equations. In the next subsection we depart from the usual quantum mechanical treatment by asking what happens to the fringes when the source of radiation is spatially extended.

EXERCISES

Exercise 9.1 *Problem: Single-Mirror Interference*

X-rays with wavelength 8.33 \AA (0.833 nm) coming from a point source can be reflected at shallow angles of incidence from a plane mirror. The direct ray from a point source

1. More precisely, if $\delta\varphi(t)$ wanders by $\sim\pi$ on a timescale $\tau_c \gg 2\pi/\omega_o$ (the waves' *coherence time*), then the waves are contained in a bandwidth $\Delta\omega_o \sim 2\pi/\tau_c \ll \omega_o$ centered on ω_o , k is in a band $\Delta k \sim k\Delta\omega/\omega_o$, and the resulting superposition of precisely monochromatic waves has fringe minima with fluxes F_{\min} that are smaller than the maxima by $F_{\min}/F_{\max} \sim (\pi\Delta\omega/\omega_o)^2 \ll 1$. [One can see this in order of magnitude by superposing the flux (9.1b) with wave number k and the same flux with wave number $k + \Delta k$.] Throughout this section, until Eq. (9.15), we presume that the waves have such a small bandwidth (such a long coherence time) that this F_{\min}/F_{\max} is completely negligible; for example, $1 - F_{\min}/F_{\max}$ is far closer to unity than any fringe visibility V [Eq. (9.8)] that is of interest to us. This can be achieved in practice by either controlling the waves' source or by band-pass filtering the measured signals just before detecting them.

to a detector 3 m away interferes with the reflected ray to produce fringes with spacing $25 \mu\text{m}$. Calculate the distance of the X-ray source from the mirror plane.

9.2.2 Interference with an Extended Source: Van Cittert-Zernike Theorem

9.2.2

We approach the topic of extended sources in steps. Our first step was taken in the last subsection, where we dealt with an idealized, single, incident plane wave, such as might be produced by an ideal, distant laser. We have called this type of radiation “perfectly coherent,” which we have implicitly taken to mean that the field oscillates with a fixed angular frequency ω_o and a randomly but very slowly varying phase $\delta\varphi(t)$ (see footnote 1), and thus, for all practical purposes, there is a time-independent phase difference between any two points in the region under consideration.

perfect coherence

As our second step, we keep the incoming waves perfectly coherent and perfectly planar, but change their incoming direction in Fig. 9.1 so it makes a small angle α to the optic axis (and correspondingly, its wavefronts make an angle α to the plane of the slits) as shown in Fig. 9.1c. Then the distribution of energy flux in the Fraunhofer diffraction pattern on the screen will be modified to

$$F(\theta) \propto |e^{-ika(\theta-\alpha)/2} + e^{+ika(\theta-\alpha)/2}|^2 \propto \cos^2\left(\frac{ka(\theta-\alpha)}{2}\right) \propto \{1 + \cos[ka(\theta-\alpha)]\}. \quad (9.2)$$

interference fringes for perfectly coherent waves from angle α

Notice that, as the direction α of the incoming waves is varied, the locations of the bright and dark fringes change by $\Delta\theta = \alpha$, but the fringes remain fully sharp (their minima remain essentially zero; cf. footnote 1). Thus, the positions of the fringes carry information about the direction to the source.

Now, in our third and final step, we deal with an extended source (i.e., one whose radiation comes from a finite range of angles α), with (for simplicity) $|\alpha| \ll 1$. We assume that the source is monochromatic (and in practice we can make it very nearly monochromatic by band-pass filtering the waves just before detection). However, in keeping with how all realistic monochromatic sources (including band-pass filtered sources) behave, we give it a randomly fluctuating phase $\delta\varphi(t)$ [and amplitude $A(t)$], and require that the timescale on which the phase and amplitude wander (the waves’ coherence time) be long compared to the waves’ period $2\pi/\omega_o$; cf. footnote 1.

We shall also assume that the sources of the light propagating in different directions are independent and uncorrelated. Typically, they are separate electrons, ions, atoms, or molecules. To make this precise, we write the field in the form²

$$\Psi(x, z, t) = e^{i(kz - \omega_o t)} \int \psi(\alpha, t) e^{ik\alpha x} d\alpha, \quad (9.3)$$

wave field from extended source

2. As in Chap. 8, we denote the full field by Ψ and reserve ψ to denote the portion of the field from which a monochromatic part $e^{-i\omega_o t}$ or $e^{i(kz - \omega_o t)}$ has been factored out.

incoherent superposition of radiation

where $\psi(\alpha, t) = Ae^{-i\delta\phi}$ is the slowly wandering complex amplitude of the waves from direction α . When we consider the total flux arriving at a given point (x, z) from two different directions α_1 and α_2 and average it over times long compared to the waves' coherence time, then we lose all interference between the two contributions:

$$|\overline{\psi(\alpha_1, t) + \psi(\alpha_2, t)}|^2 = \overline{|\psi(\alpha_1, t)|^2} + \overline{|\psi(\alpha_2, t)|^2}. \quad (9.4)$$

Such radiation is said to be incoherent in the incoming angle α , and we say that the contributions from different directions *superpose incoherently*. This is just a fancy way of saying that their intensities (averaged over time) add linearly.

The angularly incoherent light from our extended source is sent through two Young's slits and produces fringes on a screen in the distant Fraunhofer region. We assume that the coherence time for the light from each source point is very long compared to the difference in light travel time to the screen via the two different slits. Then the light from each source point in the extended source forms the sharp interference fringes described by Eq. (9.2). However, because contributions from different source directions add incoherently, the flux distribution on the screen is a linear sum of the fluxes from source points:

$$F(\theta) \propto \int d\alpha I(\alpha) \{1 + \cos[ka(\theta - \alpha)]\}. \quad (9.5)$$

Here $I(\alpha)d\alpha \propto \overline{|\psi(\alpha, t)|^2}d\alpha$ is the flux incident on the plane of the slits from the infinitesimal range $d\alpha$ of directions, so $I(\alpha)$ is the radiation's *intensity* (its energy per unit time falling on a unit area and coming from a unit angle). The remainder of the integrand, $1 + \cos[ka(\theta - \alpha)]$, is the Fraunhofer diffraction pattern [Eq. (9.2)] for coherent radiation from direction α .

We presume that the range of angles present in the waves, $\Delta\alpha$, is large compared to their fractional bandwidth $\Delta\alpha \gg \Delta\omega/\omega_0$; so, whereas the finite but tiny bandwidth produced negligible smearing out of the interference fringes (see footnote 1 in this chapter), the finite but small range of directions may produce significant smearing [i.e., the minima of $F(\theta)$ might not be very sharp]. We quantify the fringes' non-sharpness and their locations by writing the slit-produced flux distribution (9.5) in the form

interference fringes from extended source

$$F(\theta) = F_S [1 + \Re\{\gamma_{\perp}(ka)e^{-ika\theta}\}], \quad (9.6a)$$

where

$$F_S \equiv \int d\alpha I(\alpha) \quad (9.6b)$$

(subscript S for "source") is the total flux arriving at the slits from the source, and

degree of lateral coherence

$$\gamma_{\perp}(ka) \equiv \frac{\int d\alpha I(\alpha)e^{ika\alpha}}{F_S} \quad (9.7a)$$

is defined as the radiation's *degree of spatial (or lateral) coherence*.³ The phase of γ_{\perp} determines the angular locations of the fringes; its modulus determines their depth (the amount of their smearing due to the source's finite angular size).

The nonzero value of $\gamma_{\perp}(ka)$ reflects the existence of some degree of relative coherence between the waves arriving at the two slits, whose separation is a . The radiation can have this finite spatial coherence, despite its complete lack of angular coherence, because each angle contributes coherently to the field at the two slits. The lack of coherence for different angles reduces the net spatial coherence (smears the fringes), but it does not drive the coherence all the way to zero (does not completely destroy the fringes).

Equation (9.7a) states that the degree of lateral coherence of the radiation from an extended, angularly incoherent source is the Fourier transform of the source's angular intensity pattern. Correspondingly, if one knows the degree of lateral coherence as a function of the (dimensionless) distance ka , from it one can reconstruct the source's angular intensity pattern by Fourier inversion:

$$I(\alpha) = F_S \int \frac{d(ka)}{2\pi} \gamma_{\perp}(ka) e^{-ika\alpha}. \quad (9.7b)$$

The two Fourier relations (9.7a) and (9.7b) make up the *van Cittert-Zernike theorem*. In Ex. 9.8, we shall see that this theorem is a complex-variable version of Chap. 6's *Wiener-Khinchine theorem* for random processes.

Because of its Fourier-transform relationship to the source's angular intensity pattern $I(\alpha)$, the degree of spatial coherence $\gamma_{\perp}(ka)$ is of great practical importance. For a given choice of ka (a given distance between the slits), γ_{\perp} is a complex number that one can read off the interference fringes of Eq. (9.6a) and Fig. 9.1d as follows. Its modulus is

$$|\gamma_{\perp}| \equiv V = \frac{F_{\max} - F_{\min}}{F_{\max} + F_{\min}}, \quad (9.8)$$

where F_{\max} and F_{\min} are the maximum and minimum values of the flux F on the screen; and its phase $\arg(\gamma_{\perp})$ is ka times the displacement $\Delta\theta$ of the centers of the bright fringes from the optic axis. The modulus (9.8) is called the *fringe visibility*, or simply the *visibility*, because it measures the fractional contrast in the fringes [Eq. (9.8)], and this name is the reason for the symbol V . Analogously, the complex quantity γ_{\perp} (or a close relative) is sometimes known as the *complex fringe visibility*. Notice that V can lie anywhere in the range from zero (no contrast; fringes completely undetectable) to unity (monochromatic plane wave; contrast as large as possible).

3. In Sec. 9.2.6, we introduce the degree of temporal coherence (also known as longitudinal coherence) to describe the correlation along the direction of propagation. The correlation in a general, lateral and longitudinal, direction is called the degree of coherence (Sec. 9.2.8).

van Cittert-Zernike theorem for lateral coherence

fringe visibility, or visibility

complex fringe visibility

phase of γ_{\perp}

When the phase $\arg(\gamma_{\perp})$ of the complex visibility (degree of coherence) is zero, there is a bright fringe precisely on the optic axis. This will be the case for a source that is symmetric about the optic axis, for example. If the symmetry point of such a source is gradually moved off the optic axis by an angle $\delta\alpha$, the fringe pattern will shift correspondingly by $\delta\theta = \delta\alpha$, which will show up as a corresponding shift in the argument of the fringe visibility, $\arg(\gamma_{\perp}) = ka\delta\alpha$.

The above analysis shows that Young's slits, even when used virtually, are nicely suited to measuring both the modulus and the phase of the complex fringe visibility (the degree of spatial coherence) of the radiation from an extended source.

9.2.3

9.2.3 More General Formulation of Spatial Coherence; Lateral Coherence Length

It is not necessary to project the light onto a screen to determine the contrast and angular positions of the fringes. For example, if we had measured the field at the locations of the two slits, we could have combined the signals electronically and cross correlated them numerically to determine what the fringe pattern would be with slits. All we are doing with the Young's slits is sampling the wave field at two different points, which we now label 1 and 2. Observing the fringes corresponds to adding a phase φ ($= ka\theta$) to the field at one of the points and then adding the fields and measuring the flux $\propto |\psi_1 + \psi_2 e^{i\varphi}|^2$ averaged over many periods. Now, since the source is far away, the rms value of the wave field will be the same at the two slits: $\overline{|\psi_1|^2} = \overline{|\psi_2|^2} \equiv \overline{|\psi|^2}$. We can therefore express this time-averaged flux in the symmetric-looking form

$$\begin{aligned} F(\varphi) &\propto \overline{(\psi_1 + \psi_2 e^{i\varphi})(\psi_1^* + \psi_2^* e^{-i\varphi})} \\ &\propto 1 + \Re \left(\frac{\overline{\psi_1 \psi_2^*}}{\overline{|\psi|^2}} e^{-i\varphi} \right). \end{aligned} \quad (9.9)$$

degree of spatial coherence

Here a bar denotes an average over times long compared to the coherence times for ψ_1 and ψ_2 . Comparing with Eq. (9.6a) and using $\varphi = ka\theta$, we identify

$$\boxed{\gamma_{\perp 12} = \frac{\overline{\psi_1 \psi_2^*}}{\overline{|\psi|^2}}} \quad (9.10)$$

as the *degree of spatial coherence* in the radiation field between the two points 1 and 2. Equation (9.10) is the general definition of degree of spatial coherence. Equation (9.6a) is the special case for points separated by a lateral distance a .

If the radiation field is strongly correlated between the two points, we describe it as having strong spatial or lateral coherence. Correspondingly, we shall define a field's *lateral coherence length* l_{\perp} as the linear size of a region over which the field is strongly correlated (has $V = |\gamma_{\perp}| \sim 1$). If the angle subtended by the source is $\sim \delta\alpha$, then by virtue of the van Cittert-Zernike theorem [Eqs. (9.7)] and the usual reciprocal relation for Fourier transforms, the radiation field's lateral coherence length will be

spatial or lateral coherence length

$$l_{\perp} \sim \frac{2\pi}{k \delta\alpha} = \frac{\lambda}{\delta\alpha}. \quad (9.11)$$

This relation has a simple physical interpretation. Consider two beams of radiation coming from opposite sides of the brightest portion of the source. These beams are separated by the incoming angle $\delta\alpha$. As one moves laterally in the plane of the Young's slits, one sees a varying relative phase delay between these two beams. The coherence length l_{\perp} is the distance over which the variations in that relative phase delay are of order 2π : $k \delta\alpha l_{\perp} \sim 2\pi$.

9.2.4 Generalization to 2 Dimensions

9.2.4

We have so far just considered a 1-dimensional intensity distribution $I(\alpha)$ observed through the familiar Young's slits. However, most sources will be 2-dimensional, so to investigate the full radiation pattern, we should allow the waves to come from 2-dimensional angular directions α :

$$\Psi = e^{i(kz - \omega_0 t)} \int \psi(\alpha, t) e^{ik\alpha \cdot \mathbf{x}} d^2\alpha \equiv e^{i(kz - \omega_0 t)} \psi(\mathbf{x}, t) \quad (9.12a)$$

[where $\psi(\alpha, t)$ is slowly varying in time], and we should use several pairs of slits aligned along different directions. Stated more generally, we should sample the wave field (9.12a) at a variety of points separated by a variety of 2-dimensional vectors \mathbf{a} transverse to the direction of wave propagation. The complex visibility (degree of spatial coherence) will then be a function of $k\mathbf{a}$,

$$\gamma_{\perp}(k\mathbf{a}) = \frac{\overline{\psi(\mathbf{x}, t) \psi^*(\mathbf{x} + \mathbf{a}, t)}}{|\overline{\psi}|^2}, \quad (9.12b)$$

complex visibility,
or degree of spatial
coherence

and the van Cittert-Zernike theorem (9.7) will take the 2-dimensional form

$$\gamma_{\perp}(k\mathbf{a}) = \frac{\int d\Omega_{\alpha} I(\alpha) e^{ik\mathbf{a} \cdot \alpha}}{F_S}, \quad (9.13a)$$

2-dimensional van Cittert-
Zernike theorem

$$I(\alpha) = F_S \int \frac{d^2(k\mathbf{a})}{(2\pi)^2} \gamma_{\perp}(k\mathbf{a}) e^{-ik\mathbf{a} \cdot \alpha}. \quad (9.13b)$$

Here $I(\alpha) \propto \overline{|\psi(\alpha, t)|^2}$ is the source's *intensity* (energy per unit time crossing a unit area from a unit solid angle $d\Omega_{\alpha}$); $F_S = \int d\Omega_{\alpha} I(\alpha)$ is the source's total energy flux; and $d^2(k\mathbf{a}) = k^2 d\Sigma_a$ is a (dimensionless) surface area element in the lateral plane.

Exercise 9.2 Problem: Lateral Coherence of Solar Radiation

EXERCISES

How closely separated must a pair of Young's slits be to see strong fringes from the Sun (angular diameter $\sim 0.5^\circ$) at visual wavelengths? Suppose that this condition is

just satisfied, and the slits are $10\ \mu\text{m}$ in width. Roughly how many fringes would you expect to see?

Exercise 9.3 *Problem: Degree of Coherence for a Source*

with Gaussian Intensity Distribution

A circularly symmetric light source has an intensity distribution $I(\alpha) = I_0 \exp[-\alpha^2/(2\alpha_0^2)]$, where α is the angular radius measured from the optic axis. Compute the degree of spatial coherence. What is the lateral coherence length? What happens to the degree of spatial coherence and the interference fringe pattern if the source is displaced from the optic axis?

9.2.5

9.2.5 Michelson Stellar Interferometer; Astronomical Seeing

The classic implementation of Young's slits for measuring spatial coherence is Michelson's stellar interferometer, which Albert Michelson and Francis Pease (1921) used for measuring the angular diameters of Betelgeuse and several other bright stars in 1920.⁴ The starlight was sampled at two small mirrors separated by a variable distance $a \leq 6\ \text{m}$ and was then reflected into the 100-inch (2.5-m) telescope on Mount Wilson, California, to form interference fringes (Fig. 9.2). (As we have emphasized, the way in which the fringes are formed is unimportant; all that matters is the two locations where the light is sampled, i.e., the first two mirrors in Fig. 9.2.) As Michelson and Pease increased the separation a between the mirrors, the fringe visibility V decreased. Michelson and Pease modeled Betelgeuse (rather badly, in fact) as a circular disk of uniform brightness, $I(\alpha) = 1$ for $|\alpha| < \alpha_r$ and 0 for $|\alpha| > \alpha_r$, so its visibility was given, according to Eq. (9.13a), as

$$V = \gamma_{\perp} = 2 \text{jinc}(ka\alpha_r) \tag{9.14}$$

where α_r is the star's true angular radius, and $\text{jinc}(\xi) = J_1(\xi)/\xi$. They identified the separation $a \simeq 3\ \text{m}$, where the fringes disappeared, with the first zero of the function $\text{jinc}(ka\alpha_r)$. From this and the mean wavelength $\lambda = 575\ \text{nm}$ of the starlight, they inferred that the angular radius of Betelgeuse is $\alpha_r \sim 0.02\ \text{arcsec}$, which at Betelgeuse's then-estimated distance of 60 pc (180 light-years) corresponds to a physical radius ~ 300 times larger than that of the Sun. The modern parallax-measured distance is 200 pc, so Betelgeuse's physical radius is actually $\sim 1,000$ times larger than the Sun.

This technique only works for big, bright stars and is very difficult to use, because turbulence in Earth's atmosphere causes the fringes to keep moving around; see Box 9.2 and Ex. 9.4 for details.

4. Similar principles are relevant to imaging by Earth-observing satellites where one looks down, not up. In this case, there is the important distinction that most of the diffraction happens relatively close to the source, not the detector.

FIGURE 9.2 Schematic illustration of a Michelson stellar interferometer.

EXERCISES

Exercise 9.4 Example and Derivation: Time-Averaged Visibility and Image for a Distant Star Seen through Earth's Turbulent Atmosphere T2

Fill in the details of the analysis of time-averaged seeing in Box 9.2. More specifically, do the following. If you have difficulty, Roddier (1981) may be helpful.

- (a) Give an order-of-magnitude derivation of Eq. (4a) in Box 9.2 for the mean-square phase fluctuation of light induced by propagation through a thin, turbulent layer of atmosphere. [Hint: Consider turbulent cells of size a , each of which produces some $\delta\varphi$, and argue that the contributions add up as a random walk.]
- (b) Deduce the factor 2.91 in Eq. (4a) in Box 9.2 by evaluating

$$D_{\delta\varphi} = k^2 \left\langle \left\{ \int_z^{z+\delta h} [\delta n(\mathbf{x} + \mathbf{a}, z, t) - \delta n(\mathbf{x}, z, t)] dz \right\}^2 \right\rangle.$$

- (c) Derive Eq. (4b) in Box 9.2 for the time-averaged complex visibility after propagating through the thin layer. [Hint: Because $\zeta \equiv \delta\varphi(\mathbf{x}, t) - \delta\varphi(\mathbf{x} + \mathbf{a}, t)$ is the result of contributions from a huge number of independent turbulent cells, the central limit theorem (Sec. 6.3.2) suggests it is a Gaussian random variable though, in fact intermittency (Sec. 15.3) can make it rather non-Gaussian. Idealizing it as Gaussian, evaluate $\gamma_{\perp} = \langle e^{i\zeta} \rangle = \langle \int_{-\infty}^{\infty} p(\zeta) e^{i\zeta} d\zeta \rangle$ with $p(\zeta)$ the Gaussian distribution.]
- (d) Use the point-spread function (8.28) for free propagation of the light field ψ to show that, under free propagation, the complex visibility $\gamma_{\perp}(\mathbf{a}, z, t) = \langle \psi(\mathbf{x} + \mathbf{a}, z, t) \psi^*(\mathbf{x}, z, t) \rangle$ (with averaging over \mathbf{x} and t) is constant (i.e., independent of height z).
- (e) By combining parts c and d, deduce Eqs. (5) in Box 9.2 for the mean-square phase fluctuations and spacetime-averaged visibility on the ground.
- (f) Perform a numerical Fourier transform of $\bar{\gamma}_{\perp}(\mathbf{a})$ [Eq. (5b) in Box 9.2] to get the time-averaged intensity distribution $I(\alpha)$. Construct a log-log plot of it, and compare with panel b of the first figure in Box 9.2. What is r_o for the observational data shown in that figure?

BOX 9.2. ASTRONOMICAL SEEING, SPECKLE IMAGE PROCESSING, AND ADAPTIVE OPTICS T2

When light from a star passes through turbulent layers of Earth's atmosphere, the turbulently varying index of refraction $n(\mathbf{x}, t)$ diffracts the light in a random, time varying way. One result is "twinkling" (fluctuations in the flux observed by eye on the ground, with fluctuational frequencies $f_o \sim 100$ Hz). Another is astronomical seeing: the production of many images of the star (i.e., *speckles*) as seen through a large optical telescope (panel a of the box figure), with the image pattern fluctuating at ~ 100 Hz.

Here and in Ex. 9.4 we quantify astronomical seeing using the theory of 2-dimensional lateral coherence. We do this not because seeing is important (though it is), but rather because our analysis provides an excellent illustration of three fundamental concepts working together: (i) turbulence in fluids and its Kolmogorov spectrum (Chap. 15), (ii) random processes (Chap. 6), and (iii) coherence of light (this chapter).

We begin by deriving, for a star with arbitrarily small angular diameter, the time-averaged complex visibility γ_{\perp} observed on the ground and the visibility's Fourier transform [the observed intensity distribution averaged

(a) Picture of a bright star with a dimmer companion star, as seen through the Russian 6-m telescope in the Caucasus Mountains, in an exposure shorter than 10 ms. Atmospheric turbulence creates a large number of images of each star (speckles) spread over a region with angular diameter of order 2 arcsec. (b) The theory discussed in the text and in Ex. 9.4 predicts the solid curve for the time-averaged intensity distribution for a single bright star. Notice the logarithmic axes. The dotted curve is an estimate of the influence of the small-scale cutoff of the turbulence, and the dashed curve is a Gaussian. The circles are observational data. Panel (a), Gerd Weigelt; panel (b), adapted from Roddier (1981).

(continued)

over the speckles, $\bar{I}(\boldsymbol{\alpha})$. Then we briefly discuss the temporally fluctuating speckle pattern and techniques for extracting information from it.

TIME-AVERAGED VISIBILITY AND ANGULAR DISTRIBUTION OF INTENSITY

When analyzing light propagation through a turbulent atmosphere, it is convenient to describe the turbulent fluctuations of the index of refraction by their spatial correlation function $C_{\mathbf{n}}(\boldsymbol{\xi}) \equiv \langle \delta n(\mathbf{X}, t) \delta n(\mathbf{X} + \boldsymbol{\xi}, t) \rangle$ (discussed in Sec. 6.4.1); or, better yet, by \mathbf{n} 's *mean-square fluctuation on the lengthscale* ξ ,

$$D_{\mathbf{n}}(\boldsymbol{\xi}) \equiv \langle [\delta n(\mathbf{X} + \boldsymbol{\xi}, t) - \delta n(\mathbf{X}, t)]^2 \rangle = 2[\sigma_{\mathbf{n}}^2 - C_{\mathbf{n}}(\boldsymbol{\xi})], \quad (1)$$

which is called \mathbf{n} 's *structure function*. Here δn is the perturbation of the index of refraction, \mathbf{X} is location in 3-dimensional space, t is time, $\langle \cdot \rangle$ denotes a spacetime average, and $\sigma_{\mathbf{n}}^2 \equiv \langle \delta n^2 \rangle = C_{\mathbf{n}}(0)$ is the variance of the fluctuations.

In Sec. 15.4.4, we show that, for strong and isotropic turbulence, $D_{\mathbf{n}}$ has the functional form $D_{\mathbf{n}} \propto \xi^{2/3}$ (where $\xi \equiv |\boldsymbol{\xi}|$), with a multiplicative coefficient $d_{\mathbf{n}}^2$ that characterizes the strength of the perturbations:

$$D_{\mathbf{n}}(\boldsymbol{\xi}) = d_{\mathbf{n}}^2 \xi^{2/3} \quad (2)$$

[Eq. (15.29)]. The $2/3$ power is called the *Kolmogorov spectrum* for the turbulence.

When light from a very distant star (a point source), directly overhead for simplicity, reaches Earth's atmosphere, its phase fronts lie in horizontal planes, so the frequency ω component of the electric field is $\psi = e^{ikz}$, where z increases downward. (Here we have factored out the field's overall amplitude.) When propagating through a thin layer of turbulent atmosphere of thickness δh , the light acquires the phase fluctuation

$$\delta\varphi(\mathbf{x}, t) = k \int_z^{z+\delta h} \delta n(\mathbf{x}, z, t) dz. \quad (3)$$

Here \mathbf{x} is the transverse (i.e., horizontal) location, and Eq. (3) follows from $d\varphi = k dz$, with $k = (n/c)\omega$ and $n \simeq 1$.

In Ex. 9.4, we derive some spacetime-averaged consequences of the phase fluctuations (3):

1. When the light emerges from the thin, turbulent layer, it has acquired a mean-square phase fluctuation on transverse lengthscale a given by

$$D_{\delta\varphi}(\mathbf{a}) \equiv \langle [\delta\varphi(\mathbf{x} + \mathbf{a}, t) - \delta\varphi(\mathbf{x}, t)]^2 \rangle = 2.91 d_{\mathbf{n}}^2 \delta h k^2 a^{5/3} \quad (4a)$$

(continued)

BOX 9.2. (continued)

[Eq. (2)], and a spacetime-averaged complex visibility given by

$$\begin{aligned}\bar{\gamma}_{\perp}(\mathbf{a}) &= \langle \psi(\mathbf{x}, t) \psi^*(\mathbf{x} + \mathbf{a}, t) \rangle = \langle \exp \{i [\delta\varphi(\mathbf{x}, t) - \delta\varphi(\mathbf{x} + \mathbf{a}, t)]\} \rangle \\ &= \exp \left[-\frac{1}{2} D_{\delta\varphi}(a) \right] = \exp \left[-1.455 d_{\mathbf{n}}^2 \delta h k^2 a^{5/3} \right]. \quad (4b)\end{aligned}$$

2. Free propagation (including free-propagator diffraction effects, which are important for long-distance propagation) preserves the spacetime-averaged complex visibility: $d\bar{\gamma}_{\perp}/dz = 0$.
3. Therefore, not surprisingly, when the turbulence is spread out vertically in some arbitrary manner, the net mean-square phase shift and time-averaged complex visibility observed on the ground are $D_{\varphi}(\mathbf{a}) = 2.91 \left[\int d_{\mathbf{n}}^2(z) dz \right] k^2 a^{5/3}$, and $\bar{\gamma}_{\perp}(\mathbf{a}) = \exp \left[-\frac{1}{2} D_{\varphi}(a) \right]$.

It is conventional to introduce a transverse lengthscale

$$r_o \equiv \left[0.423 k^2 \int d_{\mathbf{n}}^2(z) dz \right]^{-3/5}$$

called the *Fried parameter*, in terms of which D_{φ} and $\bar{\gamma}_{\perp}$ are

$$D_{\varphi}(\mathbf{a}) = 6.88(a/r_o)^{5/3}, \quad (5a)$$

$$\bar{\gamma}_{\perp}(\mathbf{a}) = \exp \left[-\frac{1}{2} D_{\varphi}(a) \right] = \exp \left[-3.44(a/r_o)^{5/3} \right]. \quad (5b)$$

This remarkably simple result provides opportunities to test the Kolmogorov power law. For light from a distant star, one can use a large telescope to measure $\bar{\gamma}_{\perp}(a)$ and then plot $\ln \bar{\gamma}_{\perp}$ as a function of a . Equation (5b) predicts a slope 5/3 for this plot, and observations confirm that prediction.

Notice that the Fried parameter r_o is the lengthscale on which the rms phase fluctuation $\varphi_{\text{rms}} = \sqrt{D_{\varphi}(a = r_o)}$ is $\sqrt{6.88} = 2.62$ radians: r_o is the transverse lengthscale beyond which the turbulence-induced phase fluctuations are large compared to unity. These large random phase fluctuations drive $\bar{\gamma}_{\perp}$ rapidly toward zero with increasing distance a [Eq. (5b)], that is, they cause the light field to become spatially decorrelated with itself for distances $a \gtrsim r_o$. Therefore, r_o is (approximately) the time-averaged light field's spatial correlation length on the ground. Moreover, since $\bar{\gamma}_{\perp}$ is preserved under free propagation from the turbulent region to the ground, r_o must be the transverse correlation length of the light as it exits the turbulent region that

(continued)

produces the seeing. A correlated region with transverse size r_o is called an *isoplanatic patch*.

The observed time-averaged intensity $\bar{I}(\boldsymbol{\alpha})$ from the point-source star is the Fourier transform of the complex visibility (5b); see Eq. (9.13b). This transform cannot be performed analytically, but a numerical computation gives the solid curve in panel b of the figure above, which agrees remarkably well with observations out to $\sim 10^{-4}$ of the central intensity, where the Kolmogorov power law is expected to break down. Notice that the intensity distribution has a large-radius tail with far larger intensity than a Gaussian distribution (the dashed curve). This large-radius light is produced by large-angle diffraction, which is caused by very small-spatial-scale fluctuations (eddies) in the index of refraction.

Astronomers attribute to this time-averaged $I(\boldsymbol{\alpha})$ a full width at half maximum (FWHM) angular diameter $\alpha_{\text{Kol}}^{\text{FWHM}} = 0.98\lambda/r_o$ (Ex. 9.4). For blue light in very good seeing conditions, r_o is about 20 cm and $\alpha_{\text{Kol}}^{\text{FWHM}}$ is about 0.5 arcsec. Much more common is $r_o \sim 10$ cm and $\alpha_{\text{Kol}}^{\text{FWHM}} \sim 1$ arcsec.

SPECKLE PATTERN AND ITS INFORMATION

The speckle pattern seen on short timescales, $\lesssim 1/f_o \sim 0.01$ s, can be understood in terms of the turbulence's isoplanatic patches (see the drawing below). When the light field exits the turbulent region, at a height $h \lesssim 1$ km, the isoplanatic patches on its wavefronts, with transverse size r_o , are planar to within roughly a reduced wavelength $\lambda = 1/k = \lambda/(2\pi)$ (since the rms phase variation across a patch is just 2.62 radians). Each patch carries an image of the star, or whatever other object the astronomer is observing. The patch's light rays make an angle $\theta \lesssim \alpha_{\text{Kol}}^{\text{FWHM}} = 0.98\lambda/r_o$ to the vertical. The patch's Fresnel length from the ground is $r_F = \sqrt{\lambda h} \lesssim 2$ cm (since $\lambda \sim 0.5 \mu\text{m}$ and $h \lesssim 1$ km). This is significantly smaller than the patch size $r_o \sim 10$ to 20 cm; so there is little diffraction in the trip to ground. When these patches reach

(continued)

BOX 9.2. (continued)

a large telescope (one with diameter $D \gg r_o$), each is focused to produce an image of the object centered on the angular position θ of its rays (dotted lines in the drawing). These images are the speckles seen in panel a of the first box figure.

The speckle pattern varies rapidly, because winds at high altitude sweep the isoplanatic patches through the star's light rays. For a wind speed $u \sim 20 \text{ m s}^{-1}$, the frequency of the pattern's fluctuations is $f_o \sim u/r_o \sim 100 \text{ Hz}$, in agreement with observations.

To study the speckles and extract information about the object's above-atmosphere intensity distribution $I_o(\boldsymbol{\alpha})$, one must observe them on timescales $\lesssim 1/f_o \sim 10 \text{ ms}$. The first observations of this sort were the measurements of a few stellar diameters by Michelson and Pease, using the Michelson stellar interferometer (Sec. 9.2.7). The fringes they saw were produced by the speckles, and because the phase of each speckle's fringes was random, the many speckles contributed incoherently to produce a far smaller net fringe visibility V than in the absence of atmospheric turbulence. Moreover, because the speckle pattern varied at $f_o \sim 100 \text{ Hz}$, the net visibility and its phase also varied at $f_o \sim 100 \text{ Hz}$. Fortunately, the human eye can discern things that vary this fast, so Michelson and Pease were able to see the fringes.

In the modern era of CCDs, fast electronics, and powerful computers, a variety of more sophisticated techniques have been devised and implemented for observing these speckles and extracting their information. Two common techniques are speckle-image processing and adaptive optics.

In *speckle image processing*, which is really only usable for bright sources, one makes optical measurements of the speckle pattern (sometimes with multi-pinhole masks) on timescales $\lesssim 0.01 \text{ s}$ for which the speckles are unchanging. One then uses optical or computational techniques to construct fourth-order or sixth-order correlations of the light field, for example, $\int \gamma_{\perp}(\mathbf{a} - \mathbf{a}') \gamma_{\perp}^*(\mathbf{a}') d^2 a'$ (which is fourth-order in the field), from which a good approximation to the source's above-atmosphere intensity distribution $I_o(\boldsymbol{\alpha})$ can be computed.

In *adaptive optics*, one focuses not on the speckles themselves, but on the turbulence-induced distortions of the wavefronts arriving at the large telescope's mirror. The simplest implementation uses *natural guide stars* to act as point sources. Unfortunately the incidence of sufficiently bright stars only allows a small fraction of the sky to be examined using this technique.

(continued)

BOX 9.2. (continued)

Therefore, *laser guide stars* are created by shining collimated laser light close to the direction of the astronomical sources under study. The laser light generates the guide star via either Rayleigh scattering by molecules at modest altitude (~ 20 km) or resonant scattering from a layer of sodium atoms at high altitude (~ 90 km).

The guide star must be within an angular distance $\lesssim r_o/h \sim 3$ arcsec of the astronomical object one is observing (where $h \sim 10$ km is the height of the highest turbulent layers that contribute significantly to the seeing). This $\lesssim 3$ arcsec separation guarantees that light rays arriving at the same spot on the telescope mirror from the object and from the artificial star will have traversed the same isoplanatic patches of turbulent atmosphere and thus have experienced the same phase delay and acquired the same wavefront distortions. One measures the wavefront distortions of the artificial star's light and dynamically reshapes the telescope mirror so as to compensate for them. This removes the distortions not only from the artificial star's wavefronts but also from the astronomical object's wavefronts. Thereby one converts the speckle pattern into the object's true intensity distribution $I_o(\alpha)$.

Two recent successes of adaptive optics are to observe the stars orbiting the massive black hole in our galactic center and thereby measure its mass (Ghez et al., 2008; Genzel, Eisenhauer, and Gillessen, 2010); and to image exoplanets directly by masking out the light—typically millions of times brighter than the planet—from the stars that they orbit (Macintosh et al., 2014).

The techniques described here also find application to the propagation of radio waves through the turbulent interplanetary and interstellar media. The refractive index is due to the presence of free electrons in a plasma (see Sec. 21.4.1). Interestingly, this turbulence is commonly characterized by a Kolmogorov spectrum, though the presence of a magnetic field makes it anisotropic.

These techniques are also starting to find application in ophthalmology and industry.

- (g) Reexpress the turbulence-broadened image's FWHM as $\alpha_{\text{Kol}}^{\text{FWHM}} = 0.98\lambda/r_o$. Show that the Airy intensity distribution for light for a circular aperture of diameter D [Eq. (8.18)] has FWHM $\alpha_{\text{Airy}}^{\text{FWHM}} = 1.03\lambda/D$.
- (h) The fact that the coefficients in these two expressions for α^{FWHM} are both close to unity implies that when the diameter $D \lesssim r_o$, the seeing is determined by the telescope. Conversely, when $D \gtrsim r_o$ (which is true for essentially all ground-based

research optical telescopes), it is the atmosphere that determines the image quality. Large telescopes act only as “light buckets,” unless some additional correctives are applied, such as speckle image processing or adaptive optics (Box 9.2). A common measure of the performance of a telescope with or without this correction is the *Strehl ratio*, S , which is the ratio of the peak intensity in the actual image of a point source on the telescope’s optic axis to the peak intensity in the Airy disk for the telescope’s aperture. Show that without correction, $S = 1.00(r_o/D)^2$. Modern adaptive optics systems on large telescopes can achieve $S \sim 0.5$.

9.2.6

9.2.6 Temporal Coherence

In addition to the degree of spatial (or lateral) coherence, which measures the correlation of the field transverse to the direction of wave propagation, we can also measure the *degree of temporal coherence*, also called the *degree of longitudinal coherence*. This describes the correlation at a given time at two points separated by a distance s along the direction of propagation. Equivalently, it measures the field sampled at a fixed position at two times differing by $\tau = s/c$. When (as in our discussion of spatial coherence) the waves are nearly monochromatic so the field arriving at the fixed position has the form $\Psi = \psi(t)e^{-i\omega_0 t}$, then the degree of temporal coherence is complex and has a form completely analogous to the transverse case [Eq. (9.12b)]:

degree of temporal or longitudinal coherence for nearly monochromatic radiation

$$\gamma_{\parallel}(\tau) = \frac{\overline{\psi(t)\psi^*(t+\tau)}}{|\overline{\psi}|^2} \quad \text{for nearly monochromatic radiation.} \quad (9.15)$$

Here the average is over sufficiently long times t for the averaged value to settle down to an unchanging value.

When studying temporal coherence, one often wishes to deal with waves that contain a wide range of frequencies—such as the nearly Planckian (blackbody) cosmic microwave radiation emerging from the very early universe (Ex. 9.6). In this case, one should not factor any $e^{-i\omega_0 t}$ out of the field Ψ , and one gains nothing by regarding $\Psi(t)$ as complex, so the *temporal coherence*

degree of temporal coherence for broadband radiation

$$\gamma_{\parallel}(\tau) = \frac{\overline{\Psi(t)\Psi(t+\tau)}}{\overline{\Psi}^2} \quad \text{for real } \Psi \text{ and broadband radiation} \quad (9.16)$$

is also real. We use this real γ_{\parallel} throughout this subsection and the next. It obviously is the correlation function of Ψ [Eq. (6.19)] renormalized so $\gamma_{\parallel}(0) = 1$.

As τ is increased, γ_{\parallel} typically remains near unity until some critical value τ_c is reached, and then it begins to fall off toward zero. The critical value τ_c , the longest time over which the field is strongly coherent, is the coherence time, of which we have already spoken: If the wave is roughly monochromatic, so $\Psi(t) \propto \cos[\omega_0 t + \delta\varphi(t)]$, with ω_0 fixed and the phase $\delta\varphi$ randomly varying in time, then it should be clear that

the mean time for $\delta\varphi$ to change by an amount of order unity is the coherence time τ_c at which γ_{\parallel} begins to fall significantly.

The uncertainty principle dictates that a field with coherence time τ_c , when Fourier analyzed in time, must contain significant power over a bandwidth $\Delta f = \Delta\omega/(2\pi) \sim 1/\tau_c$. Correspondingly, if we define the field's *longitudinal coherence length* by

$$l_{\parallel} \equiv c\tau_c, \quad (9.17)$$

then l_{\parallel} for broadband radiation will be only a few times the peak wavelength, but for a narrow spectral line of width $\Delta\lambda$, it will be $\lambda^2/\Delta\lambda$.

These relations between the coherence time or longitudinal coherence length and the field's spectral energy flux are order-of-magnitude consequences not only of the uncertainty relation, but also of the temporal analog of the van Cittert-Zernike theorem. That analog is just the Wiener-Khinchine theorem in disguise, and it can be derived by the same methods as we used in the transverse spatial domain. In that theorem the degree of lateral coherence γ_{\perp} is replaced by the degree of temporal coherence γ_{\parallel} , and the angular intensity distribution $I(\alpha)$ (distribution of energy over angle) is replaced by the field's spectral energy flux $F_{\omega}(\omega)$ (the energy crossing a unit area per unit time and per unit angular frequency ω)—which is also called its *spectrum*.⁵ The theorem takes the explicit form

$$\gamma_{\parallel}(\tau) = \frac{\int_{-\infty}^{\infty} d\omega F_{\omega}(\omega) e^{i\omega\tau}}{F_S} = \frac{2 \int_0^{\infty} d\omega F_{\omega}(\omega) \cos \omega\tau}{F_S} \quad (9.18a)$$

for real $\Psi(t)$, valid for broadband radiation

and

$$F_{\omega}(\omega) = F_S \int_{-\infty}^{\infty} \frac{d\tau}{2\pi} \gamma_{\parallel}(\tau) e^{-i\omega\tau} = 2F_S \int_0^{\infty} \frac{d\tau}{2\pi} \gamma_{\parallel}(\tau) \cos \omega\tau. \quad (9.18b)$$

[Here the normalization of our Fourier transform and the sign of its exponential are those conventionally used in optics, and differ from those used in the theory of random processes (Chap. 6). Also, because we have chosen Ψ to be real, $F_{\omega}(-\omega) = F_{\omega}(+\omega)$ and $\gamma_{\parallel}(-\tau) = \gamma_{\parallel}(+\tau)$.] One can measure γ_{\parallel} by combining the radiation from two points displaced longitudinally to produce interference fringes just as we did when measuring spatial coherence. This type of interference is sometimes called *interference by division of the amplitude*, in contrast with “interference by division of the wavefront” for a Young's-slit-type measurement of lateral spatial coherence (next-to-last paragraph of Sec. 9.2.1).

5. Note that the spectral energy flux (spectrum) is simply related to the spectral density of the field: if the field Ψ is so normalized that the energy density is $U = \beta \Psi_{,t} \Psi_{,t}$ with β some constant, then $F_{\omega}(\omega) = \beta c \omega^2 / (2\pi) S_{\Psi}(f)$, with $f = \omega / (2\pi)$.

9.2.7

9.2.7 Michelson Interferometer and Fourier-Transform Spectroscopy

Michelson interferometer

The classic instrument for measuring the degree of longitudinal coherence is the Michelson interferometer of Fig. 9.3 (not to be confused with the Michelson stellar interferometer). In the simplest version, incident light (e.g., in the form of a Gaussian beam; Sec. 8.5.5) is split by a beam splitter into two beams, which are reflected off different plane mirrors and then recombined. The relative positions of the mirrors are adjustable so that the two light paths can have slightly different lengths. (An early version of this instrument was used in the famous Michelson-Morley experiment.) There are two ways to view the fringes. One way is to tilt one of the reflecting mirrors slightly so there is a range of path lengths in one of the arms. Light and dark interference bands (fringes) can then be seen across the circular cross section of the recombined beam. The second method is conceptually more direct but requires aligning the mirrors sufficiently accurately so the phase fronts of the two beams are parallel after recombination and the recombined beam has no banded structure. The end mirror in one arm of the interferometer is then slowly moved backward or forward, and as it moves, the recombined light slowly changes from dark to light to dark and so on.

It is interesting to interpret this second method in terms of the Doppler shift. One beam of light undergoes a Doppler shift on reflection off the moving mirror. There is then a beat wave produced when it is recombined with the unshifted radiation of the other beam.

Whichever method is used (tilted mirror or longitudinal motion of mirror), the visibility $\gamma_{||}$ of the interference fringes measures the beam's degree of longitudinal coherence, which is related to the spectral energy flux (spectrum) F_{ω} by Eqs. (9.18).

Let us give an example. Suppose we observe a spectral line with rest angular frequency ω_0 that is broadened by random thermal motions of the emitting atoms. Then the line profile is

$$F_{\omega} \propto \exp\left(-\frac{(\omega_0 - \omega)^2}{2(\Delta\omega)^2}\right). \quad (9.19a)$$

The width of the line is given by the formula for the Doppler shift,

$$\Delta\omega \sim \omega_0 [k_B T / (mc^2)]^{1/2},$$

where T is the temperature of the emitting atoms, and m is their mass. (We ignore other sources of line broadening, e.g., natural broadening and pressure broadening,

FIGURE 9.3 Michelson interferometer.

which actually dominate under normal conditions.) For example, for hydrogen at $T = 10^3$ K, the Doppler-broadened line width is $\Delta\omega \sim 10^{-5}\omega_0$.

By Fourier transforming this line profile, using the well-known result that the Fourier transform of a Gaussian is another Gaussian and invoking the fundamental relations (9.18) between the spectrum and temporal coherence, we obtain

$$\gamma_{\parallel}(\tau) = \exp\left(-\frac{\tau^2(\Delta\omega)^2}{2}\right) \cos \omega_0\tau. \quad (9.19b)$$

If we had used the nearly monochromatic formalism with the field written as $\Psi = \psi(t)e^{-i\omega_0 t}$, then we would have obtained

$$\gamma_{\parallel}(\tau) = \exp\left(-\frac{\tau^2(\Delta\omega)^2}{2}\right) e^{i\omega_0\tau}, \quad (9.19c)$$

the real part of which is our broadband formalism's γ_{\parallel} . In either case, γ_{\parallel} oscillates with angular frequency ω_0 , and the amplitude of this oscillation is the *fringe visibility* V :

$$V = \exp\left(-\frac{\tau^2(\Delta\omega)^2}{2}\right). \quad (9.19d)$$

The variation $V(\tau)$ of this visibility with lag time τ is sometimes called an *interferogram*. For time lags $\tau \ll (\Delta\omega)^{-1}$, the line appears to be monochromatic, and fringes with unit visibility should be seen. However, for lags $\tau \gtrsim (\Delta\omega)^{-1}$, the fringe visibility will decrease exponentially with increasing τ^2 . In our Doppler-broadened hydrogen-line example with $\Delta\omega \sim 10^{-5}\omega_0$, the rest angular frequency is $\omega_0 \sim 3 \times 10^{15}$ rad s $^{-1}$, so the longitudinal coherence length is $l_{\parallel} = c\tau_c \sim 10$ mm. No fringes will be seen when the radiation is combined from points separated by much more than this distance.

This procedure is an example of *Fourier transform spectroscopy*, in which, by measuring the degree of temporal coherence $\gamma_{\parallel}(\tau)$ and then Fourier transforming

fringe visibility

interferogram

Fourier transform spectroscopy

it [Eq. (9.18)], one infers the shape of the radiation's spectrum, or in this case, the width of a specific spectral line.

When (as in Ex. 9.6) the waves are very broad band, the degree of longitudinal coherence $\gamma_{\parallel}(\tau)$ will not have the form of a sinusoidal oscillation (regular fringes) with slowly varying amplitude (visibility). Nevertheless, the broadband van Cittert-Zernike theorem [Eqs. (9.18)] still guarantees that the spectrum (spectral energy flux) will be the Fourier transform of the coherence $\gamma_{\parallel}(\tau)$, which can be measured by a Michelson interferometer.

EXERCISES

Exercise 9.6 *Problem: COBE Measurement of the Cosmic Microwave Background Radiation*

An example of a Michelson interferometer is the Far Infrared Absolute Spectrophotometer (FIRAS) carried by the Cosmic Background Explorer satellite (COBE). COBE studied the spectrum and anisotropies of the cosmic microwave background radiation (CMB) that emerged from the very early, hot phase of our universe's expansion (Sec. 28.3.3). One of the goals of the COBE mission was to see whether the CMB spectrum really has the shape of 2.7 K blackbody (Planckian) radiation, or if it is highly distorted, as some measurements made on rocket flights had suggested. COBE's spectrophotometer used Fourier transform spectroscopy to meet this goal: it compared accurately the degree of longitudinal coherence γ_{\parallel} of the CMB radiation with that of a calibrated source on board the spacecraft, which was known to be a blackbody at about 2.7 K. The comparison was made by alternately feeding radiation from the microwave background and radiation from the calibrated source into the same Michelson interferometer and comparing their fringe spacings. The result (Mather et al., 1994) was that the background radiation has a spectrum that is Planckian with temperature 2.726 ± 0.010 K over the wavelength range 0.5–5.0 mm, in agreement with simple cosmological theory that we shall explore in the last chapter of this book.

- (a) Suppose that the CMB had had a Wien spectrum

$$F_{\omega} \propto \omega^3 \exp[-\hbar\omega/(k_B T)].$$

Show that the visibility of the fringes would have been

$$V = |\gamma_{\parallel}| \propto \frac{|s^4 - 6s_0^2 s^2 + s_0^4|}{(s^2 + s_0^2)^4} \quad (9.20)$$

where $s = c\tau$ is longitudinal distance, and calculate a numerical value for s_0 .

- (b) Compute the interferogram $V(\tau)$ for a Planck function either analytically (perhaps with the help of a computer) or numerically using a fast Fourier transform. Compare graphically the interferogram for the Wien and Planck spectra.

9.2.8 Degree of Coherence; Relation to Theory of Random Processes

9.2.8

Having separately discussed spatial and temporal coherence, we now can easily perform a final generalization and define the full degree of coherence of the radiation field between two points separated both laterally by a vector \mathbf{a} and longitudinally by a distance s (or equivalently, by a time $\tau = s/c$). If we restrict ourselves to nearly monochromatic waves and use the complex formalism so the waves are written as $\Psi = e^{i(kz - \omega t)} \psi(\mathbf{x}, t)$ [Eq. (9.12a)], then we have

$$\gamma_{12}(\mathbf{ka}, \tau) \equiv \frac{\overline{\psi(\mathbf{x}_1, t) \psi^*(\mathbf{x}_1 + \mathbf{a}, t + \tau)}}{\left[\overline{|\psi(\mathbf{x}_1, t)|^2} \overline{|\psi(\mathbf{x}_1 + \mathbf{a}, t)|^2} \right]^{1/2}} = \frac{\overline{\psi(\mathbf{x}_1, t) \psi^*(\mathbf{x}_1 + \mathbf{a}, t + \tau)}}{\overline{|\psi|^2}}. \quad (9.21)$$

In the denominator of the second expression we have used the fact that, because the source is far away, $\overline{|\psi|^2}$ is independent of the spatial location at which it is evaluated, in the region of interest. Consistent with the definition (9.21), we can define a *volume of coherence* \mathcal{V}_c as the product of the longitudinal coherence length $l_{\parallel} = c\tau_c$ and the square of the transverse coherence length l_{\perp}^2 : $\mathcal{V}_c = l_{\perp}^2 c\tau_c$.

The 3-dimensional version of the van Cittert-Zernike theorem relates the complex degree of coherence (9.21) to the radiation's *specific intensity*, $I_{\omega}(\boldsymbol{\alpha}, \omega)$, also called its spectral intensity (i.e., the energy crossing a unit area per unit time per unit solid angle and per unit angular frequency, or energy "per unit everything"). (Since the frequency ν and the angular frequency ω are related by $\omega = 2\pi\nu$, the specific intensity I_{ω} of this chapter and that I_{ν} of Chap. 3 are related by $I_{\nu} = 2\pi I_{\omega}$.) The 3-dimensional van Cittert-Zernike theorem states that

$$\gamma_{12}(\mathbf{ka}, \tau) = \frac{\int d\Omega_{\alpha} d\omega I_{\omega}(\boldsymbol{\alpha}, \omega) e^{i(\mathbf{ka} \cdot \boldsymbol{\alpha} + \omega\tau)}}{F_S}, \quad (9.22a)$$

and

$$I_{\omega}(\boldsymbol{\alpha}, \omega) = F_S \int \frac{d\tau d^2ka}{(2\pi)^3} \gamma_{12}(\mathbf{ka}, \tau) e^{-i(\mathbf{ka} \cdot \boldsymbol{\alpha} + \omega\tau)}. \quad (9.22b)$$

There obviously must be an intimate relationship between the theory of random processes, as developed in Chap. 6, and the theory of a wave's coherence, as we have developed it in Sec. 9.2. That relationship is explained in Ex. 9.8.

3-dimensional van Cittert-
Zernike theorem

Exercise 9.7 Problem: Decomposition of Degree of Coherence

We have defined the degree of coherence $\gamma_{12}(\mathbf{a}, \tau)$ for two points in the radiation field separated laterally by a distance \mathbf{a} and longitudinally by a time τ . Under what conditions will this be given by the product of the spatial and temporal degrees of coherence?

$$\gamma_{12}(\mathbf{a}, \tau) = \gamma_{\perp}(\mathbf{a})\gamma_{\parallel}(\tau). \quad (9.23)$$

EXERCISES

Exercise 9.8 ***Example: Complex Random Processes and the van Cittert-Zernike Theorem*

In Chap. 6 we developed the theory of real-valued random processes that vary randomly with time t (i.e., that are defined on a 1-dimensional space in which t is a coordinate). Here we generalize a few elements of that theory to a complex-valued random process $\Phi(\mathbf{x})$ defined on a (Euclidean) space with n dimensions. We assume the process to be stationary and to have vanishing mean (cf. Chap. 6 for definitions). For $\Phi(\mathbf{x})$ we define a complex-valued correlation function by

$$C_{\Phi}(\boldsymbol{\xi}) \equiv \overline{\Phi(\mathbf{x})\Phi^*(\mathbf{x} + \boldsymbol{\xi})} \quad (9.24a)$$

(where $*$ denotes complex conjugation) and a real-valued spectral density by

$$S_{\Phi}(\mathbf{k}) = \lim_{L \rightarrow \infty} \frac{1}{L^n} |\tilde{\Phi}_L(\mathbf{k})|^2. \quad (9.24b)$$

Here Φ_L is Φ confined to a box of side L (i.e., set to zero outside that box), and the tilde denotes a Fourier transform defined using the conventions of Chap. 6:

$$\tilde{\Phi}_L(\mathbf{k}) = \int \Phi_L(\mathbf{x}) e^{-i\mathbf{k}\cdot\mathbf{x}} d^n x, \quad \Phi_L(\mathbf{x}) = \int \tilde{\Phi}_L(\mathbf{k}) e^{+i\mathbf{k}\cdot\mathbf{x}} \frac{d^n k}{(2\pi)^n}. \quad (9.25)$$

Because Φ is complex rather than real, $C_{\Phi}(\boldsymbol{\xi})$ is complex; and as we shall see below, its complexity implies that [although $S_{\Phi}(\mathbf{k})$ is real], $S_{\Phi}(-\mathbf{k}) \neq S_{\Phi}(\mathbf{k})$. This fact prevents us from folding negative \mathbf{k} into positive \mathbf{k} and thereby making $S_{\Phi}(\mathbf{k})$ into a “single-sided” spectral density as we did for real random processes in Chap. 6. In this complex case we must distinguish $-\mathbf{k}$ from $+\mathbf{k}$ and similarly $-\boldsymbol{\xi}$ from $+\boldsymbol{\xi}$.

(a) The complex Wiener-Khintchine theorem [analog of Eq. (6.29)] states that

$$S_{\Phi}(\mathbf{k}) = \int C_{\Phi}(\boldsymbol{\xi}) e^{+i\mathbf{k}\cdot\boldsymbol{\xi}} d^n \boldsymbol{\xi}, \quad (9.26a)$$

$$C_{\Phi}(\boldsymbol{\xi}) = \int S_{\Phi}(\mathbf{k}) e^{-i\mathbf{k}\cdot\boldsymbol{\xi}} \frac{d^n k}{(2\pi)^n}. \quad (9.26b)$$

Derive these relations. [Hint: Use Parseval’s theorem in the form $\int A(\mathbf{x})B^*(\mathbf{x})d^n x = \int \tilde{A}(\mathbf{k})\tilde{B}^*(\mathbf{k})d^n k/(2\pi)^n$ with $A(\mathbf{x}) = \Phi_L(\mathbf{x})$ and $B(\mathbf{x}) = \Phi_L(\mathbf{x} + \boldsymbol{\xi})$, and then take the limit as $L \rightarrow \infty$.] Because $S_{\Phi}(\mathbf{k})$ is real, this Wiener-Khintchine theorem implies that $C_{\Phi}(-\boldsymbol{\xi}) = C_{\Phi}^*(\boldsymbol{\xi})$. Show that this is so directly from the definition (9.24a) of $C_{\Phi}(\boldsymbol{\xi})$. Because $C_{\Phi}(\boldsymbol{\xi})$ is complex, the Wiener-Khintchine theorem implies that $S_{\Phi}(\mathbf{k}) \neq S_{\Phi}(-\mathbf{k})$.

(b) Let $\psi(\mathbf{x}, t)$ be the complex-valued wave field defined in Eq. (9.12a), and restrict \mathbf{x} to range only over the two transverse dimensions so ψ is defined on a 3-dimensional space. Define $\Phi(\mathbf{x}, t) \equiv \psi(\mathbf{x}, t) / \left[|\psi(\mathbf{x}, t)|^2 \right]^{1/2}$. Show that

$$C_{\Phi}(\mathbf{a}, \tau) = \gamma_{12}(k\mathbf{a}, \tau), \quad S_{\Phi}(-\boldsymbol{\alpha}k, -\omega) = \text{const} \times \frac{I_{\omega}(\boldsymbol{\alpha}, \omega)}{F_S}, \quad (9.27)$$

and that the complex Wiener-Khintchine theorem (9.26) is the van Cittert-Zernike theorem (9.22). (Note: The minus signs in S_ϕ result from the difference in Fourier transform conventions between the theory of random processes [Eq. (9.25) and Chap. 6] and the theory of optical coherence [this chapter].) Evaluate the constant in Eq. (9.27).

9.3 Radio Telescopes

9.3

The interferometry technique pioneered by Michelson for measuring the angular sizes of stars at visual wavelengths has been applied to great effect in radio astronomy.

A modern radio telescope is a large surface that reflects radio waves onto a “feed,” where the waves’ fluctuating electric field creates a tiny electric voltage that subsequently can be amplified and measured electronically. Modern radio telescopes have diameters D that range from ~ 10 m to the ~ 300 m of the Arecibo telescope in Puerto Rico. A typical observing wavelength might be $\lambda \sim 6$ cm. This implies an angular resolution $\theta_A \sim \lambda/D \sim 2 \text{ arcmin}(\lambda/6 \text{ cm})(D/100 \text{ m})^{-1}$ [Eq. (8.18) and subsequent discussion]. However, many of the most interesting cosmic sources are much smaller than this. To achieve much better angular resolution, the technique of radio interferometry was pioneered in the 1950s and has been steadily developing since then.⁶

radio telescope
interferometry

9.3.1 Two-Element Radio Interferometer

9.3.1

If we have two radio telescopes, then we can think of them as two Young’s slits, and we can link them using a combination of waveguides and electric cables, as shown in Fig. 9.4. When they are both pointed at a source, they both measure the electric field in radio waves from that source. We combine their signals by narrowband filtering their voltages to make them nearly monochromatic and then either adding the filtered voltages and measuring the power, or multiplying the two voltages directly. In either case a measurement of the degree of coherence [Eq. (9.10)] can be achieved. [If the source is not vertically above the two telescopes, one obtains some nonlateral component of the full degree of coherence $\gamma_{12}(\mathbf{a}, \tau)$. However, by introducing a time delay into one of the signals, as in Fig. 9.4, one can measure the degree of lateral coherence $\gamma_\perp(\mathbf{a})$, which is what the astronomer usually needs.]

The objective is usually to produce an image of the radio waves’ source. This is achieved by Fourier inverting the lateral degree of coherence $\gamma_\perp(\mathbf{a})$ [Eq. (9.13b)], which therefore must be measured for a variety of values of the relative separation vector \mathbf{a} of the telescopes perpendicular to the source’s direction. As Earth rotates, the separation vector will trace out half an ellipse in the 2-dimensional \mathbf{a} plane every 12 hours. [The source intensity is a real quantity, so we can use Eq. (9.13a) to deduce

6. This type of interferometry is also developing fast at optical wavelengths. This was not possible until optical technology became good enough to monitor the phase of light as well as its amplitude, at separate locations, and then produce interference.

FIGURE 9.4 Two-element radio interferometer.

that $\gamma_{\perp}(-\mathbf{a}) = \gamma_{\perp}^*(\mathbf{a})$, which gives the other half of the ellipse.] By changing the spacing between the two telescopes daily and collecting data for a number of days, the degree of coherence can be well sampled. This technique⁷ is known as *Earth-rotation aperture synthesis*, because the telescopes are being made to have the angular resolution of a giant telescope as big as their maximum separation, with the aid of Earth's rotation. They do not, of course, have the sensitivity of this giant telescope.

aperture synthesis

9.3.2

9.3.2 Multiple-Element Radio Interferometers

In practice, a modern radio interferometer has many more than two telescopes. For example, the Karl G. Jansky Very Large Array (JVLA) in New Mexico (USA) has 27 individual telescopes arranged in a Y pattern and operating simultaneously, with a maximum baseline of 36 km and a minimum observing wavelength of 7 mm. The degree of coherence can thus be measured simultaneously over $27 \times 26/2 = 351$ different relative separations. The results of these measurements can then be interpolated to give values of $\gamma_{\perp}(\mathbf{a})$ on a regular grid of points (usually $2^N \times 2^N$ for some integer N). This is then suitable for applying the fast Fourier transform algorithm to infer the source structure $I(\boldsymbol{\alpha})$.

JVLA

ALMA

The Atacama Large Millimeter Array (ALMA) being constructed in Chile is already (2016) operational. It comprises 66 telescopes observing with wavelengths between 0.3 and 9.6 mm and baselines as long as 16 km. Future ambitions at longer radio wavelengths are centered on the proposed Square Kilometer Array (SKA) to be built in South Africa and Australia comprising thousands of dishes with a combined collecting area of a square kilometer.

7. For which Martin Ryle was awarded the Nobel Prize.

9.3.3 Closure Phase

9.3.3

phase errors

Among the many technical complications of interferometry is one that brings out an interesting point about Fourier methods. It is usually much easier to measure the modulus than the phase of the complex degree of coherence. This is partly because it is hard to introduce the necessary delays in the electronics accurately enough to know where the zero of the fringe pattern should be located and partly because unknown, fluctuating phase delays are introduced into the phase of the field as the wave propagates through the upper atmosphere and ionosphere. [This is a radio variant of the problem of “seeing” for optical telescopes (cf. Box 9.2), and it also plagues the Michelson stellar interferometer.] It might therefore be thought that we would have to make do with just the modulus of the degree of coherence (i.e., the fringe visibility) to perform the Fourier inversion for the source structure. This is not so.

Consider a three-element interferometer measuring fields ψ_1 , ψ_2 , and ψ_3 , and suppose that at each telescope there are unknown phase errors, $\delta\varphi_1$, $\delta\varphi_2$, and $\delta\varphi_3$ (Fig. 9.5). For baseline \mathbf{a}_{12} , we measure the degree of coherence $\gamma_{\perp 12} \propto \overline{\psi_1 \psi_2^*}$, a complex number with phase $\Phi_{12} = \varphi_{12} + \delta\varphi_1 - \delta\varphi_2$, where φ_{12} is the phase of $\gamma_{\perp 12}$ in the absence of phase errors. If we also measure the degrees of coherence for the other two pairs of telescopes in the triangle and derive their phases Φ_{23} and Φ_{31} , we can then calculate the quantity

$$\begin{aligned} C_{123} &= \Phi_{12} + \Phi_{23} + \Phi_{31} \\ &= \varphi_{12} + \varphi_{23} + \varphi_{31}, \end{aligned} \quad (9.28)$$

from which the phase errors cancel out.

The quantity C_{123} , known as the *closure phase*, can be measured with high accuracy. In the JVLA, there are $27 \times 26 \times 25/6 = 2,925$ such closure phases, and they can all be measured with considerable redundancy. Although absolute phase information cannot be recovered, 93% of the telescopes’ relative phases can be inferred in this manner and used to construct an image far superior to what could be achieved without any phase information.

closure phase

FIGURE 9.5 Closure-phase measurement using a triangle of telescopes.

When the telescope spacings are well sampled and the source is bright enough to carry out these image-processing techniques, an interferometer can have an angular resolving power approaching that of an equivalent filled aperture as large as the maximum telescope spacing. For the JVLA the best angular resolution is 50 milliarcsec and at ALMA it will be as fine as 4 milliarcsec, thousands of times better than single dishes.

Even greater angular resolution is achieved with a technique known as very long baseline interferometry (VLBI). Here the telescopes can be located on different continents and instead of linking them directly, the oscillating field amplitudes $\psi(t)$ are stored electronically. Then they are combined digitally long after the observation to compute the complex degree of coherence and thence the source structure $I(\alpha)$. In this way angular resolutions more than 300 times better than those achievable by the JVLA have been obtained. Structure smaller than a milliarcsec, corresponding to a few light-years at cosmological distances, can be measured in this manner. A most exciting prospect is to use submillimeter VLBI to resolve marginally the event horizons of massive black holes, specifically, the four-million-solar-mass hole at the center of our galaxy and the six-billion-solar-mass hole at the center of the nearby galaxy M87. Existing observations by a collaboration called the “event horizon telescope” have already (2016) measured interference fringes on angular scales ~ 5 times larger than these black holes’ gravitational radii, i.e. $\sim 10 GM/c^2$.

EXERCISES

Exercise 9.9 Example: Radio Interferometry from Space

The longest radio-telescope separation available in 2016 is that between telescopes on Earth’s surface and a 10-m diameter radio telescope in the Russian RadioAstron satellite, which was launched into a highly elliptical orbit around Earth in summer 2011, with perigee $\sim 10,000$ km (1.6 Earth radii) and apogee $\sim 350,000$ km (55 Earth radii).

- (a) Radio astronomers conventionally describe the specific intensity $I_\omega(\alpha, \omega)$ of a source in terms of its brightness temperature. This is the temperature $T_b(\omega)$ that a blackbody would have to emit, in the Rayleigh-Jeans (low-frequency) end of its spectrum, to produce the same specific intensity as the source. Show that for a single (linear or circular) polarization, if the solid angle subtended by a source is $\Delta\Omega$ and the spectral energy flux measured from the source is $F_\omega \equiv \int I_\omega d\Omega = I_\omega \Delta\Omega$, then the brightness temperature is

$$T_b = \frac{(2\pi)^3 c^2 I_\omega}{k_B \omega^2} = \frac{(2\pi)^3 c^2 F_\omega}{k_B \omega^2 \Delta\Omega}, \quad (9.29)$$

where k_B is Boltzmann’s constant.

- (b) The brightest quasars emit radio spectral fluxes of about $F_\omega = 10^{-25} \text{ W m}^{-2} \text{ Hz}^{-1}$, independent of frequency. The smaller such a quasar is, the larger will be its brightness temperature. Thus, one can characterize the small-

est sources that a radio-telescope system can resolve by the highest brightness temperatures it can measure. Show that the maximum brightness temperature measurable by the Earth-to-orbit RadioAstron interferometer is independent of the frequency at which the observation is made, and estimate its numerical value.

9.4 Etalons and Fabry-Perot Interferometers

9.4

We have shown how a Michelson interferometer (Fig. 9.3) can be used as a Fourier-transform spectrometer: one measures the complex fringe visibility as a function of the two arms' optical path difference and then takes the visibility's Fourier transform to obtain the spectrum of the radiation. The inverse process is also powerful. One can drive a Michelson interferometer with radiation with a known, steady spectrum (usually close to monochromatic), and look for time variations of the positions of its fringes caused by changes in the relative optical path lengths of the interferometer's two arms. This was the philosophy of the famous Michelson-Morley experiment to search for ether drift, and it is also the underlying principle of a laser interferometer ("interferometric") gravitational-wave detector.

To reach the sensitivity required for gravitational-wave detection, one must modify the Michelson interferometer by making the light travel back and forth in each arm many times, thereby amplifying the phase shift caused by changes in the arm lengths. This is achieved by converting each arm into a Fabry-Perot interferometer. In this section, we study Fabry-Perot interferometers and some of their other applications, and in Sec. 9.5, we explore their use in gravitational-wave detection.

9.4.1 Multiple-Beam Interferometry; Etalons

9.4.1

Fabry-Perot interferometry is based on trapping monochromatic light between two highly reflecting surfaces. To understand such trapping, let us consider the concrete situation where the reflecting surfaces are flat and parallel to each other, and the transparent medium between the surfaces has one index of refraction n , while the medium outside the surfaces has another index n' (Fig. 9.6). Such a device is sometimes called an *etalon*. One example is a glass slab in air ($n \simeq 1.5$, $n' \simeq 1$); another is a vacuum maintained between two glass mirrors ($n = 1$, $n' \simeq 1.5$). For concreteness, we discuss the slab case, though all our formulas are equally valid for a vacuum between mirrors or for any other etalon.

etalon

Suppose that a monochromatic plane wave (i.e., with parallel rays) with angular frequency ω is incident on one of the slab's reflecting surfaces, where it is partially reflected and partially transmitted with refraction. The transmitted wave will propagate through to the second surface, where it will be partially reflected and partially transmitted. The reflected portion will return to the first surface, where it too will be split, and so on (Fig. 9.6a). The resulting total fields in and outside the slab can be computed by summing the series of sequential reflections and transmissions (Ex. 9.12). Alternatively, they can be computed as follows.

FIGURE 9.6 Multiple-beam interferometry using a type of Fabry-Perot etalon.

Assume, for pedagogical simplicity, that there is translational invariance along the slab (i.e., the slab and incoming wave are perfectly planar). Then the series, if summed, would lead to the five waves shown in Fig. 9.6b: an incident wave (ψ_i), a reflected wave (ψ_r), a transmitted wave (ψ_t), and two internal waves (ψ_a and ψ_b).

amplitude reflection and transmission coefficients

We introduce amplitude reflection and transmission coefficients, denoted r and t , for waves incident on the slab surface from outside. Likewise, we introduce coefficients r' , t' for waves incident on the slab from inside. These coefficients are functions of the angles of incidence and the light's polarization. They can be computed using electromagnetic theory (e.g., Hecht, 2017, Sec. 4.6.2), but this will not concern us here.

Armed with these definitions, we can express the reflected and transmitted waves at the first surface (location A in Fig. 9.7) in the form

$$\begin{aligned}\psi_r &= r\psi_i + t'\psi_b, \\ \psi_a &= t\psi_i + r'\psi_b,\end{aligned}\tag{9.30a}$$

where ψ_i , ψ_a , ψ_b , and ψ_r are the values of ψ at A for waves impinging on or leaving the surface along the paths i , a , b , and r , respectively, depicted in Fig. 9.7. Simple geometry shows that the waves at the second surface are as depicted in Fig. 9.7. Correspondingly, the relationships between the ingoing and outgoing waves there are

$$\begin{aligned}\psi_b e^{-iks_1} &= r'\psi_a e^{ik(s_1-s_2)}, \\ \psi_t &= t'\psi_a e^{iks_1},\end{aligned}\tag{9.30b}$$

where $k = n\omega/c$ is the wave number in the slab, and (as is shown in the figure) s_1 and s_2 are defined as

$$s_1 = d \sec \theta, \quad s_2 = 2d \tan \theta \sin \theta,\tag{9.30c}$$

with d the thickness of the slab, and θ the angle that the wavefronts inside the slab make to the slab's faces.

In solving Eqs. (9.30) for the net transmitted and reflected waves ψ_t and ψ_r in terms of the incident wave ψ_i , we need *reciprocity relations* between the reflection

FIGURE 9.7 Construction for calculating the phase differences across the slab for the two internal waves in an etalon.

and transmission coefficients τ and t for waves that hit the reflecting surfaces from one side, and those between τ' and t' for waves from the other side. These reciprocity relations are analyzed quite generally in Ex. 9.10. To derive the reciprocity relations in our case of sharp boundaries between homogeneous media, consider the limit in which the slab thickness $d \rightarrow 0$. This is allowed because the wave equation is linear, and the solution for one surface can be superposed on that for the other surface. In this limit $s_1 = s_2 = 0$ and the slab must become transparent, so

$$\psi_r = 0, \quad \psi_t = \psi_i. \quad (9.31)$$

Equations (9.30a), (9.30b), and (9.31) are then six homogeneous equations in the five wave amplitudes ψ_i , ψ_r , ψ_t , ψ_a , and ψ_b , from which we can extract the two desired reciprocity relations:

$$\tau' = -\tau, \quad tt' - \tau\tau' = 1. \quad (9.32)$$

reciprocity relations

Since there is no mechanism to produce a phase shift as the waves propagate across a perfectly sharp boundary, it is reasonable to expect τ , τ' , t , and t' all to be real, as indeed they are (Ex. 9.10). [If the interface has a finite thickness, it is possible to adjust the spatial origins on the two sides of the interface so as to make τ , τ' , t , and t' all be real, leading to the reciprocity relations (9.32), but a price will be paid; see Ex. 9.10.]

Now return to the case of finite slab thickness. By solving Eqs. (9.30) for the reflected and transmitted fields and invoking the reciprocity relations (9.32), we obtain

$$\frac{\psi_r}{\psi_i} \equiv \tau_e = \frac{\tau(1 - e^{i\varphi})}{1 - \tau^2 e^{i\varphi}}, \quad \frac{\psi_t}{\psi_i} \equiv t_e = \frac{(1 - \tau^2)e^{i\varphi/(2 \cos^2 \theta)}}{1 - \tau^2 e^{i\varphi}}. \quad (9.33a)$$

Here τ_e and t_e are the etalon's reflection and transmission coefficients, and $\varphi = k(2s_1 - s_2)$, which reduces to

$$\varphi = 2n\omega d \cos \theta / c, \quad (9.33b)$$

is the light's round-trip phase shift (along path a and then b) inside the etalon, relative to the phase of the incoming light that it meets at location A . If φ is a multiple of 2π , the round-trip light will superpose coherently on the new, incoming light.

We are particularly interested in the *reflectivity and transmissivity* for the energy flux—the coefficients that tell us what fraction of the total flux (and therefore also the total power) incident on the etalon is reflected by it and what fraction emerges from its other side:

etalon's reflectivity and transmissivity

$$R = |\tau_e|^2 = \frac{|\psi_r|^2}{|\psi_i|^2} = \frac{2\tau^2(1 - \cos \varphi)}{1 - 2\tau^2 \cos \varphi + \tau^4}, \quad T = |t_e|^2 = \frac{|\psi_t|^2}{|\psi_i|^2} = \frac{(1 - \tau^2)^2}{1 - 2\tau^2 \cos \varphi + \tau^4}. \quad (9.33c)$$

From these expressions, we see that

energy conservation

$$R + T = 1, \quad (9.33d)$$

which says that the energy flux reflected from the slab plus that transmitted is equal to that impinging on the slab (energy conservation). It is actually the reciprocity relations (9.32) for the amplitude reflection and transmission coefficients that enforce this energy conservation. If they had contained a provision for absorption or scattering of light in the interfaces, $R + T$ would have been less than one.

We discuss the etalon's reflectivity and transmissivity, Eq. (9.33c), at length in Sec. 9.4.2. But first, in a set of example exercises, we clarify some important issues related to the above analysis.

EXERCISES

Exercise 9.10 Example: Reciprocity Relations for a Locally Planar Optical Device

Modern mirrors, etalons, beam splitters, and other optical devices are generally made of glass or fused silica (quartz) and have dielectric coatings on their surfaces. The coatings consist of alternating layers of materials with different dielectric constants, so the index of refraction n varies periodically. If, for example, the period of n 's variations is half a wavelength of the radiation, then waves reflected from successive dielectric layers build up coherently, producing a large net reflection coefficient; the result is a highly reflecting mirror.

In this exercise, we use a method due to Stokes to derive the reciprocity relations for devices with dielectric coatings, and in fact for much more general devices. Specifically, our derivation will be valid for locally plane-fronted, monochromatic waves

FIGURE 9.8 Construction for deriving reciprocity relations for amplitude transmission and reflection coefficients.

impinging on an arbitrary, locally planar, lossless optical device.⁸ The device could be a mirror, a surface with an antireflection coating (Ex. 9.13 below), an etalon, or any sequence of such objects with locally parallel surfaces.

Let a plane, monochromatic wave $\psi_i e^{i\mathbf{k}_i \cdot \mathbf{x}} e^{-i\omega t}$ impinge on the optical device from above, and orient the device so its normal is in the z direction and it is translation invariant in the x and y directions; see Fig. 9.8a. Then the reflected and transmitted waves are as shown in the figure. Because the medium below the device can have a different index of refraction from that above, the waves' propagation direction below may be different from that above, as shown. For reasons explained in part (e), we denote position below the device by \mathbf{x}' and position above the device by \mathbf{x} . Some arbitrary choice has been made for the locations of the vertical origins $z = 0$ and $z' = 0$ on the two sides of the device.

- (a) Consider a thought experiment in which the waves of Fig. 9.8a are time-reversed, so they impinge on the device from the original reflection and transmission directions and emerge toward the original input direction, as shown in Fig. 9.8b. If the device had been lossy, the time-reversed waves would not satisfy the field's wave equation; the absence of losses guarantees they do. Show that mathematically, the time reversal can be achieved by complex conjugating the spatial part of the waves while leaving the temporal part $e^{-i\omega t}$ unchanged. (Such phase conjugation can be achieved in practice using techniques of nonlinear optics, as we

8. By "locally" plane-fronted and planar, we mean that transverse variations are on scales sufficiently long compared to the wavelength of light that we can use the plane-wave analysis sketched here; for example, the spherical mirrors and Gaussian beams of an interferometric gravitational-wave detector (see Fig. 9.13 in Sec. 9.5) easily satisfy this requirement. By lossless we mean that there is no absorption or scattering of the light.

shall see in the next chapter.) Show, correspondingly, that the spatial part of the time-reversed waves is described by the formulas shown in Fig. 9.8b.

- (b) Use the reflection and transmission coefficients to compute the waves produced by the inputs of Fig. 9.8b. From the requirement that the wave emerging from the device's upward side must have the form shown in the figure, conclude that

$$1 = \tau\tau^* + t't^*. \quad (9.34a)$$

Similarly, from the requirement that no wave emerge from the device's downward side, conclude that

$$0 = t\tau^* + t'^*\tau'. \quad (9.34b)$$

Eqs. (9.34) are the most general form of the reciprocity relations for lossless, planar devices.

- (c) For a sharp interface between two homogeneous media, combine these general reciprocity relations with the ones derived in the text [Eqs. (9.32)] to show that t , t' , τ , and τ' are all real (as was asserted in the text).
- (d) For the etalon of Figs. 9.6 and 9.7, τ_e and t_e are given by Eqs. (9.33a). What do the reciprocity relations tell us about the coefficients for light propagating in the opposite direction, τ'_e and t'_e ?
- (e) Show that for a general optical device, the reflection and transmission coefficients can all be made real by appropriate, independent *adjustments of the origins of the vertical coordinates* z (for points above the device) and z' (for points below the device). More specifically, show that by setting $z_{\text{new}} = z_{\text{old}} + \delta z$ and $z'_{\text{new}} = z'_{\text{old}} + \delta z'$ and choosing δz and $\delta z'$ appropriately, one can make t and τ real. Show further that the reciprocity relations (9.34a) and (9.34b) then imply that t' and τ' are also real. Finally, show that this adjustment of origins brings the real reciprocity relations into the same form (9.32) as for a sharp interface between two homogeneous media.

As attractive as it may be to have these coefficients real, one must keep in mind some disadvantages: (i) the displaced origins for z and z' in general will depend on frequency, and correspondingly, (ii) frequency-dependent information (most importantly, frequency-dependent phase shifts of the light) is lost by making the coefficients real. If the phase shifts depend only weakly on frequency over the band of interest (as is typically the case for the dielectric coating of a mirror face), then these disadvantages are unimportant and it is conventional to choose the coefficients real. If the phase shifts depend strongly on frequency over the band of interest [e.g., for the etalon of Eqs. (9.33a), when its two faces are highly reflecting and its round-trip phase φ is near a multiple of 2π], the disadvantages are severe. One then should leave the origins frequency independent, and correspondingly leave the device's τ , τ' , t , and t' complex [as we have for the etalon in Eqs. (9.33a)].

Exercise 9.11 ***Example: Transmission and Reflection Coefficients for an Interface between Dielectric Media*

Consider monochromatic electromagnetic waves that propagate from a medium with index of refraction n_1 into a medium with index of refraction n_2 . Let z be a Cartesian coordinate perpendicular to the planar interface between the media.

- (a) From the Helmholtz equation $[-\omega^2 + (c^2/n^2)\nabla^2]\psi = 0$, show that both ψ and $\psi_{,z}$ must be continuous across the interface.
- (b) Using these continuity requirements, show that for light propagating orthogonal to the interface (z direction), the reflection and transmission coefficients, in going from medium 1 to medium 2, are

$$\boxed{\tau = \frac{n_1 - n_2}{n_1 + n_2}, \quad t = \frac{2n_1}{n_1 + n_2}.} \quad (9.35)$$

Notice that these τ and t are both real.

- (c) Use the reciprocity relations (9.34) to deduce the reflection and transmission coefficients τ' and t' for a wave propagating in the opposite direction, from medium 2 to medium 1.

Exercise 9.12 ***Example: Etalon's Light Fields Computed by Summing the Contributions from a Sequence of Round Trips*

Study the step-by-step buildup of the field inside an etalon and the etalon's transmitted field, when the input field is suddenly turned on. More specifically, carry out the following steps.

- (a) When the wave first turns on, the transmitted field inside the etalon, at point A of Fig. 9.7, is $\psi_a = t\psi_i$, which is very small if the reflectivity is high so that $|t| \ll 1$. Show (with the aid of Fig. 9.7) that, after one round-trip-travel time in the etalon, the transmitted field at A is $\psi_a = t\psi_i + (\tau')^2 e^{i\varphi} t\psi_i$. Show that for high reflectivity and on resonance, the tiny transmitted field has doubled in amplitude and its energy flux has quadrupled.
- (b) Compute the transmitted field ψ_a at A after more and more round trips, and watch it build up. Sum the series to obtain the steady-state field ψ_a . Explain the final, steady-state amplitude: why is it not infinite, and why, physically, does it have the value you have derived?
- (c) Show that, at any time during this buildup, the field transmitted out the far side of the etalon is $\psi_t = t'\psi_a e^{iks_1}$ [Eq. (9.30b)]. What is the final, steady-state transmitted field? Your answer should be Eqs. (9.33a).

Exercise 9.13 ***Example: Anti-Reflection Coating*

A common technique used to reduce the reflection at the surface of a lens is to coat it with a quarter wavelength of material with refractive index equal to the geometric mean of the refractive indices of air and glass.

- (a) Show that this does indeed lead to perfect transmission of normally incident light.
- (b) Roughly how thick must the layer be to avoid reflection of blue light? Estimate the energy-flux reflection coefficient for red light in this case.

[Hint: The amplitude reflection coefficients at an interface are given by Eqs. (9.35).]

Exercise 9.14 *Problem: Oil Slick*

When a thin layer of oil lies on top of water, one sometimes sees beautiful, multi-colored, irregular bands of light reflecting off the oil layer. Explain qualitatively what causes this.

9.4.2

9.4.2 Fabry-Perot Interferometer and Modes of a Fabry-Perot Cavity with Spherical Mirrors

Fabry-Perot interferometer

When an etalon's two faces are highly reflecting (reflection coefficient r near unity), we can think of them as mirrors, between which the light resonates. The etalon is then a special case of a *Fabry-Perot interferometer*. The general case is any device in which light resonates between two high-reflectivity mirrors. The mirrors need not be planar and need not have the same reflectivities, and the resonating light need not be plane fronted.

A common example is the optical cavity of Fig. 7.9, formed by two mirrors that are segments of spheres, which we studied using geometric optics in Ex. 7.12. Because the phase fronts of a Gaussian beam (Sec. 8.5.5) are also spherical, such a beam can resonate in the optical cavity if (i) the beam's waist location and waist radius are adjusted so its phase-front radii of curvature, at the mirrors, are the same as the mirrors' radii of curvature, and (ii) the light's frequency is adjusted so a half-integral number of wavelengths fit perfectly inside the cavity. Box 9.3 gives details for the case where the two mirrors have identical radii of curvature. In that box we also learn that the Gaussian beams are not the only eigenmodes that can resonate inside such a cavity. Other, "higher-order" modes can also resonate. They have more complex transverse distributions of the light. There are two families of such modes: one with rectangular transverse light distributions, and the other with wedge-shaped, spoke-like light distributions.

For any Fabry-Perot interferometer with identical mirrors, driven by light with a transverse cross section that matches one of the interferometer's modes, one can study the interferometer's response to the driving light by the same kind of analysis as we used for an etalon in the previous section. And the result will be the same: the interferometer's reflected and transmitted light, at a given transverse location $\{x, y\}$, will be given by

$$\frac{\psi_r}{\psi_i} \equiv r_{\text{FP}} = \frac{r(1 - e^{i\varphi})}{1 - r^2 e^{i\varphi}}, \quad \frac{\psi_t}{\psi_i} \equiv t_{\text{FP}} = \frac{(1 - r^2)e^{i\varphi/2}}{1 - r^2 e^{i\varphi}} \quad (9.36)$$

BOX 9.3. MODES OF A FABRY-PEROT CAVITY WITH SPHERICAL MIRRORS

Consider a Fabry-Perot cavity whose spherical mirrors have the same radius of curvature R and are separated by a distance L . Introduce (i) Cartesian coordinates with $z = 0$ at the cavity's center, and (ii) the same functions we used for Gaussian beams [Eqs. (8.40b)]:

$$z_0 = \frac{k\sigma_0^2}{2} = \frac{\pi\sigma_0^2}{\lambda}, \quad \sigma_z = \sigma_0(1 + z^2/z_0^2)^{1/2}, \quad R_z = z(1 + z_0^2/z^2), \quad (1)$$

with k the wave number and σ_0 a measure of the transverse size of the beam at the cavity's center. Then it is straightforward to verify that the following functions (i) satisfy the Helmholtz equation, (ii) are orthonormal when integrated over their transverse Cartesian coordinates x and y , and (iii) have phase fronts (surfaces of constant phase) that are spheres with radius of curvature R_z :

$$\begin{aligned} \psi_{mn}(x, y, z) = & \frac{e^{-(x^2+y^2)/\sigma_z^2}}{\sqrt{2^{m+n-1}\pi m!n!}\sigma_z} H_m\left(\frac{\sqrt{2}x}{\sigma_z}\right) H_n\left(\frac{\sqrt{2}y}{\sigma_z}\right) \\ & \times \exp\left\{i\left[\frac{k(x^2+y^2)}{2R_z} + kz - (n+m+1)\tan^{-1}\frac{z}{z_0}\right]\right\}. \quad (2) \end{aligned}$$

Here $H_n(\xi) = (-1)^n e^{\xi^2} d^n e^{-\xi^2} / d\xi^n$ is the Hermite polynomial of index n , and m and n range over nonnegative integers. By adjusting σ_0 , we can make the phase-front radius of curvature R_z match that, R , of the mirrors at the mirror locations, $z = \pm L/2$. Then the u_{mn} are a transversely orthonormal set of modes for the light field inside the cavity. Their flux distribution $|u_{mn}|^2$ on each mirror consists of an $m + 1$ by $n + 1$ matrix of discrete spots; see panel b in the box figure. The mode with $m = n = 0$ (panel a) is the Gaussian beam explored in the previous chapter: Eqs. (8.40). A given mode, specified by $\{m, n, k\}$, cannot resonate inside the cavity unless its wave number matches the cavity length, in the sense that the total phase shift in traveling from the cavity center $z = 0$ to the cavity end ($z = \pm L/2$) is an integral multiple of $\pi/2$; that is, $kL/2 - (n + m + 1)\tan^{-1}[L/(2z_0)] = N\pi/2$ for some integer N .

There is a second family of modes that can resonate in the cavity, one whose eigenfunctions separate in circular polar coordinates:

$$\begin{aligned} \psi_{pm}(\varpi, \phi, z) = & \frac{2p!e^{-\varpi^2/\sigma_z^2}}{\sqrt{1+\delta_{m0}}\pi(p+m)!\sigma_z} \left(\frac{\sqrt{2}\varpi}{\sigma_z}\right)^m L_p^m\left(\frac{2\varpi^2}{\sigma_z^2}\right) \begin{pmatrix} \cos m\phi \text{ or} \\ \sin m\phi \end{pmatrix} \\ & \times \exp\left\{i\left[\frac{k\varpi^2}{2R_z} + kz - (2p+m+1)\tan^{-1}\frac{z}{z_0}\right]\right\}, \quad (3) \end{aligned}$$

(continued)

BOX 9.3. (continued)

Energy flux distributions for (a) the Gaussian mode, (b) the Hermite mode of order 3,2, (c) the associated Laguerre mode of order 2,3. The contours are at 90%, 80%, . . . , 10% of maximum.

where $L_p^m(\xi) = (1/p!) e^\xi \xi^{-m} d^p/d\xi^p(e^{-\xi} \xi^{p+m})$ is the associated Laguerre polynomial, and the indices p and m range over nonnegative integers. These modes make spots on the mirrors shaped like azimuthal wedges cut radially by circles; see panel c in the box figure. Again, they can resonate only if the phase change from the center of the cavity to an end mirror at $z = \pm L/2$ is an integral multiple of $\pi/2$: $kL/2 - (2p + m + 1) \tan^{-1}[L/(2z_0)] = N\pi/2$.

As one goes to larger mode numbers m, n (Hermite modes) or p, m (associated Laguerre modes), the region with substantial light power gets larger (see the box figure). As a result, more light gets lost off the edges of the cavity's mirrors. So unless the mirrors are made very large, high-order modes have large losses and do not resonate well.

For further details on these modes, see, for example, Yariv and Yeh (2007, Secs. 2.5–2.8 and 4.3).

[Eqs. (9.33a) with $\theta = 0$ so the light rays are orthogonal to the mirrors]. Here r is the mirrors' reflection coefficient, and the round-trip phase is now

$$\varphi = 2\pi\omega/\omega_f + \varphi_G, \quad \text{where } \omega_f = 2\pi/\tau_{rt}. \quad (9.37)$$

Here τ_{rt} is the time required for a high-frequency photon to travel round-trip in the interferometer along the optic axis, from one mirror to the other; ω_f (called the *free spectral range*) is, as we shall see, the angular-frequency separation between the interferometer's resonances; and φ_G is an additive contribution (the Gouy phase), caused by the curvature of the phase fronts [e.g., the $\tan^{-1}(z/z_o)$ term in Eq. (8.40a) for a Gaussian beam and in Eqs. (2) and (3) of Box 9.3 for higher-order modes]. Because φ_G is of order one while $2\pi\omega/\omega_f$ is huge compared to one, and because φ_G changes very slowly with changing light frequency, it is unimportant in principle (and we henceforth shall ignore it). However, it is important in practice: it causes modes with different transverse light distributions (e.g., the Gaussian and higher-order modes in Box 9.3), which have different Gouy phases, to resonate at different frequencies.

The Fabry-Perot interferometer's power transmissivity T and reflectivity R are given by Eqs. (9.33c), which we can rewrite in the following simplified form:

$$T = 1 - R = \frac{1}{1 + (2\mathcal{F}/\pi)^2 \sin^2 \frac{1}{2}\varphi}. \quad (9.38)$$

Here \mathcal{F} , called the interferometer's *finesse*, is defined by

$$\mathcal{F} \equiv \pi\tau/(1 - r^2). \quad (9.39)$$

[This finesse should not be confused with the *coefficient of finesse* $F = (2\mathcal{F}/\pi)^2$, which is sometimes used in optics, but which we eschew to avoid confusion.]

In Fig. 9.9 we plot, as functions of the round-trip phase $\varphi = 2\pi\omega/\omega_f$ (ignoring φ_G), the interferometer's power reflectivity and transmissivity T and R , and the phase changes $\arg(t_{FP})$ and $\arg(r_{FP})$ of the light that is transmitted and reflected by the interferometer.

Notice in Fig. 9.9a that, when the finesse \mathcal{F} is large compared to unity, the interferometer exhibits sharp resonances at frequencies separated by the free spectral range ω_f . On resonance, the interferometer is perfectly transmitting ($T = 1$); away from resonance, it is nearly perfectly reflecting ($R \simeq 1$). The *full width at half maximum* (FWHM) of each sharp transmission resonance is given by

$$\delta\varphi_{1/2} = \frac{2\pi}{\mathcal{F}}, \quad \delta\omega_{1/2} = \frac{\omega_f}{\mathcal{F}}. \quad (9.40a)$$

In other words, if the frequency ω of the light is swept slowly through resonance, the transmission will be within 50% of its peak value (unity) over a bandwidth $\delta\omega_{1/2} = \omega_f/\mathcal{F}$. Notice also, in Fig. 9.9b, that for large finesse, the phase of the reflected and

(b)

FIGURE 9.9 (a) Power transmissivity and reflectivity [Eq. (9.38)] for a Fabry-Perot interferometer with identical mirrors that have reflection coefficients τ , as a function of the round-trip phase shift φ inside the interferometer. (b) The phase of the light transmitted (red) or reflected (blue) from the interferometer, relative to the input phase [Eqs. (9.36)]. The interferometer's finesse \mathcal{F} is related to the mirrors' reflectivity by Eq. (9.39).

transmitted light near resonance changes very rapidly with a change in frequency of the driving light. Precisely on resonance, that rate of change is

resonance rate of change of phase

$$\left(\frac{d \arg(t_{FP})}{d\omega} \right)_{\text{on resonance}} = \left(\frac{d \arg(r_{FP})}{d\omega} \right)_{\text{on resonance}} = \frac{2\mathcal{F}}{\omega_f} = \frac{2}{\delta\omega_{1/2}}. \quad (9.40b)$$

The large transmissivity at resonance for large finesse can be understood by considering what happens when one first turns on the incident wave. Since the reflectivity

of the first (input) mirror is near unity, the incoming wave has a large amplitude for reflection, and correspondingly, only a tiny amplitude for transmission into the optical cavity. The tiny bit that gets transmitted travels through the first mirror, gets strongly reflected from the second mirror, and returns to the first precisely in phase with the incoming wave (because φ is an integer multiple of 2π). Correspondingly, it superposes coherently on the tiny field being transmitted by the incoming wave, and so the net wave inside the cavity is doubled. After one more round trip inside the slab, this wave returns to the first face again in phase with the tiny field being transmitted by the incoming wave; again they superpose coherently, and the internal wave now has a three-times-larger amplitude than it began with. This process continues until a very strong field has built up inside the cavity (Ex. 9.12). As it builds up, that field begins to leak out of the cavity's first mirror with just such a phase as to destructively interfere with the wave being reflected there. The net reflected wave is thereby driven close to zero. The field leaking out of the second mirror has no other wave to interfere with. It remains strong, so the interferometer settles down into a steady state with strong net transmission. Heuristically, one can say that, because the wave inside the cavity is continually constructively superposing on itself, the cavity sucks almost all the incoming wave into itself, and then ejects it out the other side. Quantum mechanically, this sucking is due to the photons' Bose-Einstein statistics: the photons "want" to be in the same quantum state. We shall study this phenomenon in the context of plasmons that obey Bose-Einstein statistics in Sec. 23.3.2.

This discussion makes it clear that, when the properties of the input light are changed, a high-finesse Fabry-Perot interferometer will change its response rather slowly—on a timescale approximately equal to the inverse of the resonance FWHM (i.e., the finesse times the round-trip travel time):

$$\tau_{\text{response}} \sim \frac{2\pi}{\delta\omega_{1/2}} = \mathcal{F} \tau_{\text{rt}}. \quad (9.40c)$$

These properties of a high-finesse Fabry-Perot interferometer are similar to those of a high- Q mechanical or electrical oscillator. The similarity arises because, in both cases, energy is being stored in a resonant, sinusoidal manner inside the device (the oscillator or the interferometer). For the interferometer, the light's round-trip travel time τ_{rt} is analogous to the oscillator's period, the interferometer's free spectral range ω_f is analogous to the oscillator's resonant angular frequency, and the interferometer's finesse \mathcal{F} is analogous to the oscillator's quality factor Q . However, there are some major differences between an ordinary oscillator and a Fabry-Perot interferometer. Perhaps the most important is that the interferometer has several large families of resonant modes (families characterized by the number of longitudinal nodes between the mirrors and by the 2-dimensional transverse distributions of the light), whereas an oscillator has just one mode. This gives an interferometer much greater versatility than a simple oscillator possesses.

9.4.3 Fabry-Perot Applications: Spectrometer, Laser, Mode-Cleaning Cavity, Beam-Shaping Cavity, PDH Laser Stabilization, Optical Frequency Comb T2

Just as mechanical and electrical oscillators have a wide variety of important applications in science and technology, so also do Fabry-Perot interferometers. In this section, we sketch a few of them.

SPECTROMETER

In the case of a Fabry-Perot etalon (highly reflecting parallel mirrors; plane-parallel light beam), the resonant transmission enables the etalon to be used as a spectrometer. The round-trip phase change $\varphi = 2n\omega d \cos \theta/c$ inside the etalon varies linearly with the wave's angular frequency ω , but only waves with round-trip phase φ near an integer multiple of 2π will be transmitted efficiently. The etalon can be tuned to a particular frequency by varying either the slab width d or the angle of incidence of the radiation (and thence the angle θ inside the etalon). Either way, impressively good chromatic resolving power can be achieved. We say that waves with two nearby frequencies can just be resolved by an etalon when the half-power point of the transmission coefficient of one wave coincides with the half-power point of the transmission coefficient of the other. Using Eq. (9.38) we find that the phases for the two frequencies must differ by $\delta\varphi \simeq 2\pi/\mathcal{F}$. Correspondingly, since $\varphi = 2n\omega d \cos \theta/c$, the *chromatic resolving power* is

chromatic resolving power
of a spectrometer

$$\mathcal{R} = \frac{\omega}{\delta\omega} = \frac{4\pi nd \cos \theta}{\lambda_{\text{vac}} \delta\varphi} = \frac{2nd \cos \theta \mathcal{F}}{\lambda_{\text{vac}}}. \quad (9.41)$$

Here $\lambda_{\text{vac}} = 2\pi c/\omega$ is the wavelength in vacuum (i.e., outside the etalon).

LASER

Fabry-Perot interferometers are exploited in the construction of many types of lasers. For example, in a gas-phase laser, the atoms are excited to emit a spectral line. This radiation is spontaneously emitted isotropically over a wide range of frequencies. Placing the gas between the mirrors of a Fabry-Perot interferometer allows one or more highly collimated and narrowband modes to be trapped and, while trapped, to be amplified by stimulated emission (i.e., to lase). See Sec. 10.2.1.

MODE CLEANER FOR A MESSY LASER BEAM

The output beam from a laser often has a rather messy cross sectional profile, for example because it contains multiple modes of excitation of the Fabry-Perot interferometer in which the lasing material resides (see the discussion of possible modes in Box 9.3). For many applications, one needs a much cleaner laser beam (e.g., one with a Gaussian profile). To clean the beam, one can send it into a high-finesse Fabry-Perot cavity with identical spherical mirrors, whose mirror curvatures and cavity length are adjusted so that, among the modes present in the beam, only the desired Gaussian mode will resonate and thereby be transmitted (see the sharp transmission peaks in Fig. 9.9a). The beam's unwanted modes will not resonate in the cavity, and therefore will be reflected backward off its input mirror, leaving the transmitted beam clean.

cleaning a light beam

BEAM-SHAPING CAVITY

In some applications one wants a light beam whose cross sectional distribution of flux $F(x, y)$ is different from any of the modes that resonate in a spherical-mirror cavity—for example, one might want a circular, flat-topped flux distribution $F(\varpi)$ with steeply dropping edges, like the shape of a circular mesa in a North American desert. One can achieve the desired light distribution (or something approximating it) as follows. Build a Fabry-Perot cavity with identical mirrors that are shaped in such a way that there is a cavity mode with the desired distribution. Then drive the cavity with a Gaussian beam. That portion of the beam with the desired flux distribution will resonate in the interferometer and leak out of the other mirror as the desired beam; the rest of the input beam will be rejected by the cavity.

reshaping a light beam

LASER STABILIZATION

There are two main ways to stabilize the frequency of a laser. One is to lock it onto the frequency of some fundamental atomic or molecular transition. The other is to lock it onto a resonant frequency of a mechanically stable Fabry-Perot cavity—a technique called *Pound-Drever-Hall (PDH) locking*.

PDH locking

In PDH locking to a cavity with identical mirrors, one passes the laser's output light (with frequency ω) through a device that modulates its frequency,⁹ so ω becomes $\omega + \delta\omega$ with $\delta\omega = \sigma \cos(\Omega t)$ and $\sigma \ll \delta\omega_{1/2}$, the cavity resonance's FWHM. One then sends the modulated light into the cavity and monitors the reflected light power. Assume, for simplicity, that the modulation is slow compared to the cavity response time, $\Omega \ll 1/\tau_{\text{response}}$. Then the cavity's response at any moment will be that for steady light, that is, the reflected power will be $P_i R(\omega + \delta\omega)$, where R is the reflectivity at frequency $\omega + \delta\omega$. Using Eq. (9.38) for the reflectivity, specialized to frequencies very near resonance so the denominator is close to one, and using Eqs. (9.37) and (9.40a), we bring the reflected power into the form

$$\begin{aligned} P_r &= P_i R(\omega + \delta\omega) = P_i \times \left[R(\omega) + \frac{dR}{d\omega} \delta\omega(t) \right] \\ &= P_i \left[R(\omega) + \frac{8\sigma(\omega - \omega_o)}{(\delta\omega_{1/2})^2} \cos \Omega t \right], \end{aligned} \quad (9.42)$$

where ω_o is the cavity's resonant frequency (at which φ is an integral multiple of 2π).

The modulated part of the reflected power has an amplitude directly proportional to the laser's frequency error, $\omega - \omega_o$. In the PDH technique, one monitors this modulated power with a photodetector, followed by a band-pass filter on the photodetector's output electric current to get rid of the unmodulated part of the signal [arising from $P_i R(\omega)$]. The amplitude of the resulting, modulated output current is proportional

9. Actually, one sends it through a phase modulator called a *Pockels cell*, consisting of a crystal whose index of refraction is modulated by applying an oscillating voltage to it. The resulting phase modulation, $\delta\phi \propto \sin \Omega t$, is equivalent to a frequency modulation, $\delta\omega = d\delta\phi/dt \propto \cos \Omega t$.

to $\omega - \omega_o$ and is used to control a *feedback circuit* that drives the laser back toward the desired, cavity-resonant frequency ω_o . (See, e.g., Black, 2001, for details.)

In Ex. 9.15 it is shown that, if one needs a faster feedback and therefore requires a modulation frequency $\Omega \gtrsim 1/\tau_{\text{response}}$, this PDH locking technique still works.

This technique was invented by Ronald Drever for use in interferometric gravitational-wave detectors, relying on earlier ideas of Robert Pound, and it was first demonstrated experimentally by Drever and John Hall. It is now used widely in many areas of science and technology.

OPTICAL FREQUENCY COMB

John Hall and Theodor Hänsch were awarded the 2005 Nobel Prize for development of the optical frequency comb. This powerful tool is based on an optical cavity of length L , filled with a lasing medium that creates and maintains a sharply pulsed internal light field with the following form (Fig. 9.10):

$$\psi = \psi_o(z - V_g t) \exp[ik_p(z - V_p t)]. \quad (9.43)$$

Here

1. we use a z coordinate that increases monotonically along the optic axis as one moves rightward from mirror 1 to mirror 2, then leftward from 2 to 1, then rightward from 1 to 2, and so forth;
2. $\exp[ik_p(z - V_p t)]$ is the p th longitudinal monochromatic mode of the cavity, with wave number $k_p \equiv p\pi/L$, phase velocity V_p , and angular frequency $k_p V_p$ lying in the optical range $\sim 10^{15}$ Hz;
3. $\psi_o(z - V_g t)$ is the envelope of a wave packet so narrow that only about one wavelength of the mode p can fit inside it;
4. the envelope travels with group velocity V_g and does not spread.

For the wave packet not to spread, V_g must have the same (constant) value over all frequencies contained in the packet, which means that the dispersion relation must have $0 = (\partial V_g / \partial k) = \partial^2 \omega / \partial k^2$; ω must be linear in k :

$$\omega = V_g(k + \kappa) \quad (9.44)$$

for some constant κ , which is typically considerably smaller than the wave numbers k contained in the packet.

It was a huge technical challenge to build a lasing cavity that creates and sustains a very narrow wave packet of this sort. Two of the keys to this achievement were (i) using a nonlinear lasing medium that amplifies light more strongly at high energy fluxes $|\psi|^2$ than at low ones and thereby tends to produce intense, short pulses rather than long, monochromatic waves and (ii) using some trickery to ensure that the lasing medium and anything else in the cavity jointly give rise to the linear dispersion relation (9.44) over a sufficiently wide frequency band. For some of the details, see Sec. 10.2.3. Because the sharp wave packet (9.43) has fixed relationships between the phases of the

FIGURE 9.10 The sharply pulsed electric field [Eq. (9.43)] inside a Fabry-Perot cavity. The envelope is shown dotted; the red curve is the full field ψ .

various monochromatic modes that make it up, the lasing optical cavity that creates it is called a *mode-locked laser*.

As the internal field's pulse hits mirror 2 time and again, it transmits through the mirror a sequence of outgoing pulses separated by the wave packet's round-trip travel time in the cavity, $\tau_{rt} = 2L/V_g$. Assuming, for pedagogical clarity, a Gaussian shape for each pulse, the oscillating internal field (9.43) produces the outgoing field $\psi \propto \sum_n \exp[-\sigma^2(t - z/c - n\tau_{rt})^2/2] \exp[-ik_p V_p(t - z/c)]$. Here $1/\sigma$ is the pulse length in time, and we have assumed vacuum-light-speed propagation outside the cavity. It is helpful to rewrite the frequency $k_p V_p$ of the oscillatory piece of this field as the sum of its nearest multiple of the cavity's free spectral range, $\omega_f = 2\pi/\tau_{rt}$, plus a frequency shift ω_s : $k_p V_p = q\omega_f + \omega_s$. The integer $q = (\text{largest integer contained in } k_p V_p/\omega_f)$ will typically be quite close to p , and ω_s is guaranteed to lie in the interval $0 \leq \omega_s < \omega_f$. The emerging electric field is then

$$\psi \propto \sum_n \exp[-\sigma^2(t - z/c - n\tau_{rt})^2/2] \exp[-i(q\omega_f + \omega_s)(t - z/c)] \quad (9.45a)$$

(Fig. 9.11a).

This entire emerging field is periodic in $t - z/c$ with period $\tau_{rt} = 2\pi/\omega_f$, except for the frequency-shift term $\exp[-i\omega_s(t - z/c)]$. The periodic piece can be expanded as a sum over discrete frequencies that are multiples of $\omega_f = 2\pi/\tau_{rt}$. Since the Fourier transform of a Gaussian is a Gaussian, this sum, augmented by the frequency shift term, turns out to be

$$\psi \propto \sum_{m=-\infty}^{+\infty} \exp\left[\frac{-(m - q)^2 \omega_f^2}{2\sigma^2}\right] \exp[-i(m\omega_f + \omega_s)(t - z/c)]. \quad (9.45b)$$

The set of discrete frequencies (spectral lines) appearing in this outgoing field is the *frequency comb* displayed in Fig. 9.11b.

mode-locked laser

pulsed electric field from mode-locked laser

electric field's optical frequency comb

FIGURE 9.11 Optical frequency comb. (a) The pulsed electric field (9.45a) emerging from the cavity. (b) The field's comb spectrum. Each line, labeled by m , has angular frequency $m\omega_f$, and is shown with height proportional to its power, $\propto \exp[-(m - q)^2 \omega_f^2 / \sigma^2]$ [cf. Eq. (9.45b)].

Some concrete numbers make clear how very remarkable this pulsed electric field (9.45a) and its frequency comb (9.45b) are:

1. The Fabry-Perot cavity typically has a length L somewhere between ~ 3 cm and ~ 3 m, so (with the group velocity V_g of order the vacuum light speed) the round-trip travel time and free spectral range are $\tau_{rt} = 2L/V_g \sim 0.3$ to 30 ns; and $\omega_f/2\pi \sim 1/\tau_{rt} \sim 30$ MHz to 3 GHz, which are radio and microwave frequencies, respectively. Since the shift frequency is $\omega_s < \omega_f$, it is also in the radio or microwave band.
2. The comb's central frequency is in the optical, $q\omega_f/2\pi \sim 3 \times 10^{14}$ Hz, so the harmonic number of the central frequency is $q \sim 10^5$ to 10^7 , roughly a million.
3. The pulse width $\sim 2/\sigma$ contains roughly one period ($2\pi/q\omega_f$) of the central frequency, so $\sigma \sim q\omega_f/3$, which means that most of the comb's power is contained in the range $m \sim 2q/3$ to $m \sim 4q/3$ (i.e., there are roughly a million strong teeth in the comb).

It is possible to lock the comb's free spectral range ω_f to a very good cesium atomic clock, whose oscillation frequency ~ 9 GHz is stable to $\delta\omega/\omega \sim 10^{-13}$ (Fig. 6.11), so ω_f has that same phenomenal stability. One can then measure the shift frequency ω_s ,

and calibrate the comb (identify the precise mode number m of each frequency in the comb) as follows.

1. Arbitrarily choose a tooth at the low-frequency end of the comb, $m_o \simeq 2q/3$ (Fig. 9.11b); it has frequency $\omega_o = m_o\omega_f + \omega_s$.
2. Separate the light in that tooth from light in the other teeth, and send a beam of that tooth's light through a frequency doubler (to be discussed in Sec. 10.7.1), thereby getting a beam with frequency $2\omega_o = 2(m_o\omega_f + \omega_s)$.
3. By beating this beam against the light in teeth at $m \sim 4q/3$, identify the tooth that most closely matches this beam's frequency. It will have frequency $2m_o\omega_f + \omega_s$, and the frequency difference (beat frequency) will be ω_s .

This reveals ω_s to very high accuracy, and one can count the number of teeth ($m_o - 1$) between this tooth $2m_o$ and its undoubled parent m_o , thereby learning the precise numerical value of m_o . From this, by tooth counting, one learns the precise mode numbers m of all the optical-band teeth in the comb, and also their frequencies $m\omega_f + \omega_s$.

With the comb now calibrated, it can be used to measure the frequency of any other beam of light in the optical band in terms of the ticking frequency of the cesium clock, to which the entire comb has been locked. The optical frequency accuracies thereby achieved are orders of magnitude better than were possible before this optical frequency comb was developed. And in the near future, as optical-frequency atomic clocks become much more accurate and stable than the microwave-frequency cesium clock (see the footnote in Sec. 6.6.1), this comb will be used to calibrate microwave and radio frequencies in terms of the ticking rates of optical frequency clocks.

For further details about optical frequency combs, see the review articles by Cundiff (2002) and Cundiff and Ye (2003).

Exercise 9.15 *Problem: PDH Laser Stabilization* T2

Show that the PDH method for locking a laser's frequency to an optical cavity works for modulations faster than the cavity's response time, $\Omega \gtrsim 1/\tau_{\text{response}}$, and even works for $\Omega \gg 1/\tau_{\text{response}}$. More specifically, show that the reflected power still contains the information needed for feedback to the laser. [For a quite general analysis and some experimental details, see Black (2001).]

Exercise 9.16 *Derivation: Optical Frequency Comb* T2

Fill in the details of the derivation of all the equations in the section describing the optical frequency comb.

Exercise 9.17 ***Problem: Sagnac Interferometer* T2

A Sagnac interferometer is a rudimentary version of a laser gyroscope for measuring rotation with respect to an inertial frame. The optical configuration is shown in

FIGURE 9.12 Sagnac interferometer used as a type of laser gyro.

Fig. 9.12. Light from a laser L is split by a beam splitter B and travels both clockwise and counterclockwise around the optical circuit, reflecting off three plane mirrors. The light is then recombined at B , and interference fringes are viewed through the telescope T . The whole assembly rotates with angular velocity Ω . Calculate the difference in the time it takes light to traverse the circuit in the two directions, and show that the consequent fringe shift (total number of fringes that enter the telescope during one round trip of the light in the interferometer) can be expressed as $\Delta N = 4A\Omega/(c\lambda)$, where λ is the wavelength, and A is the area bounded by the beams. Show further that, for a square Sagnac interferometer with side length L , the rate at which fringes enter the telescope is $\Omega L/\lambda$.

9.5 Laser Interferometer Gravitational-Wave Detectors T2

As we discuss in Chap. 27, gravitational waves are predicted to exist by general relativity theory, and their emission by the binary neutron-star system PSR B1913+16 has been monitored since 1974, via their back-action on the binary's orbital motion. As orbital energy is lost to gravitational waves, the binary gradually spirals inward, so its orbital angular velocity gradually increases. The measured rate of increase agrees with general relativity's predictions to within the experimental accuracy of a fraction of a percent (for which Russell Hulse and Joseph Taylor received the 1993 Nobel Prize in physics). Unfortunately, the gravitational analog of Hertz's famous laboratory emission and detection of electromagnetic waves has not yet been performed, and cannot be in the authors' lifetime because of the waves' extreme weakness. For waves strong enough to be detectable on Earth, one must turn to violent astrophysical events, such as the collision and coalescence of two neutron stars or black holes.

When the gravitational waves from such an event reach Earth and pass through a laboratory, general relativity predicts that they will produce tiny relative accelerations of free test masses. The resulting oscillatory variation of the distance between two such masses can be measured optically using a Michelson interferometer, in which (to increase the signal strength) each of the two arms is operated as a Fabry-Perot

FIGURE 9.13 Schematic design of an initial gravitational-wave interferometer operated in LIGO (at Livingston, Louisiana, and Hanford, Washington, USA) during 2005–2010.

cavity. Two such instruments, called *interferometric gravitational wave detectors* [for which Rainer Weiss (1972) was the primary inventor, with important contributions from Ronald Drever and many others] made the first discovery of gravitational waves arriving at Earth on September 14, 2015 (Abbott et al., 2016a). The waves came from the last few orbits of inspiral and the collision of two black holes with masses $29M_{\odot}$ and $36M_{\odot}$, where M_{\odot} is the Sun’s mass.

The observatory that discovered these waves is called LIGO, the Laser Interferometer Gravitational Wave Observatory, and its interferometric detectors were second generation instruments, called advanced LIGO. These advanced LIGO detectors are more complex than is appropriate to analyze in this chapter, so we shall focus instead on the first generation detectors called initial LIGO (Abbott et al., 2009b), and then near the end of this section we shall briefly describe how advanced LIGO differs from initial LIGO.

In each of the initial LIGO gravitational-wave detectors, the two cavities are aligned along perpendicular directions, as shown in Fig. 9.13. A Gaussian beam of light (Sec. 8.5.5) from a laser passes through a beam splitter, creating two beams with correlated phases. The beams excite the two cavities near resonance. Each cavity has an end mirror with extremely high reflectivity,¹⁰ $1 - \tau_e^2 < 10^{-4}$, and a corner mirror (“input mirror”) with a lower reflectivity, $1 - \tau_i^2 \sim 0.03$. Because of this lower reflectivity, by contrast with the etalons discussed in previous sections, the resonant light leaks out through the input mirror instead of through the end mirror. This reflectivity of the input mirror is so adjusted that the typical photon is stored in

interferometric
gravitational wave
detector

advanced LIGO

initial LIGO

mirror reflectivity

10. Because LIGO operates with monochromatic light, it is convenient to adjust the phases of the mirrors’ reflection and transmission coefficients so τ and t are both real; cf. Ex. 9.10e. We do so here.

the cavity for roughly half the period of the expected gravitational waves (a few milliseconds), which means that the input mirror's reflectivity τ_i^2 , the arm length L , and the gravitational-wave angular frequency ω_{gw} are related by

$$\frac{4L}{c(1-\tau_i^2)} \sim \frac{1}{\omega_{\text{gw}}}. \quad (9.46)$$

The light emerging from the cavity, like that transmitted by an etalon, has a phase that is highly sensitive to the separation between the mirrors: a tiny change δL in their separation produces a change in the outgoing phase

$$\delta\phi_o \simeq \frac{8\omega\delta L}{c} \frac{1}{(1-\tau_i^2)} \sim \frac{2\omega}{\omega_{\text{gw}}} \frac{\delta L}{L} \quad (9.47)$$

in the limit $1 - \tau_i \ll 1$; see Ex. 9.18. The outgoing light beams from the two cavities return to the beam splitter and are recombined there. The relative distances from the beam splitter to the cavities are adjusted so that, in the absence of any perturbations of the cavity lengths, almost all the interfered light goes back toward the laser, and only a tiny (but nonzero) amount goes toward the photodetector of Fig. 9.13, which monitors the output. Perturbations δL_1 and δL_2 in the cavity lengths then produce a change

phase shift induced by mirror motions

$$\delta\phi_{o1} - \delta\phi_{o2} \sim \frac{2\omega}{\omega_{\text{gw}}} \frac{(\delta L_1 - \delta L_2)}{L} \quad (9.48)$$

in the relative phases at the beam splitter, and this in turn produces a change of the light power entering the photodetector. By using two cavities in this way and keeping their light-storage times (and hence response times) the same, one makes the light power entering the photodetector be insensitive to fluctuations in the laser frequency. This is crucial for obtaining the high sensitivities that gravitational-wave detection requires.

The mirrors at the ends of each cavity are suspended as pendula, and when a gravitational wave with dimensionless amplitude h (discussed in Chap. 27) passes, it moves the mirrors back and forth, producing changes

mirror motions produced by gravitational wave

$$\delta L_1 - \delta L_2 = hL \quad (9.49)$$

in the arm-length difference. The resulting change in the relative phases of the two beams returning to the beam splitter,

$$\delta\phi_{o1} - \delta\phi_{o2} \sim \frac{2\omega}{\omega_{\text{gw}}} h, \quad (9.50)$$

is monitored via the changes in power that it produces for the light going into the photodetector. If one builds the entire detector optimally and uses the best possible photodetector, these phase changes can be measured with a photon shot-noise-limited precision of $\sim 1/\sqrt{N}$. Here $N \sim [W_\ell/(\hbar\omega)](\pi/\omega_{\text{gw}})$ is the number of photons put into

detectable phase shift

the detector by the laser (with power W_ℓ) during half a gravitational-wave period.¹¹ By combining this with Eq. (9.50), we see that the weakest wave that can be detected (at signal-to-noise ratio 1) is

$$h \sim \left(\frac{\hbar \omega_{\text{gw}}^3}{4\pi \omega W_\ell} \right)^{1/2}. \quad (9.51)$$

For a laser power $W_\ell \sim 5$ W, and $\omega_{\text{gw}} \sim 10^3$ s⁻¹, $\omega \sim 2 \times 10^{15}$ s⁻¹, this gravitational-wave sensitivity (noise level) is $h \sim 1 \times 10^{-21}$.

When operated in this manner, about 97% of the light returns toward the laser from the beam splitter and the other 3% goes out the end mirror, goes into the photodetector, gets absorbed, or is scattered due to imperfections in the optics. In LIGO's initial detectors, the 97% returning toward the laser was recycled back into the interferometer, in phase with new laser light, by placing a mirror between the laser and the beam splitter. This “power recycling mirror” (shown dashed in Fig. 9.13) made the entire optical system into a big optical resonator with two subresonators (the arms' Fabry-Perot cavities), and the practical result was a 50-fold increase in the input light power, from 5 W to 250 W—and an optical power in each arm of about $\frac{1}{2} \times 250$ W \times $4/(1 - r_i^2) \sim 15$ kW; see Abbott et al. (2009b, Fig. 3). When operated in this manner, the interferometer achieved a noise level $h \sim 1 \times 10^{-21}/\sqrt{50} \sim 1 \times 10^{-22}$. For a more accurate analysis of the sensitivity, see Exs. 9.18 and 9.19.

This estimate of sensitivity is actually the rms noise in a bandwidth equal to frequency at the minimum of LIGO's noise curve. Figure 6.7 shows the noise curve as the square root of the spectral density of the measured arm-length difference $\xi \equiv L_1 - L_2$, $\sqrt{S_\xi(f)}$. Since the waves produce a change of ξ given by $\delta\xi = hL$ [Eq. (9.49)], the corresponding noise-induced fluctuations in the measured h have $S_h = S_\xi/L^2$, and the rms noise fluctuations in a bandwidth equal to frequency f are $h_{\text{rms}} = \sqrt{S_h f} = (1/L)\sqrt{S_\xi f}$. Inserting $\sqrt{S_\xi} \simeq 10^{-19}$ m Hz^{-1/2} and $f \simeq 100$ Hz from Fig. 6.7, and $L = 4$ km for the LIGO arm length, we obtain $h_{\text{rms}} \simeq 2.5 \times 10^{-22}$, a factor 2.5 larger than our 1×10^{-22} estimate—in part because thermal noise is roughly as large as photon shot noise at 100 Hz.

There are enormous obstacles to achieving such high sensitivity. Here we name just a few. Imperfections in the optics will absorb some of the high light power, heating the mirrors and beam splitter and causing them to deform. Even without such heating, the mirrors and beam splitter must be exceedingly smooth and near perfectly shaped to minimize the scattering of light from them (which causes noise; Ex. 8.15). Thermal noise in the mirrors and their suspensions (described by the fluctuation-dissipation

estimate of weakest detectable gravitational wave

power recycling

measured noise in initial LIGO

experimental challenges

11. This measurement accuracy is related to the Poisson distribution of the photons entering the interferometer's two arms: if N is the mean number of photons during a half gravitational-wave period, then the variance is \sqrt{N} , and the fractional fluctuation is $1/\sqrt{N}$. The interferometer's shot noise is actually caused by a beating of quantum electrodynamical vacuum fluctuations against the laser's light; for details see Caves (1980).

T2

theorem) will cause the mirrors to move in manners that simulate the effects of a gravitational wave (Secs. 6.8.2 and 11.9.2), as will seismic- and acoustic-induced vibrations of the mirror suspensions. LIGO's arms must be long (4 km) to minimize the effects of these noise sources. While photon shot noise dominates above the noise curve's minimum, $f \gtrsim 100$ Hz, these and other noises dominate at lower frequencies.

The initial LIGO detectors operated from 2005 to 2010, carrying out gravitational-wave searches, much of the time in collaboration with international partners (the French-Italian VIRGO and British/German GEO600 detectors). From 2010 to 2015, the second generation advanced LIGO detectors were installed in the LIGO vacuum system, with amplitude design sensitivity 10-fold higher than the initial detectors. These advanced detectors discovered gravitational waves in September 2015, just before their first search officially began, and when their sensitivity at the noise-curve minimum was about 3 times worse than their design but 3 times better than initial LIGO.

advanced LIGO noise and discovery of gravitational waves

advanced LIGO's signal recycling mirror

One of several major changes, in going from initial LIGO to advanced LIGO, was the insertion of a "signal recycling mirror" between the beam splitter and the photodetector (Abbott et al., 2016b). The output signal light, in the cavity bounded by this new mirror and the two input mirrors, "sucks" signal light out of the interferometer arms due to Bose-Einstein statistics. This permits laser light to be stored in the arm cavities far longer than half a gravitational wave period (and thereby build up to higher intensity), while the signal light gets extracted in roughly a half period. This added complication is why we chose not to analyze the advanced detectors.

EXERCISES

Exercise 9.18 *Derivation and Problem: Phase Shift in LIGO Arm Cavity* T2

In this exercise and the next, simplify the analysis by treating each Gaussian light beam as though it were a plane wave. The answers for the phase shifts will be the same as for a true Gaussian beam, because on the optic axis, the Gaussian beam's phase [Eq. (8.40a) with $\varpi = 0$] is the same as that of a plane wave, except for the Gouy phase $\tan^{-1}(z/z_0)$, which is very slowly changing and thus is irrelevant.

- (a) For the interferometric gravitational-wave detector depicted in Fig. 9.13 (with the arms' input mirrors having amplitude reflectivities τ_i close to unity and the end mirrors idealized as perfectly reflecting), analyze the light propagation in cavity 1 by the same techniques as used for an etalon in Sec. 9.4.1. Show that, if ψ_{i1} is the light field impinging on the input mirror, then the total reflected light field ψ_{r1} is

$$\psi_{r1} = e^{i\varphi_1} \frac{1 - \tau_i e^{-i\varphi_1}}{1 - \tau_i e^{i\varphi_1}} \psi_{i1}, \quad \text{where } \varphi_1 = 2kL_1. \quad (9.52a)$$

- (b) From this, infer that the reflected flux $|\psi_{r1}|^2$ is identical to the cavity's input flux $|\psi_{i1}|^2$, as it must be, since no light can emerge through the perfectly reflecting end mirror.

- (c) The arm cavity is operated on resonance, so φ_1 is an integer multiple of 2π . From Eq. (9.52a) infer that (up to fractional errors of order $1 - \tau_i$) a change δL_1 in the length of cavity 1 produces a change

$$\delta\varphi_{r1} = \frac{8k\delta L_1}{1 - \tau_i^2}. \quad (9.52b)$$

With slightly different notation, this is Eq. (9.47), which we used in the text's order-of-magnitude analysis of LIGO's sensitivity. In this exercise and the next, we carry out a more precise analysis.

Exercise 9.19 *Example: Photon Shot Noise in LIGO* T2

This exercise continues the preceding one. We continue to treat the light beams as plane waves.

- (a) Denote by ψ_ℓ the light field from the laser that impinges on the beam splitter and gets split in two, with half going into each arm (Fig. 9.13). Using the equations from Ex. 9.18 and Sec. 9.5, infer that the light field returning to the beam splitter from arm 1 is $\psi_{s1} = \frac{1}{\sqrt{2}}\psi_\ell e^{i\varphi_1}(1 + i\delta\varphi_{r1})$, where φ_1 is some net accumulated phase that depends on the separation between the beam splitter and the input mirror of arm 1.
- (b) Using the same formula for the field ψ_{s2} from arm 2, and assuming that the phase changes between beam splitter and input mirror are almost the same in the two arms, so $\varphi_o \equiv \varphi_1 - \varphi_2$ is small compared to unity (mod 2π), show that the light field that emerges from the beam splitter, traveling toward the photodetector, is

$$\psi_{\text{pd}} = \frac{1}{\sqrt{2}}(\psi_{s1} - \psi_{s2}) = \frac{i}{2}(\varphi_o + \delta\varphi_{r1} - \delta\varphi_{r2})\psi_\ell \quad (9.53a)$$

to first order in the small phases. Show that the condition $|\varphi_o| \ll 1$ corresponds to the experimenters' having adjusted the positions of the input mirrors in such a way that almost all the light returns toward the laser, and only a small fraction goes toward the photodetector.

- (c) For simplicity, let the gravitational wave travel through the interferometer from directly overhead and have an optimally oriented polarization. Then, as we shall see in Chap. 27 [Eq. (27.81)], the dimensionless gravitational-wave field $h(t)$ produces the arm-length changes $\delta L_1 = -\delta L_2 = \frac{1}{2}h(t)L$, where L is the unperturbed arm length. Show, then, that the field traveling toward the photodetector is

$$\psi_{\text{pd}} = \frac{i}{2}(\varphi_o + \delta\varphi_{\text{gw}})\psi_\ell, \quad \text{where} \quad \delta\varphi_{\text{gw}} = \frac{8kL}{1 - \tau_i^2}h(t) = \frac{16\pi L/\lambda}{1 - \tau_i^2}h(t). \quad (9.53b)$$

The experimenter adjusts φ_o so it is large compared to the tiny $\delta\varphi_{\text{gw}}$.

- (d) Actually, this equation has been derived assuming, when analyzing the arm cavities [Eq. (9.52a)], that the arm lengths are static. Explain why it should still be nearly valid when the gravitational waves are moving the mirrors, so long as

the gravitational-wave half-period $1/(2f) = \pi/\omega_{\text{gw}}$ is somewhat longer than the mean time that a photon is stored inside an arm cavity, or so long as $f \ll f_o$, where

$$f_o \equiv \frac{1 - \tau_i^2}{4\pi} \frac{c}{2L}. \quad (9.54)$$

Assume that this is so. For the initial LIGO detectors, $1 - \tau_i^2 \sim 0.03$ and $L = 4$ km, so $f_o \sim 90$ Hz.

- (e) Show that, if W_ℓ is the laser power impinging on the beam splitter (proportional to $|\psi_\ell|^2$), then the steady-state light power going toward the photodetector is $W_{\text{pd}} = (\varphi_o/2)^2 W_\ell$, and the time variation in that light power due to the gravitational wave (the gravitational-wave signal) is

$$W_{\text{gw}}(t) = \sqrt{W_\ell W_{\text{pd}}} \frac{16\pi L/\lambda}{1 - \tau_i^2} h(t). \quad (9.55a)$$

The photodetector monitors these changes $W_{\text{gw}}(t)$ in the light power W_{pd} and from them infers the gravitational-wave field $h(t)$. This is called a “DC” or “homodyne” readout system; it works by beating the gravitational-wave signal field ($\propto \delta\varphi_{\text{gw}}$) against the steady light field (“local oscillator,” $\propto \varphi_o$) to produce the signal light power $W_{\text{gw}}(t) \propto h(t)$.

- (f) Shot noise in the interferometer’s output light power W_{pd} gives rise to noise in the measured gravitational-wave field $h(t)$. From Eq. (9.55a) show that the spectral density of the noise in the measured $h(t)$ is

$$S_h(f) = \left(\frac{(1 - \tau_i^2)\lambda}{16\pi L} \right)^2 \frac{S_{W_{\text{pd}}}}{W_\ell W_{\text{pd}}}. \quad (9.55b)$$

In Sec. 6.7.4, we derived the formula $S_{W_{\text{pd}}} = 2\mathcal{R}(\hbar\omega)^2 = 2W_{\text{pd}}\hbar\omega$ [Eq. (6.69)] for the (frequency-independent) spectral density of a steady, monochromatic light beam’s power fluctuations due to shot noise; here $\mathcal{R} = W_{\text{pd}}/(\hbar\omega)$ is the average rate of arrival of photons. Combining with Eq. (9.55b), deduce your final formula for the spectral density of the noise in the inferred gravitational-wave signal:

$$S_h(f) = \left(\frac{(1 - \tau_i^2)\lambda}{16\pi L} \right)^2 \frac{2}{W_\ell/(\hbar\omega)}. \quad (9.56a)$$

From this deduce the rms noise in a bandwidth equal to frequency

$$h_{\text{rms}} = \sqrt{f S_h} = \left(\frac{(1 - \tau_i^2)\lambda}{16\pi L\sqrt{N}} \right), \quad \text{where} \quad N = \frac{W_\ell}{\hbar\omega} \frac{1}{2f} \quad (9.56b)$$

is the number of photons that impinge on the beam splitter, from the laser, in half a gravitational-wave period.

- (g) In Ex. 9.20 we shall derive (as a challenge) the modification to the spectral density that arises at frequencies $f \gtrsim f_o$. The signal strength that gets through the interferometer is reduced because the arm length is increasing, then decreasing, then increasing again (and so forth) while the typical photon is in an arm cavity. The result of the analysis is an increase of $S_h(f)$ by $1 + (f/f_o)^2$, so we have

$$S_h(f) = \left(\frac{(1 - \tau_i^2)\lambda}{16\pi L} \right)^2 \frac{2}{W_\ell/\hbar\omega} \left(1 + \frac{f^2}{f_o^2} \right). \quad (9.57)$$

Compare this with the measured noise, at frequencies above $f_o \sim 90$ Hz in the initial LIGO detectors (Fig. 6.7 with $\xi = hL$), using the initial LIGO parameters: $\lambda = 1.06 \mu\text{m}$, $\omega = 2\pi c/\lambda \simeq 2 \times 10^{15} \text{ s}^{-1}$, $L = 4 \text{ km}$, $W_\ell = 250 \text{ W}$, $1 - \tau_i^2 = 0.03$. It should agree fairly well with the measured noise at frequencies $f \gtrsim f_o$, where most of the noise is due to photon shot noise. Also compare the noise (9.57) in a bandwidth equal to frequency $\sqrt{f S_h}$ and evaluated at frequency $f = f_o$ with the estimate (9.51) worked out in the text.

Exercise 9.20 Challenge: LIGO Shot Noise at $f \gtrsim f_o$ T2

Derive the factor $1 + (f/f_o)^2$ by which the spectral density of the shot noise is increased at frequencies $f \gtrsim f_o$. [Hint: Redo the analysis of the arm cavity fields, part (a) of Ex. 9.19, using an arm length that varies sinusoidally at frequency f due to a sinusoidal gravitational wave, and then use the techniques of Ex. 9.19 to deduce $S_h(f)$.]

9.6 Power Correlations and Photon Statistics: Hanbury Brown and Twiss Intensity Interferometer

9.6

A type of interferometer that is rather different from those studied earlier in this chapter was proposed and constructed by Robert Hanbury Brown and Richard Q. Twiss in 1956. In this interferometer, light powers, rather than amplitudes, are combined to measure the degree of coherence of the radiation field. This is often called an *intensity interferometer*, because the optics community often uses the word “intensity” to mean energy flux (power per unit area).

intensity interferometer

In their original experiment, Hanbury Brown and Twiss divided light from an incandescent mercury lamp and sent it along two paths of variable length before detecting photons in each beam separately using a photodetector (see Fig. 9.14). The electrical output from each photodetector measures the rate of arrival of its beam’s photons, or equivalently, its beam’s power $W(t)$, which we can write as $K(\Re\Psi)^2$,

FIGURE 9.14 Hanbury Brown and Twiss intensity interferometer.

fluctuations of power W in each beam

where K is a constant. This W exhibits fluctuations δW about its mean value \overline{W} , and it was found that the fluctuations in the two beams were correlated. How can this be?

The light that was detected originated from many random and independent emitters and therefore obeys Gaussian statistics, according to the central limit theorem (Sec. 6.3.2). This turns out to mean that the fourth-order correlations of the wave field Ψ with itself can be expressed in terms of the second-order correlations (i.e., in terms of the degree of coherence $\gamma_{||}$).

More specifically, continuing to treat the wave field Ψ as a scalar, we (i) write each beam's power as the sum over a set of Fourier components Ψ_j with precise frequencies ω_j and slowly wandering, complex amplitudes $W(t) = (\sum_j \Re \Psi_j)^2$; (ii) form the product $W(t)W(t + \tau)$; (iii) keep only terms that will have nonzero averages by virtue of containing products of the form $\propto e^{+i\omega_j t} e^{-i\omega_j t} e^{+i\omega_k t} e^{-i\omega_k t}$ (where j and k are generally not the same); and (iv) average over time. Thereby we obtain

$$\begin{aligned} \overline{W(t)W(t + \tau)} &= K^2 \overline{\Psi(t)\Psi^*(t) \times \Psi(t + \tau)\Psi^*(t + \tau)} \\ &\quad + K^2 \overline{\Psi(t)\Psi^*(t + \tau) \times \Psi^*(t)\Psi(t + \tau)} \\ &= \overline{W}^2 [1 + |\gamma_{||}(\tau)|^2] \end{aligned} \quad (9.58)$$

[cf. Eq. (9.16) with Ψ allowed to be complex]. If we now measure the relative fluctuations, we find that

$$\frac{\overline{\delta W(t)\delta W(t + \tau)}}{\overline{W(t)}^2} = \frac{\overline{W(t)W(t + \tau)} - \overline{W(t)}^2}{\overline{W(t)}^2} = |\gamma_{||}(\tau)|^2. \quad (9.59)$$

longitudinal correlation of beam power

[Note: This analysis is only correct if the radiation comes from many uncorrelated sources—the many independently emitting mercury atoms in Fig. 9.14—and therefore has Gaussian statistics.]

Equation (9.59) tells us that the power as well as the amplitude of coherent radiation must exhibit a positive longitudinal correlation, and the degree of coherence for the fluxes is equal to the squared modulus of the degree of coherence for the amplitudes. Although this result was rather controversial at the time the experiments were

first performed, it is easy to interpret qualitatively if we think in terms of photons rather than classical waves. Photons are bosons and are therefore positively correlated even in thermal equilibrium; cf. Chaps. 3 and 4. When they arrive at the beam splitter of Fig. 9.14, they clump more than would be expected for a random distribution of classical particles, a phenomenon called photon bunching.¹² In fact, treating the problem from the point of view of photon statistics gives an answer equivalent to Eq. (9.59).

explanation of power correlation by Bose-Einstein statistics: photon bunching

Some practical considerations should be mentioned. The first is that Eq. (9.59), derived for a scalar wave, is really only valid for electromagnetic waves if they are completely polarized. If the incident waves are unpolarized, then the intensity fluctuations are reduced by a factor of two. The second point is that, in the Hanbury Brown and Twiss experiments, the photon counts were actually averaged over longer times than the correlation time of the incident radiation. This reduced the magnitude of the measured effect further.

Nevertheless, after successfully measuring temporal power correlations, Hanbury Brown and Twiss constructed a *stellar intensity interferometer*, with which they were able to measure the angular diameters of bright stars. This method had the advantage that it did not depend on the phase of the incident radiation, so the results were insensitive to atmospheric fluctuations (seeing), one of the drawbacks of the Michelson stellar interferometer (Sec. 9.2.5). Indeed, it is not even necessary to use accurately ground mirrors to measure the effect. The method has the disadvantage that it can only measure the modulus of the degree of coherence; the phase is lost. It was the first example of using fourth-order correlations of the light field to extract image information from light that has passed through Earth's turbulent atmosphere (Box 9.2).

stellar intensity interferometer

Exercise 9.21 *Derivation: Power Correlations*

By expressing the field as either a Fourier sum or a Fourier integral complete the argument that leads to Eq. (9.58).

EXERCISES**Exercise 9.22** *Problem: Electron Intensity Interferometry*

Is it possible to construct an intensity interferometer (i.e., a number-flux interferometer) to measure the coherence properties of a beam of electrons? What qualitative differences do you expect there to be from a photon-intensity interferometer? What do you expect Eq. (9.59) to become?

12. Pions emerging from high-energy, heavy ion collisions exhibit similar bunching because pions, like photons, are bosons.

Bibliographic Note

For pedagogical introductions to interference and coherence at an elementary level in greater detail than this chapter, see Klein and Furtak (1986) and Hecht (2017). For more advanced treatments, we like Pedrotti, Pedrotti, and Pedrotti (2007), Saleh and Teich (2007), Ghatak (2010), and especially Brooker (2003). For a particularly deep and thorough discussion of coherence, see Goodman (1985). For modern applications of interferometry (including the optical frequency comb), see Yariv and Yeh (2007), and at a more elementary level, Francon and Willmans (1966) and Hariharan (2007).

Nonlinear Optics

The development of the maser and laser . . . followed no script except to hew to the nature of humans groping to understand, to explore, and to create . . .

CHARLES H. TOWNES (2002)

10.1 Overview

10.1

Communication technology is undergoing a revolution, and computer technology may do so soon—a revolution in which the key devices used (e.g., switches and communication lines) are changing from radio and microwave frequencies to optical frequencies. This revolution has been made possible by the invention and development of lasers (especially semiconductor diode lasers) and other technology developments, such as nonlinear media whose polarization P_i is a nonlinear function of the applied electric field, $P_i = \epsilon_0(\chi_{ij}E^j + 2d_{ijk}E^jE^k + 4\chi_{ijkl}E^jE^kE^l + \dots)$. In this chapter we study lasers, nonlinear media, and various nonlinear optics applications that are based on them.

Most courses in elementary physics idealize the world as linear. From the simple harmonic oscillator to Maxwell's equations to the Schrödinger equation, most elementary physical laws one studies are linear, and most of the applications studied make use of this linearity. In the real world, however, nonlinearities abound, creating such phenomena as avalanches, breaking ocean waves, holograms, optical switches, and neural networks; and in the past three decades nonlinearities and their applications have become major themes in physics research, both basic and applied. This chapter, with its exploration of nonlinear effects in optics, serves as a first introduction to some fundamental nonlinear phenomena and their present and future applications. In later chapters, we revisit some of these phenomena and meet others, in the context of fluids (Chaps. 16 and 17), plasmas (Chap. 23), and spacetime curvature (Chaps. 25–28).

Since highly coherent and monochromatic laser light is one of the key foundations on which modern nonlinear optics has been built, we begin in Sec. 10.2 with a review of the basic physics principles that underlie the laser: the pumping of an active medium to produce a molecular population inversion and the stimulated emission of radiation from the inverted population. Then we briefly describe the wide variety of lasers now available, how a few of them are pumped, and the characteristics of their light. As

BOX 10.1. READERS' GUIDE

- This chapter depends substantially on Secs. 7.2, 7.3, and 7.7.1 (geometric optics).
- Sec. 10.6, on wave-wave mixing, is an important foundation for Chap. 23 on the nonlinear dynamics of plasmas, and (to a lesser extent) for the discussions of solitary waves (solitons) in Secs. 16.3 and 23.6. Nothing else in this book relies substantially on this chapter.

an important example (crucial for the optical frequency combs of Sec. 9.4.3), we give details about mode-locked lasers.

In Sec. 10.3, we meet our first example of an application of nonlinear optics: holography. In the simplest variant of holography, a 3-dimensional, monochromatic image of an object is produced by a two-step process: recording a hologram of the image, and then passing coherent light through the hologram to reconstruct the image. We analyze this recording and reconstruction and then describe a few of the many variants of holography now available and some of their practical applications.

Holography differs from more modern nonlinear optics applications in not being a real-time process. Real-time processes have been made possible by nonlinear media and other new technologies. In Sec. 10.4, we study an example of a real-time, nonlinear-optics process: phase conjugation of light by a phase-conjugating mirror (though we delay a detailed discussion of how such mirrors work until Sec. 10.8.2). In Sec. 10.4, we also see how phase conjugation can be used to counteract the distortion of images and signals by media through which they travel.

In Sec. 10.5, we introduce nonlinear media and formulate Maxwell's equations for waves propagating through such media. As an example, we briefly discuss electro-optic effects, where a slowly changing electric field modulates the optical properties of a nonlinear crystal, thereby modulating light waves that propagate through it. Then in Sec. 10.6, we develop a detailed description of how such a nonlinear crystal couples two optical waves to produce a new, third wave—so-called “three-wave mixing.” Three-wave mixing has many important applications in modern technology. In Sec. 10.7, we describe and analyze several: frequency doubling (e.g., in a green laser pointer), optical parametric amplification of signals, and driving light into a squeezed state (e.g., the squeezed vacuum of quantum electrodynamics).

In an isotropic medium, three-wave mixing is suppressed, but a new, fourth wave can be produced by three incoming waves. In Sec. 10.8, we describe and analyze this four-wave mixing and how it is used in phase-conjugate mirrors and produces problems in the optical fibers widely used to transmit internet, television, and telephone signals.

These topics just scratch the surface of the exciting field of nonlinear optics, but they will give the reader an overview and some major insights into this field, and into nonlinear phenomena in the physical world.

10.2 Lasers

10.2

10.2.1 Basic Principles of the Laser

10.2.1

In quantum mechanics one identifies three different types of interaction of light with material systems (atoms, molecules, atomic nuclei, electrons, etc.): (i) *spontaneous emission*, in which a material system in an excited state spontaneously drops into a state of lesser excitation and emits a photon in the process; (ii) *absorption*, in which an incoming photon is absorbed by a material system, exciting it; and (iii) *stimulated emission*, in which a material system, initially in some excited state, is “tickled” by passing photons, and this tickling stimulates it to emit a photon of the same sort (in the same state) as the photons that tickled it.

spontaneous emission, absorption, and stimulated emission

As peculiar as stimulated emission may seem at first sight, in fact it is easily understood and analyzed classically. It is nothing but “negative absorption”: In classical physics, when a light beam with electric field $E = \Re[Ae^{i(kz - \omega t + \varphi)}]$ travels through an absorbing medium, its real amplitude A decays exponentially with the distance propagated, $A \propto e^{-\mu z/2}$ (corresponding to an energy-flux decay $F \propto e^{-\mu z}$), while its frequency ω , wave number k , and phase φ remain nearly constant. For normal materials, the absorption rate $\mu = F^{-1}dF/dz$ is positive, and the energy lost goes ultimately into heat. However, one can imagine a material with an internally stored energy that amplifies a passing light beam. Such a material would have a negative absorption rate, $\mu < 0$, and correspondingly, the amplitude of the passing light would grow with the distance traveled, $A \propto e^{+|\mu|z/2}$, while its frequency, wave number, and phase would remain nearly constant. Such materials do exist; they are called “active media,” and their amplification of passing waves is stimulated emission.

active medium

This elementary, classical description of stimulated emission is equivalent to the quantum mechanical description in the domain where the stimulated emission is strong: the domain of large photon-occupation numbers $\eta \gg 1$ (which, as we learned in Sec. 3.2.5, is the domain of classical waves).

The classical description of stimulated emission takes for granted the existence of an active medium. To understand the nature of such a medium, we must turn to quantum mechanics.

As a first step toward such understanding, consider a beam of monochromatic light with frequency ω that impinges on a collection of molecules (or atoms or charged particles) that are all in the same quantum mechanical state $|1\rangle$. Suppose the molecules have a second state $|2\rangle$ with energy $E_2 = E_1 + \hbar\omega$. Then the light will resonantly excite the molecules from their initial state $|1\rangle$ to the higher state $|2\rangle$, and in the process photons will be absorbed (Fig. 10.1a). The strength of the interaction is proportional to the beam’s energy flux F . Stated more precisely, the rate of absorption of photons

FIGURE 10.1 (a) *Photon absorption*. A photon with energy $\hbar\omega = E_2 - E_1$ excites a molecule from its ground state, with energy E_1 to an excited state with energy E_2 (as depicted by an energy-level diagram). (b) *Stimulated emission*. The molecule is initially in its excited state, and the incoming photon stimulates it to deexcite into its ground state, emitting a photon identical to the incoming one.

is proportional to the number flux of photons in the beam, $dn/dAdt = F/(\hbar\omega)$, and thence is proportional to F , in accord with the classical description of absorption.

Next suppose that when the light beam first arrives, the atoms are all in the higher state $|2\rangle$ rather than the lower state $|1\rangle$. There will still be a resonant interaction, but this time the interaction will deexcite the atoms, with an accompanying emission of photons (Fig. 10.1b). As in the absorption case, the strength of the interaction is proportional to the flux of the incoming beam (i.e., the rate of emission of new photons is proportional to the number flux of photons that the beam already has), and thence it is also proportional to the beam's energy flux F . A quantum mechanical analysis shows that the photons from this stimulated emission come out in the same quantum state as is occupied by the photons of the incoming beam (Bose-Einstein statistics: photons, being bosons, tend to congregate in the same state). Correspondingly, when viewed classically, the beam's flux will be amplified at a rate proportional to its initial flux, with no change of its frequency, wave number, or phase.

In Nature, molecules usually have their energy levels populated in accord with the laws of statistical (thermodynamic) equilibrium. Such thermalized populations, as we saw at the end of Sec. 4.4.1, entail a ratio $N_2/N_1 = \exp[-(E_2 - E_1)/(k_B T)] < 1$ for the number N_2 of molecules in state $|2\rangle$ to the number N_1 in state $|1\rangle$. Here T is the molecular temperature, and for simplicity it is assumed that the states are nondegenerate. Since there are more molecules in the lower state $|1\rangle$ than the higher one $|2\rangle$, an incoming light beam will experience more absorption than stimulated emission.

population inversion

By contrast, occasionally in Nature and often in the laboratory a collection of molecules develops a "population inversion" in which $N_2 > N_1$. The two states can then be thought of as having a negative temperature with respect to each other. Light propagating through population-inverted molecules will experience more stimulated emission than absorption (i.e., it will be amplified). The result is "light amplification by stimulated emission," or "laser" action.

laser

This basic principle underlying the laser has been known since the early years of quantum mechanics, but only in the 1950s did physicists succeed in designing, constructing, and operating real lasers. The first proposals for practical devices were

FIGURE 10.2 The mechanism for creating the population inversion that underlies laser action. The horizontal lines and band represent energy levels of a molecule, and the arrows represent transitions in which the molecules are excited by pumping or decay by emission of photons.

made, independently, in the United States by Weber (1953) and Gordon, Zeiger, and Townes (1954), and in the Soviet Union by Basov and Prokhorov (1954, 1955). The first successful construction and operation of a laser was by Gordon, Zeiger, and Townes (1954, 1955), and soon thereafter by Basov and Prokhorov—though these first lasers actually used radiation not at optical frequencies but rather at microwave frequencies and were based on a population inversion of ammonia molecules (see Feynman, Leighton, and Sands, 2013, Chap. 9), and thus were called *masers*. The first optical frequency laser, one based on a population inversion of chromium ions in a ruby crystal, was constructed and operated by Maiman (1960).

The key to laser action is the population inversion. Population inversions are incompatible with thermodynamic equilibrium; thus, to achieve them, one must manipulate the molecules in a nonequilibrium way. This is usually done by some concrete variant of the process shown in the energy-level diagram of Fig. 10.2. Some sort of pump mechanism (to be discussed in the next section) rapidly excites molecules from the ground state into some group of absorption states. The molecules then decay rapidly from the absorption states into the state $|2\rangle$, which is metastable (i.e., has a long lifetime against spontaneous decay), so the molecules linger there. The laser transition is from state $|2\rangle$ to state $|1\rangle$. Once a molecule has decayed into state $|1\rangle$, it quickly decays on down to the ground state and then may be quickly pumped back up into the absorption states. This is called “four-level pumping.” It is instead called “three-level pumping” if state $|1\rangle$ is the ground state.

If the pump acts suddenly and briefly, this process produces a temporary population inversion of states $|2\rangle$ and $|1\rangle$, with which an incoming, weak burst of “seed” light can interact to produce a burst of amplification. The result is a pulsed laser. If the pump acts continuously, the result may be a permanently maintained population inversion with which continuous seed light can interact to produce continuous-wave laser light.

pump mechanism

pulsed lasers and continuous-wave lasers

FIGURE 10.3 The use of a Fabry-Perot cavity to enhance the interaction of the light in a laser with its active medium.

As the laser beam travels through the active medium (the population-inverted molecules), its flux F builds up with distance z as $dF/dz = F/\ell_o$, so $F(z) = F_o e^{z/\ell_o}$. Here F_o is the initial flux, and $\ell_o \equiv 1/|\mu|$ (the e -folding length) depends on the strength of the population inversion and the strength of the coupling between the light and the active medium. Typically, ℓ_o is so long that strong lasing action cannot be achieved by a single pass through the active medium. In this case, the lasing action is enhanced by placing the active medium inside a Fabry-Perot cavity (Fig. 10.3 and Sec. 9.4.3). The length L of the cavity is adjusted to maximize the output power, which occurs when the lasing transition frequency $\omega = (E_2 - E_1)/\hbar$ is an eigenfrequency of the cavity. The lasing action then excites a standing wave mode of the cavity, from which the light leaks out through one or both cavity mirrors. If \mathcal{F} is the cavity's finesse [approximately the average number of times a photon bounces back and forth inside the cavity before escaping through a mirror; cf. Eq. (9.39)], then the cavity increases the distance that typical photons travel through the active medium by a factor $\sim \mathcal{F}$, thereby increasing the energy flux of the light output by a factor $\sim e^{\mathcal{F}L/\ell_o}$.

Typically, many modes of the Fabry-Perot cavity are excited, so the laser's output is multimodal and contains a mixture of polarizations. When a single mode and polarization are desired, the polarization is made pure by oblique optical elements at the ends of the laser that transmit only the desired polarization, and all the modes except one are removed from the output light by a variety of techniques (e.g., filtering with a second Fabry-Perot cavity; Sec. 9.4.3).

For an ideal laser (one, e.g., with a perfectly steady pump maintaining a perfectly steady population inversion that in turn maintains perfectly steady lasing), the light comes out in the most perfectly classical state that quantum mechanics allows. This state, called a *quantum mechanical coherent state*, has a perfectly sinusoidally oscillating electric field on which is superimposed the smallest amount of noise (the smallest wandering of phase and amplitude) allowed by quantum mechanics: the noise of quantum electrodynamical vacuum fluctuations. The value of the oscillations' well-defined phase is determined by the phase of the seed field from which the coherent state was built up by lasing. Real lasers have additional noise due to a variety of practical factors, but nevertheless, their outputs are usually highly coherent, with long coherence times.

coherent-state laser light

10.2.2 Types of Lasers and Their Performances and Applications

10.2.2

Lasers can have continuous, nearly monochromatic output, or they can be pulsed. Their active media can be liquids, gases (ionized or neutral), or solids (semiconductors, glasses, or crystals; usually carefully doped with impurities). Lasers can be pumped by radiation (e.g., from a flash tube), by atomic collisions that drive the lasing atoms into their excited states, by nonequilibrium chemical reactions, or by electric fields associated with electric currents (e.g., in semiconductor diode lasers that can be powered by ordinary batteries and are easily modulated for optical communication).

laser pump mechanisms

Lasers can be made to pulse by turning the pump on and off, by mode-locked operation (Sec. 10.2.3), or by Q -switching (turning off the lasing, e.g., by inserting into the Fabry-Perot cavity an electro-optic material that absorbs light until the pump has produced a huge population inversion, and then suddenly applying an electric field to the absorber, which makes it transparent and restores the lasing).

pulsed lasers

Laser pulses can be as short as a few femtoseconds (thus enabling experimental investigations of fast chemical reactions) and they can carry as much as 20,000 J with duration of a few picoseconds and pulse power $\sim 10^{15}$ W (at the U.S. National Ignition Facility in Livermore, California, for controlled fusion).

The most powerful continuous laser in the United States is the Mid-Infrared Advanced Chemical Laser (MIRACL), developed by the Navy to shoot down missiles and satellites, with ~ 1 MW power in a 14×14 cm² beam lasting ~ 70 s. Continuous CO₂ lasers with powers ~ 3 kW are used industrially for cutting and welding metal.

continuous lasers

The beam from a Q -switched CO₂ laser with ~ 1 GW power can be concentrated into a region with transverse dimensions as small as one wavelength (~ 1 μ m), yielding a local energy flux of 10^{21} W m⁻², an rms magnetic field strength of ~ 3 kT, an electric field of ~ 1 TV m⁻¹, and an electrical potential difference across a wavelength of ~ 1 MeV. It then should not be surprising that high-power lasers can create electron-positron-pair plasmas!

For many applications, large power is irrelevant or undesirable, but high frequency stability (a long coherence time) is often crucial. By locking the laser frequency to an optical frequency atomic transition (e.g., in the Al⁺ atomic clock; see footnote in Sec. 6.6.1), one can achieve a frequency stability $\Delta f/f \sim 10^{-17}$, so $\Delta f \sim 3$ mHz, for hours or longer, corresponding to coherence times of ~ 100 s and coherence lengths of $\sim 3 \times 10^7$ km. By locking the frequency to a mode of a physically highly stable Fabry-Perot cavity (e.g., PDH locking; Sec. 9.4.3), stabilities have been achieved as high as $\Delta f/f \sim 10^{-16}$ for times of ~ 1 hr in a physically solid cavity (the superconducting cavity stabilized oscillator), and $\Delta f/f \sim 10^{-22}$ for a few ms in LIGO's 4-km-long cavity with freely hanging mirrors and sophisticated seismic isolation (Sec. 9.5).

locking a laser's frequency

When first invented, lasers were called “a solution looking for a problem.” Now they permeate everyday life and high technology. Examples are supermarket bar-code readers, laser pointers, DVD players, eye surgery, laser printers, laser cutting and

welding, laser gyroscopes (which are standard on commercial aircraft), laser-based surveying, Raman spectroscopy, laser fusion, optical communication, optically based computers, holography, maser amplifiers, and atomic clocks.

10.2.3 Ti:Sapphire Mode-Locked Laser

As a concrete example of a modern, specialized laser, consider the titanium-sapphire (Ti:sapphire) mode-locked laser (Cundiff, 2002) that is used to generate the optical frequency comb described in Sec. 9.4.3. Recall that this laser's light must be concentrated in a very short pulse that travels unchanged back and forth between its Fabry-Perot mirrors. The pulse is made from phase-locked (Gaussian) modes of the optical cavity that extend over a huge frequency band, $\Delta\omega \sim \omega$. Among other things, this mode-locked laser illustrates the use of an optical nonlinearity called the "Kerr effect," whose underlying physics we describe later in this chapter (Sec. 10.8.3).

As we discussed in Sec. 9.4.3, this mode-locked laser must (i) more strongly amplify modes with high energy flux than with low (this pushes the light into the short, high-flux pulse), and (ii) its (Gaussian) modes must have a group velocity V_g that is independent of frequency over the frequency band $\Delta\omega \sim \omega$ (this enables the pulse to stay short rather than disperse).

Figure 10.4 illustrates the Ti:sapphire laser that achieves this. The active medium is a sapphire crystal doped with titanium ions. This medium exhibits the optical Kerr effect, which means that its index of refraction n is a sum of two terms, one independent of the light's energy flux; the other proportional to the flux [Eq. (10.69)]. The flux-dependent term slows the light's speed near the beam's center and thereby focuses the beam, making its cross section smaller. A circular aperture attenuates large light beams but not small. As a result, the lasing is stronger the smaller the beam (which means the higher its flux). This drives the lasing light into the desired short, high-flux pulse.

The Ti:sapphire crystal has a group velocity that increases with frequency. The two prisms and mirror (Fig. 10.4) compensate this. The first prism bends low-frequency light more than high, so the high-frequency light traverses more glass in the second prism and is slowed. By adjusting the mirror tilt, one adjusts the amount of slowing to keep the round-trip-averaged phase velocity the same at high frequencies as at low.

mode-locked laser produces frequency comb

FIGURE 10.4 The Ti:sapphire mode-locked laser. Adapted from Cundiff (2002).

The laser then generates multimode, high-intensity, pulsed light (with pulse durations that can be as short as attoseconds, when augmented by a technique called chirped pulse amplification), resulting in the optical frequency comb of Sec. 9.4.3.

10.2.4 Free Electron Laser

10.2.4

The free electron laser is quite different from the lasers we have been discussing. A collimated beam of essentially monoenergetic electrons (the population inversion) passes through an undulator comprising an alternating transverse magnetic field, which causes the electrons to radiate X-rays along the direction of the beam. From a classical perspective, this X-ray-frequency electromagnetic wave induces correlated electron motions, which emit coherently, enhancing the X-ray wave. In other words, the undulating electron beam lases.

As an example, the LINAC Coherent Light Source (LCLS) at SLAC National Accelerator Laboratory can produce femtosecond pulses of keV X-rays with pulse frequency 120 Hz and peak intensity $\sim 10^9$ times higher than that achievable from a conventional synchrotron. An upgrade, LCLS-II, is planned to start operating in 2020 with a pulse frequency ~ 100 kHz and an increase in average brightness of $\sim 10^3$.

Exercise 10.1 *Challenge: Nuclear Powered X-Ray Laser*

EXERCISES

A device much ballyhooed in the United States during the presidency of Ronald Reagan, but thankfully never fully deployed, was a futuristic, superpowerful X-ray laser pumped by a nuclear explosion. As part of Reagan's Strategic Defense Initiative ("Star Wars"), this laser was supposed to shoot down Soviet missiles.

How would you design a nuclear powered X-ray laser? The energy for the pump comes from a nuclear explosion that you set off in space above Earth. You want to use that energy to create a population inversion in an active medium that will lase at X-ray wavelengths, and you want to focus the resulting X-ray beam onto an intercontinental ballistic missile that is rising out of Earth's atmosphere. What would you use for the active medium? How would you guarantee that a population inversion is created in the active medium? How would you focus the resulting X-ray beam? (Note: This is a highly nontrivial exercise, intended more as a stimulus for thought than as a test of one's understanding of things taught in this book.)

10.3 Holography

10.3

Holography is an old¹ and well-explored example of nonlinear optics—an example in which the nonlinear interaction of light with itself is produced not in real time, but rather by means of a recording followed by a later readout (e.g., Cathey, 1974; Iizuka, 1987).

1. Holography was invented by Dennis Gabor (1948) for use in electron microscopy. The first practical optical holograms were made in 1962, soon after lasers became available.

FIGURE 10.5 Ordinary photography.

By contrast with ordinary photography (Fig. 10.5), which produces a colored, 2-dimensional image of 3-dimensional objects, holography (Figs. 10.6 and 10.8) normally produces a monochromatic 3-dimensional image of 3-dimensional objects. Roughly speaking, the two processes contain the same amount of information, two items at each location in the image. For ordinary photography, they are the energy flux and color; for holography, the energy flux and phase of monochromatic light.

It is the phase, lost from an ordinary photograph but preserved in holography, that carries the information about the third dimension. Our brain deduces the distance to a point on an object from the difference in the directions of propagation of the point's light as it arrives at our two eyes. Those propagation directions are encoded in the light as variations of the phase with transverse location [see, e.g., the point-spread function for a thin lens, Eq. (8.29)].

ordinary photography

In an ordinary photograph (Fig. 10.5), white light scatters off an object, with different colors scattering at different strengths. The resulting colored light is focused through a lens to form a colored image on a photographic plate or a CCD. The plate or CCD records the color and energy flux at each point or pixel in the focal plane, thereby producing the ordinary photograph.

hologram

In holography, one records a hologram with flux and phase information (see Fig. 10.6), and one then uses the hologram to reconstruct the 3-dimensional, monochromatic, holographic image (see Fig. 10.8).

10.3.1

10.3.1 Recording a Hologram

Consider, first, the recording of the hologram. Monochromatic, linearly polarized plane-wave light with electric field

$$E = \Re[\psi(x, y, z)e^{-i\omega t}], \quad (10.1)$$

angular frequency ω , and wave number $k = \omega/c$ illuminates the object and also a mirror, as shown in Fig. 10.6. The light must be spatially coherent over the entire

FIGURE 10.6 Recording a hologram.

region of mirror plus object. The propagation vector \mathbf{k} of the illuminating light lies in the y - z plane at some angle θ_o to the z -axis, and the mirror lies in the x - y plane. The mirror reflects the illuminating light, producing a so-called “reference beam,” which we call the *mirror wave*:

$$\psi_{\text{mirror}} = M e^{ik(z \cos \theta_o - y \sin \theta_o)}, \quad (10.2)$$

where M is a real constant. The object (shown in Fig. 10.6) scatters the illuminating light, producing a wave that propagates in the z direction toward the recording medium (a photographic plate, for concreteness). We call this the *object wave* and denote it

$$\psi_{\text{object}} = \mathcal{O}(x, y, z) e^{ikz}. \quad (10.3)$$

It is the slowly varying complex amplitude $\mathcal{O}(x, y, z)$ of this object wave that carries the 3-dimensional, but monochromatic, information about the object’s appearance. Thus it is this $\mathcal{O}(x, y, z)$ that will be reconstructed in the second step of holography.

In the first step (Fig. 10.6), the object wave propagates along the z direction to the photographic plate (or, more commonly today, a photoresist) at $z = 0$, where it interferes with the mirror wave to produce the transverse pattern of energy flux

$$\begin{aligned} F(x, y) &\propto |\mathcal{O} + M e^{-iky \sin \theta_o}|^2 \\ &= M^2 + |\mathcal{O}(x, y, z = 0)|^2 + \mathcal{O}(x, y, z = 0) M e^{iky \sin \theta_o} \\ &\quad + \mathcal{O}^*(x, y, z = 0) M e^{-iky \sin \theta_o}. \end{aligned} \quad (10.4)$$

(Here and throughout this chapter, $*$ denotes complex conjugation.) The plate is blackened at each point in proportion to this flux. The plate is then developed, and a positive or negative print (it doesn’t matter which because of Babinet’s principle,

reference beam or mirror wave

object wave

FIGURE 10.7 (a) Ordinary photograph of an object. (b) Hologram of the same object. (c) Magnification of the hologram. Photos courtesy Jason Sapan, Holographic Studios, New York City.

Sec. 8.3.3) is made on a transparent sheet of plastic or glass. This print, the *hologram*, has a transmissivity as a function of x and y that is proportional to the flux distribution (10.4):

$$\begin{aligned} \mathfrak{t}(x, y) \propto M^2 + |\mathcal{O}(x, y, z = 0)|^2 + \mathcal{O}(x, y, z = 0)Me^{iky \sin \theta_o} \\ + \mathcal{O}^*(x, y, z = 0)Me^{-iky \sin \theta_o}. \end{aligned} \quad (10.5)$$

In this transmissivity we meet our first example of nonlinearity: $\mathfrak{t}(x, y)$ contains a nonlinear superposition of the mirror wave and the object wave. Stated more precisely, the superposition is not a linear sum of wave fields, but instead is a sum of products of one wave field with the complex conjugate of another wave field. A further nonlinearity will arise in the reconstruction of the holographic image [Eq. (10.7)].

Figure 10.7 shows an example. Figure 10.7a is an ordinary photograph of an object, Fig. 10.7b is a hologram of the same object, and Fig. 10.7c is a blow-up of a portion of that hologram. The object is not at all recognizable in the hologram, because the object wave \mathcal{O} was not focused to form an image at the plane of the photographic plate. Rather, light from each region of the object was scattered to and recorded by all regions of the photographic plate. Nevertheless, the plate contains the full details of the scattered light $\mathcal{O}(x, y, z = 0)$, including its phase. That information is recorded in the piece $M(\mathcal{O}e^{iky \sin \theta_o} + \mathcal{O}^*e^{-iky \sin \theta_o}) = 2M \Re(\mathcal{O}e^{iky \sin \theta_o})$ of the hologram's transmissivity. This piece oscillates sinusoidally in the y direction with wavelength $2\pi/(k \sin \theta_o)$; and the amplitude and phase of its oscillations are modulated by the object wave $\mathcal{O}(x, y, z = 0)$. Those modulated oscillations show up clearly when one magnifies the hologram (Fig. 10.7c); they turn the hologram into a sort of diffraction grating, with the object wave $\mathcal{O}(x, y, z = 0)$ encoded as variations of the darkness and spacings of the grating lines.

hologram's transmissivity

hologram's nonlinearity

hologram's information encoding

FIGURE 10.8 Reconstructing the holographic image from the hologram. Note that $\sin \theta_s = 2 \sin \theta_o$.

What about the other pieces of the transmissivity (10.5), which superpose linearly on the diffraction grating? One piece, $t \propto M^2$, is spatially uniform and thus has no effect except to make the lightest parts of the hologram slightly gray rather than leaving it absolutely transparent (since this hologram is a negative rather than a positive). The other piece, $t \propto |\mathcal{O}|^2$, is the flux of the object's unfocused, scattered light. It produces a graying and whitening of the hologram (Fig. 10.7b) that varies on lengthscales long compared to the grating's wavelength $2\pi/(k \sin \theta_o)$ and thus blots out the diffraction grating a bit here and there, but it does not change the amplitude or phase of the grating's modulation.

10.3.2 Reconstructing the 3-Dimensional Image from a Hologram

To reconstruct the object's 3-dimensional wave, $\mathcal{O}(x, y, z)e^{ikz}$, one sends through the hologram monochromatic, plane-wave light identical to the mirror light used in making the hologram (Fig. 10.8). If, for pedagogical simplicity, we place the hologram at the same location $z = 0$ as was previously occupied by the photographic plate, then the incoming light has the same form (10.2) as the original mirror wave, but with an amplitude that we denote as R , corresponding to the phrase *reference beam* that is used to describe this incoming light:

$$\psi_{\text{reference}} = R e^{ik(z \cos \theta_o - y \sin \theta_o)}. \quad (10.6)$$

In passing through the hologram at $z = 0$, this reference beam is partially absorbed and partially transmitted. The result, immediately on exiting from the hologram,

10.3.2

reference beam for reconstructing 3-dimensional image

is a reconstructed light-wave field whose value and normal derivative are given by [cf. Eq. (10.5)]

reconstructed wave

$$\begin{aligned}
 \psi_{\text{reconstructed}} \Big|_{z=0} &\equiv \mathcal{R}(x, y, z=0) = t(x, y) R e^{-iky \sin \theta_o} \\
 &= \left[M^2 + |\mathcal{O}(x, y, z=0)|^2 \right] R e^{-iky \sin \theta_o} \\
 &\quad + MR\mathcal{O}(x, y, z=0) \\
 &\quad + MR\mathcal{O}^*(x, y, z=0) e^{-i2ky \sin \theta_o}; \\
 \psi_{\text{reconstructed},z} \Big|_{z=0} &\equiv \mathcal{Z}(x, y, z=0) = ik \cos \theta_o \mathcal{R}(x, y, z=0). \tag{10.7}
 \end{aligned}$$

This field and normal derivative act as initial data for the subsequent evolution of the reconstructed wave. Note that the field and derivative, and thus also the reconstructed wave, are triply nonlinear: each term in Eq. (10.7) is a product of (i) the original mirror wave M used to construct the hologram or the original object wave \mathcal{O} , (ii) \mathcal{O}^* or $M^* = M$, and (iii) the reference wave R that is being used in the holographic reconstruction.

The evolution of the reconstructed wave beyond the hologram (at $z > 0$) can be computed by combining the initial data [Eq. (10.7)] for $\psi_{\text{reconstructed}}$ and $\psi_{\text{reconstructed},z}$ at $z = 0$ with the Helmholtz-Kirchhoff formula (8.4); see Exs. 10.2 and 10.6. From the four terms in Eq. (10.7) [which arise from the four terms in the hologram's transmissivity $t(x, y)$, Eq. (10.5)], the reconstruction produces four wave fields; see Fig. 10.8. The direction of propagation of each of these waves can easily be inferred from the vertical spacing of its phase fronts along the outgoing face of the hologram, or equivalently, from the relation $\partial \psi_{\text{reconstructed}} / \partial y = ik_y \psi_{\text{reconstructed}} = -ik \sin \theta \psi$, where θ is the angle of propagation relative to the horizontal z direction. Since, immediately in front of the hologram, $\psi_{\text{reconstructed}} = \mathcal{R}$, the propagation angle is

$$\sin \theta = \frac{\partial \mathcal{R} / \partial y}{-ik \mathcal{R}}. \tag{10.8}$$

Comparing with Eqs. (10.5) and (10.7), we see that the first two, slowly spatially varying, terms in the transmissivity, $t \propto M^2$ and $T \propto |\mathcal{O}|^2$, both produce waves that propagate in the same direction as the reference wave, $\theta = \theta_o$. This combined wave has an uninteresting, smoothly and slowly varying energy-flux pattern.

The two diffraction-grating terms in the hologram's transmissivity produce two interesting waves. One, arising from $t \propto \mathcal{O}(x, y, z=0) M e^{iky \sin \theta_o}$ [and produced by the $MR\mathcal{O}$ term of the initial conditions (10.7)], is *precisely the same object wave* $\psi_{\text{object}} = \mathcal{O}(x, y, z) e^{ikz}$ (aside from overall amplitude) *as one would have seen while making the hologram if one had replaced the photographic plate by a window and looked through it*. This object wave, carrying [encoded in $\mathcal{O}(x, y, z)$] the holographic image with full 3-dimensionality, propagates in the z direction, $\theta = 0$.

object wave and its 3-dimensional image

The transmissivity's second diffraction-grating term,

$$t \propto \mathcal{O}^*(x, y, z = 0) M e^{-iky \sin \theta_o},$$

acting via the $M R \mathcal{O}^*$ term of the initial conditions (10.7), gives rise to a secondary wave, which [according to Eq. (10.8)] propagates at an angle θ_s to the z -axis, where

$$\sin \theta_s = 2 \sin \theta_o. \quad (10.9)$$

(If $\theta_o > 30^\circ$, then $2 \sin \theta_o > 1$, which means θ_s cannot be a real angle, and there will be no secondary wave.) *This secondary wave, if it exists, carries an image that is encoded in the complex conjugate $\mathcal{O}^*(x, y, z = 0)$ of the transverse (i.e., x, y) part of the original object wave.* Since complex conjugation of an oscillatory wave just reverses the sign of the wave's phase, this wave in some sense is a “phase conjugate” of the original object wave.

When one recalls that the electric and magnetic fields that make up an electromagnetic wave are actually real rather than complex, and that we are using complex wave fields to describe electromagnetic waves only for mathematical convenience, one then realizes that this phase conjugation of the object wave is actually a highly nonlinear process. There is no way, by linear manipulations of the real electric and magnetic fields, to produce the phase-conjugated wave from the original object wave.

In Sec. 10.4 we develop in detail the theory of phase-conjugated waves, and in Ex. 10.6, we relate our holographically constructed secondary wave to that theory. As we shall see, our secondary wave is not quite the same as the phase-conjugated object wave, but it is the same aside from some distortion along the y direction and a change in propagation direction. More specifically, *if one looks into the object wave with one's eyes* (i.e., if one focuses it onto one's retinas), *one sees the original object in all its 3-dimensional glory, though single colored, sitting behind the hologram at the object's original position* (shown in Fig. 10.8). Because the image one sees is behind the hologram, it is called a *virtual image*. *If, instead, one looks into the secondary wave with one's eyes, one sees the original 3-dimensional object, sitting in front of the hologram but turned inside out and distorted* (also shown in the figure). For example, if the object is a human face, the secondary image looks like the interior of a mask made from that human face, with distortion along the y direction. Because this secondary image appears to be in front of the hologram, it is called a *real image*—even though one can pass one's hands through it and feel nothing but thin air.

secondary (phase conjugate) wave

object wave's image is virtual

secondary wave's image is real

10.3.3 Other Types of Holography; Applications

10.3.3

There are many variants on the basic holographic technique depicted in Figs. 10.6–10.8. These include the following.

PHASE HOLOGRAPHY

Instead of darkening the high-flux regions of the hologram as in photography, one produces a phase-shifting screen, whose phase shift (due to thickening of the hologram's material) is proportional to the incoming flux. Such a phase hologram transmits more of the reference-wave light than a standard, darkened hologram, thus making a brighter reconstructed image.

VOLUME HOLOGRAPHY

The hologram is a number of wavelengths deep rather than being just 2-dimensional. For example, it could be made from a thick photographic emulsion, in which the absorption length for light is longer than the thickness. Such a hologram has a 3-dimensional grating structure (grating “surfaces” rather than grating “lines”), with two consequences. When one reconstructs the holographic image from it in the manner of Fig. 10.8, (i) the third dimension of the grating suppresses the secondary wave while enhancing the (desired) object wave, so more power goes into it; and (ii) the reference wave's incoming angle θ_o must be controlled much more precisely, as modest errors suppress the reconstructed object wave. This second consequence enables one to record multiple images in a volume hologram, each using its own angle θ_o for the illuminating light and reference wave.

3-dimensional gratings

REFLECTION HOLOGRAPHY

One reads out the hologram by reflecting light off of it rather than transmitting light through it, and the hologram's diffraction grating produces a 3-dimensional holographic image by the same process as in transmission; see Ex. 10.3.

WHITE-LIGHT HOLOGRAPHY

The hologram is recorded with monochromatic light as usual, but it is optimized for reading out with white light. Even for the simple 2-dimensional hologram of Fig. 10.8, if one sends in white light at the angle θ_o , one will get a 3-dimensional object wave: the hologram's grating will diffract various wavelengths in various directions. In the direction of the original object wave (the horizontal direction in Fig. 10.8), one gets a 3-dimensional reconstructed image of the same color as was used when constructing the hologram. When one moves away from that direction (vertically in Fig. 10.8), one sees the color of the 3-dimensional image continuously change (Ex. 10.2b). White-light reflection holograms are used on credit cards and money as impediments to counterfeiting; they have even been used on postage stamps.

colored holograms

COMPUTATIONAL HOLOGRAMS

Just as one can draw 2-dimensional pictures numerically, pixel-by-pixel, so one can also create and modify holograms numerically, then read them out optically.

FULL-COLOR HOLOGRAPHY

A full-color holographic image of an object can be constructed by superposing three monochromatic holographic images with the three primary colors—red, green, and

FIGURE 10.9 In-and-out vibrations of a guitar body visualized via holographic interferometry with green light. The dark and bright curves are a contour map, in units of the green light's wavelength, of the amplitude of vibration. Image courtesy Bernard Richardson, Cardiff University.

blue. One way to achieve this is to construct a single volume hologram using illuminating light from red, green, and blue laser beams, each arriving from a different 2-dimensional direction θ_o . Each beam produces a diffraction grating in the hologram with a different orientation and with spatial wave number corresponding to the beam's color. The 3-dimensional image can then be reconstructed using three white-light reference waves, one from each of the original three directions θ_o . The hologram will pick out of each beam the appropriate primary color, and produce the desired three overlapping images, which the eye will interpret as having approximately the true colors of the original object.

combining red, green, and blue holograms

HOLOGRAPHIC INTERFEROMETRY

One can observe changes in the shape of a surface at about the micrometer level by constructing two holograms, one of the original surface and the other of the changed surface, and then interfering the reconstructed light from the two holograms. Among other things, this holographic interferometry is used to observe small strains and vibrations of solid bodies—for example, sonic vibrations of a guitar in Fig. 10.9.

HOLOGRAPHIC LENSES

Instead of designing a hologram to reconstruct a 3-dimensional image, one can design it to manipulate light beams in most any way one wishes. As a simple example (Ex. 10.4c) of such a holographic lens, one can construct a holographic lens that

splits one beam into two and focuses each of the two beams on a different spot. Holographic lenses are widely used in everyday technology, for example, to read bar codes in supermarket checkouts and to read the information off CDs, DVDs, and BDs (Ex. 10.5).

FUTURE APPLICATIONS

Major applications of holography that are under development include (i) dynamically changing volume holograms for 3-dimensional movies (which, of course, will require no eye glasses), and (ii) volume holograms for storage of large amounts of data—up to terabytes cm^{-3} .

EXERCISES

Exercise 10.2 *Derivation and Problem: Holographically Reconstructed Wave*

- (a) Use the Helmholtz-Kirchhoff integral (8.4) or (8.6) to compute all four pieces of the holographically reconstructed wave field. Show that the piece generated by

$$t \propto \mathcal{O}(x, y, z = 0) M e^{iky \sin \theta_o}$$

is the same (aside from overall amplitude) as the field $\psi_{\text{object}} = \mathcal{O}(x, y, z) e^{-i\omega t}$ that would have resulted if when making the hologram (Fig. 10.6), the mirror wave had been absent and the photographic plate replaced by a window. Show that the other pieces have the forms and propagation directions indicated heuristically in Fig. 10.8. We shall examine the secondary wave, generated by $t \propto M \mathcal{O}^* e^{-iky \sin \theta_o}$, in Ex. 10.6.

- (b) Suppose that plane-parallel white light is used in the holographic reconstruction of Fig. 10.8. Derive an expression for the direction in which one sees the object's 3-dimensional image have a given color (or equivalently, wave number). Assume that the original hologram was made with green light and $\theta_o = 45^\circ$. What are the angles at which one sees the image as violet, green, yellow, and red?

Exercise 10.3 *Problem: Recording a Reflection Hologram*

How would you record a hologram if you want to read it out via reflection? Draw diagrams illustrating this, similar to Figs. 10.6 and 10.8. [Hint: The mirror wave and object wave can impinge on the photographic plate from either side; it's your choice.]

Exercise 10.4 *Example: Holographic Lens to Split and Focus a Light Beam*

A holographic lens, like any other hologram, can be described by its transmissivity $t(x, y)$.

- (a) What $t(x, y)$ will take a reference wave, impinging from the θ_o direction (as in Fig. 10.8) and produce from it a primary object wave that converges on the spot

$(x, y, z) = (0, 0, d)$? [Hint: Consider, at the hologram's plane, a superposition of the incoming mirror wave and the point-spread function (8.28), which represents a beam that diverges from a point source. Then phase conjugate the point-spread function, so it converges to a point instead of diverging.]

- (b) Draw a contour plot of the transmissivity $t(x, y)$ of the lens in part (a). Notice the resemblance to the Fresnel zone plate of Sec. 8.4.4. Explain the connection of the two, paying attention to how the holographic lens changes when one alters the chosen angle θ_o of the reference wave.
- (c) What $t(x, y)$ will take a reference wave, impinging from the θ_o direction, and produce from it a primary wave that splits in two, with equal light powers converging on the spots $(x, y, z) = (-a, 0, d)$ and $(x, y, z) = (+a, 0, d)$?

Exercise 10.5 ***Problem: CDs, DVDs, and BDs*

Information on CDs, DVDs, and BDs (compact, digital video, and blu-ray disks) is recorded and read out using holographic lenses, but it is not stored holographically. Rather, it is stored in a linear binary code consisting of pits and no-pits (for 0 and 1) along a narrow spiraling track. In each successive generation of storage device, the laser light has been pushed to a shorter wavelength ($\lambda = 780$ nm for CDs, 650 nm for DVDs, and 405 nm for BDs), and in each generation, the efficiency of the information storage has been improved. In CDs, the information is stored in a single holographic layer on the surface of the disk; in DVDs and BDs, it is usually stored in a single layer but can also be stored in as many as four layers, one above the other, though with a modest price in access time.

- (a) Explain why one can expect to record in a disk's recording layer, at the very most, (close to) four bits of information per square wavelength of the recording light.
- (b) The actual storage capacities are up to 900 MB for CDs, 4.7 GB for DVDs, and 25 GB for BDs. How efficient are each of these technologies relative to the maximum given in part (a)?
- (c) Estimate the number of volumes of the *Encyclopedia Britannica* that can be recorded on a CD, on a DVD, and on a BD.

10.4 Phase-Conjugate Optics

10.4

Nonlinear optical techniques make it possible to phase conjugate an optical wave in real time, by contrast with holography, where the phase conjugation requires recording a hologram and then reconstructing the wave later. In this section, we explore the properties of phase-conjugated waves of any sort (light, sound, plasma waves, etc.), and in the next section, we discuss technology by which real-time phase conjugation is achieved for light.

The basic ideas and foundations for phase conjugation of waves were laid in Moscow by Boris Yakovovich Zel'dovich² and his colleagues (1972) and at Caltech by Amnon Yariv (1978).

phase conjugation

Phase conjugation is the process of taking a monochromatic wave

$$\Psi_O = \Re[\psi(x, y, z)e^{-i\omega t}] = \frac{1}{2}(\psi e^{-i\omega t} + \psi^* e^{+i\omega t}), \quad (10.10a)$$

and from it constructing the wave

$$\Psi_{PC} = \Re[\psi^*(x, y, z)e^{-i\omega t}] = \frac{1}{2}(\psi^* e^{-i\omega t} + \psi e^{+i\omega t}). \quad (10.10b)$$

phase-conjugating mirror

Notice that the phase-conjugated wave Ψ_{PC} is obtainable from the original wave Ψ_O by time reversal, $t \rightarrow -t$. This has a number of important consequences. One is that Ψ_{PC} propagates in the opposite direction to Ψ_O . Others are explained most clearly with the help of a *phase-conjugating mirror*.

Consider a wave Ψ_O with spatial modulation (i.e., a wave that carries a picture or a signal of some sort). Let the wave propagate in the z direction (rightward in Fig. 10.10), so that

incoming wave

$$\psi = \mathcal{A}(x, y, z)e^{i(kz - \omega t)}, \quad (10.11)$$

where $\mathcal{A} = Ae^{i\varphi}$ is a complex amplitude whose modulus A and phase φ change slowly in x , y , and z (slowly compared to the wave's wavelength $\lambda = 2\pi/k$). Suppose that this wave propagates through a time-independent medium with slowly varying physical properties [e.g., a dielectric medium with slowly varying index of refraction $n(x, y, z)$]. These slow variations will distort the wave's complex amplitude as it propagates. The wave equation for the real, classical field $\Psi = \Re[\psi e^{-i\omega t}]$ will have the form $\mathcal{L}\Psi - \partial^2\Psi/\partial t^2 = 0$, where \mathcal{L} is a real spatial differential operator that depends on the medium's slowly varying physical properties. This wave equation implies that the complex field ψ satisfies

$$\mathcal{L}\psi + \omega^2\psi = 0 \quad (10.12)$$

[which is the Helmholtz equation (8.1b) if \mathcal{L} is the vacuum wave operator]. Equation (10.12) is the evolution equation for the wave's complex amplitude.

phase conjugating mirror and its phase conjugated wave Ψ_{PC}

Let the distorted, rightward propagating wave Ψ_O reflect off a mirror located at $z = 0$. If the mirror is a phase-conjugating one, then very near it (at z near zero) the reflected wave will have the form

$$\Psi_{PC} = \Re[\mathcal{A}^*(x, y, z = 0)e^{i(-kz - \omega t)}], \quad (10.13)$$

2. Zel'dovich is the famous son of a famous Russian/Jewish physicist, Yakov Borisovich Zel'dovich, who with Andrei Dmitrievich Sakharov fathered the Soviet hydrogen bomb and then went on to become a dominant figure internationally in astrophysics and cosmology.

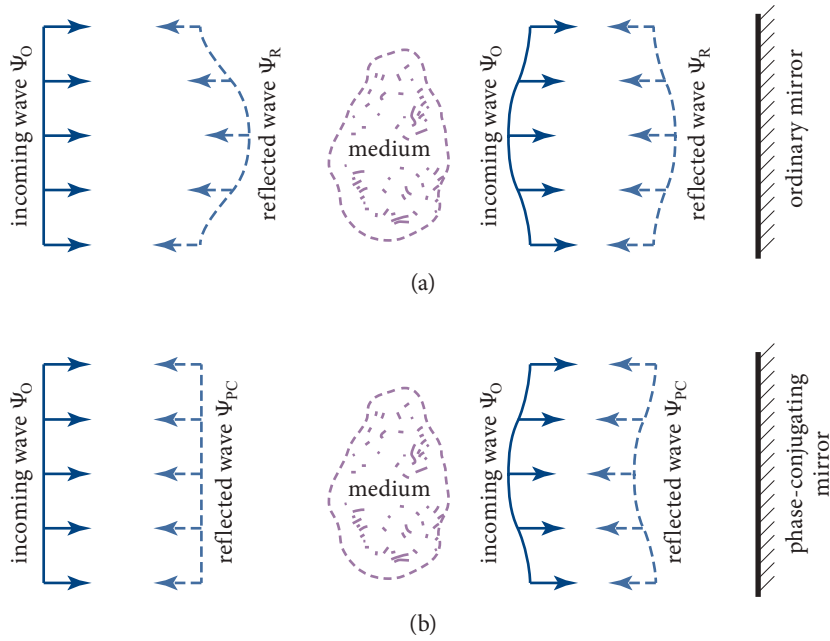

FIGURE 10.10 A rightward propagating wave and the reflected wave produced by (a) an ordinary mirror and (b) a phase-conjugating mirror. In both cases the waves propagate through a medium with spatially variable properties, which distorts their phase fronts. In case (a) the distortion is reinforced by the second passage through the variable medium; in case (b) the distortion is removed by the second passage.

while if it is an ordinary mirror, then the reflected wave will be

$$\Psi_R = \Re[\pm \mathcal{A}(x, y, z = 0)e^{i(-kz - \omega t)}]. \quad (10.14)$$

(Here the sign depends on the physics of the wave. For example, if Ψ is the transverse electric field of an electromagnetic wave and the mirror is a perfect conductor, the sign will be minus to guarantee that the total electric field, original plus reflected, vanishes at the mirror's surface.)

These two waves, the phase-conjugated one Ψ_{PC} and the ordinary reflected one Ψ_R , have very different surfaces of constant phase (*phase fronts*). The phase of the incoming wave Ψ_O [Eqs. (10.10a) and (10.11)] as it nears the mirror ($z = 0$) is $\varphi + kz$, so (taking account of the fact that φ is slowly varying) the surfaces of constant phase are $z = -\varphi(x, y, z = 0)/k$. Similarly, the phase of the wave Ψ_R [Eq. (10.14)] reflected from the ordinary mirror is $\varphi - kz$, so its surfaces of constant phase near the mirror are $z = +\varphi(x, y, z = 0)/k$, which are reversed from those of the incoming wave, as shown in the upper right of Fig. 10.10. Finally, the phase of the wave Ψ_{PC} [Eq. (10.13)] reflected from the phase-conjugating mirror is $-\varphi - kz$, so its surfaces of constant phase near the mirror are $z = -\varphi(x, y, z = 0)/k$, which are the same as those of the

ordinary mirror and its reflected wave Ψ_R

phase fronts of Ψ_{PC} and Ψ_R

FIGURE 10.11 The use of a phase-conjugating mirror in an optical transmission line to prevent the fiber from distorting an optical image. The distortions put onto the image as it propagates through the first segment of fiber are removed during propagation through the second segment.

incoming wave (lower right of Fig. 10.10), even though the two waves are propagating in opposite directions.

The phase fronts of the original incoming wave and the phase-conjugated wave are the same not only near the phase-conjugating mirror; they are the same everywhere. More specifically, as the phase-conjugated wave Ψ_{PC} propagates away from the mirror [near which it is described by Eq. (10.13)], the propagation equation (10.12) forces it to evolve in such a way as to remain always the phase conjugate of the incoming wave:

$$\Psi_{\text{PC}} = \Re[\mathcal{A}^*(x, y, z)e^{-ikz}e^{-i\omega t}]. \quad (10.15)$$

This should be obvious: because the differential operator \mathcal{L} in the propagation equation (10.12) for $\psi(x, y, z) = \mathcal{A}e^{ikz}$ is real, $\psi^*(x, y, z) = \mathcal{A}^*e^{-ikz}$ will satisfy this propagation equation when $\psi(x, y, z)$ does.

That the reflected wave Ψ_{PC} always remains the phase conjugate of the incoming wave Ψ_{O} means that *the distortions put onto the incoming wave, as it propagates rightward through the inhomogeneous medium, get removed from the phase-conjugated wave as it propagates back leftward* (Fig. 10.10).

This removal of distortions has a number of important applications. One is for image transmission in optical fibers. Normally when an optical fiber is used to transmit an optical image, the transverse spatial variations $n(x, y)$ of the fiber's index of refraction (which are required to hold the light in the fiber; Ex. 7.8) distort the image somewhat. The distortions can be eliminated by using a sequence of identical segments of optical fibers separated by phase-conjugating mirrors (Fig. 10.11). A few other applications include (i) real-time holography; (ii) removal of phase distortions in Fabry-Perot cavities by making one of the mirrors a phase-conjugating one, with a resulting improvement in the shape of the beam that emerges from the cavity; (iii) devices that can memorize an optical image and compare it to other images; (iv) the production of squeezed light (Ex. 10.16); and (v) improved focusing of laser light for laser fusion.

distortion removal in Ψ_{PC}

As we shall see in the next section, phase-conjugating mirrors rely crucially on the sinusoidal time evolution of the wave field; they integrate that sinusoidal evolution coherently over some timescale $\hat{\tau}$ (typically microseconds to nanoseconds) to produce the phase-conjugated wave. Correspondingly, if an incoming wave varies on timescales τ long compared to this $\hat{\tau}$ (e.g., if it carries a temporal modulation with bandwidth $\Delta\omega \sim 1/\tau$ small compared to $1/\hat{\tau}$), then the wave's temporal modulations will *not* be time reversed by the phase-conjugating mirror. For example, if the wave impinging on a phase-conjugating mirror has a frequency that is ω_a initially, and then gradually, over a time τ , increases to $\omega_b = \omega_a + 2\pi/\tau$, then the phase-conjugated wave will not emerge from the mirror with frequency ω_b first and ω_a later. Rather, it will emerge with ω_a first and ω_b later (same order as for the original wave). When the incoming wave's temporal variations are fast compared to the mirror's integration time, $\tau \ll \hat{\tau}$, the mirror encounters a variety of frequencies during its integration time and ceases to function properly. Thus, *even though phase conjugation is equivalent to time reversal in a formal sense, a phase-conjugating mirror cannot time reverse a temporal signal. It only time reverses monochromatic waves (which might carry a spatial signal).*

phase conjugation and time reversal

Exercise 10.6 *Derivation and Example: Secondary Wave in Holography*

Consider the secondary wave generated by $t \propto MO^* e^{-iky \sin \theta_o}$ in the holographic reconstruction process of Fig. 10.8, Eq. (10.7), and Ex. 10.2.

EXERCISES

- (a) Assume, for simplicity, that the mirror and reference waves propagate nearly perpendicular to the hologram, so $\theta_o \ll 90^\circ$ and $\theta_s \simeq 2\theta_o \ll 90^\circ$; but assume that θ_s is still large enough that fairly far from the hologram the object wave and secondary waves separate cleanly from each other. Then, taking account of the fact that the object wave field has the form $\mathcal{O}(x, y, z)e^{ikz}$, show that the secondary wave is the phase-conjugated object wave defined in this section, except that it is propagating in the $+z$ direction rather than $-z$ (i.e., it has been reflected through the $z = 0$ plane). Then use this and the discussion of phase conjugation in the text to show that the secondary wave carries an image that resides in front of the hologram and is turned inside out, as discussed near the end of Sec. 10.3. Show, further, that if θ_o is not $\ll 90^\circ$ (but is $< 30^\circ$, so θ_s is a real angle, and the secondary image actually exists), then the secondary image is changed by a distortion along the y direction. What is the nature of the distortion, a squashing or a stretch?
 - (b) Suppose that a hologram has been made with $\theta_o < 30^\circ$. Show that it is possible to perform image reconstruction with a modified reference wave (different from Fig. 10.8) in such a manner that the secondary, phase-conjugated wave emerges precisely perpendicular to the hologram and undistorted.
-

10.5

10.5 Maxwell's Equations in a Nonlinear Medium; Nonlinear Dielectric Susceptibilities; Electro-Optic Effects

In nonlinear optics, one is often concerned with media that are electrically polarized with *polarization* (electric dipole moment per unit volume) \mathbf{P} but have no free charges or currents and are unmagnetized. In such a medium the charge and current densities associated with the polarization are

$$\rho_P = -\nabla \cdot \mathbf{P}, \quad \mathbf{j}_P = \frac{\partial \mathbf{P}}{\partial t}, \quad (10.16a)$$

and Maxwell's equations in SI units take the form

$$\nabla \cdot \mathbf{E} = \frac{\rho_P}{\epsilon_0}, \quad \nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \nabla \times \mathbf{B} = \mu_0 \left(\mathbf{j}_P + \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} \right), \quad (10.16b)$$

which should be familiar. When rewritten in terms of the electric displacement vector

$$\mathbf{D} \equiv \epsilon_0 \mathbf{E} + \mathbf{P}, \quad (10.17)$$

these Maxwell equations take the alternative form

$$\nabla \cdot \mathbf{D} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \nabla \times \mathbf{B} = \mu_0 \frac{\partial \mathbf{D}}{\partial t}, \quad (10.18)$$

which should also be familiar. By taking the curl of the third equation (10.16b), using the relation $\nabla \times \nabla \times \mathbf{E} = -\nabla^2 \mathbf{E} + \nabla(\nabla \cdot \mathbf{E})$, and combining with the time derivative of the fourth equation (10.16b) and with $\epsilon_0 \mu_0 = 1/c^2$ and $\mathbf{j}_P = \partial \mathbf{P} / \partial t$, we obtain the following wave equation for the electric field, sourced by the medium's polarization:

wave equation for light in a polarizable medium

$$\nabla^2 \mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) = \frac{1}{c^2} \frac{\partial^2 (\mathbf{E} + \mathbf{P} / \epsilon_0)}{\partial t^2}. \quad (10.19)$$

If the electric field is sufficiently weak and the medium is homogeneous and isotropic (the case treated in most textbooks on electromagnetic theory), the polarization \mathbf{P} is proportional to the electric field: $\mathbf{P} = \epsilon_0 \chi_0 \mathbf{E}$, where χ_0 is the medium's electrical susceptibility. In this case the medium does not introduce any nonlinearities into Maxwell's equations, the right-hand side of Eq. (10.19) becomes $[(1 + \chi_0)/c^2] \partial^2 \mathbf{E} / \partial t^2$, the divergence of Eq. (10.19) implies that the divergence of \mathbf{E} vanishes, and therefore Eq. (10.19) becomes the standard dispersionless wave equation:

$$\nabla^2 \mathbf{E} - \frac{n^2}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = 0, \quad \text{with } n^2 = 1 + \chi_0. \quad (10.20)$$

In many dielectric media, however, a strong electric field can produce a polarization that is nonlinear in the field. In such nonlinear media, the general expression for the (real) polarization in terms of the (real) electric field is

polarization in a nonlinear medium

$$P_i = \epsilon_0 (\chi_{ij} E_j + 2d_{ijk} E_j E_k + 4\chi_{ijkl} E_j E_k E_l + \dots), \quad (10.21)$$

where we sum over repeated indices. Here χ_{ij} , the linear susceptibility, is proportional to the 3-dimensional metric, $\chi_{ij} = \chi_0 g_{ij} = \chi_0 \delta_{ij}$, if the medium is isotropic (i.e., if all directions in it are equivalent), but otherwise it is tensorial; and the d_{ijk} and χ_{ijkl} are nonlinear susceptibilities, referred to as *second-order* and *third-order*, respectively, because of the two and three \mathbf{E} terms that multiply them in Eq. (10.21). The normalizations used for these second- and third-order susceptibilities differ from one researcher to another: sometimes the factor ϵ_0 is omitted in Eq. (10.21); occasionally the factors of 2 and 4 are omitted. A compressed 2-index notation is sometimes used for the components of d_{ijk} ; see Box 10.2 in Sec. 10.6.

With \mathbf{P} given by Eq. (10.21), the wave equation (10.19) becomes

$$\nabla^2 \mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) - \frac{1}{c^2} \boldsymbol{\epsilon} \cdot \frac{\partial^2 \mathbf{E}}{\partial t^2} = \frac{1}{c^2 \epsilon_0} \frac{\partial^2 \mathbf{P}^{\text{NL}}}{\partial t^2}, \quad \text{where } \epsilon_{ij} = \delta_{ij} + \chi_{ij} \quad (10.22a)$$

is the “dielectric tensor,” and \mathbf{P}^{NL} is the nonlinear part of the polarization:

$$P_i^{\text{NL}} = \epsilon_0 (2d_{ijk} E_j E_k + 4\chi_{ijkl} E_j E_k E_l + \dots). \quad (10.22b)$$

When \mathbf{P}^{NL} is strong enough to be important and a monochromatic wave at frequency ω enters the medium, the nonlinearities lead to harmonic generation—the production of secondary waves with frequencies $2\omega, 3\omega, \dots$; see Secs. 10.7.1 and 10.8.1. As a result, an electric field in the medium cannot oscillate at just one frequency, and each of the electric fields in expression (10.22b) for the nonlinear polarization must be a sum of pieces with different frequencies. Because *the susceptibilities can depend on frequency*, this means that, when using expression (10.21), one sometimes must break up P_i and each E_i into its frequency components and use different values of the susceptibility to couple the different frequencies together. For example, one of the terms in Eq. (10.22b) will become

$$P_i^{(4)} = 4\epsilon_0 \chi_{ijkl} E_j^{(1)} E_k^{(2)} E_l^{(3)}, \quad (10.23)$$

where $E_j^{(n)}$ oscillates at frequency ω_n , $P_i^{(4)}$ oscillates at frequency ω_4 , and χ_{ijkl} depends on the four frequencies $\omega_1, \dots, \omega_4$. Although this is complicated in the general case, in most practical applications, resonant coupling (or equivalently, energy and momentum conservation for photons) guarantees that only a single set of frequencies is important, and the resulting analysis simplifies substantially (see, e.g., Sec. 10.6.1).

Because all the tensor indices on the susceptibilities except the first index get contracted into the electric field in expression (10.21), we are free (and it is conventional) to define the susceptibilities as symmetric under interchange of any pair of indices that does not include the first. When [as has been tacitly assumed in Eq. (10.21)]

second-order and third-order nonlinear susceptibilities

dielectric tensor ϵ_{ij}

harmonic generation by nonlinearities

there is no hysteresis in the medium's response to the electric field, the energy density of interaction between the polarization and the electric field is

polarizational energy density

$$U = \epsilon_0 \left(\frac{\chi_{ij} E_i E_j}{2} + \frac{2d_{ijk} E_i E_j E_k}{3} + \frac{4\chi_{ijkl} E_i E_j E_k E_l}{4} + \dots \right), \quad (10.24a)$$

and the polarization is related to this energy of interaction, in Cartesian coordinates, by

$$P_i = \frac{\partial U}{\partial E_i}, \quad (10.24b)$$

which agrees with Eq. (10.21) *providing the susceptibilities are symmetric under interchange of all pairs of indices, including the first*. We shall assume such symmetry.³ If the crystal is isotropic (as will be the case if it has cubic symmetry and reflection symmetry), then each of its tensorial susceptibilities is constructable from the metric $g_{ij} = \delta_{ij}$ and a single scalar susceptibility (see Ex. 10.7):⁴

susceptibilities for isotropic crystal

$$\chi_{ij} = \chi_0 g_{ij}, \quad d_{ijk} = 0, \quad \chi_{ijkl} = \frac{1}{3} \chi_4 (g_{ij} g_{kl} + g_{ik} g_{jl} + g_{il} g_{jk}), \quad \chi_{ijklm} = 0, \dots \quad (10.25)$$

A simple model of a crystal that explains how nonlinear susceptibilities can arise is the following. Imagine each ion in the crystal as having a valence electron that can oscillate in response to a sinusoidal electric field. The electron can be regarded as residing in a potential well, which, for low-amplitude oscillations, is very nearly harmonic (potential energy quadratic in displacement; restoring force proportional to displacement; “spring constant” independent of displacement). However, if the electron's displacement from equilibrium becomes a significant fraction of the interionic distance, it will begin to feel the electrostatic attraction of the neighboring ions, and its spring constant will weaken. So the potential the electron sees is really not that of a harmonic oscillator, but rather that of an *anharmonic oscillator*, $V(x) = \alpha x^2 - \beta x^3 + \dots$, where x is the electron's displacement from equilibrium. The nonlinearities in this potential cause the electron's amplitude of oscillation, when driven by a sinusoidal electric field,

3. For further details see, e.g., Sharma (2006, Sec. 14.3) or Yariv (1989, Secs. 16.2 and 16.3). In a lossy medium, symmetry on the first index is lost; see Yariv and Yeh (2007, Sec. 8.1).
4. There is a caveat to these symmetry arguments. When the nonlinear susceptibilities depend significantly on the frequencies of the three or four waves, then these simple symmetries can be broken. For example, the third-order susceptibility χ_{ijkl} for an isotropic medium depends on which of the three input waves is paired with the output wave in Eq. (10.25); so when one orders the input waves with wave 1 on the j index, 2 on the k index, and 3 on the l index (and output 4 on the i index), the three terms in χ_{ijkl} [Eq. (10.25)] have different scalar coefficients. We ignore this subtlety in the remainder of this chapter. (For details, see, e.g., Sharma, 2006, Sec. 14.3.)

to be nonlinear in the field strength, and that nonlinear displacement causes the crystal's polarization to be nonlinear (e.g., Yariv, 1989, Sec. 16.3). For most crystals, the spatial arrangement of the ions causes the electron's potential energy V to be different for displacements in different directions, which causes the nonlinear susceptibilities to be anisotropic.

Because the total energy required to liberate the electron from its lattice site is roughly 1 eV and the separation between lattice sites is $\sim 10^{-10}$ m, the characteristic electric field for strong instantaneous nonlinearities is $\sim 1 \text{ V}(10^{-10} \text{ m})^{-1} = 10^{10} \text{ V m}^{-1} = 1 \text{ V}(100 \text{ pm})^{-1}$. Correspondingly, since d_{ijk} has dimensions 1/(electric field) and χ_{ijkl} has dimensions 1/(electric field)², rough upper limits on their Cartesian components are

$$d_{ijk} \lesssim 100 \text{ pm V}^{-1}, \quad \chi_4 \sim \chi_{ijkl} \lesssim (100 \text{ pm V}^{-1})^2. \quad (10.26)$$

magnitudes of nonlinear susceptibilities

For comparison, because stronger fields will pull electrons out of solids, the strongest continuous-wave electric fields that occur in practical applications are $E \sim 10^6 \text{ V m}^{-1}$, corresponding to maximum intensities $F \sim 1 \text{ kW mm}^{-2} = 1 \text{ GW m}^{-2}$. These numbers dictate that, unless the second-order d_{ijk} are suppressed by isotropy, they will produce much larger effects than the third-order χ_{ijkl} , which in turn will dominate over all higher orders.

In the next few sections, we explore how the nonlinear susceptibilities produce nonlinear couplings of optical waves. There is, however, another application that we must mention in passing. When a slowly changing, non-wave electric field E_k is applied to a nonlinear medium, it can be thought of as producing a change in the linear dielectric tensor for waves $\Delta\chi_{ij} = 2(d_{ijk} + d_{ikj})E_k + \text{quadratic terms}$ [cf. Eq. (10.22b)]. This is an example (Boyd, 2008) of an *electro-optic effect*: the modification of optical properties of a medium by an applied electric field. Electro-optic effects are important in modern optical technology. For example, Pockels cells (used to modulate Gaussian light beams), optical switches (used in Q -switched lasers), and liquid-crystal displays (used for computer screens and television screens) are based on electro-optic effects. For some details of several important electro-optic effects and their applications, see, for example, Yariv and Yeh (2007, Chap. 9).

electro-optic effects

Exercise 10.7 *Derivation and Example: Nonlinear Susceptibilities for an Isotropic Medium*

Explain why the nonlinear susceptibilities for an isotropic medium have the forms given in Eq. (10.25). [Hint: Use the facts that the χ s must be symmetric in all their indices, and that, because the medium is isotropic, they must be constructable from

EXERCISES

the only isotropic tensors available to us, the (symmetric) metric tensor g_{ij} and the (antisymmetric) Levi-Civita tensor ϵ_{ijk} .] What are the corresponding forms, in an isotropic medium, of χ_{ijklmn} and $\chi_{ijklmnp}$? [Note: We will encounter an argument similar to this, in Ex. 28.1, for the form of the Riemann tensor in an isotropic universe.]

10.6 Three-Wave Mixing in Nonlinear Crystals

10.6.1 Resonance Conditions for Three-Wave Mixing

three-wave and four-wave mixing

When a beam of light is sent through a nonlinear crystal, the nonlinear susceptibilities produce wave-wave mixing. The mixing due to the second-order susceptibility d_{ijk} is called *three-wave mixing*, because three electric fields appear in the polarization-induced interaction energy, Eq. (10.24a). The mixing produced by the third-order χ_{ijkl} is similarly called *four-wave mixing*. Three-wave mixing dominates in an anisotropic medium, but it is suppressed when the medium is isotropic, leaving four-wave mixing as the leading-order nonlinearity.

For use in our analyses of three-wave mixing, in Box 10.2 we list the second-order susceptibilities and some other properties of several specific nonlinear crystals.

Let us examine three-wave mixing in a general anisotropic crystal. Because the nonlinear susceptibilities are so small [i.e., because the input wave will generally be far weaker than $10^{10} \text{ V m}^{-1} = 1 \text{ V}(100 \text{ pm})^{-1}$], the nonlinearities can be regarded as small perturbations. Suppose that two waves, labeled $n = 1$ and $n = 2$, are injected into the anisotropic crystal, and let their wave vectors be \mathbf{k}_n when one ignores the (perturbative) nonlinear susceptibilities but keeps the large linear χ_{ij} . Because χ_{ij} is an anisotropic function of frequency, the dispersion relation $\Omega(\mathbf{k})$ for these waves (ignoring the nonlinearities) will typically be anisotropic. The frequencies of the two input waves satisfy the dispersion relation, $\omega_n = \Omega(\mathbf{k}_n)$, and the waves' forms are

$$E_j^{(n)} = \Re \left(\mathcal{A}_j^{(n)} e^{i(\mathbf{k}_n \cdot \mathbf{x} - \omega_n t)} \right) = \frac{1}{2} \left(\mathcal{A}_j^{(n)} e^{i(\mathbf{k}_n \cdot \mathbf{x} - \omega_n t)} + \mathcal{A}_j^{(n)*} e^{i(-\mathbf{k}_n \cdot \mathbf{x} + \omega_n t)} \right), \quad (10.27)$$

where we have denoted their vectorial complex amplitudes by $\mathcal{A}_j^{(n)}$. We adopt the convention that wave 1 is the wave with the larger frequency, so $\omega_1 - \omega_2 \geq 0$.

These two input waves couple, via the second-order nonlinear susceptibility d_{ijk} , to produce the following contribution to the medium's nonlinear polarization vector:

polarization for 3-wave mixing

$$\begin{aligned} P_i^{(3)} &= 2\epsilon_0 d_{ijk} 2E_j^{(1)} E_k^{(2)} \\ &= \epsilon_0 d_{ijk} \left(\mathcal{A}_j^{(1)} \mathcal{A}_k^{(2)} e^{i(\mathbf{k}_1 + \mathbf{k}_2) \cdot \mathbf{x}} e^{i(\omega_1 + \omega_2)t} + \mathcal{A}_j^{(1)} \mathcal{A}_k^{(2)*} e^{i(\mathbf{k}_1 - \mathbf{k}_2) \cdot \mathbf{x}} e^{i(\omega_1 - \omega_2)t} + \text{cc} \right), \end{aligned} \quad (10.28)$$

BOX 10.2. PROPERTIES OF SOME ANISOTROPIC, NONLINEAR CRYSTALS

NOTATION FOR SECOND-ORDER SUSCEPTIBILITIES

In tabulations of the second-order nonlinear susceptibilities d_{ijk} , a compressed two-index notation d_{ab} is often used, with the indices running over

$$a: 1 = x, \quad 2 = y, \quad 3 = z,$$

$$b: 1 = xx, \quad 2 = yy, \quad 3 = zz, \quad 4 = yz = zy, \quad 5 = xz = zx, \quad 6 = xy = yx. \quad (1)$$

CRYSTALS WITH LARGE SECOND-ORDER SUSCEPTIBILITIES

The following crystals have especially large second-order susceptibilities:

$$\begin{aligned} \text{Te: tellurium} \quad d_{11} = d_{xxx} &= 650 \text{ pm V}^{-1} \\ \text{CdGeAs}_2 \quad d_{36} = d_{zyx} &= 450 \text{ pm V}^{-1} \\ \text{Se: selenium} \quad d_{11} = d_{xxx} &= 160 \text{ pm V}^{-1}. \end{aligned} \quad (2)$$

However, they are not widely used in nonlinear optics, because some of their other properties are unfavorable. By contrast, glasses containing tellurium or selenium have moderately large nonlinearities and are useful.

KH_2PO_4

Potassium dihydrogen phosphate (KDP) is among the most widely used nonlinear crystals in 2016, not because of its nonlinear susceptibilities (which are quite modest) but because (i) it can sustain large electric fields without suffering damage, (ii) it is highly birefringent (different light speeds in different directions and for different polarizations, which as we shall see in Sec. 10.6.3 is useful for phase matching), and (iii) it has large electro-optic coefficients (end of Sec. 10.5). At linear order, it is axisymmetric around the z -axis, and its indices of refraction and susceptibilities have the following dependence on wavelength λ (measured in microns), which we use in Sec. 10.6.3 and Fig. 10.12a:

$$\begin{aligned} (n_o)^2 = 1 + \chi_{xx} = 1 + \chi_{yy} &= 2.259276 + \frac{0.01008956}{\lambda^2 - 0.012942625} + \frac{13.005522\lambda^2}{\lambda^2 - 400}, \\ (n_e)^2 = 1 + \chi_{zz} &= 2.132668 + \frac{0.008637494}{\lambda^2 - 0.012281043} + \frac{3.2279924\lambda^2}{\lambda^2 - 400}. \end{aligned} \quad (3)$$

The second-order nonlinearities break the axisymmetry of KDP, giving rise to

$$d_{36} = d_{zyx} = 0.44 \text{ pm V}^{-1}. \quad (4)$$

Although this is three orders of magnitude smaller than the largest nonlinearities available, its smallness is compensated for by its ability to sustain large electric fields.

(continued)

BOX 10.2. (continued)

KTiOPO₄

Potassium titanyl phosphate (KTP) is quite widely used in 2016 (e.g., in green laser pointers; Ex. 10.13). At linear order it is nonaxisymmetric, but with only modest birefringence: its indices of refraction along its three principal axes, at the indicated wavelengths, are

$$\begin{aligned} 1,064 \text{ nm: } n_x &= \sqrt{1 + \chi_{xx}} = 1.740, & n_y &= \sqrt{1 + \chi_{yy}} = 1.747, \\ n_z &= \sqrt{1 + \chi_{zz}} = 1.830; \\ 532 \text{ nm: } n_x &= \sqrt{1 + \chi_{xx}} = 1.779, & n_y &= \sqrt{1 + \chi_{yy}} = 1.790, \\ n_z &= \sqrt{1 + \chi_{zz}} = 1.887. \end{aligned} \quad (5)$$

Its third-order nonlinearities are moderately large. In units of pm V⁻¹, they are

$$\begin{aligned} d_{31} = d_{zxx} &= 6.5, & d_{32} = d_{zyy} &= 5.0, & d_{33} = d_{zzz} &= 13.7, \\ d_{24} = d_{xyz} = d_{xzy} &= 7.6, & d_{15} = d_{xxz} = d_{xzx} &= 6.1. \end{aligned} \quad (6)$$

Notice that symmetry on the first index is modestly broken: $d_{zxx} = 6.5 \neq d_{xzx} = 7.6$. This symmetry breaking is caused by the crystal's dissipating a small portion of the light power that drives it.

EVOLUTION OF MATERIALS

Over the past three decades materials scientists have found and developed nonlinear crystals with ever-improving properties. By the time you read this book, the most widely used crystals are likely to have changed.

where “cc” means complex conjugate.⁵ This sinusoidally oscillating polarization produces source terms in Maxwell's equations (10.16b) and the wave equation (10.19): an oscillating, polarization-induced charge density $\rho_P = -\nabla \cdot \mathbf{P}^{(3)}$ and current density $\mathbf{j}_P = \partial \mathbf{P}^{(3)} / \partial t$. This polarization charge and current, like $\mathbf{P}^{(3)}$ itself [Eq. (10.28)], consist of two traveling waves, one with frequency and wave vector

$$\omega_3 = \omega_1 + \omega_2, \quad \mathbf{k}_3 = \mathbf{k}_1 + \mathbf{k}_2; \quad (10.29a)$$

the other with frequency and wave vector

$$\omega_3 = \omega_1 - \omega_2, \quad \mathbf{k}_3 = \mathbf{k}_1 - \mathbf{k}_2. \quad (10.29b)$$

resonance conditions and dispersion relation for new, third wave

5. The reason for the factor 2 in the definition $P_i = 2\epsilon_0 d_{ijk} E_j E_k$ is to guarantee a factor unity in Eq. (10.28) and in the resulting coupling constant κ of Eq. (10.38).

If either of these (ω_3, \mathbf{k}_3) satisfies the medium's dispersion relation $\omega = \Omega(\mathbf{k})$, then the polarization will generate an electromagnetic wave $E_j^{(3)}$ that propagates along in resonance with its polarization-vector source in the wave equation

$$\nabla^2 \mathbf{E}^{(3)} - \nabla(\nabla \cdot \mathbf{E}^{(3)}) + \frac{\omega_3^2}{c^2} \boldsymbol{\epsilon} \cdot \mathbf{E}^{(3)} = \frac{1}{c^2 \epsilon_0} \frac{\partial^2 \mathbf{P}^{(3)}}{\partial t^2} \quad (10.30)$$

[the frequency- ω_3 part of Eq. (10.22a)]. Therefore, this new electromagnetic wave, with frequency ω_3 and wave vector \mathbf{k}_3 , will grow as it propagates.

For most choices of the input waves—most choices of $\{\mathbf{k}_1, \omega_1 = \Omega(\mathbf{k}_1), \mathbf{k}_2, \omega_2 = \Omega(\mathbf{k}_2)\}$ —neither of the polarizations $\mathbf{P}^{(3)}$ will have a frequency $\omega_3 = \omega_1 \pm \omega_2$ and wave vector $\mathbf{k}_3 = \mathbf{k}_1 \pm \mathbf{k}_2$ that satisfy the medium's dispersion relation, and thus neither will be able to create a third electromagnetic wave resonantly; the wave-wave mixing is ineffective. However, for certain special choices of the input waves, resonant coupling will be achieved, and a strong third wave will be produced. See Sec. 10.6.3 for details.

In nonlinear optics, enforcing the resonance conditions (10.29), with all three waves satisfying their dispersion relations, is called *phase matching*, because it guarantees that the new wave propagates along in phase with the polarization produced by the two old waves.

The resonance conditions (10.29) have simple quantum mechanical interpretations—a fact that is not at all accidental: quantum mechanics underlies the classical theory that we are developing. Each classical wave is carried by photons that have discrete energies $\mathcal{E}_n = \hbar\omega_n$ and discrete momenta $\mathbf{p}_n = \hbar\mathbf{k}_n$. The input waves are able to produce resonantly waves with $\omega_3 = \omega_1 \pm \omega_2$ and $\mathbf{k}_3 = \mathbf{k}_1 \pm \mathbf{k}_2$, if those waves satisfy the dispersion relation. Restated in quantum mechanical terms, the condition of resonance with the “+” sign rather than the “−” is

$$\mathcal{E}_3 = \mathcal{E}_1 + \mathcal{E}_2, \quad \mathbf{p}_3 = \mathbf{p}_1 + \mathbf{p}_2. \quad (10.31a)$$

This has the quantum mechanical meaning that one photon of energy \mathcal{E}_1 and momentum \mathbf{p}_1 , and another of energy \mathcal{E}_2 and momentum \mathbf{p}_2 combine together, via the medium's nonlinearities, and are annihilated (in the language of quantum field theory). By their annihilation they create a new photon with energy $\mathcal{E}_3 = \mathcal{E}_1 + \mathcal{E}_2$ and momentum $\mathbf{p}_3 = \mathbf{p}_1 + \mathbf{p}_2$. Thus the classical condition of resonance is the quantum mechanical condition of energy-momentum conservation for the sets of photons involved in a process of quantum annihilation and creation. For this process to proceed, not only must energy-momentum conservation be satisfied, but also all three photons must have energies and momenta that obey the photons' semiclassical hamiltonian relation $\mathcal{E} = H(\mathbf{p})$ (i.e., the dispersion relation $\omega = \Omega(\mathbf{k})$ with $H = \hbar\Omega$, $\mathcal{E} = \hbar\omega$, and $\mathbf{p} = \hbar\mathbf{k}$).

phase matching

quantum description of resonance conditions

one photon created from two

two photons created from one

Similarly, the classical conditions of resonance with the “−” sign rather than the “+” can be written (after bringing photon 2 to the left-hand side) as

$$\mathcal{E}_3 + \mathcal{E}_2 = \mathcal{E}_1, \quad \mathbf{p}_3 + \mathbf{p}_2 = \mathbf{p}_1. \quad (10.31b)$$

This has the quantum mechanical meaning that one photon of energy \mathcal{E}_1 and momentum \mathbf{p}_1 is annihilated, via the medium’s nonlinearities, and from its energy and momentum two photons are created, with energies $\mathcal{E}_2, \mathcal{E}_3$ and momenta $\mathbf{p}_2, \mathbf{p}_3$ that satisfy energy-momentum conservation.

Resonance conditions play a major role in other areas of physics, whenever one deals with nonlinear wave-wave coupling or wave-particle coupling. In this book we meet them again in both classical language and quantum language when studying excitations of plasmas (Chap. 23).

10.6.2 10.6.2 Three-Wave-Mixing Evolution Equations

in a Medium That Is Dispersion-Free and Isotropic at Linear Order

Consider the simple, idealized case where the linear part of the susceptibility χ_{jk} is isotropic and frequency independent, $\chi_{jk} = \chi_0 g_{jk}$; correspondingly, Maxwell’s equations imply $\nabla \cdot \mathbf{E} = 0$. The Track-One part of this chapter will be confined to this idealized case. In Sec. 10.6.3 (Track Two), we treat the more realistic case, which has dispersion and anisotropy at linear order.

In our idealized case the dispersion relation, ignoring the nonlinearities, takes the simple, nondispersive form [which follows from Eq. (10.20)]:

$$\omega = \frac{c}{n}k, \quad \text{where } k = |\mathbf{k}|, \quad n = \sqrt{1 + \chi_0}. \quad (10.32)$$

Consider three-wave mixing for waves 1, 2, and 3 that all propagate in the same z direction with wave numbers that satisfy the resonance condition $k_3 = k_1 + k_2$. The dispersion-free dispersion relation (10.32) guarantees that the frequencies will also resonate: $\omega_3 = \omega_1 + \omega_2$. If we write the new wave as $E_i^{(3)} = \Re(\mathcal{A}_i^{(3)} e^{i(k_3 z - \omega_3 t)}) = \frac{1}{2} \mathcal{A}_i^{(3)} e^{i(k_3 z - \omega_3 t)} + \text{cc}$, then its evolution equation (10.30), when combined with Eqs. (10.27) and (10.28), takes the form

$$\nabla^2 \left(\mathcal{A}_i^{(3)} e^{i(k_3 z - \omega_3 t)} \right) + \frac{n^2 \omega_3^2}{c^2} \mathcal{A}_i^{(3)} e^{i(k_3 z - \omega_3 t)} = -2 \frac{\omega_3^2}{c^2} d_{ijk} \mathcal{A}_j^{(1)} \mathcal{A}_k^{(2)} e^{i(k_3 z - \omega_3 t)}. \quad (10.33)$$

Using the dispersion relation (10.32) and the fact that the lengthscale on which wave 3 changes is long compared to its wavelength (which is always the case, because the fields are always much weaker than 10^{10} V m^{-1}), the left-hand side becomes $2ik_3 d\mathcal{A}_i^{(3)}/dz$, and Eq. (10.33) then becomes (with the aid of the dispersion relation) $d\mathcal{A}_i^{(3)}/dz = i(k_3/n^2)d_{ijk}\mathcal{A}_j^{(1)}\mathcal{A}_k^{(2)}$. This and similar computations for evolution of the other two waves (Ex. 10.8) give the following equations for the rates of change of the three waves’ complex amplitudes:

$$\frac{d\mathcal{A}_i^{(3)}}{dz} = i \frac{k_3}{n^2} d_{ijk} \mathcal{A}_j^{(1)} \mathcal{A}_k^{(2)} \quad \text{at } \omega_3 = \omega_1 + \omega_2, \quad k_3 = k_1 + k_2; \quad (10.34a)$$

$$\frac{d\mathcal{A}_i^{(1)}}{dz} = i \frac{k_1}{n^2} d_{ijk} \mathcal{A}_j^{(3)} \mathcal{A}_k^{(2)*} \quad \text{at } \omega_1 = \omega_3 - \omega_2, \quad k_1 = k_3 - k_2; \quad (10.34b)$$

$$\frac{d\mathcal{A}_i^{(2)}}{dz} = i \frac{k_2}{n^2} d_{ijk} \mathcal{A}_j^{(3)} \mathcal{A}_k^{(1)*} \quad \text{at } \omega_2 = \omega_3 - \omega_1, \quad k_2 = k_3 - k_1. \quad (10.34c)$$

Therefore, each wave's amplitude changes with distance z traveled at a rate proportional to the product of the field strengths of the other two waves.

It is instructive to rewrite the evolution equations (10.34) in terms of *renormalized scalar amplitudes* \mathfrak{A}_n and *unit-normed polarization vectors* $f_j^{(n)}$ for the three waves $n = 1, 2, 3$:

$$\mathcal{A}_j^{(n)} = \sqrt{\frac{2k_n}{\epsilon_0 n^2}} \mathfrak{A}_n f_j^{(n)} = \sqrt{\frac{2\omega_n}{\epsilon_0 c n}} \mathfrak{A}_n f_j^{(n)}. \quad (10.35)$$

renormalized wave amplitudes

This renormalization is motivated by the fact that $|\mathfrak{A}_n|^2$ is proportional to the flux of quanta $dN_n/dAdt$ associated with wave n . Specifically, the energy density in wave n is (neglecting nonlinearities) $U = \epsilon_o(1 + \chi_o)\overline{\mathbf{E}^2} = \frac{1}{2}\epsilon_o n^2 |\mathcal{A}^{(n)}|^2$ (where the bar means time average); the energy flux is this U times the wave speed c/n :

$$F_n = \frac{1}{2} \epsilon_o n c |\mathcal{A}^{(n)}|^2 = \omega_n |\mathfrak{A}_n|^2; \quad (10.36)$$

and the flux of quanta is this F_n divided by the energy $\mathcal{E}_n = \hbar\omega_n$ of each quantum: $dN_n/dAdt = |\mathfrak{A}_n|^2/\hbar$, where dA is a unit area orthogonal to \mathbf{k}_n .

The three-wave-mixing evolution equations (10.34), rewritten in terms of the renormalized amplitudes, take the simple form

$$\begin{aligned} \frac{d\mathfrak{A}_3}{dz} &= i\kappa \mathfrak{A}_1 \mathfrak{A}_2, & \frac{d\mathfrak{A}_1}{dz} &= i\kappa \mathfrak{A}_3 \mathfrak{A}_2^*, & \frac{d\mathfrak{A}_2}{dz} &= i\kappa \mathfrak{A}_3 \mathfrak{A}_1^*; \\ \kappa &= \sqrt{\frac{2\omega_1 \omega_2 \omega_3}{\epsilon_0 c^3 n^3}} d_{ijk} f_i^{(1)} f_j^{(2)} f_k^{(3)}. \end{aligned} \quad (10.37)$$

three-wave mixing evolution equations in an isotropic, dispersion-free medium

It is straightforward to verify that these evolution equations guarantee energy conservation $d(F_1 + F_2 + F_3)/dz = 0$, with F_n given by Eq. (10.36). Therefore, at least one wave will grow and at least one wave will decay due to three-wave mixing.

When waves 1 and 2 are the same wave, the three-wave mixing leads to frequency doubling: $\omega_3 = 2\omega_1$. In this case, the nonlinear polarization that produces the third wave is $P_i = \epsilon_0 d_{ijk} E_j^{(1)} E_k^{(1)}$, by contrast with that when waves 1 and 2 are different, $P_i = 2\epsilon_0 d_{ijk} E_j^{(1)} E_k^{(2)}$ [Eq. (10.28)]. [In the latter case the factor 2 arises because we are dealing with cross terms in $(E_j^{(1)} + E_j^{(2)})(E_k^{(1)} + E_k^{(2)})$.] Losing the factor 2 and

frequency doubling

making wave 2 the same as wave 1 leads to an obvious modification of the evolution equations (10.37):

evolution equations for frequency doubling

$$\frac{d\mathfrak{A}_3}{dz} = \frac{i\kappa}{2}(\mathfrak{A}_1)^2, \quad \frac{d\mathfrak{A}_1}{dz} = i\kappa\mathfrak{A}_3\mathfrak{A}_1^*; \quad \kappa = \sqrt{\frac{2\omega_1^2\omega_3}{\epsilon_0 c^3 n^3}} d_{ijk} f_i^{(1)} f_j^{(1)} f_k^{(3)}. \quad (10.38)$$

Once again, it is easy to verify energy conservation, $d(F_1 + F_3)/dz = 0$. We discuss frequency doubling in Sec. 10.7.1.

10.6.3

10.6.3 Three-Wave Mixing in a Birefringent Crystal:
Phase Matching and Evolution Equations **T2**

ORDINARY WAVES, EXTRAORDINARY WAVES, AND DISPERSION RELATIONS

In reality, all nonlinear media have frequency-dependent dispersion relations and most are anisotropic at linear order and therefore birefringent (different wave speeds in different directions). An example is the crystal KDP (Box 10.2), which is symmetric around the z -axis and has indices of refraction⁶

birefringent crystal

$$n_o = \sqrt{1 + \chi_{xx}} = \sqrt{1 + \chi_{yy}}, \quad n_e = \sqrt{1 + \chi_{zz}} \quad (10.39)$$

that depend on the light's wave number $k = 2\pi/\lambda$ in the manner shown in Fig. 10.12a and in Eq. (3) of Box 10.2. The subscript o stands for *ordinary*; e , for *extraordinary*; see the next paragraph.

Maxwell's equations imply that, in this crystal, for plane, monochromatic waves propagating in the x - z plane at an angle θ to the symmetry axis [$\mathbf{k} = k(\sin \theta \mathbf{e}_x + \cos \theta \mathbf{e}_z)$], there are two dispersion relations corresponding to the two polarizations of the electric field:

1. If \mathbf{E} is orthogonal to the symmetry axis, then (as is shown in Ex. 10.9), it must also be orthogonal to the propagation direction (i.e., must point in the \mathbf{e}_y direction), and the dispersion relation is

$$\frac{\omega/k}{c} = (\text{phase speed in units of speed of light}) = \frac{1}{n_o}, \quad (10.40a)$$

6. For each wave, the index of refraction is the ratio of light's vacuum speed c to the wave's phase speed $V_{\text{ph}} = \omega/k$.

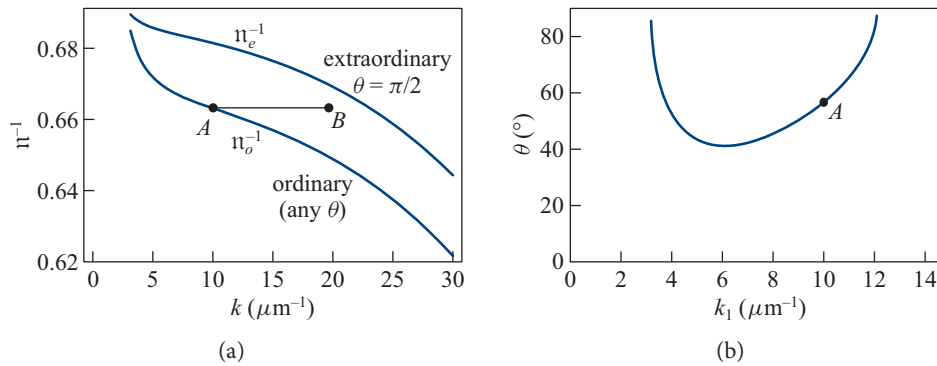

FIGURE 10.12 (a) The inverse of the index of refraction n^{-1} (equal to the phase speed in units of the speed of light) for electromagnetic waves propagating at an angle θ to the symmetry axis of a KDP crystal, as a function of wave number k in reciprocal microns. See Eq. (10.40a) for the lower curve and Eq. (10.40b) with $\theta = \pi/2$ for the upper curve. For extraordinary waves propagating at an arbitrary angle θ to the crystal's symmetry axis, n^{-1} is a mean [Eq. (10.40b)] of the two plotted curves. The plotted curves are fit by the analytical formulas (3) of Box 10.2. (b) The angle θ to the symmetry axis at which ordinary waves with wave number k_1 (e.g., point A) must propagate for three-wave mixing to be able to produce frequency-doubled or phase-conjugated extraordinary waves (e.g., point B).

independent of the angle θ . These waves are called *ordinary*, and their phase speed (10.40a) is the lower curve in Fig. 10.12a; at $k = 10 \mu\text{m}^{-1}$ (point A), the phase speed is $0.663c$, while at $k = 20 \mu\text{m}^{-1}$, it is $0.649c$.

- If \mathbf{E} is not orthogonal to the symmetry axis, then (Ex. 10.9) it must lie in the plane formed by \mathbf{k} and the symmetry axis (the x - z plane, with $E_x/E_z = -(\mathbf{n}_e/\mathbf{n}_o)^2 \cot \theta$ (which means that \mathbf{E} is not orthogonal to the propagation direction unless the crystal is isotropic, $\mathbf{n}_e = \mathbf{n}_o$, which it is not); and the dispersion relation is

$$\frac{\omega/k}{c} = \frac{1}{\mathbf{n}} = \sqrt{\frac{\cos^2 \theta}{\mathbf{n}_o^2} + \frac{\sin^2 \theta}{\mathbf{n}_e^2}}. \quad (10.40b)$$

In this case the waves are called *extraordinary*.⁷ As the propagation direction varies from parallel to the symmetry axis ($\cos \theta = 1$) to perpendicular ($\sin \theta = 1$), this extraordinary phase speed varies from c/\mathbf{n}_o (the lower curve in Fig. 10.12; $0.663c$ at $k = 10 \mu\text{m}^{-1}$), to c/\mathbf{n}_e (the upper curve; $0.681c$ at $k = 10 \mu\text{m}^{-1}$).

- When studying perturbations of a cold, magnetized plasma (Sec. 21.5.3) we will meet two wave modes that have these same names: ordinary and extraordinary. However, because of the physical differences between an axially symmetric magnetized plasma and an axially symmetric birefringent crystal, the physics of those plasma modes (e.g., the direction of their oscillating electric field) is rather different from that of the crystal modes studied here.

ordinary waves

extraordinary waves

PHASE MATCHING FOR FREQUENCY DOUBLING IN A KDP CRYSTAL

This birefringence enables one to achieve phase matching (satisfy the resonance conditions) in three-wave mixing. As an example, consider the resonance conditions for a *frequency-doubling device* (discussed in further detail in Sec. 10.7.1): one in which the two input waves are identical, so $\mathbf{k}_1 = \mathbf{k}_2$ and $\mathbf{k}_3 = 2\mathbf{k}_1$ point in the same direction. Let this common propagation direction be at an angle θ to the symmetry axis. Then the resonance conditions reduce to the demands that the output wave number be twice the input wave number, $k_3 = 2k_1$, and the output phase speed be the same as the input phase speed, $\omega_3/k_3 = \omega_1/k_1$. Now, for waves of the same type (both ordinary or both extraordinary), the phase speed is a monotonic decreasing function of wave number [Fig. 10.12a and Eqs. (10.40)], so there is no choice of propagation angle θ that enables these resonance conditions to be satisfied. The only way to satisfy them is by using ordinary input waves and extraordinary output waves, and then only for a special, frequency-dependent propagation direction. This technique is called *type I phase matching*; “type I” because there are other techniques for phase matching (i.e., for arranging that the resonance conditions be satisfied; see, e.g., Table 8.4 of Yariv and Yeh, 2007).

As an example, if the input waves are ordinary, with $k_1 = 10 \mu\text{m}^{-1}$ (approximately the value for light from a ruby laser; point *A* in Fig. 10.12a), then the output waves must be extraordinary and must have the same phase speed as the input waves (same height in Fig. 10.12a) and have $k_3 = 2k_1 = 20 \mu\text{m}^{-1}$ (i.e., point *B*). This phase speed is between $c/n_e(2k_1)$ and $c/n_o(2k_1)$, and thus can be achieved for a special choice of propagation angle: $\theta = 56.7^\circ$ (point *A* in Fig. 10.12b). In general, Eqs. (10.40) imply that the unique propagation direction θ at which the resonance conditions can be satisfied is the following function of the input wave number k_1 :

$$\sin^2 \theta = \frac{1/n_o^2(k_1) - 1/n_o^2(2k_1)}{1/n_e^2(2k_1) - 1/n_o^2(2k_1)}. \quad (10.41)$$

This resonance angle is plotted as a function of wave number for KDP in Fig. 10.12b.

This special case of identical input waves illustrates a general phenomenon: *at fixed input frequencies, the resonance conditions can be satisfied only for special, discrete input and output directions.*

For our frequency-doubling example, the extraordinary dispersion relation (10.40b) for the output wave can be rewritten as

$$\omega = \frac{ck}{n} = \Omega_e(\mathbf{k}) = c \sqrt{\frac{k_z^2}{n_o(k)^2} + \frac{k_x^2}{n_e(k)^2}}, \quad \text{where } k = \sqrt{k_x^2 + k_z^2}. \quad (10.42)$$

Correspondingly, the group velocity⁸ $V_g^j = \partial\Omega/\partial k_j$ for the output wave has components

$$\begin{aligned} V_g^x &= V_{\text{ph}} \sin \theta \left(\frac{n^2}{n_e^2} - \frac{n^2 \cos^2 \theta}{n_o^2} \frac{d \ln n_o}{d \ln k} - \frac{n^2 \sin^2 \theta}{n_e^2} \frac{d \ln n_e}{d \ln k} \right), \\ V_g^z &= V_{\text{ph}} \cos \theta \left(\frac{n^2}{n_o^2} - \frac{n^2 \cos^2 \theta}{n_o^2} \frac{d \ln n_o}{d \ln k} - \frac{n^2 \sin^2 \theta}{n_e^2} \frac{d \ln n_e}{d \ln k} \right), \end{aligned} \quad (10.43)$$

where $V_{\text{ph}} = \omega/k = c/n$ is the phase velocity. For an ordinary input wave with $k_1 = 10 \mu\text{m}^{-1}$ (point *A* in Fig. 10.12) and an extraordinary output wave with $k_3 = 20 \mu\text{m}^{-1}$ (point *B*), these formulas give for the direction of the output group velocity (direction along which the output waves grow) $\theta_g = \arctan(V_g^x/V_g^z) = 58.4^\circ$, compared to the direction of the common input-output phase velocity $\theta = 56.7^\circ$. They give for the magnitude of the group velocity $V_g = 0.628c$, compared to the common phase velocity $v_{\text{ph}} = 0.663c$. Thus, the differences between the group velocity and the phase velocity are small, but they do differ.

EVOLUTION EQUATIONS

Once one has found wave vectors and frequencies that satisfy the resonance conditions, the evolution equations for the two (or three) coupled waves have the same form as in the idealized dispersion-free, isotropic case [Eqs. (10.38) or (10.37)], but with the following minor modifications.

Let planar input waves impinge on a homogeneous, nonlinear crystal at some plane $z = 0$ and therefore (by symmetry) have energy fluxes inside the crystal that evolve as functions of z only: $\mathbf{F}_n = \mathbf{F}_n(z)$ for waves $n = 1$ and 3 in the case of frequency doubling (or 1, 2, and 3 in the case of three different waves). Then energy conservation dictates that

$$\frac{d}{dz} \sum_n F_{nz} = 0, \quad (10.44)$$

where $F_{nz}(z)$ is the z component of the energy flux for wave n . It is convenient to define a complex amplitude \mathfrak{A}_n for wave n that is related to the wave's complex electric field amplitude by an analog of Eq. (10.35):

$$\mathcal{A}_j^{(n)} = \zeta_n \sqrt{\frac{2\omega_n}{\epsilon_0 c n_n}} \mathfrak{A}_n f_j^{(n)}. \quad (10.45)$$

renormalized amplitude in birefringent crystal

Here $f_j^{(n)}$ is the wave's polarization vector [Eq. (10.35)], n_n is its index of refraction (defined by $\omega_n/k_n = c/n_n$), and ζ_n is some positive real constant that depends on the

8. Since a wave's energy travels with the group velocity, it must be that $\mathbf{V}_g = \mathbf{E} \times \mathbf{H}/U$, where U is the wave's energy density, $\mathbf{E} \times \mathbf{H}$ is its Poynting vector (energy flux), and $\mathbf{H} = \mathbf{B}/\mu_0$ (in our dielectric medium). It can be shown explicitly that, indeed, this is the case.

relative directions of \mathbf{k}_n , $\mathbf{f}^{(n)}$, and \mathbf{e}_z and has a value ensuring that

$$F_{nz} = \omega_n |\mathfrak{A}_n|^2 \quad (10.46)$$

[same as Eq. (10.36) but with F_n replaced by F_{nz}]. Since the energy flux is $\hbar\omega_n$ times the photon-number flux, this equation tells us that $|\mathfrak{A}_n|^2/\hbar$ is the photon-number flux (just like the idealized case).

Because the evolution equations involve the same photon creation and annihilation processes as in the idealized case, they must have the same mathematical form as in that case [Eqs. (10.38) or (10.37)], except for the magnitude of the coupling constant. (For a proof, see Ex. 10.10.) Specifically, for frequency doubling of a wave 1 to produce wave 3 ($\omega_3 = 2\omega_1$), the resonant evolution equations and coupling constant are

$$\frac{d\mathfrak{A}_3}{dz} = \frac{i\kappa}{2} (\mathfrak{A}_1)^2, \quad \frac{d\mathfrak{A}_1}{dz} = i\kappa \mathfrak{A}_3 \mathfrak{A}_1^*, \quad \kappa = \beta \sqrt{\frac{2\omega_1^2 \omega_3}{\epsilon_0 c^3 n_1^2 n_3}} d_{ijk} f_i^{(1)} f_j^{(1)} f_k^{(3)}$$

(10.47)

[cf. Eqs. (10.38) for the idealized case]. For resonant mixing of three different waves ($\omega_3 = \omega_1 + \omega_2$), they are

$$\frac{d\mathfrak{A}_3}{dz} = i\kappa \mathfrak{A}_1 \mathfrak{A}_2, \quad \frac{d\mathfrak{A}_1}{dz} = i\kappa \mathfrak{A}_3 \mathfrak{A}_2^*, \quad \frac{d\mathfrak{A}_2}{dz} = i\kappa \mathfrak{A}_3 \mathfrak{A}_1^*;$$

$$\kappa = \beta' \sqrt{\frac{2\omega_1 \omega_2 \omega_3}{\epsilon_0 c^3 n_1 n_2 n_3}} d_{ijk} f_i^{(1)} f_j^{(2)} f_k^{(3)}$$

(10.48)

[cf. Eqs. (10.37) for the idealized case]. Here β and β' are constants of order unity that depend on the relative directions of \mathbf{e}_z and the wave vectors \mathbf{k}_n and polarization vectors $\mathbf{f}^{(n)}$; see Ex. 10.10.

It is useful to keep in mind the following magnitudes of the quantities that appear in these three-wave-mixing equations (Ex. 10.11):

$$F_n \lesssim 1 \text{ GW m}^{-2}, \quad |\mathfrak{A}_n| \lesssim 10^{-3} \text{ J}^{1/2} \text{ m}^{-1}, \quad \kappa \lesssim 10^5 \text{ J}^{-1/2}, \quad |\kappa \mathfrak{A}_n| \lesssim 1 \text{ cm}^{-1}.$$

(10.49)

We use the evolution equations (10.47) and (10.48) in Sec. 10.7 to explore several applications of three-wave mixing.

One can reformulate the equations of three-wave mixing in fully quantum mechanical language, with a focus on the mean occupation numbers of the wave modes. This is commonly done in plasma physics; in Sec. 23.3.6 we discuss the example of coupled electrostatic waves in a plasma.

Exercise 10.9 ***Example: Dispersion Relation for an Anisotropic Medium* T2

Consider a wave propagating through a dielectric medium that is anisotropic, but not necessarily—for the moment—axisymmetric. Let the wave be sufficiently weak that nonlinear effects are unimportant. Then the nonlinear wave equation (10.22a) takes the linear form

$$-\nabla^2 \mathbf{E} + \nabla(\nabla \cdot \mathbf{E}) = -\frac{1}{c^2} \boldsymbol{\epsilon} \cdot \frac{\partial^2 \mathbf{E}}{\partial t^2}. \quad (10.50)$$

- (a) Specialize to a monochromatic plane wave with angular frequency ω and wave vector \mathbf{k} . Show that the wave equation (10.50) reduces to

$$L_{ij} E_j = 0, \quad \text{where } L_{ij} = k_i k_j - k^2 \delta_{ij} + \frac{\omega^2}{c^2} \epsilon_{ij}. \quad (10.51a)$$

This equation says that E_j is an eigenvector of L_{ij} with vanishing eigenvalue, which is possible if and only if

$$\det \|L_{ij}\| = 0. \quad (10.51b)$$

This vanishing determinant is the waves' dispersion relation. We use it in Chap. 21 to study waves in plasmas.

- (b) Next specialize to an axisymmetric medium, and orient the symmetry axis along the z direction, so the only nonvanishing components of the dielectric tensor ϵ_{ij} are $\epsilon_{11} = \epsilon_{22}$ and ϵ_{33} . Let the wave propagate in a direction $\hat{\mathbf{k}}$ that makes an angle θ to the symmetry axis. Show that in this case L_{ij} has the form

$$\|L_{ij}\| = k^2 \begin{vmatrix} (n_o/n)^2 - \cos^2 \theta & 0 & \sin \theta \cos \theta \\ 0 & (n_o/n)^2 - 1 & 0 \\ \sin \theta \cos \theta & 0 & (n_e/n)^2 - \sin^2 \theta \end{vmatrix}, \quad (10.52a)$$

and the dispersion relation (10.51b) reduces to

$$\left(\frac{1}{n^2} - \frac{1}{n_o^2} \right) \left(\frac{1}{n^2} - \frac{\cos^2 \theta}{n_o^2} - \frac{\sin^2 \theta}{n_e^2} \right) = 0, \quad (10.52b)$$

where $1/n = \omega/kc$, $n_o = \sqrt{\epsilon_{11}} = \sqrt{\epsilon_{22}}$, and $n_e = \sqrt{\epsilon_{33}}$, in accord with Eq. (10.39).

- (c) Show that this dispersion relation has the two solutions (ordinary and extraordinary) discussed in the text, Eqs. (10.40a) and (10.40b), and show that the electric fields associated with these two solutions point in the directions described in the text.

Exercise 10.10 ***Derivation and Example: Evolution Equations for Realistic Wave-Wave Mixing* T2

Derive the evolution equations (10.48) for three-wave mixing. [The derivation of those (10.47) for frequency doubling is similar.] You could proceed as follows.

- (a) Insert expressions (10.27) and (10.28) into the general wave equation (10.30) and extract the portions with frequency $\omega_3 = \omega_1 + \omega_2$, thereby obtaining the generalization of Eq. (10.33):

$$\begin{aligned} \nabla^2 \left(\mathcal{A}_i^{(3)} e^{i(k_3 z - \omega_3 t)} \right) - \frac{\partial^2}{\partial x^i \partial x^j} \left(\mathcal{A}_j^{(3)} e^{i(k_3 z - \omega_3 t)} \right) + \frac{\omega_3^2}{c^2} \epsilon_{ij} \mathcal{A}_j^{(3)} e^{i(k_3 z - \omega_3 t)} \\ = -2 \frac{\omega_3^2}{c^2} d_{ijk} \mathcal{A}_j^{(1)} \mathcal{A}_k^{(2)} e^{i(k_3 z - \omega_3 t)}. \end{aligned} \quad (10.53)$$

- (b) Explain why $e^{i(\mathbf{k}_3 \cdot \mathbf{x} - \omega_3 t)} \mathbf{f}^{(3)}$ satisfies the homogeneous wave equation (10.50). Then, splitting each wave into its scalar field and polarization vector, $\mathcal{A}_i^{(n)} \equiv \mathcal{A}^{(n)} f_i^{(n)}$, and letting each $\mathcal{A}^{(n)}$ be a function of z (because of the boundary condition that the three-wave mixing begins at the crystal face $z = 0$), show that Eq. (10.53) reduces to

$$\alpha_3 d\mathcal{A}^{(3)}/dz = i(k_3/n_3^2) d_{ijk} f_j^{(1)} f_k^{(2)} \mathcal{A}^{(1)} \mathcal{A}^{(2)},$$

where α_3 is a constant of order unity that depends on the relative orientations of the unit vectors \mathbf{e}_z , $\mathbf{f}^{(3)}$, and $\hat{\mathbf{k}}_3$. Note that, aside from α_3 , this is the same evolution equation as for our idealized isotropic, dispersion-free medium, Eq. (10.34a). Show that, similarly, $\mathcal{A}^{(1)}(z)$ and $\mathcal{A}^{(2)}(z)$ satisfy the same equations (10.34b) and (10.34c) as in the idealized case, aside from multiplicative constants α_1 and α_2 .

- (c) Adopting the renormalizations $\mathcal{A}^{(n)} = \zeta_n \sqrt{2\omega_n/(\epsilon_0 c n_n)} \mathfrak{A}_n$ [Eq. (10.45)] with ζ_n so chosen that the photon-number flux for wave n is proportional to $|\mathfrak{A}_n|^2$, show that your evolution equations for \mathcal{A}_n become Eqs. (10.48), except that the factor β' and thence the value of κ might be different for each equation.
- (d) Since the evolution entails one photon with frequency ω_1 and one with frequency ω_2 annihilating to produce a photon with frequency ω_3 , it must be that $d|\mathfrak{A}_1|^3/dz = d|\mathfrak{A}_2|^3/dz = -d|\mathfrak{A}_3|^2/dz$. (These are called *Manley-Rowe relations*.) By imposing this on your evolution equations in part (c), deduce that all three coupling constants κ must be the same, and thence also that all three β' must be the same; therefore the evolution equations take precisely the claimed form, Eqs. (10.48).

Exercise 10.11 **Derivation: Magnitudes of Three-Wave-Mixing Quantities T2

Derive Eqs. (10.49). [Hint: The maximum energy flux in a wave arises from the limit $E \lesssim 10^6 \text{ V m}^{-1}$ on the wave's electric field to ensure that it not pull electrons out of the surface of the nonlinear medium. The maximum coupling constant κ arises from the largest values $|d_{ijk}| \lesssim 10 \text{ pm V}^{-1}$ for materials typically used in three-wave mixing (Box 10.2).]

10.7 Applications of Three-Wave Mixing: Frequency Doubling, Optical Parametric Amplification, and Squeezed Light

10.7

10.7.1 Frequency Doubling

10.7.1

Frequency doubling (also called *second harmonic generation*) is one of the most important applications of wave-wave mixing. As we have already discussed briefly in Secs. 10.6.2 (Track One) and 10.6.3 (Track Two), it can be achieved by passing a single wave (which plays the role of both wave $n = 1$ and wave $n = 2$) through a nonlinear crystal, with the propagation direction chosen to satisfy the resonance conditions. As we have also seen in the previous section (Track Two), the crystal's birefringence and dispersion have little influence on the growth of the output wave, $n = 3$ with $\omega_3 = 2\omega_1$; it grows with distance inside the crystal at a rate given by Eqs. (10.47), which is the same as in the Track-One case of a medium that is isotropic at linear order, Eqs. (10.38), aside from the factor β of order unity in the coupling constant κ . By doing a sufficiently good job of phase matching (satisfying the resonance conditions) and choosing the thickness of the crystal appropriately, one can achieve close to 100% conversion of the input-wave energy into frequency-doubled energy. More specifically, if wave 1 enters the crystal at $z = 0$ with $\mathfrak{A}_1(0) = \mathfrak{A}_{1o}$, which we choose (without loss of generality) to be real, and if there is no incoming wave 3 so $\mathfrak{A}_3(0) = 0$, then the solution to the evolution equations (10.47) or (10.38) is

second harmonic generation (frequency doubling)

efficiency of frequency doubling

$$\mathfrak{A}_3 = \frac{i}{\sqrt{2}} \mathfrak{A}_{1o} \tanh\left(\frac{\kappa}{\sqrt{2}} \mathfrak{A}_{1o} z\right), \quad \mathfrak{A}_1 = \mathfrak{A}_{1o} \operatorname{sech}\left(\frac{\kappa}{\sqrt{2}} \mathfrak{A}_{1o} z\right). \quad (10.54)$$

wave amplitude evolution

It is easy to see that this solution has the following properties. (i) It satisfies energy conservation, $2|\mathfrak{A}_3|^2 + |\mathfrak{A}_1|^2 = |\mathfrak{A}_{1o}|^2$. (ii) At a depth $z = 1.246/(\kappa\mathfrak{A}_{1o})$ in the crystal, half the initial energy has been frequency doubled. (iii) As z increases beyond this half-doubling depth, the light asymptotes to fully frequency doubled.

One might expect the frequency doubling to proceed onward to $4\omega_1$, and so forth. However, it typically does not, because these higher-frequency waves typically fail to satisfy the crystal's dispersion relation.

As an example, the neodymium:YAG ($\text{Nd}^{3+}:\text{YAG}$) laser, which is based on an yttrium-aluminum-garnet crystal with trivalent neodymium impurities, is among the most attractive of all lasers for a combination of high frequency stability, moderately high power, and high efficiency. However, this laser operates in the infrared, at a wavelength of 1.064 microns. For many purposes, one wants optical light. This can be achieved by frequency doubling the laser's output, thereby obtaining 0.532-micron (green) light. This is how green laser pointers, used in lecturing, work (though in 2016 they are typically driven not by Nd:YAG but rather a relative; see Ex. 10.13).

Nd: YAG laser

Frequency doubling also plays a key role in laser fusion, where intense, pulsed laser beams, focused on a pellet of fusion fuel, compress and heat the pellet to high densities and temperatures. Because the beam's energy flux is inversely proportional to the area

of its focused cross section—and because the larger the wavelength, the more seriously diffraction impedes making the cross section small—in order to achieve efficient compression of the pellet, it is important to give the beam a very short wavelength. This is achieved by multiple frequency doublings, which can and do occur in the experimental setup of laser fusion.

EXERCISES

Exercise 10.12 *Derivation: Saturation in Frequency Doubling*

Derive the solution (10.54) to the evolution equations (10.47) for frequency doubling, and verify that it has the claimed properties.

Exercise 10.13 ***Example: Frequency Doubling in a Green Laser Pointer*

Green laser pointers, popular in 2016, have the structure shown in Fig. 10.13. A battery-driven infrared diode laser puts out 808-nm light that pumps a Nd:YVO₄ laser crystal (neodymium-doped yttrium vanadate; a relative of Nd:YAG). The 1,064-nm light beam from this Nd:YVO₄ laser is frequency doubled by a KTP crystal, resulting in 532-nm green light. An infrared filter removes all the 880-nm and 1,064-nm light from the output, leaving only the green.

- (a) To make the frequency doubling as efficient as possible, the light is focused to as small a beam radius ϖ_o as diffraction allows as it travels through the KTP crystal. Assuming that the crystal length is $L \simeq 3$ mm, show that $\varpi_o \simeq \sqrt{\lambda L / (4\pi n_1)} \simeq$

FIGURE 10.13 Structure of a green laser pointer, circa 2012. Adapted with minor changes from a drawing copyright by Samuel M. Goldwasser (Sam's Laser FAQ at <http://www.repairfaq.org/lasersam.htm>), and printed here with his permission.

12 μm (about 12 times larger than the 1,064-nm wavelength). [Hint: Use the properties of Gaussian beams; Sec. 8.5.5 adjusted for propagation in a medium with index of refraction n_1 .]

- (b) The 1,064-nm beam has an input power $W_{10} \simeq 100$ mW as it enters the KTP crystal. Show that its energy flux and its electric field strength are $F \simeq 230$ MW m^{-2} and $\mathcal{A}^{(1)} \simeq 400$ kV m^{-1} .
- (c) Assuming that phase matching has been carried out successfully (i.e., photon energy and momentum conservation have been enforced), explain why it is reasonable to expect the quantity $\beta d_{ijk} f_i^{(1)} f_j^{(1)} f_k^{(3)}$ in the coupling constant κ to be roughly 4 pm/V [cf. Eq. (6) of Box 10.2]. Then show that the green output beam at the end of the KTP crystal has $|\mathfrak{A}_3|^2 \sim 0.7 \times 10^{-4} \mathfrak{A}_{10}^2$, corresponding to an output power $W_3 \sim 1.5 \times 10^{-4} W_{10} \simeq 0.015$ mW. This is far below the output power, 5 mW, of typical green laser pointers. How do you think the output power is boosted by a factor $\sim 5/0.015 \simeq 300$?
- (d) The answer is (i) to put reflective coatings on the two ends of the KTP crystal so it becomes a Fabry-Perot resonator for the 1.064 μm input field; and also (ii) make the input face (but not the output face) reflective for the 0.532 μm green light. Show that, if the 1.064 μm resonator has a finesse $\mathcal{F} \simeq 30$, then the green-light output power will be increased to $\simeq 5$ mW.
- (e) Explain why this strategy makes the output power sensitive to the temperature of the KTP crystal. To minimize this sensitivity, the crystal is oriented so that its input and output faces are orthogonal to its (approximate) symmetry axis—the z -axis—for which the thermal expansion coefficient is very small ($0.6 \times 10^{-6}/\text{C}$, by contrast with $\simeq 10 \times 10^{-6}/\text{C}$ along other axes. Show that, in this case, a temperature increase or reduction of 6 C from the pointer's optimal 22 C (room temperature) will reduce the output power from 5 mW to much less than 1 mW. Astronomers complain that green laser pointers stop working outdoors on cool evenings.

10.7.2 Optical Parametric Amplification

In optical parametric amplification, the energy of a *pump wave* is used to amplify an initially weak *signal wave* and also amplify an uninteresting *idler wave*. The waves satisfy the resonance conditions with $\omega_p = \omega_s + \omega_i$. The pump wave and signal wave are fed into an anisotropic nonlinear crystal, propagating in (nearly) the same direction, with nonzero renormalized amplitudes \mathfrak{A}_{p0} and \mathfrak{A}_{s0} at $z = 0$. The idler wave has $\mathfrak{A}_{i0} = 0$ at the entry plane. Because the pump wave is so strong, it is negligibly influenced by the three-wave mixing (i.e., \mathfrak{A}_p remains constant inside the crystal).

The evolution equations for the (renormalized) signal and idler amplitudes are

$$\frac{d\mathfrak{A}_s}{dz} = i\kappa\mathfrak{A}_p\mathfrak{A}_i^*, \quad \frac{d\mathfrak{A}_i}{dz} = i\kappa\mathfrak{A}_p\mathfrak{A}_s^* \quad (10.55)$$

10.7.2

optical parametric amplification; pump wave, signal wave, idler wave

[Eqs. (10.48) or (10.37)]. For the initial conditions of weak signal wave and no idler wave, the solution to these equations is

wave amplitude evolution

$$\mathfrak{A}_s = \mathfrak{A}_{s0} \cosh(|\gamma|z), \quad \mathfrak{A}_i = \frac{\gamma}{|\gamma|} \mathfrak{A}_{s0}^* \sinh(|\gamma|z); \quad \gamma \equiv i\kappa\mathfrak{A}_p. \quad (10.56)$$

Thus the signal field grows exponentially, after an initial pause, with an e -folding length $1/|\gamma|$, which for strong three-wave nonlinearities is of order 1 cm [Ex. (10.14)].

EXERCISES

Exercise 10.14 Derivation: e -Folding Length for an Optical Parametric Amplifier

Estimate the magnitude of the e -folding length for an optical parametric amplifier that is based on a strong three-wave nonlinearity.

10.7.3

10.7.3 Degenerate Optical Parametric Amplification: Squeezed Light

degenerate optical parametric amplification

Consider optical parametric amplification with the signal and idler frequencies identical, so the idler field is the same as the signal field, and the pump frequency is twice the signal frequency: $\omega_p = 2\omega_s$. This condition is called *degenerate*. Adjust the phase of the pump field so that $\gamma = i\kappa\mathfrak{A}_p$ is real and positive. Then the equation of evolution for the signal field is the same as appears in frequency doubling [Eqs. (10.47) or (10.38)]:

$$d\mathfrak{A}_s/dz = \gamma\mathfrak{A}_s^*. \quad (10.57)$$

The resulting evolution is most clearly understood by decomposing \mathfrak{A}_s into its real and imaginary parts (as we did in Ex. 6.23 when studying thermal noise in an oscillator): $\mathfrak{A}_s = X_1 + iX_2$. Then the time-evolving electric field is

$$E \propto \Re(\mathfrak{A}_s e^{i(k_s z - \omega_s t)}) = X_1 \cos(k_s z - \omega_s t) + X_2 \sin(k_s z - \omega_s t). \quad (10.58)$$

Therefore, X_1 is the amplitude of the field's cosine quadrature, and X_2 is the amplitude of its sine quadrature. Equation (10.57) then says that $dX_1/dz = \gamma X_1$, $dX_2/dz = -\gamma X_2$, so we have

$$X_1 = X_{10} e^{\gamma z}, \quad X_2 = X_{20} e^{-\gamma z}. \quad (10.59)$$

squeezing

Therefore, the wave's cosine quadrature gets amplified as the wave propagates, and its sine quadrature is attenuated. This is called *squeezing*, because X_2 is reduced (squeezed) while X_1 is increased. It is a phenomenon known to children who swing; see Ex. 10.15.

Squeezing is especially interesting when it is applied to noise. Typically, a wave has equal amounts of noise in its two quadratures (i.e., the standard deviations ΔX_1 and ΔX_2 of the two quadratures are equal, as was the case in Ex. 6.23). When such a wave is squeezed, its two standard deviations get altered in such a way that their product is unchanged:

$$\Delta X_1 = \Delta X_{10} e^{\gamma z}; \quad \Delta X_2 = \Delta X_{20} e^{-\gamma z}, \quad \Delta X_1 \Delta X_2 = \text{const} \quad (10.60)$$

FIGURE 10.14 Error boxes in the complex amplitude plane for several different electromagnetic waves: (a) Classical light. (b) Phase-squeezed light. (c) Amplitude-squeezed light. (d) The quantum electrodynamic vacuum. (e) The squeezed vacuum.

(see Fig. 10.14). When, as here, the standard deviations of two quadratures differ, the light is said to be in a *squeezed state*.

In quantum theory, X_1 and X_2 are complementary observables; they are described by Hermitian operators that do not commute. The uncertainty principle associated with their noncommutation implies that their product $\Delta X_1 \Delta X_2$ has some minimum possible value. This minimum is achieved by the wave's vacuum state, which has $\Delta X_1 = \Delta X_2$ with values corresponding to a half quantum of energy (vacuum fluctuations) in the field mode that we are studying. When this “quantum electrodynamic vacuum” is fed into a degenerate optical parametric amplifier, the vacuum noise gets squeezed in the same manner [Eq. (10.59)] as any other noise.

Squeezed states of light, including this *squeezed vacuum*, have great value for fundamental physics experiments and technology. Most importantly, they can be used to reduce the photon shot noise of an interferometer below the standard quantum limit of $\Delta N = \sqrt{N}$ (Poisson statistics), thereby improving the signal-to-noise ratio in certain communications devices and in laser interferometer gravitational-wave detectors such as LIGO (Caves, 1981; McClelland et al., 2011; Oelker et al., 2016). We explore some properties of squeezed light in Ex. 10.16.

squeezed state of light

squeezed vacuum

Exercise 10.15 ***Example: Squeezing by Children Who Swing*

A child, standing in a swing, bends her knees and then straightens them twice per swing period, making the distance ℓ from the swing's support to her center of mass oscillate as $\ell = \ell_0 + \ell_1 \sin 2\omega_0 t$. Here $\omega_0 = \sqrt{g\ell_0}$ is the swing's mean angular frequency.

- (a) Show that the swing's angular displacement from vertical, θ , obeys the equation of motion

$$\frac{d^2\theta}{dt^2} + \omega_0^2\theta = -\omega_1^2 \sin(2\omega_0 t)\theta, \quad (10.61)$$

where $\omega_1 = \sqrt{g\ell_1}$, and θ is assumed to be small, $\theta \ll 1$.

EXERCISES

FIGURE 10.15 The error band for the electric field $E(t)$, as measured at a fixed location in space, when phase-squeezed light passes by.

- (b) Write $\theta = X_1 \cos \omega_0 t + X_2 \sin \omega_0 t$. Assuming that $\ell_1 \ll \ell_0$ so $\omega_1 \ll \omega_0$, show that the child's knee bending (her "pumping" the swing) squeezes X_1 and amplifies X_2 (parametric amplification):

$$X_1(t) = X_1(0)e^{-[\omega_1^2/(2\omega_0)]t}, \quad X_2(t) = X_2(0)e^{+[\omega_1^2/(2\omega_0)]t} \quad (10.62)$$

- (c) Explain how this squeezing is related to the child's conscious manipulation of the swing (i.e., to her strategy for increasing the swing's amplitude when she starts up, and her strategy for reducing the amplitude when she wants to quit swinging).

Exercise 10.16 ***Example: Squeezed States of Light*

Consider a plane, monochromatic electromagnetic wave with angular frequency ω , whose electric field is expressed in terms of its complex amplitude $X_1 + iX_2$ by Eq. (10.58). Because the field (inevitably) is noisy, its quadrature amplitudes X_1 and X_2 are random processes with means \bar{X}_1, \bar{X}_2 and variances $\Delta X_1, \Delta X_2$.

- (a) Normal, classical light has equal amounts of noise in its two quadratures. Explain why it can be represented by Fig. 10.14a.
- (b) Explain why Fig. 10.14b represents *phase-squeezed light*, and show that its electric field as a function of time has the form shown in Fig. 10.15.
- (c) Explain why Fig. 10.14c represents *amplitude-squeezed light*, and construct a diagram of its electric field as a function of time analogous to Fig. 10.15.
- (d) Figure 10.14d represents the vacuum state of light's frequency- ω plane-wave mode. Give a formula for the diameter of the mode's circular error box. Construct a diagram of the electric field as a function of time analogous to Fig. 10.15.
- (e) Figure 10.14e represents the squeezed vacuum. Construct a diagram of its electric field as a function of time analogous to Fig. 10.15.

10.8 Four-Wave Mixing in Isotropic Media

10.8.1 Third-Order Susceptibilities and Field Strengths

The nonlinear polarization for four-wave mixing, $P_i^{(4)} = 4\epsilon_0\chi_{ijkl}E_jE_kE_l$ [Eq. (10.21)], is typically smaller than that, $P_i^{(3)} = 2\epsilon_0d_{ijk}E_jE_k$, for three-wave mix-

TABLE 10.1: Materials used in four-wave mixing

Material	Wavelength		χ_{1111} (pm ² V ⁻²)	n_2 (10 ⁻²⁰ m ² W ⁻¹)
	(μ m)	n		
Fused silica	0.694	1.455	56	3
SF ₆ glass	1.06	1.77	590	21
CS ₂ liquid	1.06	1.594	6,400	290
2-methyl-4-nitroaniline (MNA) organic crystal ^a		1.8	1.7×10^5	5,800
PTS polydiacetylene polymeric crystal ^a		1.88	5.5×10^5	1.8×10^4

a. Also has large d_{ijk} .

Notes: At the indicated light wavelength, n is the index of refraction, χ_{1111} is the third-order nonlinear susceptibility, and n_2 is the Kerr coefficient of Eq. (10.69). Adapted from Yariv and Yeh (2007, Table 8.8), whose χ_{1111} is $1/\epsilon_0$ times ours.

ing by $\sim E|\chi/d| \sim (10^6 \text{ V m}^{-1})(100 \text{ pm V}^{-1}) \sim 10^{-4}$. (Here we have used the largest electric field that solids typically can support.) Therefore (as we have already discussed), only when d_{ijk} is greatly suppressed by isotropy of the nonlinear material does χ_{ijkl} and four-wave mixing become the dominant nonlinearity. And in that case, we expect the propagation lengthscale for strong, cumulative four-wave mixing to be $\sim 10^4$ larger than that (~ 1 cm) for the strongest three-wave mixing (i.e., $\ell_{4w} \gtrsim 100$ m).

In reality, as we shall see in Sec. 10.8.2, this estimate is overly pessimistic. In special materials, ℓ_{4w} can be less than a meter (though still much bigger than the three-wave mixing's centimeter). Two factors enable this. (i) If the nonlinear material is a fluid (e.g., CS₂) confined by solid walls, then it can support somewhat larger electric field strengths than a nonlinear crystal's maximum, 10^6 V m^{-1} . (ii) If the nonlinear material is made of molecules significantly larger than 10^{-10} m (e.g., organic molecules), then the molecular electric dipoles induced by an electric field can be significantly larger than our estimates (10.26); correspondingly, $|\chi_{ijkl}|$ can significantly exceed $(100 \text{ pm V}^{-1})^2$; see Table 10.1.

In Secs. 10.8.2 and 10.8.3, we give (i) an example with strong four-wave mixing: phase conjugation by a half-meter-long cell containing CS₂ liquid and then (ii) an example with weak but important four-wave mixing: light propagation in a multikilometer-long fused-silica optical fiber.

10.8.2 Phase Conjugation via Four-Wave Mixing in CS₂ Fluid

As an example of four-wave mixing, we discuss phase conjugation in a rectangular cell that contains carbon disulfide (CS₂) liquid (Fig. 10.16a). The fluid is pumped by two

order of magnitude estimate for strength of four-wave mixing

10.8.2

phase conjugation by four-wave mixing

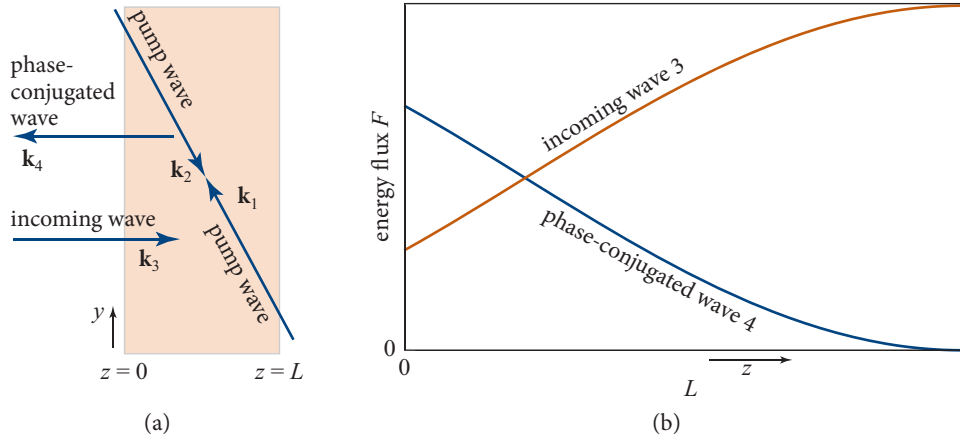

FIGURE 10.16 (a) A phase-conjugating mirror based on four-wave mixing. (b) The evolution of the incoming wave's flux and the phase-conjugated wave's flux inside the mirror (the nonlinear medium).

strong waves, 1 and 2, propagating in opposite directions with the same frequency as the incoming wave 3 that is to be phase conjugated. The pump waves are planar without modulation, but wave 3 has a spatial modulation (slow compared to the wave number) that carries, for example, a picture; $\mathcal{A}_3 = \mathcal{A}_3(x, y; z)$. As we shall see, nonlinear interaction of the two pump waves 1 and 2 and the incoming wave 3 produces outgoing wave 4, which is the phase conjugate of wave 3. All four waves propagate in planes of constant x and have their electric fields in the x direction, so the relevant component of the third-order nonlinearity is $\chi_{xxxx} = \chi_{1111}$.

The resonance conditions (photon energy and momentum conservation) for this four-wave mixing process are $\omega_4 = \omega_1 + \omega_2 - \omega_3$ and $\mathbf{k}_4 = \mathbf{k}_1 + \mathbf{k}_2 - \mathbf{k}_3$. Since the three input waves all have the same frequency, $\omega_1 = \omega_2 = \omega_3 = \omega$, the output wave 4 will also have $\omega_4 = \omega$, so this is *fully degenerate four-wave mixing*. The pump waves propagate in opposite directions, so they satisfy $\mathbf{k}_1 = -\mathbf{k}_2$, whence the output wave has $\mathbf{k}_4 = -\mathbf{k}_3$. That is, it propagates in the opposite direction to the input wave 3 and has the same frequency, as it must, if it is to be (as we claim) the phase conjugate of 3.

The nonlinear polarization that generates wave 4 is

$$P_x^{(4)} = 4\epsilon_0\chi_{1111}(E_x^{(1)}E_x^{(2)}E_x^{(3)} + E_x^{(2)}E_x^{(3)}E_x^{(1)} + \dots).$$

There are six terms in the sum (six ways to order the three waves), so

$$P_x^{(4)} = 24\epsilon_0\chi_{1111}E_x^{(1)}E_x^{(2)}E_x^{(3)}.$$

Inserting

$$E_x^{(n)} = \frac{1}{2}(\mathcal{A}^{(n)}e^{i(\mathbf{k}_n \cdot \mathbf{x} - \omega_n t)} + \mathcal{A}^{(n)*}e^{i(-\mathbf{k}_n + \omega_n t)})$$

resonance conditions for four-wave mixing

into this $P_x^{(4)}$ and plucking out the relevant term for our phase-conjugation process (with the signal wave 3 phase conjugated and the pump waves not), we obtain

$$P_x^{(4)} = 3\epsilon_0\chi_{1111}\mathcal{A}^{(1)}\mathcal{A}^{(2)}\mathcal{A}^{(3)*}e^{i(\mathbf{k}_4\cdot\mathbf{x}-\omega_4t)}. \quad (10.63)$$

Inserting this expression into the wave equation for wave 4 in an isotropic medium, $(\nabla^2 + n^2\omega_4^2/c^2)(\mathcal{A}^{(4)}e^{i(\mathbf{k}_4\cdot\mathbf{x}-\omega_4t)}) = -(\omega_4^2/c^2)P_x^{(4)}$ [analog of the isotropic-medium wave equation (10.33) for three-wave mixing] and making use of the fact that the lengthscale on which wave 4 changes is long compared to its wavelength, we obtain the following evolution equation for wave 4, which we augment with that for wave 3, obtained in the same way:

$$\frac{d\mathcal{A}^{(4)}}{dz} = -\frac{3ik}{n^2}\chi_{1111}\mathcal{A}^{(1)}\mathcal{A}^{(2)}\mathcal{A}^{(3)*}, \quad \frac{d\mathcal{A}^{(3)}}{dz} = -\frac{3ik}{n^2}\chi_{1111}\mathcal{A}^{(1)}\mathcal{A}^{(2)}\mathcal{A}^{(4)*}. \quad (10.64)$$

Here we have dropped subscripts from k , since all waves have the same scalar wave number, and we have used the dispersion relation $\omega/k = c/n$ common to all four waves (since they all have the same frequency). We have not written down the evolution equations for the pump waves, because in practice they are very much stronger than the incoming and phase-conjugated waves, so they change hardly at all during the evolution.

It is convenient to change normalizations of the wave fields, as in three-wave mixing, from $\mathcal{A}^{(n)}$ (the electric field) to \mathfrak{A}_n (the square root of energy flux divided by frequency, $\mathfrak{A}_n = \sqrt{F_n/\omega_n}$):

$$\mathcal{A}^{(n)} = \sqrt{\frac{2k}{\epsilon_0 n^2}}\mathfrak{A}_n = \sqrt{\frac{2\omega_n}{\epsilon_0 c n}}\mathfrak{A}_n \quad (10.65)$$

renormalized wave amplitudes

[Eq. (10.35)]. Inserting these into the evolution equations (10.64) and absorbing the constant pump-wave amplitudes into a coupling constant, we obtain

$$\boxed{\frac{d\mathfrak{A}_4}{dz} = -i\kappa\mathfrak{A}_3^*, \quad \frac{d\mathfrak{A}_3}{dz} = i\kappa\mathfrak{A}_4^*; \quad \kappa = \frac{6\omega^2}{c^2 n^2 \epsilon_0}\chi_{1111}\mathfrak{A}_1\mathfrak{A}_2.} \quad (10.66)$$

evolution equations for fully degenerate four-wave mixing in an isotropic medium

Equations (10.66) are our final, simple equations for the evolution of the input and phase-conjugate waves in our isotropic, nonlinear medium (CS₂ liquid). Inserting the index of refraction $n = 1.594$ and nonlinear susceptibility $\chi_{1111} = 6,400$ (pm/V)² for CS₂ (Table 10.1), the angular frequency corresponding to 1.064 μm wavelength light from, say, a Nd:YAG laser, and letting both pump waves $n = 1$ and 2 have energy fluxes $F_n = \omega|\mathfrak{A}_n|^2 = 5 \times 10^{10}$ W m⁻² (corresponding to electric field amplitudes 6.1×10^6 V m⁻¹, six times larger than good nonlinear crystals can support), we obtain for the magnitude of the coupling constant $|\kappa| = 1/0.59$ m⁻¹. Thus, the CS₂ cell of Fig. 10.16a need only be a half meter thick to produce strong phase conjugation.

For an input wave $\mathfrak{A}_{3o}(x, y)$ at the cell's front face $z = 0$ and no input wave 4 at $z = L$, the solution to the evolution equations (10.66) is easily found to be, in the interior of the cell:

$$\begin{aligned}\mathfrak{A}_4(x, y, z) &= \frac{-i\kappa}{|\kappa|} \left(\frac{\sin[|\kappa|(z-L)]}{\cos[|\kappa|L]} \right) \mathfrak{A}_{3o}^*(x, y), \\ \mathfrak{A}_3(x, y, z) &= \left(\frac{\cos[|\kappa|(z-L)]}{\cos[|\kappa|L]} \right) \mathfrak{A}_{3o}(x, y).\end{aligned}\quad (10.67)$$

The corresponding energy fluxes, $F_n = \omega|\mathfrak{A}_n|^2$ are plotted in Fig. 10.16b, for a crystal thickness $L = 1/|\kappa| = 0.59$ m. Notice that the pump waves amplify the rightward propagating input wave, so it grows from the crystal front to the crystal back. At the same time, the interaction of the input wave with the pump waves generates the leftward propagating phase-conjugated wave, which begins with zero strength at the back of the crystal and grows (when $L \sim 1/|\kappa|$) to be stronger than the input wave at the crystal front.

EXERCISES

Exercise 10.17 ***Problem: Photon Creation and Annihilation in a Phase-Conjugating Mirror*

Describe the creation and annihilation of photons that underlies a phase-conjugating mirror's four-wave mixing. Specifically, how many photons of each wave are created or annihilated? [Hint: See the discussion of photon creation and annihilation for three-wave mixing at the end of Sec. 10.6.1.]

Exercise 10.18 ***Problem: Spontaneous Oscillation in Four-Wave Mixing*

Suppose the thickness of the nonlinear medium of the text's four-wave mixing analysis is $L = \pi/(2\kappa)$, so the denominators in Eqs. (10.67) are zero. Explain the physical nature of the resulting evolution of waves 3 and 4.

Exercise 10.19 *Problem: Squeezed Light Produced by Phase Conjugation*

Suppose a light beam is split in two by a beam splitter. One beam is reflected off an ordinary mirror and the other off a phase-conjugating mirror. The beams are then recombined at the beam splitter. Suppose that the powers returning to the beam splitter are nearly the same; they differ by a fractional amount $\Delta P/P = \epsilon \ll 1$. Show that the recombined light is in a strongly squeezed state, and discuss how one can guarantee it is phase squeezed, or (if one prefers) amplitude squeezed.

10.8.3

10.8.3 Optical Kerr Effect and Four-Wave Mixing in an Optical Fiber

Suppose that an isotropic, nonlinear medium is driven by a single input plane wave polarized in the x direction, $E_x = \Re[\mathcal{A}e^{-(kz-\omega t)}]$. This input wave produces the following polarization that propagates along with itself in resonance (Ex. 10.20):

$$P_x = \epsilon_0\chi_0 E_x + 6\epsilon_0\chi_{1111} \overline{E^2} E_x. \quad (10.68)$$

Here the second term is due to four-wave mixing, and $\overline{E^2}$ is the time average of the square of the electric field, which can be expressed in terms of the energy flux as $\overline{E^2} = F/(\epsilon_0 n c)$. The four-wave-mixing term can be regarded as a nonlinear correction to χ_0 : $\Delta\chi_0 = 6\chi_{1111}\overline{E^2} = [6\chi_{1111}/(nc\epsilon_0)]F$. Since the index of refraction is $n = \sqrt{1 + \chi_0}$, this corresponds to a fractional change of index of refraction given by

$$\Delta n = n_2 F, \quad \text{where } n_2 = \frac{3\chi_{1111}}{n^2 c \epsilon_0}. \quad (10.69)$$

This nonlinear change of n is called the *optical Kerr effect*, and the coefficient n_2 is the *Kerr coefficient* and has dimensions of $1/(\text{energy flux})$, or $\text{m}^2 \text{W}^{-1}$. Values for n_2 for several materials are listed in Table 10.1.

optical Kerr effect; Kerr coefficient

We have already briefly discussed an important application of the optical Kerr effect: the self-focusing of a laser beam, which plays a key role in mode locked lasers (Sec. 10.2.3) and also in laser fusion.

The optical Kerr effect is also important in the optical fibers used in modern communication (e.g., to carry telephone, television, and internet signals to your home). Such fibers are generally designed to support just one spatial mode of propagation: the fundamental Gaussian mode of Sec. 8.5.5 or some analog of it. Their light-carrying cores are typically made from fused silica doped with particular impurities, so their Kerr coefficients are $n_2 \simeq 3 \times 10^{-20} \text{ m}^2 \text{W}^{-1}$ (Table 10.1). Although the fibers are not spatially homogeneous and the wave is not planar, one can show (and it should not be surprising) that the fibers nonetheless exhibit the optical Kerr effect, with $\Delta n = n_2 F_{\text{eff}}$. Here F_{eff} , the *effective energy flux*, is the light beam's power P divided by an effective cross sectional area, $\pi\sigma_0^2$, with σ_0 the Gaussian beam's radius, defined in Eq. (8.39): $F_{\text{eff}} = P/\pi\sigma_0^2$; see Yariv and Yeh (2007, Sec. 14.1).

As a realistic indication of the importance of the optical Kerr effect in communication fibers, consider a signal beam with mean power $P = 10 \text{ mW}$ and a beam radius $\sigma_0 = 5 \mu\text{m}$ and thence an effective energy flux $F_{\text{eff}} = 127 \text{ MW m}^{-2}$. If the wavelength is $2\pi/k = 0.694 \mu\text{m}$, then Table 10.1 gives $n = 1.455$ and $n_2 = 3 \times 10^{-20} \text{ m}^2 \text{W}^{-1}$. When this beam travels a distance $L = 50 \text{ km}$ along the fiber, its light experiences a phase shift

$$\Delta\phi = \frac{\Delta n}{n} k L = \frac{n_2}{n} F k L \simeq 1.2 \text{ rad}. \quad (10.70)$$

A phase shift of this size or larger can cause significant problems for optical communication. For example:

1. Variations of the flux, when pulsed signals are being transmitted, cause time-varying phase shifts that modify the signals' phase evolution (*self-phase modulation*). One consequence of this is the broadening of each pulse; another is a nonlinearly induced chirping of each pulse (slightly lower frequency at beginning and higher at end).

2. Fibers generally carry many channels of communication with slightly different carrier frequencies, and the time-varying flux of one channel can modify the phase evolution of another (*cross-phase modulation*).

Various techniques have been developed to deal with these issues (see, e.g., Yariv and Yeh, 2007, Chap. 14).

In long optical fibers, pulse broadening due to the nonlinear optical Kerr effect can be counterbalanced by a narrowing of a pulse due to linear dispersion (dependence of group velocity on frequency). The result is an *optical soliton*: a pulse of light with a special shape that travels down the fiber without any broadening or narrowing (see, e.g., Yariv and Yeh, 2007, Sec. 14.5). In Sec. 16.3, we study in full mathematical detail this soliton phenomenon for nonlinear waves on the surface of water; in Sec. 23.6, we study it for nonlinear waves in plasmas.

optical soliton

EXERCISES

Exercise 10.20 *Derivation: Optical Kerr Effect*

- (a) Derive Eq. (10.68) for the polarization induced in an isotropic medium by a linearly polarized electromagnetic wave.
- (b) Fill in the remaining details of the derivation of Eq. (10.69) for the optical Kerr effect.

Bibliographic Note

For a lucid and detailed discussion of lasers and their applications, see Saleh and Teich (2007), and at a more advanced level, Yariv and Yeh (2007). For less detailed but clear discussions, see standard optics textbooks, such as Jenkins and White (1976), Ghatak (2010), and Hecht (2017).

For a lucid and detailed discussion of holography and its applications, see Goodman (2005). Most optics textbooks contain less detailed but clear discussions. We like Jenkins and White (1976), Brooker (2003), Sharma (2006), Ghatak (2010), and Hecht (2017).

Wave-wave mixing in nonlinear media is discussed in great detail and with many applications by Yariv and Yeh (2007). Some readers might find an earlier book by Yariv (1989) pedagogically easier; it was written when the subject was less rich, but the foundations were already in place, and it has more of a quantum mechanical focus. The fundamental concepts of wave-wave mixing and its underlying physical processes are treated especially nicely by Boyd (2008). A more elementary treatment with focus on applications is given by Saleh and Teich (2007). Among treatments in standard optics texts, we like Sharma (2006).

ELASTICITY

Although ancient civilizations built magnificent pyramids, palaces, and cathedrals and presumably developed insights into how to avoid their collapse, mathematical models for this (the theory of elasticity) were not developed until the seventeenth century and later.

The seventeenth-century focus was on a beam (e.g., a vertical building support) under compression or tension. Galileo initiated this study in 1632, followed most notably by Robert Hooke¹ in 1660. Bent beams became the focus with the work of Edme Mariotte in 1680. Bending and compression came together with Leonhard Euler's 1744 theory of the buckling of a compressed beam and his derivation of the complex shapes of very thin wires, whose ends are pushed toward each other (*elastica*). These ideas were extended to 2-dimensional thin plates by Marie-Sophie Germain and Joseph-Louis Lagrange in 1811–1816 in a study that was brought to full fruition by Augustus Edward Hugh Love in 1888. The full theory of 3-dimensional, stressed, elastic objects was developed by Claude-Louis Navier and by Augustin-Louis Cauchy in 1821–1822. A number of great mathematicians and natural philosophers then developed techniques for solving the Navier-Cauchy equations, particularly for phenomena relevant to railroads and construction. In 1956, with the advent of modern digital computers, M. J. Turner, R. W. Clough, H. C. Martin, and L. J. Topp pioneered finite-element methods for numerically modeling stressed bodies. Finite-element numerical simulations are now a standard tool for designing mechanical structures and devices, and, more generally, for solving difficult elasticity problems.

These historical highlights cannot begin to do justice to the history of elasticity research. For much more detail see, for example, the (out-of-date) long introduction in Love (1927); and for far more detail than most anyone wants, see the (even more out-of-date) two-volume work by Todhunter and Pearson (1886).

1. One of whose many occupations was architect.

Despite its centuries-old foundations, elasticity remains of great importance today, and its modern applications include some truly interesting phenomena. Among those applications, most of which we shall touch on in this book, are

1. the design of bridges, skyscrapers, automobiles, and other structures and mechanical devices and the study of their structural failure;
2. the development and applications of new materials, such as carbon nanotubes, which are so light and strong that one could aspire to use them to build a tether connecting a geostationary satellite to Earth's surface;
3. the design of high-precision physics experiments with torsion pendula and microcantilevers, including brane-worlds-motivated searches for gravitational evidence of macroscopic higher dimensions of space;
4. the creation of nano-scale cantilever probes in atomic-force microscopes;
5. the study of biophysical systems, such as DNA molecules, cell walls, and the Venus fly trap plant; and
6. the study of plate tectonics, quakes, seismic waves, and seismic tomography in Earth and other planets. Much of the modern, geophysical description of mountain building involves buckling and fracture within the lithosphere through viscoelastic processes that combine the principles of elasticity with those of fluid dynamics discussed in Part V.

Indeed, elastic solids are so central to everyday life and to modern science that a basic understanding of their behavior should be part of the repertoire of every physicist. That is the goal of Part IV of the book.

We devote just two chapters to elasticity. The first (Chap. 11) will focus on *elastostatics*: the properties of materials and solid objects that are in static equilibrium, with all forces and torques balancing out. The second (Chap. 12) will focus on *elastodynamics*: the dynamical behavior of materials and solid objects that are perturbed away from equilibrium.

Elastostatics

Ut tensio, sic vis

ROBERT HOOKE (1678)

11.1 Overview

11.1

From the viewpoint of continuum mechanics, a *solid* is a substance that recovers its original shape after the application and removal of any small stress. Note the requirement that this be true for *any* small stress. Many fluids (e.g., water) satisfy our definition as long as the applied stress is isotropic, but they will deform permanently under a shear stress. Other materials (e.g., Earth's crust) are only solid for limited times but undergo plastic flow when a small stress is applied for a long time.

We focus our attention in this chapter on solids whose deformation (quantified by a *tensorial strain*) is linearly proportional to the applied, small, *tensorial stress*. This linear, 3-dimensional stress-strain relationship, which we develop and explore in this chapter, generalizes Hooke's famous 1-dimensional law, which states that if an elastic wire or rod is stretched by an applied force F (Fig. 11.1a), its fractional change of length (its strain) is proportional to the force, $\Delta\ell/\ell \propto F$.

Hooke's law

Hooke's law turns out to be one component of a 3-dimensional stress-strain relation, but to understand it deeply in that language, we must first define and understand the *strain tensor* and the *stress tensor*. Our approach to these tensors follows the geometric, frame-independent philosophy introduced in Chap. 1. Some readers may wish to review that philosophy and mathematics by rereading or browsing Chap. 1.

We begin our development of elasticity theory in Sec. 11.2 by introducing, in a frame-independent way, the vectorial displacement field $\xi(\mathbf{x})$ inside a stressed body (Fig. 11.1b), and its gradient $\nabla\xi$, whose symmetric part is the strain tensor \mathbf{S} . We then express the strain tensor as the sum of an expansion Θ that represents volume changes and a shear Σ that represents shape changes.

In Sec. 11.3.1, we introduce the stress tensor, and in Sec. 11.3.2, we discuss the realms in which there is a linear relationship between stress and strain, and ways in which linearity can fail. In Sec. 11.3.3, assuming linearity, we discuss how the material resists volume change by developing an opposing isotropic stress, with a stress/strain ratio that is equal to the *bulk modulus* K . We discuss how the material also

BOX 11.1. READERS' GUIDE

- This chapter relies heavily on the geometric view of Newtonian physics (including vector and tensor analysis) laid out in Chap. 1.
- Chapter 12 (Elastodynamics) is an extension of this chapter; to understand it, this chapter must be mastered.
- The idea of the irreducible tensorial parts of a tensor, and its most important example, decomposition of the gradient of a displacement vector into expansion, rotation, and shear (Sec. 11.2.2 and Box 11.2) will be encountered again in Part V (Fluid Dynamics), Part VI (Plasma Physics), and Part VII (General Relativity).
- Differentiation of vectors and tensors with the help of connection coefficients (Sec. 11.8; Track Two) will be used occasionally in Part V (Fluid Dynamics) and Part VI (Plasma Physics), and will be generalized to nonorthonormal bases in Part VII (General Relativity), where it will become Track One and will be used extensively.
- No other portions of this chapter are important for subsequent parts of this book.

FIGURE 11.1 (a) Hooke's 1-dimensional law for a rod stretched by a force F : $\Delta\ell/\ell \propto F$. (b) The 3-dimensional displacement vector $\xi(\mathbf{x})$ inside the stretched rod.

resists a shear-type strain by developing an opposing shear stress with a stress/strain ratio equal to twice the shear modulus 2μ . In Sec. 11.3.4, we evaluate the energy density stored in elastostatic strains; in Sec. 11.3.5, we explore the influence of thermal expansion on the stress-strain relationship; and in Sec. 11.3.6, we discuss the atomic-force origin of the elastostatic stresses and use atomic considerations to estimate

the magnitudes of the bulk and shear moduli. Then in Sec. 11.3.7, we compute the elastic force density inside a linear material as the divergence of the sum of its elastic stresses, and we formulate the law of elastostatic stress balance (the Navier-Cauchy equation) as the vanishing sum of the material's internal elastic force density and any other force densities that may act (usually a gravitational force density due to the weight of the elastic material). We discuss the analogy between this elastostatic stress-balance equation and Maxwell's electrostatic and magnetostatic equations. We describe how mathematical techniques common in electrostatics can also be applied to solve the Navier-Cauchy equation, subject to boundary conditions that describe external forces.

In Sec. 11.4, as a simple example, we use our 3-dimensional formulas to deduce Hooke's law for the 1-dimensional longitudinal stress and strain in a stretched wire.

When the elastic body that one studies is very thin in two dimensions compared to the third (e.g., a wire or rod), we can reduce the 3-dimensional elastostatic equations to a set of coupled 1-dimensional equations by taking moments of the elastostatic equations. We illustrate this technique in Sec. 11.5, where we treat the bending of beams and other examples.

Elasticity theory, as developed in this chapter, is an example of a common (some would complain far too common) approach to physics problems, namely, to linearize them. Linearization may be acceptable when the distortions are small. However, when deformed by sufficiently strong forces, elastic media may become unstable to small displacements, which can then grow to large amplitude, causing rupture. We study an example of this in Sec. 11.6: the buckling of a beam when subjected to a sufficiently large longitudinal stress. Buckling is associated with *bifurcation of equilibria*, a phenomenon that is common to many physical systems, not just elastostatic ones. We illustrate bifurcation in Sec. 11.6 using our beam under a compressive load, and we explore its connection to catastrophe theory.

In Sec. 11.7, we discuss dimensional reduction by the method of moments for bodies that are thin in only 1 dimension, not two, such as plates and thin mirrors. In such bodies, the 3-dimensional elastostatic equations are reduced to 2 dimensions. We illustrate our 2-dimensional formalism by the stress polishing of telescope mirrors.

Because elasticity theory entails computing gradients of vectors and tensors, and practical calculations are often best performed in cylindrical or spherical coordinate systems, we present a mathematical digression in Track-Two Sec. 11.8—an introduction to how one can perform practical calculations of gradients of vectors and tensors in the orthonormal bases associated with curvilinear coordinate systems, using the concept of a connection coefficient.

As illustrative examples of both connection coefficients and elastostatic force balance, in Track-Two Sec. 11.9 and various exercises, we give practical examples of solutions of the elastostatic force-balance equation in cylindrical coordinates using two common techniques of elastostatics and electrostatics: separation of variables (text of Sec. 11.9.2) and Green's functions (Ex. 11.27).

11.2 Displacement and Strain

We begin our study of elastostatics by introducing the elastic displacement vector, its gradient, and the irreducible tensorial parts of its gradient. We then identify the strain as the symmetric part of the displacement's gradient.

11.2.1 Displacement Vector and Its Gradient

displacement vector

Elasticity provides a major application of the tensorial techniques we developed in Chap. 1. Label the position of a *point* (a tiny bit of solid) in an unstressed body, relative to some convenient origin in the body, by its position vector \mathbf{x} . Let a force be applied, so the body deforms and the point moves from \mathbf{x} to $\mathbf{x} + \boldsymbol{\xi}(\mathbf{x})$; we call $\boldsymbol{\xi}$ the point's *displacement vector* (Fig. 11.1b). If $\boldsymbol{\xi}$ were constant (i.e., if its components in a Cartesian coordinate system were independent of location in the body), then the body would simply be translated and would undergo no deformation. To produce a deformation, we must make the displacement $\boldsymbol{\xi}$ change from one location to another. The most simple, coordinate-independent way to quantify those changes is by the gradient of $\boldsymbol{\xi}$, $\nabla\boldsymbol{\xi}$. This gradient is a second-rank tensor field, which we denote by \mathbf{W} :

$$\mathbf{W} \equiv \nabla\boldsymbol{\xi}. \quad (11.1a)$$

This tensor is a geometric object, defined independently of any coordinate system in the manner described in Sec. 1.7. In slot-naming index notation (Sec. 1.5), it is denoted

$$W_{ij} = \zeta_{i;j}, \quad (11.1b)$$

where the index j after the semicolon is the name of the gradient slot.

In a Cartesian coordinate system the components of the gradient are always just partial derivatives [Eq. (1.15c)], and therefore the Cartesian components of \mathbf{W} are

$$W_{ij} = \frac{\partial \zeta_i}{\partial x_j} = \zeta_{i,j}. \quad (11.1c)$$

(Recall that indices following a comma represent partial derivatives.) In Sec. 11.8, we learn how to compute the components of the gradient in cylindrical and spherical coordinates.

In any small neighborhood of any point \mathbf{x}_o in a deformed body, we can reconstruct the displacement vector $\boldsymbol{\xi}$ from its gradient \mathbf{W} up to an additive constant. Specifically, in Cartesian coordinates, by virtue of a Taylor-series expansion, $\boldsymbol{\xi}$ is given by

$$\begin{aligned} \zeta_i(\mathbf{x}) &= \zeta_i(\mathbf{x}_o) + (x_j - x_{oj})(\partial \zeta_i / \partial x_j) + \dots \\ &= \zeta_i(\mathbf{x}_o) + (x_j - x_{oj})W_{ij} + \dots \end{aligned} \quad (11.2)$$

If we place the origin of Cartesian coordinates at \mathbf{x}_o and let the origin move with the point there as the body deforms [so $\boldsymbol{\xi}(\mathbf{x}_o) = 0$], then Eq. (11.2) becomes

$$\zeta_i = W_{ij}x_j \quad \text{when } |\mathbf{x}| \text{ is sufficiently small.} \quad (11.3)$$

We have derived this as a relationship between components of ξ , \mathbf{x} , and \mathbf{W} in a Cartesian coordinate system. However, the indices can also be thought of as the names of slots (Sec. 1.5) and correspondingly, Eq. (11.3) can be regarded as a geometric, coordinate-independent relationship among the vectors and tensor ξ , \mathbf{x} , and \mathbf{W} .

In Ex. 11.2, we use Eq. (11.3) to gain insight into the displacements associated with various parts of the gradient \mathbf{W} .

11.2.2 Expansion, Rotation, Shear, and Strain

11.2.2

In Box 11.2, we introduce the concept of the irreducible tensorial parts of a tensor, and we state that in physics, when one encounters an unfamiliar tensor, it is often useful to identify the tensor's irreducible parts. The gradient of the displacement vector, $\mathbf{W} = \nabla \xi$, is an important example. It is a second-rank tensor. Therefore, as discussed in Box 11.2, its irreducible tensorial parts are its trace $\Theta \equiv \text{Tr}(\mathbf{W}) = W_{ii} = \nabla \cdot \xi$, which is called the deformed body's *expansion* (for reasons we shall explore below); its symmetric, trace-free part Σ , which is called the body's *shear*; and its antisymmetric part \mathbf{R} , which is called the body's *rotation*:

irreducible tensorial parts of a tensor

expansion, shear, and rotation

$$\Theta = W_{ii} = \nabla \cdot \xi, \quad (11.4a)$$

$$\Sigma_{ij} = \frac{1}{2}(W_{ij} + W_{ji}) - \frac{1}{3}\Theta g_{ij} = \frac{1}{2}(\xi_{i;j} + \xi_{j;i}) - \frac{1}{3}\xi_{k;k} g_{ij}, \quad (11.4b)$$

$$R_{ij} = \frac{1}{2}(W_{ij} - W_{ji}) = \frac{1}{2}(\xi_{i;j} - \xi_{j;i}). \quad (11.4c)$$

Here g_{ij} is the metric, which has components $g_{ij} = \delta_{ij}$ (Kronecker delta) in Cartesian coordinates, and repeated indices [the ii in Eq. (11.4a)] are to be summed [Eq. (1.9b) and subsequent discussion].

We can reconstruct $\mathbf{W} = \nabla \xi$ from these irreducible tensorial parts in the following manner [Eq. (4) of Box 11.2, rewritten in abstract notation]:

$$\nabla \xi = \mathbf{W} = \frac{1}{3}\Theta \mathbf{g} + \Sigma + \mathbf{R}. \quad (11.5)$$

Let us explore the physical effects of the three separate parts of \mathbf{W} in turn. To understand expansion, consider a small 3-dimensional piece \mathcal{V} of a deformed body (a *volume element*). When the deformation $\mathbf{x} \rightarrow \mathbf{x} + \xi$ occurs, a much smaller element of area¹ $d\Sigma$ on the surface $\partial\mathcal{V}$ of \mathcal{V} gets displaced through the vectorial distance ξ and in the process sweeps out a volume $\xi \cdot d\Sigma$. Therefore, the change in the volume element's volume, produced by ξ , is

$$\delta V = \int_{\partial\mathcal{V}} d\Sigma \cdot \xi = \int_{\mathcal{V}} dV \nabla \cdot \xi = \nabla \cdot \xi \int_{\mathcal{V}} dV = (\nabla \cdot \xi) V. \quad (11.6)$$

1. Note that we use Σ for a vectorial area and Σ for the shear tensor. There should be no confusion.

BOX 11.2. IRREDUCIBLE TENSORIAL PARTS OF A SECOND-RANK TENSOR IN 3-DIMENSIONAL EUCLIDEAN SPACE

In quantum mechanics, an important role is played by the *rotation group*: the set of all rotation matrices, viewed as a mathematical entity called a group (e.g., Mathews and Walker, 1970, Chap. 16). Each tensor in 3-dimensional Euclidean space, when rotated, is said to generate a specific *representation* of the rotation group. Tensors that are “big” (in a sense to be discussed later in this box) can be broken down into a sum of several tensors that are “as small as possible.” These smallest tensors are said to generate *irreducible representations* of the rotation group. All this mumbo-jumbo is really simple, when one thinks about tensors as geometric, frame-independent objects.

As an example, consider an arbitrary second-rank tensor W_{ij} in 3-dimensional, Euclidean space. In the text W_{ij} is the gradient of the displacement vector. From this tensor we can construct the following “smaller” tensors by linear operations that involve only W_{ij} and the metric g_{ij} . (As these smaller tensors are enumerated, the reader should think of the notation used as the basis-independent, frame-independent, slot-naming index notation of Sec. 1.5.1.) The smaller tensors are the contraction (i.e., trace) of W_{ij} ,

$$\Theta \equiv W_{ij}g_{ij} = W_{ii}; \quad (1)$$

the antisymmetric part of W_{ij} ,

$$R_{ij} \equiv \frac{1}{2}(W_{ij} - W_{ji}); \quad (2)$$

and the symmetric, trace-free part of W_{ij} ,

$$\Sigma_{ij} \equiv \frac{1}{2}(W_{ij} + W_{ji}) - \frac{1}{3}g_{ij}W_{kk}. \quad (3)$$

It is straightforward to verify that the original tensor W_{ij} can be reconstructed from these three smaller tensors plus the metric g_{ij} as follows:

$$W_{ij} = \frac{1}{3}\Theta g_{ij} + R_{ij} + \Sigma_{ij}. \quad (4)$$

One way to see the sense in which Θ , R_{ij} , and Σ_{ij} are smaller than W_{ij} is by counting the number of independent real numbers required to specify their components in an arbitrary basis. (Think of the index notation as components on a chosen basis.) The original tensor W_{ij} has three \times three = nine components ($W_{11}, W_{12}, W_{13}, W_{21}, \dots, W_{33}$), all of which are independent. By contrast, the scalar Θ has just one. The antisymmetric

(continued)

BOX 11.2. (continued)

tensor R_{ij} has just three independent components, R_{12} , R_{23} , and R_{31} . Finally, the nine components of Σ_{ij} are not independent; symmetry requires that $\Sigma_{ij} \equiv \Sigma_{ji}$, which reduces the number of independent components from nine to six; being trace-free, $\Sigma_{ii} = 0$, reduces it further from six to five. Therefore, (five independent components in Σ_{ij}) + (three independent components in R_{ij}) + (one independent component in Θ) = 9 = (number of independent components in W_{ij}).

The number of independent components (one for Θ , three for R_{ij} , and five for Σ_{ij}) is a geometric, basis-independent concept: It is the same, regardless of the basis used to count the components; and for each of the smaller tensors that make up W_{ij} , it is easily deduced without introducing a basis at all (think here in slot-naming index notation): The scalar Θ is clearly specified by just one real number. The antisymmetric tensor R_{ij} contains precisely the same amount of information as the vector

$$\phi_i \equiv -\frac{1}{2}\epsilon_{ijk}R_{jk}, \quad (5)$$

as can be seen from the fact that Eq. (5) can be inverted to give

$$R_{ij} = -\epsilon_{ijk}\phi_k; \quad (6)$$

and the vector ϕ_i can be characterized by its direction in space (two numbers) plus its length (a third). The symmetric, trace-free tensor Σ_{ij} can be characterized geometrically by the ellipsoid $(g_{ij} + \epsilon\Sigma_{ij})\zeta_i\zeta_j = 1$, where ϵ is an arbitrary number $\ll 1$, and ζ_i is a vector whose tail sits at the center of the ellipsoid and whose head moves around on the ellipsoid's surface. Because Σ_{ij} is trace-free, this ellipsoid has unit volume. Therefore, it is specified fully by the direction of its longest principal axis (two numbers) plus the direction of a second principal axis (a third number) plus the ratio of the length of the second axis to the first (a fourth number) plus the ratio of the length of the third axis to the first (a fifth number).

Each of the tensors Θ , R_{ij} (or equivalently, ϕ_i), and Σ_{ij} is irreducible in the sense that one cannot construct any smaller tensors from it, by any linear operation that involves only it, the metric, and the Levi-Civita tensor. Irreducible tensors in 3-dimensional Euclidean space always have an odd number of components. It is conventional to denote this number by $2l + 1$, where the integer l is called the “order of the irreducible representation of the

(continued)

BOX 11.2. (continued)

rotation group” that the tensor generates. For Θ , R_{ij} (or equivalently, ϕ_i), and Σ_{jk} , l is 0, 1, and 2, respectively. These three tensors can be mapped into the spherical harmonics of order $l = 0, 1, 2$; and their $2l + 1$ components correspond to the $2l + 1$ values of the quantum number $m = -l, -l + 1, \dots, l - 1, l$. (For details see, e.g., Thorne, 1980, Sec. II.C.)

In physics, when one encounters a new tensor, it is often useful to identify the tensor’s irreducible parts. They almost always play important, independent roles in the physical situation one is studying. We meet one example in this chapter, another when we study fluid dynamics (Chap. 13), and a third in general relativity (Box 25.2).

Here we have invoked Gauss’s theorem in the second equality, and in the third we have used the smallness of \mathcal{V} to infer that $\nabla \cdot \xi$ is essentially constant throughout \mathcal{V} and so can be pulled out of the integral. Therefore, the fractional change in volume is equal to the trace of the stress tensor (i.e., the expansion):

expansion as fractional volume change

$$\frac{\delta V}{V} = \nabla \cdot \xi = \Theta. \tag{11.7}$$

shearing displacements

shear’s stretch and squeeze along principal axes

See Fig. 11.2 for a simple example.

The shear tensor Σ produces the shearing displacements illustrated in Figs. 11.2 and 11.3. As the tensor has zero trace, there is no volume change when a body undergoes a pure shear deformation. The shear tensor has five independent components (Box 11.2). However, by rotating our Cartesian coordinates appropriately, we can transform away all the off-diagonal elements, leaving only the three diagonal elements Σ_{xx} , Σ_{yy} , and Σ_{zz} , which must sum to zero. This is known as a *principal-axis transformation*. Each element produces a stretch ($\Sigma_{..} > 0$) or squeeze ($\Sigma_{..} < 0$) along its

FIGURE 11.2 A simple example of the decomposition of a 2-dimensional distortion \mathbf{S} of a square body into an expansion Θ , a shear Σ , and a rotation \mathbf{R} .

FIGURE 11.3 Shear in 2 dimensions. The displacement of points in a solid undergoing pure shear is the vector field $\xi(\mathbf{x})$ given by Eq. (11.3) with W_{ji} replaced by Σ_{ji} : $\xi_j = \Sigma_{ji}x_i = \Sigma_{j1}x_1 + \Sigma_{j2}x_2$. The integral curves of this vector field are plotted in this figure. The figure is drawn using principal axes, which are Cartesian, so $\Sigma_{12} = \Sigma_{21} = 0$ and $\Sigma_{11} = -\Sigma_{22}$, which means that $\xi_1 = \Sigma_{11}x_1$ and $\xi_2 = -\Sigma_{11}x_2$; or, equivalently, $\xi_x = \Sigma_{xx}x$ and $\xi_y = -\Sigma_{xx}y$. The integral curves of this simple vector field are the hyperbolas shown. Note that the displacement increases linearly with distance from the origin. The shear shown in Fig. 11.2 is the same as this, but with the axes rotated counterclockwise by 45° .

axis,² and their vanishing sum (the vanishing trace of Σ) means that there is no net volume change. The components of the shear tensor in any Cartesian coordinate system can be written down immediately from Eq. (11.4b) by substituting the Kronecker delta δ_{ij} for the components of the metric tensor g_{ij} and treating all derivatives as partial derivatives:

$$\Sigma_{xx} = \frac{2}{3} \frac{\partial \xi_x}{\partial x} - \frac{1}{3} \left(\frac{\partial \xi_y}{\partial y} + \frac{\partial \xi_z}{\partial z} \right), \quad \Sigma_{xy} = \frac{1}{2} \left(\frac{\partial \xi_x}{\partial y} + \frac{\partial \xi_y}{\partial x} \right), \quad (11.8)$$

and similarly for the other components. The analogous equations in spherical and cylindrical coordinates are given in Sec. 11.8.

The third term \mathbf{R} in Eq. (11.5) describes a pure rotation, which does not deform the solid. To verify this, write $\xi = \phi \times \mathbf{x}$, where ϕ is a small rotation of magnitude ϕ about an axis parallel to the direction of ϕ . Using Cartesian coordinates in 3-dimensional Euclidean space, we can demonstrate by direct calculation that the symmetric part of $\mathbf{W} = \nabla \xi$ vanishes (i.e., $\Theta = \Sigma = 0$) and that

$$R_{ij} = -\epsilon_{ijk}\phi_k, \quad \phi_i = -\frac{1}{2}\epsilon_{ijk}R_{jk}. \quad (11.9a)$$

2. More explicitly, $\Sigma_{xx} > 0$ produces a stretch along the x -axis, $\Sigma_{yy} < 0$ produces a squeeze along the y -axis, etc.

rotation vector

Therefore, the elements of the tensor \mathbf{R} in a Cartesian coordinate system just involve the vectorial rotation angle ϕ . Note that expression (11.9a) for ϕ and expression (11.4c) for R_{ij} imply that ϕ is half the curl of the displacement vector:

$$\phi = \frac{1}{2} \nabla \times \xi. \quad (11.9b)$$

A simple example of rotation is shown in the last picture in Fig. 11.2.

Elastic materials resist expansion Θ and shear Σ , but they don't mind at all having their orientation in space changed (i.e., they do not resist rotations \mathbf{R}). Correspondingly, in elasticity theory a central focus is on expansion and shear. For this reason the symmetric part of the gradient of ξ ,

$$S_{ij} \equiv \frac{1}{2} (\xi_{i;j} + \xi_{j;i}) = \Sigma_{ij} + \frac{1}{3} \Theta g_{ij}, \quad (11.10)$$

which includes the expansion and shear but omits the rotation, is given a special name—the *strain*—and is paid great attention.

Let us consider some examples of strains that arise in physical systems.

1. Understanding how materials deform under various *loads* (externally applied forces) is central to mechanical, civil, and structural engineering. As we learn in Sec. 11.3.2, all Hookean materials (materials with strain proportional to stress when the stress is small) crack or break when the load is so great that any component of their strain exceeds ~ 0.1 , and almost all crack or break at strains ~ 0.001 . For this reason, in our treatment of elasticity theory (this chapter and the next), we focus on strains that are small compared to unity.
2. Continental drift can be measured on the surface of Earth using very long baseline interferometry, a technique in which two or more radio telescopes are used to detect interferometric fringes using radio waves from an astronomical point source. (A similar technique uses the Global Positioning System to achieve comparable accuracy.) By observing the fringes, it is possible to detect changes in the spacing between the telescopes as small as a fraction of a wavelength (~ 1 cm). As the telescopes are typically 1,000 km apart, this means that dimensionless strains $\sim 10^{-8}$ can be measured. The continents drift apart on a timescale $\lesssim 10^8$ yr, so it takes roughly a year for these changes to grow large enough to be measured. Such techniques are also useful for monitoring earthquake faults.
3. The smallest time-varying strains that have been measured so far involve laser interferometer gravitational-wave detectors, such as LIGO. In each arm of a LIGO interferometer, two mirrors hang freely, separated by 4 km. In 2015 their separations were monitored (at frequencies of ~ 100 Hz) to $\sim 4 \times 10^{-19}$ m, four ten-thousandths the radius of a nucleon. The associated strain is 1×10^{-22} . Although this strain is not associated with an elastic solid, it does indicate the high accuracy of optical measurement techniques.

strain tensor

Exercise 11.1 *Derivation and Practice: Reconstruction of a Tensor from Its Irreducible Tensorial Parts*

Using Eqs. (1), (2), and (3) of Box 11.2, show that $\frac{1}{3}\Theta g_{ij} + \Sigma_{ij} + R_{ij}$ is equal to W_{ij} .

Exercise 11.2 *Example: Displacement Vectors Associated with Expansion, Rotation, and Shear*

- (a) Consider a $\mathbf{W} = \nabla \boldsymbol{\xi}$ that is pure expansion: $W_{ij} = \frac{1}{3}\Theta g_{ij}$. Using Eq. (11.3) show that, in the vicinity of a chosen point, the displacement vector is $\xi_i = \frac{1}{3}\Theta x_i$. Draw this displacement vector field.
- (b) Similarly, draw $\boldsymbol{\xi}(\mathbf{x})$ for a \mathbf{W} that is pure rotation. [Hint: Express $\boldsymbol{\xi}$ in terms of the vectorial angle ϕ with the aid of Eq. (11.9b).]
- (c) Draw $\boldsymbol{\xi}(\mathbf{x})$ for a \mathbf{W} that is pure shear. To simplify the drawing, assume that the shear is confined to the x - y plane, and make your drawing for a shear whose only nonzero components are $\Sigma_{xx} = -\Sigma_{yy}$. Compare your drawing with Fig. 11.3.

11.3 Stress, Elastic Moduli, and Elastostatic Equilibrium**11.3**

11.3.1 Stress Tensor

11.3.1

The forces acting in an elastic solid are measured by a second-rank tensor, the *stress tensor* introduced in Sec. 1.9. Let us recall the definition of this stress tensor.

Consider two small, contiguous regions in a solid. If we take a small element of area $d\boldsymbol{\Sigma}$ in the contact surface with its positive sense³ (same as the direction of $d\boldsymbol{\Sigma}$ viewed as a vector) pointing from the first region toward the second, then the first region exerts a force $d\mathbf{F}$ (not necessarily normal to the surface) on the second through this area. The force the second region exerts on the first (through the area $-d\boldsymbol{\Sigma}$) will, by Newton's third law, be equal and opposite to that force. The force and the area of contact are both vectors, and there is a linear relationship between them. (If we double the area, we double the force.) The two vectors therefore will be related by a second-rank tensor, the stress tensor \mathbf{T} :

$$d\mathbf{F} = \mathbf{T} \cdot d\boldsymbol{\Sigma} = \mathbf{T}(\dots, d\boldsymbol{\Sigma}); \quad dF_i = T_{ij}d\Sigma_j. \quad (11.11)$$

stress tensor

Thus the tensor \mathbf{T} is the net (vectorial) force per unit (vectorial) area that a body exerts on its surroundings. Be aware that many books on elasticity (e.g., Landau and Lifshitz, 1986) define the stress tensor with the opposite sign to that in Eq. (11.11). Also be careful not to confuse the shear tensor Σ_{jk} with the vectorial infinitesimal surface area $d\Sigma_j$.

3. For a discussion of area elements including their positive sense, see Sec. 1.8.

We often need to compute the total elastic force acting on some finite volume \mathcal{V} . To aid in this, we make an important assumption, discussed in Sec. 11.3.6: the stress is determined by local conditions and can be computed from the local arrangement of atoms. If this assumption is valid, then (as we shall see in Sec. 11.3.6), we can compute the total force acting on the volume element by integrating the stress over its surface $\partial\mathcal{V}$:

$$\mathbf{F} = - \int_{\partial\mathcal{V}} \mathbf{T} \cdot d\boldsymbol{\Sigma} = - \int_{\mathcal{V}} \nabla \cdot \mathbf{T} dV, \quad (11.12)$$

where we have invoked Gauss's theorem, and the minus sign is included because by convention, for a closed surface $\partial\mathcal{V}$, $d\boldsymbol{\Sigma}$ points out of \mathcal{V} instead of into it.

Equation (11.12) must be true for arbitrary volumes, so we can identify the *elastic force density* \mathbf{f} acting on an elastic solid as

elastic force density

$$\mathbf{f} = -\nabla \cdot \mathbf{T}. \quad (11.13)$$

In elastostatic equilibrium, this force density must balance all other volume forces acting on the material, most commonly the gravitational force density, so

force balance equation

$$\mathbf{f} + \rho\mathbf{g} = 0, \quad (11.14)$$

where \mathbf{g} is the gravitational acceleration. (Again, there should be no confusion between the vector \mathbf{g} and the metric tensor \mathbf{g} .) There are other possible external forces, some of which we shall encounter later in the context of fluids (e.g., an electromagnetic force density). These can be added to Eq. (11.14).

Just as for the strain, the stress tensor \mathbf{T} can be decomposed into its irreducible tensorial parts, a pure trace (the *pressure* P) plus a symmetric trace-free part (the *shear stress*):

pressure and shear stress

$$\mathbf{T} = P\mathbf{g} + \mathbf{T}^{\text{shear}}; \quad P = \frac{1}{3} \text{Tr}(\mathbf{T}) = \frac{1}{3} T_{ii}. \quad (11.15)$$

There is no antisymmetric part, because the stress tensor is symmetric, as we saw in Sec. 1.9. Fluids at rest exert isotropic stresses: $\mathbf{T} = P\mathbf{g}$. They cannot exert shear stress when at rest, though when moving and shearing, they can exert a viscous shear stress, as we discuss extensively in Part V (initially in Sec. 13.7.2).

In SI units, stress is measured in units of Pascals, denoted Pa:

Pascal

$$1 \text{ Pa} = 1 \text{ N m}^{-2} = 1 \frac{\text{kg m s}^{-2}}{\text{m}^2}, \quad (11.16)$$

or sometimes in GPa = 10^9 Pa. In cgs units, stress is measured in dyne cm^{-2} . Note that $1 \text{ Pa} = 10 \text{ dyne cm}^{-2}$.

Now let us consider some examples of stresses.

1. Atmospheric pressure is equal to the weight of the air in a column of unit area extending above the surface of Earth, and thus is roughly $P \sim \rho g H \sim$

10^5 Pa, where $\rho \simeq 1 \text{ kg m}^{-3}$ is the density of air, $g \simeq 10 \text{ m s}^{-2}$ is the acceleration of gravity at Earth's surface, and $H \simeq 10 \text{ km}$ is the atmospheric scale height [$H \equiv (d \ln P/dz)^{-1}$, with z the vertical distance]. Thus 1 atmosphere is $\sim 10^5$ Pa (or, more precisely, 1.01325×10^5 Pa). The stress tensor is isotropic.

2. Suppose we hammer a nail into a block of wood. The hammer might weigh $m \sim 0.3 \text{ kg}$ and be brought to rest from a speed of $v \sim 10 \text{ m s}^{-1}$ in a distance of, say, $d \sim 3 \text{ mm}$. Then the average force exerted on the wood by the nail, as it is driven, is $F \sim mv^2/d \sim 10^4 \text{ N}$. If this is applied over an effective area $A \sim 1 \text{ mm}^2$, then the magnitude of the typical stress in the wood is $\sim F/A \sim 10^{10} \text{ Pa} \sim 10^5$ atmosphere. There is a large shear component to the stress tensor, which is responsible for separating the fibers in the wood as the nail is hammered.
3. Neutron stars are as massive as the Sun, $M \sim 2 \times 10^{30} \text{ kg}$, but have far smaller radii, $R \sim 10 \text{ km}$. Their surface gravities are therefore $g \sim GM/R^2 \sim 10^{12} \text{ m s}^{-2}$, 10 billion times that encountered on Earth. They have solid crusts of density $\rho \sim 10^{16} \text{ kg m}^{-3}$ that are about 1 km thick. In the crusts, the main contribution to the pressure is from the degeneracy of relativistic electrons (see Sec. 3.5.3). The magnitude of the stress at the base of a neutron-star crust is $P \sim \rho g H \sim 10^{31} \text{ Pa}$! The crusts are solid, because the free electrons are neutralized by a lattice of ions. However, a crust's shear modulus is only a few percent of its bulk modulus.
4. As we discuss in Sec. 28.7.1, a popular cosmological theory called *inflation* postulates that the universe underwent a period of rapid, exponential expansion during its earliest epochs. This expansion was driven by the stress associated with a *false vacuum*. The action of this stress on the universe can be described quite adequately using a classical stress tensor. If the interaction energy is $E \sim 10^{15} \text{ GeV}$, the supposed scale of grand unification, and the associated lengthscale is the Compton wavelength associated with that energy, $l \sim \hbar c/E$, then the magnitude of the stress is $\sim E/l^3 \sim 10^{97} (E/10^{15} \text{ GeV})^4 \text{ Pa}$.
5. Elementary particles interact through forces. Although it makes no sense to describe this interaction using classical elasticity, it is reasonable to make order-of-magnitude estimates of the associated stress. One promising model of these interactions involves *strings* with mass per unit length $\mu = g_s^2 c^2 / (8\pi G) \sim 1 \text{ Megaton/fermi}$ (where Megaton is not the TNT equivalent!), and cross section of order the Planck length squared, $L_P^2 = \hbar G / c^3 \sim 10^{-70} \text{ m}^2$, and tension (negative pressure) $T_{zz} \sim \mu c^2 / L_P^2 \sim 10^{110} \text{ Pa}$. Here \hbar , G , and c are Planck's reduced constant, Newton's gravitation constant, and the speed of light, and $g_s^2 \sim 0.025$ is the string coupling constant.

6. The highest possible stress is presumably associated with spacetime singularities, for example at the birth of the universe or inside a black hole. Here the characteristic energy is the Planck energy $E_P = (\hbar c^5/G)^{1/2} \sim 10^{19}$ GeV, the lengthscale is the Planck length $L_P = (\hbar G/c^3)^{1/2} \sim 10^{-35}$ m, and the associated ultimate stress is $\sim E_P/L_P^3 \sim 10^{114}$ Pa.

11.3.2 11.3.2 Realm of Validity for Hooke's Law

In elasticity theory, motivated by Hooke's Law (Fig. 11.1), we assume a linear relationship between a material's stress and strain tensors. Before doing so, however, we discuss the realm in which this linearity is true and some ways in which it can fail.

For this purpose, consider again the stretching of a rod by an applied force (Fig. 11.1a, shown again in Fig. 11.4a). For a sufficiently small stress $T_{zz} = F/A$ (with A the cross sectional area of the rod), the strain $S_{zz} = \Delta\ell/\ell$ follows Hooke's law (straight red line in Fig. 11.4b). However, at some point, called the *proportionality limit* (first big dot in Fig. 11.4b), the strain begins to depart from Hooke's law. Despite this deviation, if the stress is removed, the rod returns to its original length. At a somewhat larger stress, called the *elastic limit*, that ceases to be true; the rod is permanently stretched. At a still larger stress, called the *yield limit* or *yield point*, little or no increase in stress causes a large increase in strain, usually because the material begins to flow plastically. At an even larger stress, the *rupture point*, the rod cracks or breaks. For a ductile substance like polycrystalline copper, the proportionality limit and elastic limit both occur at about the same rather low strain $\Delta\ell/\ell \sim 10^{-4}$, but yield and rupture do not occur until $\Delta\ell/\ell \sim 10^{-3}$. For a more resilient material like cemented tungsten carbide, strains can be proportional and elastic up to $\sim 3 \times 10^{-3}$. Rubber is non-Hookean (stress is not proportional to strain) at essentially all strains; its proportionality limit is exceedingly small, but it returns to its original shape from essentially all nonrupturing deformations, which can be as large as $\Delta\ell/\ell \sim 8$ (the yield and rupture points).⁴ Especially significant is that in almost all solids except rubber, the proportionality, elastic, and yield limits are all small compared to unity.

proportionality limit

elastic limit

yield point

rupture point

11.3.3 11.3.3 Elastic Moduli and Elastostatic Stress Tensor

In realms where Hooke's law is valid, there is a corresponding linear relationship between the material's stress tensor and its strain tensor. The most general linear equation relating two second-rank tensors involves a fourth-rank tensor known as the *elastic modulus tensor* \mathbf{Y} . In slot-naming index notation,

elastic modulus tensor

$$T_{ij} = -Y_{ijkl}S_{kl}. \quad (11.17)$$

4. Rubber is made of long, polymeric molecules, and its elasticity arises from uncoiling of the molecules when a force is applied, which is a different mechanism than is found in crystalline materials (Xing, Goldbart, and Radzihovsky, 2007).

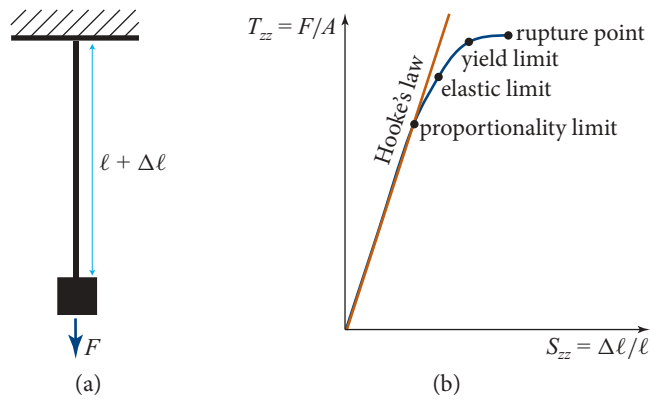

FIGURE 11.4 The stress-strain relation for a rod, showing special points at which the behavior of the rod's material changes.

Now, a general fourth-rank tensor in 3 dimensions has $3^4 = 81$ independent components. Elasticity can get complicated! However, the situation need not be so dire. There are several symmetries that we can exploit. Let us look first at the general case. As the stress and strain tensors are both symmetric, \mathbf{Y} is symmetric in its first pair of slots, and we are free to choose it symmetric in its second pair: $Y_{ijkl} = Y_{jikl} = Y_{ijlk}$. There are therefore 6 independent components Y_{ijkl} for variable i, j and fixed k, l , and vice versa. In addition, as we will show, \mathbf{Y} is symmetric under an interchange of its first and second pairs of slots: $Y_{ijkl} = Y_{klij}$. There are therefore $(6 \times 7)/2 = 21$ independent components in \mathbf{Y} . This is an improvement over 81. Many substances, notably crystals, exhibit additional symmetries, which can reduce the number of independent components considerably.

The simplest, and in fact most common, case arises when the medium is *isotropic*. In other words, there are no preferred directions in the material. This occurs when the solid is polycrystalline or amorphous and completely disordered on a scale large compared with the atomic spacing, but small compared with the solid's inhomogeneity scale.

If a medium is isotropic, then its elastic properties must be describable by scalars that relate the irreducible parts P and $\mathbf{T}^{\text{shear}}$ of the stress tensor \mathbf{T} to those, Θ and $\mathbf{\Sigma}$, of the strain tensor \mathbf{S} . The only mathematically possible, linear, coordinate-independent relationship between $\{P, \mathbf{T}^{\text{shear}}\}$ and $\{\Theta, \mathbf{\Sigma}\}$ involving solely scalars is $P = -K\Theta$, $\mathbf{T}^{\text{shear}} = -2\mu\mathbf{\Sigma}$, corresponding to a total stress tensor

$$\mathbf{T} = -K\Theta\mathbf{g} - 2\mu\mathbf{\Sigma}. \quad (11.18)$$

bulk modulus, shear modulus, and stress tensor for isotropic elastic medium

Here K is called the *bulk modulus* and μ the *shear modulus*, and the factor 2 is included for purely historical reasons. The first minus sign (with $K > 0$) ensures that the isotropic part of the stress, $-K\Theta\mathbf{g}$, resists volume changes; the second minus sign (with $\mu > 0$) ensures that the symmetric, trace-free part, $-2\mu\mathbf{\Sigma}$, resists shape changes (resists shearing).

Hooke's law (Figs. 11.1 and 11.4) can be expressed in this same stress-proportional-to-strain form. The stress, when the rod is stretched, is the force F that does the stretching divided by the rod's cross sectional area A , the strain is the rod's fractional change of length $\Delta\ell/\ell$, and so Hooke's law takes the form

$$F/A = -E\Delta\ell/\ell, \quad (11.19)$$

with E an elastic coefficient called *Young's modulus*. In Sec. 11.4, we show that E is a combination of the bulk and shear moduli: $E = 9\mu K/(3K + \mu)$.

In many treatments and applications of elasticity, the shear tensor $\mathbf{\Sigma}$ is paid little attention. The focus instead is on the strain S_{ij} and its trace $S_{kk} = \Theta$, and the elastic stress tensor (11.18) is written as $\mathbf{T} = -\lambda\Theta\mathbf{g} - 2\mu\mathbf{S}$, where $\lambda \equiv K - \frac{2}{3}\mu$. In these treatments μ and λ are called the *first and second Lamé coefficients* and are used in place of μ and K . We shall not adopt this viewpoint.

Lamé coefficients

11.3.4

11.3.4 Energy of Deformation

Take a wire of length ℓ and cross sectional area A , and stretch it (e.g., via the "Hooke's-law experiment" of Figs. 11.1 and 11.4) by an amount ζ' that grows gradually from 0 to $\Delta\ell$. When the stretch is ζ' , the force that does the stretching is [by Eq. (11.19)] $F' = EA(\zeta'/\ell) = (EV/\ell^2)\zeta'$; here $V = A\ell$ is the wire's volume, and E is its Young's modulus. As the wire is gradually lengthened, the stretching force F' does work

$$\begin{aligned} W &= \int_0^{\Delta\ell} F' d\zeta' = \int_0^{\Delta\ell} (EV/\ell^2)\zeta' d\zeta' \\ &= \frac{1}{2}EV(\Delta\ell/\ell)^2. \end{aligned}$$

This tells us that the stored elastic energy per unit volume is

$$U = \frac{1}{2}E(\Delta\ell/\ell)^2. \quad (11.20)$$

To generalize this formula to a strained, isotropic, 3-dimensional medium, consider an arbitrary but small region \mathcal{V} inside a body that has already been strained by a displacement vector field ξ_i and is thus already experiencing an elastic stress $T_{ij} = -K\Theta\delta_{ij} - 2\mu\Sigma_{ij}$ [Eq. (11.18)]. Imagine building up this displacement gradually from zero at the same rate everywhere in and around \mathcal{V} , so at some moment during the buildup the displacement field is $\xi'_i = \xi_i\epsilon$ (with the parameter ϵ gradually growing from 0 to 1). At that moment, the stress tensor (by virtue of the linearity of the stress-strain relation) is $T'_{ij} = T_{ij}\epsilon$. On the boundary $\partial\mathcal{V}$ of the region \mathcal{V} , this stress exerts a force $\Delta F'_i = -T'_{ij}\Delta\Sigma_j$ across any surface element $\Delta\Sigma_j$, from the exterior of $\partial\mathcal{V}$ to its interior. As the displacement grows, this surface force does the following amount of work on \mathcal{V} :

$$\Delta W_{\text{surf}} = \int \Delta F'_i d\xi'_i = \int (-T'_{ij}\Delta\Sigma_j) d\xi'_i = - \int_0^1 T_{ij}\epsilon \Delta\Sigma_j \xi'_i d\epsilon = -\frac{1}{2}T_{ij}\Delta\Sigma_j \xi_i. \quad (11.21)$$

The total amount of work done can be computed by adding up the contributions from all the surface elements of $\partial\mathcal{V}$:

$$W_{\text{surf}} = -\frac{1}{2} \int_{\partial\mathcal{V}} T_{ij}\xi_i d\Sigma_j = -\frac{1}{2} \int_{\mathcal{V}} (T_{ij}\xi_i)_{;j} dV = -\frac{1}{2} (T_{ij}\xi_i)_{;j} V. \quad (11.22)$$

In the second step we have used Gauss's theorem, and in the third step we have used the smallness of the region \mathcal{V} to infer that the integrand is very nearly constant and the integral is the integrand times the total volume V of \mathcal{V} .

Does W_{surf} equal the elastic energy stored in \mathcal{V} ? The answer is “no,” because we must also take account of the work done in the interior of \mathcal{V} by gravity or any other nonelastic force that may be acting. Although it is not easy in practice to turn gravity off and then on, we must do so in the following thought experiment. In the volume's final deformed state, the divergence of its elastic stress tensor is equal to the gravitational force density, $\nabla \cdot \mathbf{T} = \rho \mathbf{g}$ [Eqs. (11.13) and (11.14)]; and in the initial, undeformed and unstressed state, $\nabla \cdot \mathbf{T}$ must be zero, whence so must \mathbf{g} . Therefore, we must imagine growing the gravitational force proportional to ϵ just like we grow the displacement, strain, and stress. During this growth, with $\mathbf{g}' = \epsilon \mathbf{g}$, the gravitational force $\rho \mathbf{g}' V$ does the following amount of work on our tiny region \mathcal{V} :

$$W_{\text{grav}} = \int \rho V \mathbf{g}' \cdot d\xi' = \int_0^1 \rho V \mathbf{g} \epsilon \cdot \xi d\epsilon = \frac{1}{2} \rho V \mathbf{g} \cdot \xi = \frac{1}{2} (\nabla \cdot \mathbf{T}) \cdot \xi V = \frac{1}{2} T_{ij;j} \xi_i V. \quad (11.23)$$

The total work done to deform \mathcal{V} is the sum of the work done by the elastic force (11.22) on its surface and the gravitational force (11.23) in its interior, $W_{\text{surf}} + W_{\text{grav}} = -\frac{1}{2} (\xi_i T_{ij})_{;j} V + \frac{1}{2} T_{ij;j} \xi_i V = -\frac{1}{2} T_{ij} \xi_{i;j} V$. This work gets stored in \mathcal{V} as elastic energy, so the energy density is $U = -\frac{1}{2} T_{ij} \xi_{i;j}$. Inserting (for an isotropic material) $T_{ij} = -K \Theta g_{ij} - 2\mu \Sigma_{ij}$ and $\xi_{i;j} = \frac{1}{3} \Theta g_{ij} + \Sigma_{ij} + R_{ij}$ in this equation for U and performing some simple algebra that relies on the symmetry properties of the expansion, shear, and rotation (Ex. 11.3), we obtain

$$U = \frac{1}{2} K \Theta^2 + \mu \Sigma_{ij} \Sigma_{ij}. \quad (11.24)$$

elastic energy density at fixed temperature

Note that this elastic energy density is always positive if the elastic moduli are positive, as they must be for matter to be stable against small perturbations, and note that it is independent of the rotation R_{ij} , as it should be on physical grounds.

For the more general, anisotropic case, expression (11.24) becomes [by virtue of the stress-strain relation $T_{ij} = -Y_{ijkl} \xi_{k;l}$, Eq. (11.17)]

$$U = \frac{1}{2} \xi_{i;j} Y_{ijkl} \xi_{k;l}. \quad (11.25)$$

The volume integral of the elastic energy density given by Eq. (11.24) or (11.25) can be used as an action from which to compute the stress, by varying the displacement (Ex. 11.4). Since only the part of \mathbf{Y} that is symmetric under interchange of the first

and second pairs of slots contributes to U , only that part can affect the action-principle-derived stress. Therefore, it must be that $Y_{ijkl} = Y_{klij}$. This is the symmetry we asserted earlier.

EXERCISES

Exercise 11.3 *Derivation and Practice: Elastic Energy*

Beginning with $U = -\frac{1}{2}T_{ij}\xi_{i,j}$ [text following Eq. (11.23)], derive Eq. (11.24) for the elastic energy density inside a body.

Exercise 11.4 *Derivation and Practice: Action Principle for Elastic Stress*

For an anisotropic, elastic medium with elastic energy density $U = \frac{1}{2}\xi_{i,j}Y_{ijkl}\xi_{k,l}$, integrate this energy density over a 3-dimensional region \mathcal{V} (not necessarily small) to get the total elastic energy E . Now consider a small variation $\delta\xi_i$ in the displacement field. Evaluate the resulting change δE in the elastic energy without using the relation $T_{ij} = -Y_{ijkl}\xi_{k,l}$. Convert to a surface integral over $\partial\mathcal{V}$, and thence infer the stress-strain relation $T_{ij} = -Y_{ijkl}\xi_{k,l}$.

11.3.5

11.3.5 Thermoelasticity

In our discussion of deformation energy, we tacitly assumed that the temperature of the elastic medium was held fixed during the deformation (i.e., we ignored the possibility of any thermal expansion). Correspondingly, the energy density U that we computed is actually the physical free energy per unit volume \mathcal{F} , at some chosen temperature T_0 of a heat bath. If we increase the bath's and material's temperature from T_0 to $T = T_0 + \delta T$, then the material wants to expand by $\Theta = \delta V/V = 3\alpha\delta T$ (i.e., it will have vanishing expansional elastic energy if Θ has this value). Here α is its coefficient of linear thermal expansion. (The factor 3 is because there are three directions into which it can expand: x , y , and z .) Correspondingly, the physical-free-energy density at temperature $T = T_0 + \delta T$ is

coefficient of linear thermal expansion

elastic physical free energy

$$\mathcal{F} = \mathcal{F}_0(T) + \frac{1}{2}K(\Theta - 3\alpha\delta T)^2 + \mu\Sigma_{ij}\Sigma_{ij}. \quad (11.26)$$

The stress tensor in this heated and strained state can be computed from $T_{ij} = -\partial\mathcal{F}/\partial S_{ij}$ [a formula most easily inferred from Eq. (11.25) with U reinterpreted as \mathcal{F} and $\xi_{i,j}$ replaced by its symmetrization, S_{ij}]. Reexpressing Eq. (11.26) in terms of S_{ij} and computing the derivative, we obtain (not surprisingly!)

$$T_{ij} = -\frac{\partial\mathcal{F}}{\partial S_{ij}} = -K(\Theta - 3\alpha\delta T)\delta_{ij} - 2\mu\Sigma_{ij}. \quad (11.27)$$

What happens if we allow our material to expand *adiabatically* rather than at fixed temperature? Adiabatic expansion means expansion at fixed entropy S . Consider a small sample of material that contains mass M and has volume $V = M/\rho$. Its entropy

is $S = -[\partial(\mathcal{F}V)/\partial T]_V$ [cf. Eq. (5.33)], which, using Eq. (11.26), becomes

$$S = S_0(T) + 3\alpha K \Theta V. \quad (11.28)$$

Here we have neglected the term $-9\alpha^2 K \delta T$, which can be shown to be negligible compared to the temperature dependence of the elasticity-independent term $S_0(T)$. If our sample expands adiabatically by an amount $\Delta V = V \Delta \Theta$, then its temperature must go down by the amount $\Delta T < 0$ that keeps S fixed (i.e., that makes $\Delta S_0 = -3\alpha K V \Delta \Theta$). Noting that $T \Delta S_0$ is the change of the sample's thermal energy, which is $\rho c_V \Delta T$ (c_V is the specific heat per unit mass), we see that the temperature change is

$$\frac{\Delta T}{T} = \frac{-3\alpha K \Delta \Theta}{\rho c_V} \quad \text{for adiabatic expansion.} \quad (11.29)$$

temperature change in
adiabatic expansion

This temperature change, accompanying an adiabatic expansion, alters slightly the elastic stress [Eq. (11.27)] and thence the bulk modulus K (i.e., it gives rise to an adiabatic bulk modulus that differs slightly from the isothermal bulk modulus K introduced in previous sections). However, the differences are so small that they are generally ignored. For further details, see Landau and Lifshitz (1986, Sec. 6).

11.3.6 Molecular Origin of Elastic Stress; Estimate of Moduli

11.3.6

It is important to understand the microscopic origin of the elastic stress. Consider an ionic solid in which singly ionized ions (e.g., positively charged sodium and negatively charged chlorine) attract their nearest (opposite-species) neighbors through their mutual Coulomb attraction and repel their *next* nearest (same-species) neighbors, and so on. Overall, there is a net electrostatic attraction on each ion, which is balanced by the short-range repulsion of its bound electrons against its neighbors' bound electrons. Now consider a thin slice of material of thickness intermediate between the inter-atomic spacing and the solid's inhomogeneity scale (Fig. 11.5).

Although the electrostatic force between individual pairs of ions is long range, the material is electrically neutral on the scale of several ions; as a result, when averaged

FIGURE 11.5 A thin slice of an ionic solid (between the dark lines) that interacts electromagnetically with ions outside it. The electrostatic force on the slice is dominated by interactions between ions lying in the two thin shaded areas, a few atomic layers thick, one on each side of the slice. The force is effectively a surface force rather than a volume force. In elastostatic equilibrium, the forces on the two sides are equal and opposite, if the slice is sufficiently thin.

Notes: The final two columns are the longitudinal and transverse sound speeds c_L , c_T , defined in Chap. 12. The DNA molecule is discussed in Ex. 11.12.

over many ions, the net electric force is short range (Fig. 11.5). We can therefore treat the net force acting on the thin slice as a surface force, governed by local conditions in the material. This is essential if we are to be able to write down a localized linear stress-strain relation $T_{ij} = -Y_{ijkl}S_{kl}$ or $T_{ij} = -K\Theta\delta_{ij} - 2\mu\Sigma_{ij}$. This need not have been the case; there are other circumstances where the net electrostatic force is long range, not short. One example occurs in certain types of crystal (e.g., tourmaline), which develop internal, long-range *piezoelectric* fields when strained.

Our treatment so far has implicitly assumed that matter is continuous on all scales and that derivatives are mathematically well defined. Of course, this is not the case. In fact, we not only need to acknowledge the existence of atoms, we must also use them to compute the elastic moduli.

We can estimate the elastic moduli in ionic or metallic materials by observing that, if a crystal lattice were to be given a dimensionless strain of order unity, then the elastic stress would be of order the electrostatic force between adjacent ions divided by the area associated with each ion. If the lattice spacing is $a \sim 2 \text{ \AA} = 0.2 \text{ nm}$ and the ions are singly charged, then K and $\mu \sim e^2/4\pi\epsilon_0 a^4 \sim 100 \text{ GPa}$. This is about a million atmospheres. Covalently bonded compounds are less tightly bound and have somewhat smaller elastic moduli; exotic carbon nanotubes have larger moduli. See Table 11.1.

On the basis of this argument, it might be thought that crystals can be subjected to strains of order unity before they attain their elastic limits. However, as discussed in Sec. 11.3.2, most materials are only elastic for strains $\lesssim 10^{-3}$. The reason for this difference is that crystals are generally imperfect and are laced with *dislocations*. Relatively small stresses suffice for the dislocations to move through the solid and for the crystal thereby to undergo permanent deformation (Fig. 11.6).

magnitudes of elastic moduli

FIGURE 11.6 The ions in one layer of a crystal. In subsequent layers, going into each picture, the ion distribution is the same. (a) This perfect crystal, in which the atoms are organized in a perfectly repeating lattice, can develop very large shear strains without yielding. (b) Real materials contain dislocations that greatly reduce their rigidity. The simplest type of dislocation, shown here, is the *edge dislocation* (with the central vertical atomic layer having a terminating edge that extends into the picture). The dislocation will move transversely, and the crystal thereby will undergo inelastic deformation when the strain is typically greater than $\sim 10^{-3}$, which is $\sim 1\%$ of the yield shear strain for a perfect crystal.

EXERCISES

Exercise 11.5 *Problem: Order-of-Magnitude Estimates*

- What is the maximum size of a nonspherical asteroid? [Hint: If the asteroid is too large, its gravity will deform it into a spherical shape.]
- What length of steel wire can hang vertically without breaking? What length of carbon nanotube? What are the prospects for creating a tether that hangs to Earth's surface from a geostationary satellite?
- Can a helium balloon lift the tank used to transport its helium gas? (Purcell, 1983).

Exercise 11.6 *Problem: Jumping Heights*

Explain why all animals, from fleas to humans to elephants, can jump to roughly the same height. The field of science that deals with topics like this is called *allometry* (Ex. 11.18).

11.3.7 Elastostatic Equilibrium: Navier-Cauchy Equation

11.3.7

It is commonly the case that the elastic moduli K and μ are constant (i.e., independent of location in the medium), even though the medium is stressed in an inhomogeneous way. (This is because the strains are small and thus perturb the material properties by only small amounts.) If so, then from the elastic stress tensor $\mathbf{T} = -K\Theta\mathbf{g} - 2\mu\boldsymbol{\Sigma}$ and expressions (11.4a) and (11.4b) for the expansion and shear in terms of the displacement vector, we can deduce the following expression for the elastic force density \mathbf{f} [Eq. (11.13)] inside the body:

elastic force density

$$\mathbf{f} = -\nabla \cdot \mathbf{T} = K\nabla\Theta + 2\mu\nabla \cdot \boldsymbol{\Sigma} = \left(K + \frac{1}{3}\mu\right)\nabla(\nabla \cdot \boldsymbol{\xi}) + \mu\nabla^2\boldsymbol{\xi}; \quad (11.30)$$

FIGURE 11.7 Pill box used to derive boundary conditions in electrostatics and elastostatics.

see Ex. 11.7. Here $\nabla \cdot \boldsymbol{\Sigma}$ in index notation is $\Sigma_{ij,j} = \Sigma_{ji,j}$. Extra terms must be added if we are dealing with anisotropic materials. However, in this book Eq. (11.30) will be sufficient for our needs.

If no other countervailing forces act in the interior of the material (e.g., if there is no gravitational force), and if, as in this chapter, the material is in a static, equilibrium state rather than vibrating dynamically, then this force density will have to vanish throughout the material's interior. This vanishing of $\mathbf{f} \equiv -\nabla \cdot \mathbf{T}$ is just a fancy version of Newton's law for static situations, $\mathbf{F} = m\mathbf{a} = 0$. If the material has density ρ and is pulled on by a gravitational acceleration \mathbf{g} , then the sum of the elastostatic force per unit volume and gravitational force per unit volume must vanish, $\mathbf{f} + \rho\mathbf{g} = 0$:

Navier-Cauchy equation
for elastostatic equilibrium

$$\mathbf{f} + \rho\mathbf{g} = \left(K + \frac{1}{3}\mu \right) \nabla(\nabla \cdot \boldsymbol{\xi}) + \mu \nabla^2 \boldsymbol{\xi} + \rho\mathbf{g} = 0. \quad (11.31)$$

This is often called the *Navier-Cauchy equation*.⁵

When external forces are applied to the surface of an elastic body (e.g., when one pushes on the face of a cylinder) and gravity acts on the interior, the distribution of the strain $\boldsymbol{\xi}(\mathbf{x})$ inside the body can be computed by solving the Navier-Cauchy equation (11.31) subject to boundary conditions provided by the applied forces.

In electrostatics, one can derive boundary conditions by integrating Maxwell's equations over the interior of a thin box (a "pill box") with parallel faces that snuggle up to the boundary (Fig. 11.7). For example, by integrating $\nabla \cdot \mathbf{E} = \rho_e/\epsilon_0$ over the interior of the pill box and then applying Gauss's law to convert the left-hand side to a surface integral, we obtain the junction condition that the discontinuity in the normal component of the electric field is equal $1/\epsilon_0$ times the surface charge density. Similarly, in elastostatics one can derive boundary conditions by integrating the elastostatic equation $\nabla \cdot \mathbf{T} = 0$ over the pill box of Fig. 11.7 and then applying Gauss's law:

$$0 = \int_{\mathcal{V}} \nabla \cdot \mathbf{T} \, dV = \int_{\partial\mathcal{V}} \mathbf{T} \cdot d\boldsymbol{\Sigma} = \int_{\partial\mathcal{V}} \mathbf{T} \cdot \mathbf{n} \, dA = [(\mathbf{T} \cdot \mathbf{n})_{\text{upper face}} - (\mathbf{T} \cdot \mathbf{n})_{\text{lower face}}] A. \quad (11.32)$$

Here in the next-to-last expression we have used $d\boldsymbol{\Sigma} = \mathbf{n} \, dA$, where dA is the scalar area element, and \mathbf{n} is the unit normal to the pill-box face. In the last term we have

5. It was first written down by Claude-Louis Navier (in 1821) and in a more general form by Augustin-Louis Cauchy (in 1822).

assumed the pill box has a small face, so $\mathbf{T} \cdot \mathbf{n}$ can be treated as constant and be pulled outside the integral. The result is the boundary condition that

$$\mathbf{T} \cdot \mathbf{n} \quad \text{must be continuous across any boundary;} \quad (11.33)$$

boundary conditions for
Navier-Cauchy equation

in index notation, $T_{ij}n_j$ is continuous.

Physically, this is nothing but the law of force balance across the boundary: the force per unit area acting from the lower side to the upper side must be equal and opposite to that acting from upper to lower. As an example, if the upper face is bounded by vacuum, then the solid's stress tensor must satisfy $T_{ij}n_j = 0$ at the surface. If a normal pressure P is applied by some external agent at the upper face, then the solid must respond with a normal force equal to P : $n_i T_{ij}n_j = P$. If a vectorial force per unit area \mathcal{F}_i is applied at the upper face by some external agent, then it must be balanced: $T_{ij}n_j = -\mathcal{F}_i$.

Solving the Navier-Cauchy equation (11.32) for the displacement field $\xi(\mathbf{x})$, subject to specified boundary conditions, is a problem in elastostatics analogous to solving Maxwell's equations for an electric field subject to boundary conditions in electrostatics, or for a magnetic field subject to boundary conditions in magnetostatics. The types of solution techniques used in electrostatics and magnetostatics can also be used here. See Box 11.3.

Exercise 11.7 *Derivation and Practice: Elastic Force Density*

EXERCISES

From Eq. (11.18) derive expression (11.30) for the elastostatic force density inside an elastic body.

Exercise 11.8 ***Practice: Biharmonic Equation*

A homogeneous, isotropic, elastic solid is in equilibrium under (uniform) gravity and applied surface stresses. Use Eq. (11.30) to show that the displacement inside it, $\xi(\mathbf{x})$, is biharmonic, i.e., it satisfies the differential equation

$$\boxed{\nabla^2 \nabla^2 \xi = 0.} \quad (11.34a)$$

Show also that the expansion Θ satisfies the Laplace equation

$$\boxed{\nabla^2 \Theta = 0.} \quad (11.34b)$$

11.4 Young's Modulus and Poisson's Ratio for an Isotropic Material: A Simple Elastostatics Problem

11.4

As a simple example of an elastostatics problem, we explore the connection between our 3-dimensional theory of stress and strain and the 1-dimensional Hooke's law (Fig. 11.1).

BOX 11.3. METHODS OF SOLVING THE NAVIER-CAUCHY EQUATION

Many techniques have been devised to solve the Navier-Cauchy equation (11.31), or other equations equivalent to it, subject to appropriate boundary conditions. Among them are:

- Separation of variables. See Sec. 11.9.2.
- Green's functions. See Ex. 11.27 and Johnson (1985).
- Variational principles. See Marsden and Hughes (1986, Chap. 5) and Slaughter (2002, Chap. 10).
- Saint-Venant's principle. One changes the boundary conditions to something simpler, for which the Navier-Cauchy equation can be solved analytically, and then one uses linearity of the Navier-Cauchy equation to compute an approximate, additive correction that accounts for the difference in boundary conditions.¹
- Dimensional reduction. This method reduces the theory to 2 dimensions in the case of thin plates (Sec. 11.7), and to 1 dimension for rods and for translation-invariant plates (Sec. 11.5).
- Complex variable methods. These are particularly useful in solving the 2-dimensional equations (Boresi and Chong, 1999, Appendix 5B).
- Numerical simulations on computers. These are usually carried out by the method of finite elements, in which one approximates stressed objects by a finite set of elementary, interconnected physical elements, such as rods; thin, triangular plates; and tetrahedra (Ugural and Fenster, 2012, Chap. 7).
- Replace Navier-Cauchy by equivalent equations. For example, and widely used in the engineering literature, write force balance $T_{ij;j} = 0$ in terms of the strain tensor S_{ij} , supplement this with an equation that guarantees S_{ij} can be written as the symmetrized gradient of a vector field (the displacement vector), and develop techniques to solve these coupled equations plus boundary conditions for S_{ij} [Ugural and Fenster (2012, Sec. 2.4); also large parts of Boresi and Chong (1999) and Slaughter (2002)].
- Mathematica or other computer software. These software packages can be used to perform complicated analytical analyses. One can then explore their predictions numerically (Constantinescu and Korsunsky, 2007).

1. In 1855 Barré de Saint-Venant had the insight to realize that, under suitable conditions, the correction will be significant only locally (near the altered boundary) and not globally. (See Boresi and Chong, 1999, pp. 288ff; Ugural and Fenster, 2012, Sec. 2.16, and references therein.)

Consider a thin rod of square cross section hanging along the \mathbf{e}_z direction of a Cartesian coordinate system (Fig. 11.1). Subject the rod to a stretching force applied normally and uniformly at its ends. (It could just as easily be a rod under compression.) Its sides are free to expand or contract transversely, since no force acts on them: $dF_i = T_{ij}d\Sigma_j = 0$. As the rod is slender, vanishing of dF_i at its x and y sides implies to high accuracy that the stress components T_{ix} and T_{iy} will vanish throughout the interior; otherwise there would be a very large force density $T_{ij,j}$ inside the rod. Using $T_{ij} = -K\Theta g_{ij} - 2\mu\Sigma_{ij}$, we then obtain

$$T_{xx} = -K\Theta - 2\mu\Sigma_{xx} = 0, \quad (11.35a)$$

$$T_{yy} = -K\Theta - 2\mu\Sigma_{yy} = 0, \quad (11.35b)$$

$$T_{yz} = -2\mu\Sigma_{yz} = 0, \quad (11.35c)$$

$$T_{xz} = -2\mu\Sigma_{xz} = 0, \quad (11.35d)$$

$$T_{xy} = -2\mu\Sigma_{xy} = 0, \quad (11.35e)$$

$$T_{zz} = -K\Theta - 2\mu\Sigma_{zz}. \quad (11.35f)$$

From the first two of these equations and $\Sigma_{xx} + \Sigma_{yy} + \Sigma_{zz} = 0$, we obtain a relationship between the expansion and the nonzero components of the shear,

$$K\Theta = \mu\Sigma_{zz} = -2\mu\Sigma_{xx} = -2\mu\Sigma_{yy}; \quad (11.36)$$

and from this and Eq. (11.35f), we obtain $T_{zz} = -3K\Theta$. The decomposition of S_{ij} into its irreducible tensorial parts tells us that $S_{zz} = \xi_{z;z} = \Sigma_{zz} + \frac{1}{3}\Theta$, which becomes, on using Eq. (11.36), $\xi_{z;z} = [(3K + \mu)/(3\mu)]\Theta$. Combining with $T_{zz} = -3K\Theta$, we obtain Hooke's law and an expression for Young's modulus E in terms of the bulk and shear moduli:

$$\frac{-T_{zz}}{\xi_{z;z}} = \frac{9\mu K}{3K + \mu} = E. \quad (11.37)$$

Hooke's law and Young's modulus

It is conventional to introduce *Poisson's ratio* ν , which is minus the ratio of the lateral strain to the longitudinal strain during a deformation of this type, where the transverse motion is unconstrained. It can be expressed as a ratio of elastic moduli as follows:

$$\nu \equiv -\frac{\xi_{x;x}}{\xi_{z;z}} = -\frac{\xi_{y;y}}{\xi_{z;z}} = -\frac{\Sigma_{xx} + \frac{1}{3}\Theta}{\Sigma_{zz} + \frac{1}{3}\Theta} = \frac{3K - 2\mu}{2(3K + \mu)}, \quad (11.38)$$

Poisson's ratio

where we have used Eq. (11.36). We tabulate these relations and their inverses for future use:

$$\boxed{E = \frac{9\mu K}{3K + \mu}, \quad \nu = \frac{3K - 2\mu}{2(3K + \mu)}; \quad K = \frac{E}{3(1 - 2\nu)}, \quad \mu = \frac{E}{2(1 + \nu)}}. \quad (11.39)$$

We have already remarked that mechanical stability of a solid requires that $K, \mu > 0$. Using Eq. (11.39), we observe that this imposes a restriction on Poisson's ratio, namely that $-1 < \nu < 1/2$. For metals, Poisson's ratio is typically about $1/3$, and the shear modulus is roughly half the bulk modulus. For a substance that is easily sheared but not easily compressed, like rubber (or neutron star crusts; Sec. 11.3.6), the bulk modulus is relatively high and $\nu \simeq 1/2$ (cf. Table 11.1). For some exotic materials, Poisson's ratio can be negative (cf. Yeganeh-Haeri, Weidner, and Parise, 1992).

Although we derived them for a square strut under extension, our expressions for Young's modulus and Poisson's ratio are quite general. To see this, observe that the derivation would be unaffected if we combined many parallel, square fibers together. All that is necessary is that the transverse motion be free, so that the only applied force is uniform and normal to a pair of parallel faces.

11.5 Reducing the Elastostatic Equations to 1 Dimension for a Bent Beam: Cantilever Bridge, Foucault Pendulum, DNA Molecule, Elastica

dimensional reduction

When dealing with bodies that are much thinner in 2 dimensions than the third (e.g., rods, wires, and beams), one can use the *method of moments* to reduce the 3-dimensional elastostatic equations to ordinary differential equations in 1 dimension (a process called *dimensional reduction*). We have already met an almost trivial example of this in our discussion of Hooke's law and Young's modulus (Sec. 11.4 and Fig. 11.1). In this section, we discuss a more complicated example, the bending of a beam through a small displacement angle. In Ex. 11.13, we shall analyze a more complicated example: the bending of a long, elastic wire into a complicated shape called an *elastica*.

Our beam-bending example is motivated by a common method of bridge construction, which uses cantilevers. (A famous historical example is the old bridge over the Firth of Forth in Scotland that was completed in 1890 with a main span of half a kilometer.)

The principle is to attach two independent beams to the two shores as cantilevers, and allow them to meet in the middle. (In practice the beams are usually supported at the shores on piers and strengthened along their lengths with trusses.) Similar cantilevers, with lengths of order a micron or less, are used in atomic force microscopes and other nanotechnology applications, including quantum-information experiments.

Let us make a simple model of a cantilever (Fig. 11.8). Consider a beam clamped rigidly at one end, with length ℓ , horizontal width w , and vertical thickness h . Introduce local Cartesian coordinates with \mathbf{e}_x pointing along the beam and \mathbf{e}_z pointing vertically upward. Imagine the beam extending horizontally in the absence of gravity. Now let it sag under its own weight, so that each element is displaced through a small distance $\boldsymbol{\xi}(\mathbf{x})$. The upper part of the beam is stretched, while the lower part is compressed, so there must be a *neutral surface* where the horizontal strain $\xi_{x,x}$ vanishes.

neutral surface

FIGURE 11.8 Bending of a cantilever. (a) A beam is held rigidly at one end and extends horizontally with the other end free. We introduce an orthonormal coordinate system (x, y, z) with \mathbf{e}_x extending along the beam. We only consider small departures from equilibrium. The bottom of the beam will be compressed, the upper portion extended. There is therefore a neutral surface $z = 0$ on which the strain $\xi_{x,x}$ vanishes. (b) The beam has a rectangular cross section with horizontal width w and vertical thickness h ; its length is ℓ . (c) The bending torque M must be balanced by the torque exerted by the vertical shear force S . (d) The shear force S must vary along the beam so as to support the beam's weight per unit length, W .

This neutral surface must itself be curved downward. Let its downward displacement from the horizontal plane that it occupied before sagging be $\eta(x)$ (> 0), let a plane tangent to the neutral surface make an angle $\theta(x)$ (also > 0) with the horizontal, and adjust the x and z coordinates so x runs along the slightly curved neutral plane and z is orthogonal to it (Fig. 11.8). The longitudinal strain is then given to first order in small quantities by

$$\xi_{x,x} = \frac{z}{\mathcal{R}} = z \frac{d\theta}{dx} \simeq z \frac{d^2\eta}{dx^2}, \quad (11.40a)$$

longitudinal strain

where $\mathcal{R} = dx/d\theta > 0$ is the radius of curvature of the beam's bend, and we have chosen $z = 0$ at the neutral surface. The 1-dimensional displacement $\eta(x)$ will be the focus for dimensional reduction of the elastostatic equations.

As in our discussion of Hooke's law for a stretched rod (Sec. 11.4), we can regard the beam as composed of a bundle of long, parallel fibers, stretched or squeezed along their length and free to contract transversely. The longitudinal stress is therefore

$$T_{xx} = -E\xi_{x,x} = -Ez \frac{d^2\eta}{dx^2}. \quad (11.40b)$$

We can now compute the horizontal force density, which must vanish in elastostatic equilibrium:⁶

$$f_x = -T_{xx,x} - T_{xz,z} = Ez \frac{d^3\eta}{dx^3} - T_{xz,z} = 0. \quad (11.40c)$$

method of moments

This is a partial differential equation. We convert it into a 1-dimensional ordinary differential equation by the *method of moments*: We multiply it by z and integrate over z (i.e., we compute its “first moment”). Integrating the second term, $\int z T_{xz,z} dz$, by parts and using the boundary condition $T_{xz} = 0$ on the upper and lower surfaces of the beam, we obtain

$$\frac{Eh^3}{12} \frac{d^3\eta}{dx^3} = - \int_{-h/2}^{h/2} T_{xz} dz. \quad (11.40d)$$

Using $T_{xz} = T_{zx}$, notice that the integral, when multiplied by the beam’s width w in the y direction, is the vertical shear force $S(x)$ in the beam:

shear force, S

$$S = \int T_{zx} dy dz = w \int_{-h/2}^{h/2} T_{zx} dz = -D \frac{d^3\eta}{dx^3}. \quad (11.41a)$$

Here

flexural rigidity or bending modulus of an elastic beam, D

$$D \equiv E \int z^2 dy dz \equiv EA r_g^2 = Ewh^3/12 \quad (11.41b)$$

is called the beam’s *flexural rigidity*, or its *bending modulus*. Notice that, quite generally, D is the beam’s Young’s modulus E times the second moment of the beam’s cross sectional area A along the direction of bend. Engineers call that second moment $A r_g^2$ and call r_g the radius of gyration. For our rectangular beam, this D is $Ewh^3/12$.

As an aside, we can gain some insight into Eq. (11.41a) by examining the torques that act on a segment of the beam with length dx . As shown in Fig. 11.8c, the shear forces on the two ends of the segment exert a clockwise torque $2S(dx/2) = Sdx$. This is balanced by a counterclockwise torque due to the stretching of the upper half of the segment and compression of the lower half (i.e., due to the bending of the beam). This *bending torque* is

bending torque, M

$$M \equiv \int T_{xx} z dy dz = -D \frac{d^2\eta}{dx^2} \quad (11.41c)$$

6. Because the coordinates are slightly curvilinear rather than precisely Cartesian, our Cartesian-based analysis makes small errors. Track-Two readers who have studied Sec. 11.8 can evaluate those errors using connection-coefficient terms that were omitted from this equation: $-\Gamma_{xjk} T_{jk} - \Gamma_{jkj} T_{xk}$. Each Γ has magnitude $1/\mathcal{R}$, so these terms are of order T_{jk}/\mathcal{R} , whereas the terms kept in Eq. (11.40c) are of order T_{xx}/ℓ and T_{xz}/h . Since the thickness h and length ℓ of the beam are small compared to the beam’s radius of curvature \mathcal{R} , the connection-coefficient terms are negligible.

on the right end of the segment and minus this on the left, so torque balance says $(dM/dx)dx = Sdx$:

$$\boxed{S = dM/dx;} \quad (11.42)$$

see Fig. 11.8c. This is precisely Eq. (11.41a).

Equation (11.41a) [or equivalently, Eq. (11.42)] embodies half of the elastostatic equations. It is the x component of force balance $f_x = 0$, converted to an ordinary differential equation by evaluating its lowest nonvanishing moment: its first moment, $\int z f_x dy dz = 0$ [Eq. (11.40d)]. The other half is the z component of stress balance, which we can write as

$$T_{zx,x} + T_{zz,z} + \rho g = 0 \quad (11.43)$$

(vertical elastic force balanced by gravitational pull on the beam). We can convert this to a 1-dimensional ordinary differential equation by taking its lowest nonvanishing moment, its zeroth moment (i.e., by integrating over y and z). The result is

$$\boxed{\frac{dS}{dx} = -W,} \quad (11.44)$$

where $W = g\rho wh$ is the beam's weight per unit length (Fig. 11.8d).

weight per unit length, W

Combining our two dimensionally reduced components of force balance, Eqs. (11.41a) and (11.44), we obtain a fourth-order differential equation for our 1-dimensional displacement $\eta(x)$:

$$\boxed{\frac{d^4\eta}{dx^4} = \frac{W}{D}.} \quad (11.45)$$

elastostatic force balance equation for bent beam

(Fourth-order differential equations are characteristic of elasticity.)

Equation (11.45) can be solved subject to four appropriate boundary conditions. However, before we solve it, notice that *for a beam of a fixed length ℓ , the deflection η is inversely proportional to the flexural rigidity*. Let us give a simple example of this scaling. Floors in U.S. homes are conventionally supported by wooden joists of 2" by 6" lumber with the 6" side vertical. Suppose an inept carpenter installed the joists with the 6" side horizontal. The flexural rigidity of the joist would be reduced by a factor 9, and the center of the floor would be expected to sag 9 times as much as if the joists had been properly installed—a potentially catastrophic error.

Also, before solving Eq. (11.45), let us examine the approximations that we have made. First, we have assumed that the sag is small compared with the length of the beam, when making the small-angle approximation in Eq. (11.40a); we have also assumed the beam's radius of curvature is large compared to its length, when treating

our slightly curved coordinates as Cartesian.⁷ These assumptions will usually be valid, but are not so for the elastica studied in Ex. 11.13. Second, by using the method of moments rather than solving for the complete local stress tensor field, we have ignored the effects of some components of the stress tensor. In particular, when evaluating the bending torque [Eq. (11.41c)] we have ignored the effect of the T_{zx} component of the stress tensor. This is $O(h/\ell)T_{zx}$, and so our equations can only be accurate for fairly slender beams. Third, the extension above the neutral surface and the compression below the neutral surface lead to changes in the cross sectional shape of the beam. The fractional error here is of order the longitudinal shear, which is small for real materials.

The solution to Eq. (11.45) is a fourth-order polynomial with four unknown constants, to be set by boundary conditions. In this problem, the beam is held horizontal at the fixed end, so that $\eta(0) = \eta'(0) = 0$, where the prime denotes d/dx . At the free end, T_{zx} and T_{xx} must vanish, so the shear force S must vanish, whence $\eta'''(\ell) = 0$ [Eq. (11.41a)]; the bending torque M [Eq. (11.41c)] must also vanish, whence [by Eq. (11.42)] $\int S dx \propto \eta''(\ell) = 0$. By imposing these four boundary conditions $\eta(0) = \eta'(0) = \eta''(\ell) = \eta'''(\ell) = 0$ on the solution of Eq. (11.45), we obtain for the beam shape

$$\eta(x) = \frac{W}{D} \left(\frac{1}{4}\ell^2 x^2 - \frac{1}{6}\ell x^3 + \frac{1}{24}x^4 \right). \quad (11.46a)$$

Therefore, the end of the beam sags by

$$\eta(\ell) = \frac{W\ell^4}{8D}. \quad (11.46b)$$

Problems in which the beam rests on supports rather than being clamped can be solved in a similar manner. The boundary conditions will be altered, but the differential equation (11.45) will be unchanged.

Now suppose that we have a cantilever bridge of constant vertical thickness h and total span $2\ell \sim 100$ m made of material with density $\rho \sim 8 \times 10^3$ kg m⁻³ (e.g., steel) and Young's modulus $E \sim 100$ GPa. Suppose further that we want the center of the bridge to sag by no more than $\eta \sim 1$ m. According to Eq. (11.46b), the thickness of the beam must satisfy

$$h \gtrsim \left(\frac{3\rho g \ell^4}{2E\eta} \right)^{1/2} \sim 2.8 \text{ m}. \quad (11.47)$$

This estimate makes no allowance for all the extra strengthening and support present in real structures (e.g., via trusses and cables), and so it is an overestimate.

7. In more technical language, when neglecting the connection-coefficient terms discussed in the previous footnote.

displacement of a clamped cantilever

Exercise 11.9 *Derivation: Sag in a Cantilever*

- (a) Verify Eqs. (11.46) for the sag in a horizontal beam clamped at one end and allowed to hang freely at the other end.
- (b) Now consider a similar beam with constant cross section and loaded with weights, so that the total weight per unit length is $W(x)$. What is the sag of the free end, expressed as an integral over $W(x)$, weighted by an appropriate Green's function?

Exercise 11.10 *Example: Microcantilever*

A microcantilever, fabricated from a single crystal of silicon, is being used to test the inverse square law of gravity on micron scales (Weld et al., 2008). It is clamped horizontally at one end, and its horizontal length is $\ell = 300 \mu\text{m}$, its horizontal width is $w = 12 \mu\text{m}$, and its vertical height is $h = 1 \mu\text{m}$. (The density and Young's modulus for silicon are $\rho = 2,000 \text{ kg m}^{-3}$ and $E = 100 \text{ GPa}$, respectively.) The cantilever is loaded at its free end with a $m = 10 \mu\text{g}$ gold mass.

- (a) Show that the static deflection of the end of the cantilever is $\eta(\ell) = mg\ell^3/(3D) = 9 \mu\text{m}$, where $g = 10 \text{ m s}^{-2}$ is the acceleration due to gravity. Explain why it is permissible to ignore the weight of the cantilever.
- (b) Next suppose the mass is displaced slightly vertically and then released. Show that the natural frequency of oscillation of the cantilever is $f = 1/(2\pi)\sqrt{g/\eta(\ell)} \simeq 170 \text{ Hz}$.
- (c) A second, similar gold mass is placed $100 \mu\text{m}$ away from the first. Estimate roughly the Newtonian gravitational attraction between these two masses, and compare with the attraction of Earth. Suggest a method that exploits the natural oscillation of the cantilever to measure the tiny gravitational attraction between the two gold masses.

The motivation for developing this technique was to seek departures from Newton's inverse-square law of gravitation on \sim micron scales, which had been predicted if our universe is a membrane ("brane") in a higher-dimensional space ("bulk") with at least one macroscopic extra dimension. No such departures have been found as of 2016.

Exercise 11.11 *Example: Foucault Pendulum*

In any high-precision Foucault pendulum, it is important that the pendular restoring force be isotropic, since anisotropy will make the swinging period different in different planes and thereby cause precession of the plane of swing.

- (a) Consider a pendulum of mass m and length ℓ suspended (as shown in Fig. 11.9) by a rectangular wire with thickness h in the plane of the bend (X - Z plane) and thickness w orthogonal to that plane (Y direction). Explain why the force that the wire exerts on the mass is approximately $-\mathbf{F} = -(mg \cos \theta_o + m\ell\dot{\theta}_o^2)\mathbf{e}_x$, where g is the acceleration of gravity, θ_o is defined in the figure, and $\dot{\theta}_o$ is the time derivative of θ_o due to the swinging of the pendulum. In the second term we have

FIGURE 11.9 Foucault pendulum.

assumed that the wire is long compared to its region of bend. Express the second term in terms of the amplitude of swing θ_o^{\max} , and show that for small amplitudes $\theta_o^{\max} \ll 1$, $\mathbf{F} \simeq -mg\mathbf{e}_x$. Use this approximation in the subsequent parts.

- (b) Assuming that all along the wire, its angle $\theta(x)$ to the vertical is small, $\theta \ll 1$, show that

$$\theta(x) = \theta_o(1 - e^{-x/\lambda}), \quad (11.48a)$$

where λ (not to be confused with the second Lamé coefficient) is

$$\lambda = \frac{h}{(12\epsilon)^{1/2}}, \quad (11.48b)$$

$\epsilon = \xi_{x,x}$ is the longitudinal strain in the wire, and h is the wire's thickness in the plane of its bend. [Hint: The solution to Ex. 11.9 might be helpful.] Note that the bending of the wire is concentrated near the support, so this is where dissipation will be most important and where most of the suspension's thermal noise will arise (cf. Sec. 6.8 for discussion of thermal noise).

- (c) Hence show that the shape of the wire is given in terms of Cartesian coordinates by

$$Z = [X - \lambda(1 - e^{-X/\lambda})]\theta_o \quad (11.48c)$$

to leading order in λ , and that the pendulum period is

$$P = 2\pi \left(\frac{\ell - \lambda}{g} \right)^{1/2}. \quad (11.48d)$$

- (d) Finally, show that the pendulum periods when swinging along \mathbf{e}_x and \mathbf{e}_y differ by

$$\frac{\delta P}{P} = \left(\frac{h - w}{\ell} \right) \left(\frac{1}{48\epsilon} \right)^{1/2}. \quad (11.48e)$$

From Eq. (11.48e) one can determine how accurately the two thicknesses h and w must be equal to achieve a desired degree of isotropy in the period. A similar analysis can be carried out for the more realistic case of a slightly elliptical wire.

Exercise 11.12 *Example: DNA Molecule—Bending, Stretching, Young’s Modulus, and Yield Point*

A DNA molecule consists of two long strands wound around each other as a helix, forming a cylinder with radius $a \simeq 1$ nm. In this exercise, we explore three ways of measuring the molecule’s Young’s modulus E . For background and further details, see Marko and Cocco (2003) and Nelson (2008, Chap. 9).

- (a) Show that if a segment of DNA with length ℓ is bent into a segment of a circle with radius R , its elastic energy is $E_{\text{el}} = D\ell/(2R^2)$, where $D = (\pi/4)a^4E$ is the molecule’s flexural rigidity.
- (b) Biophysicists define the DNA’s *persistence length* ℓ_p as that length which, when bent through an angle of 90° , has elastic energy $E_{\text{el}} = k_B T$, where k_B is Boltzmann’s constant and T is the temperature of the molecule’s environment. Show that $\ell_p \simeq D/(k_B T)$. Explain why, in a thermalized environment, segments much shorter than ℓ_p will be more or less straight, and segments with length $\sim \ell_p$ will be randomly bent through angles of order 90° .
- (c) Explain why a DNA molecule with total length L will usually be found in a random coil with diameter $d \simeq \ell_p \sqrt{L/\ell_p} = \sqrt{L\ell_p}$. Observations at room temperature with $L \simeq 17 \mu\text{m}$ reveal that $d \simeq 1 \mu\text{m}$. From this show that the persistence length is $\ell_p \simeq 50$ nm at room temperature, and thence evaluate the molecule’s flexural rigidity and from it, show that the molecule’s Young’s modulus is $E \simeq 0.3$ GPa; cf. Table 11.1.
- (d) When the ends of a DNA molecule are attached to glass beads and the beads are pulled apart with a gradually increasing force F , the molecule begins to uncoil, just like rubber. To understand this semiquantitatively, think of the molecule as like a chain made of N links, each with length ℓ_p , whose interfaces can bend freely. If the force acts along the z direction, explain why the probability that any chosen link will make an angle θ to the z axis is $dP/d \cos \theta \propto \exp[+F\ell_p \cos \theta/(k_B T)]$. [Hint: This is analogous to the probability $dP/dV \propto \exp[-PV/(k_B T)]$ for the volume V of a system in contact with a bath that has pressure P and temperature T [Eq. (5.49)]; see also the discussion preceding Eq. (11.56).] Infer that when the force is F , the molecule’s length along the force’s direction is $\bar{L} \simeq L(\coth \alpha - 1/\alpha)$, where $\alpha = F\ell_p/(k_B T)$ and $L = N\ell_p$ is the length of the uncoiled molecule. Infer, further, that for $\alpha \ll 1$ (i.e., $F \ll k_B T/\ell_p \sim 0.1$ pN), our model predicts $\bar{L} \simeq \alpha L/3$, i.e. a linear force-length relation $F = (3k_B T/\ell_p)\bar{L}/L$, with a strongly temperature dependent spring constant, $3k_B T/\ell_p \propto T^2$. The measured value of this spring constant, at room temperature, is about 0.13 pN (Fig. 9.5 of Nelson, 2008). From this infer a value 0.5 GPa for the molecule’s Young’s modulus. This agrees surprisingly well with the 0.3 GPa deduced in part (c), given the crudeness of the jointed chain model.
- (e) Show that when $F \gg k_B T/\ell_p \sim 0.1$ pN, our crude model predicts (correctly) that the molecule is stretched to its full length $L = N\ell_p$. At this point, its true

elasticity should take over and allow genuine stretching. That true elasticity turns out to dominate only for forces $\gtrsim 10$ pN. [For details of what happens between 0.1 and 10 pN, see, e.g., Nelson (2008), Secs. 9.1–9.4.] For a force between ~ 10 and ~ 80 pN, the molecule is measured to obey Hooke's law, with a Young's modulus $E \simeq 0.3$ GPa that agrees with the value inferred in part (c) from its random-coil diameter. When the applied force reaches $\simeq 65$ pN, the molecule's double helix suddenly stretches greatly with small increases of force, changing its structure, so this is the molecule's yield point. Show that the strain at this yield point is $\Delta\ell/\ell \sim 0.1$; cf. Table 11.1.

Exercise 11.13 **Example: *Elastica*

Consider a slender wire of rectangular cross section with horizontal thickness h and vertical thickness w that is resting on a horizontal surface, so gravity is unimportant. Let the wire be bent in the horizontal plane as a result of equal and opposite forces F that act at its ends; Fig. 11.10. The various shapes the wire can assume are called *elastica*; they were first computed by Euler in 1744 and are discussed in Love (1927, pp. 401–404). The differential equation that governs the wire's shape is similar to that for the cantilever [Eq. (11.45)], with the simplification that the wire's weight does not enter the problem and the complication that the wire is long enough to deform through large angles.

It is convenient (as in the cantilever problem, Fig. 11.8) to introduce curvilinear coordinates with coordinate x measuring distance along the neutral surface, z measuring distance orthogonal to x in the plane of the bend (horizontal plane), and y measured perpendicular to the bending plane (vertically). The unit vectors along the x , y , and z directions are \mathbf{e}_x , \mathbf{e}_y , \mathbf{e}_z (Fig. 11.10). Let $\theta(x)$ be the angle between \mathbf{e}_x and the applied force \mathbf{F} ; $\theta(x)$ is determined, of course, by force and torque balance.

(a) Show that force balance along the x and z directions implies

$$F \cos \theta = \int T_{xx} dy dz, \quad F \sin \theta = \int T_{zx} dy dz \equiv S. \quad (11.49a)$$

(b) Show that torque balance for a short segment of wire implies

$$S = \frac{dM}{dx}, \quad (11.49b)$$

where $M(x) \equiv \int z T_{xx} dy dz$ is the bending torque.

(c) Show that the stress-strain relation in the wire implies

$$M = -D \frac{d\theta}{dx}, \quad (11.49c)$$

where $D = Ewh^3/12$ is the flexural rigidity [Eq. (11.41b)].

elastica

FIGURE 11.10 Elastica. (a) A bent wire is in elastostatic equilibrium under the action of equal and opposite forces applied at its two ends. x measures distance along the neutral surface; z measures distance orthogonal to the wire in the plane of the bend. (b)–(d) Examples of the resulting shapes.

- (d) From the relations in parts (a)–(c), derive the following differential equation for the shape of the wire:

$$\boxed{\frac{d^2\theta}{dx^2} = -\frac{F \sin \theta}{D}}. \quad (11.49d)$$

This is the same equation as describes the motion of a simple pendulum!

- (e) For Track-Two readers who have studied Sec. 11.8: Go back through your analysis and identify any place that connection coefficients would enter into a more careful computation, and explain why the connection-coefficient terms are negligible.
- (f) Find one nontrivial solution of the elastica equation (11.49d) either analytically using elliptic integrals or numerically. (The general solution can be expressed in terms of elliptic integrals.)
- (g) Solve analytically or numerically for the shape adopted by the wire corresponding to your solution in part (f), in terms of precisely Cartesian coordinates (X , Z) in the bending (horizontal) plane. Hint: Express the curvature of the wire, $1/\mathcal{R} = d\theta/dx$, as

$$\frac{d\theta}{dx} = -\frac{d^2X}{dZ^2} \left[1 + \left(\frac{dX}{dZ} \right)^2 \right]^{-3/2}. \quad (11.49e)$$

- (h) Obtain a uniform piece of wire and adjust the force \mathbf{F} to compare your answer with experiment.

11.6 Buckling and Bifurcation of Equilibria

So far, we have considered stable elastostatic equilibria and have implicitly assumed that the only reason for failure of a material is exceeding the yield limit. However, anyone who has built a house of cards knows that mechanical equilibria can be unstable, with startling consequences. In this section, we explore a specific, important example of a mechanical instability: *buckling*—the theory of which was developed long ago, in 1744 by Leonard Euler.

A tragic example of buckling was the collapse of the World Trade Center's Twin Towers on September 11, 2001. We discuss it near the end of this section, after first developing the theory in the context of a much simpler and cleaner example.

11.6.1 Elementary Theory of Buckling and Bifurcation

buckling

Take a new playing card and squeeze it between your finger and thumb (Fig. 11.11). When you squeeze gently, the card remains flat. But when you gradually increase the compressive force F past a critical value F_{crit} , the card suddenly buckles (i.e., bends), and the curvature of the bend then increases rather rapidly with increasing applied force.

To understand quantitatively the sudden onset of buckling, we derive an eigen-equation for the transverse displacement η as a function of distance x from one end of the card. (Although the card is effectively 2-dimensional, it has translation symmetry along its transverse dimension, so we can use the 1-dimensional equations of Sec. 11.5.) We suppose that the ends are free to pivot but not move transversely, so

$$\eta(0) = \eta(\ell) = 0. \quad (11.50)$$

For small displacements, the bending torque of our dimensionally reduced 1-dimensional theory is [Eq. (11.41c)]

FIGURE 11.11 A playing card of length ℓ , width w , and thickness h is subjected to a compressive force F applied at both ends. The ends of the card are free to pivot.

$$M(x) = -D \frac{d^2 \eta}{dx^2}, \quad (11.51)$$

where $D = wh^3E/12$ is the flexural rigidity [Eq. (11.41b)]. As the card is very light (negligible gravity), the total torque around location x , acting on a section of the card from x to one end, is the bending torque $M(x)$ acting at x plus the torque $-F\eta(x)$ associated with the applied force. This sum must vanish:

$$D \frac{d^2 \eta}{dx^2} + F\eta = 0. \quad (11.52)$$

The eigensolutions of Eq. (11.52) satisfying boundary conditions (11.50) are

$$\eta = \eta_0 \sin kx, \quad (11.53a)$$

with eigenvalues

$$k = \left(\frac{F}{D} \right)^{1/2} = \frac{n\pi}{\ell} \quad \text{for nonnegative integers } n. \quad (11.53b)$$

Therefore, there is a critical force (first derived by Leonhard Euler in 1744), given by

$$F_{\text{crit}} = \frac{\pi^2 D}{\ell^2} = \frac{\pi^2 wh^3 E}{12 \ell^2}. \quad (11.54)$$

critical force for buckling

When $F < F_{\text{crit}}$, there is no solution except $\eta = 0$ (an unbent card). When $F = F_{\text{crit}}$, the unbent card is still a solution, and there suddenly is the additional, arched solution (11.53) with $n = 1$, depicted in Fig. 11.11.

The linear approximation we have used cannot tell us the height η_0 of the arch as a function of F for $F \geq F_{\text{crit}}$; it reports, incorrectly, that for $F = F_{\text{crit}}$ all arch heights are allowed, and that for $F > F_{\text{crit}}$ there is no solution with $n = 1$. However, when nonlinearities are taken into account (Ex. 11.14), the $n = 1$ solution continues to exist for $F > F_{\text{crit}}$, and the arch height η_0 is related to F by

$$F = F_{\text{crit}} \left\{ 1 + \frac{1}{2} \left(\frac{\pi \eta_0}{2\ell} \right)^2 + O \left[\left(\frac{\pi \eta_0}{2\ell} \right)^4 \right] \right\}. \quad (11.55)$$

The sudden appearance of the arched equilibrium state as F is increased through F_{crit} is called a *bifurcation of equilibria*. This bifurcation also shows up in the elastodynamics of the playing card, as we deduce in Sec. 12.3.5. When $F < F_{\text{crit}}$, small perturbations of the card's unbent shape oscillate stably. When $F = F_{\text{crit}}$, the unbent card is neutrally stable, and its zero-frequency motion leads the card from its unbent equilibrium state to its $n = 1$, arched equilibrium. When $F > F_{\text{crit}}$, the straight card is an unstable equilibrium: its $n = 1$ perturbations grow in time, driving the card toward the $n = 1$ arched equilibrium state.

A nice way of looking at this bifurcation is in terms of free energy. Consider candidate equilibrium states labeled by the height η_0 of their arch. For each value of η_0 , give the card (for concreteness) the $n = 1$ sine-wave shape $\eta = \eta_0 \sin(\pi x/\ell)$. Compute the total elastic energy $E(\eta_0)$ associated with the card's bending, and subtract off the

FIGURE 11.12 Representation of bifurcation by a potential energy function $\mathfrak{Q}(\eta_0)$. When the applied force is small ($F \leq F_{\text{crit}}$), there is only one stable equilibrium. As the applied force F is increased, the bottom of the potential well flattens, and eventually (for $F > F_{\text{crit}}$) the number of equilibria increases from one to three, of which only two are stable.

work $F \delta X$ done on the card by the applied force F when the card arches from $\eta_0 = 0$ to height η_0 . [Here $\delta X(\eta_0)$ is the arch-induced decrease in straight-line separation between the card's ends.] The resulting quantity, $\mathfrak{Q}(\eta_0) = E - F \delta X$, is the card's *free energy*—analogous to the physical free energy $F = E - TS$ for a system in contact with a heat bath (Secs. 5.4.1 and 11.3.5), the enthalpic free energy when in contact with a pressure bath (Ex. 5.5h), and the Gibbs (chemical) free energy $G = E - TS + PV$ when in contact with a heat and pressure bath (Sec. 5.5). It is the relevant energy for analyzing the card's equilibrium and dynamics when the force F is continually being applied at the two ends. In Ex. 11.15 we deduce that this free energy is

free energy of a bent card or beam

$$\mathfrak{Q} = \left(\frac{\pi \eta_0}{2\ell} \right)^2 \ell \left[(F_{\text{crit}} - F) + \frac{1}{4} F_{\text{crit}} \left(\frac{\pi \eta_0}{2\ell} \right)^2 \right] + O \left[F_{\text{crit}} \ell \left(\frac{\pi \eta_0}{2\ell} \right)^6 \right], \quad (11.56)$$

which we depict in Fig. 11.12.

At small values of the compressive force $F < F_{\text{crit}}$, the free energy has only one minimum $\eta_0 = 0$ corresponding to a single stable equilibrium, the straight card. However, as the force is increased through F_{crit} , the potential minimum flattens out and then becomes a maximum flanked by two new minima (e.g., the curve $F = 1.2F_{\text{crit}}$). The maximum for $F > F_{\text{crit}}$ is the unstable, zero-displacement (straight-card) equilibrium, and the two minima are the stable, finite-amplitude equilibria with positive and negative η_0 given by Eq. (11.55).

This procedure of representing a continuous system with an infinite number of degrees of freedom by just one or a few coordinates and finding the equilibrium by minimizing a free energy is quite common and powerful.

Thus far, we have discussed only two of the card's equilibrium shapes (11.53): the straight shape $n = 0$ and the single-arch shape $n = 1$. If the card were constrained, by gentle, lateral stabilizing forces, to remain straight beyond $F = F_{\text{crit}}$, then at $F = n^2 F_{\text{crit}}$ for each $n = 2, 3, 4, \dots$, the n th-order perturbative mode, with

higher order equilibria

$\eta = \eta_0 \sin(n\pi x/\ell)$, would become unstable, and a new, stable equilibrium with this shape would bifurcate from the straight equilibrium. You can easily explore this for $n = 2$ using a new playing card.

These higher-order modes are rarely of practical importance. In the case of a beam with no lateral constraints, as F increases above F_{crit} , it will buckle into its single-arched shape. For beam dimensions commonly used in construction, a fairly modest further increase of F will bend it enough that its yield point and then rupture point are reached. To experience this yourself, take a thin meter stick, compress its ends between your two hands, and see what happens.

11.6.2 Collapse of the World Trade Center Buildings

11.6.2

Now we return to the example with which we began this section. On September 11, 2001, al-Qaeda operatives hijacked two Boeing 767 passenger airplanes and crashed them into the 110-story Twin Towers of the World Trade Center in New York City, triggering the towers' collapse a few hours later, with horrendous loss of life.

The weight of a tall building such as the towers is supported by vertical steel beams, called "columns." The longer the column is, the lower the weight it can support without buckling, since $F_{\text{crit}} = \pi^2 D/\ell^2 = \pi^2 EA(r_g/\ell)^2$, with A the beam's cross sectional area, r_g its radius of gyration along its bending direction, and ℓ its length [Eqs. (11.54) and (11.41b)].⁸ The column lengths are typically chosen such that the critical stress for buckling, $F_{\text{crit}}/A = E(\pi r_g/\ell)^2$, is roughly the same as the yield stress, $F_{\text{yield}} \simeq 0.003E$ (cf. Table 11.1), which means that the columns' *slenderness ratio* is $\ell/r_g \sim 50$. The columns are physically far longer than $50r_g$, but they are anchored to each other laterally every $\sim 50r_g$ by beams and girders in the floors, so their effective length for buckling is $\ell \sim 50r_g$. The columns' radii of gyration r_g are generally made large, without using more steel than needed to support the overhead weight, by making the columns hollow, or giving them H-shaped cross sections. In the Twin Towers, the thinnest beams had $r_g \sim 13$ cm, and they were anchored in every floor, with floor separations $\ell \simeq 3.8$ m, so their slenderness ratio was actually $\ell/r_g \simeq 30$.

According to a detailed investigation (NIST, 2005, especially Secs. 6.14.2 and 6.14.3), the crashing airplanes ignited fires in and near floors 93–99 of the North Tower and 78–83 of the South Tower, where the airplanes hit. The fires were most intense in the floors and around uninsulated central steel columns. The heated central columns lost their rigidity and began to sag, and trusses then transferred some of the weight above to the outer columns. In parallel, the heated floor structures began

description of failure modes

8. As noted in the discussion, after Eq. (11.41b), Ar_g^2 is really the second moment of the column's cross sectional area, along its direction of bend. If the column is supported at its ends against movement in both transverse directions, then the relevant second moment is the transverse tensor $\int x^i x^j dx dy$, and the direction of buckling (if it occurs) will be the eigendirection of this tensor that has the smallest eigenvalue (the column's narrowest direction).

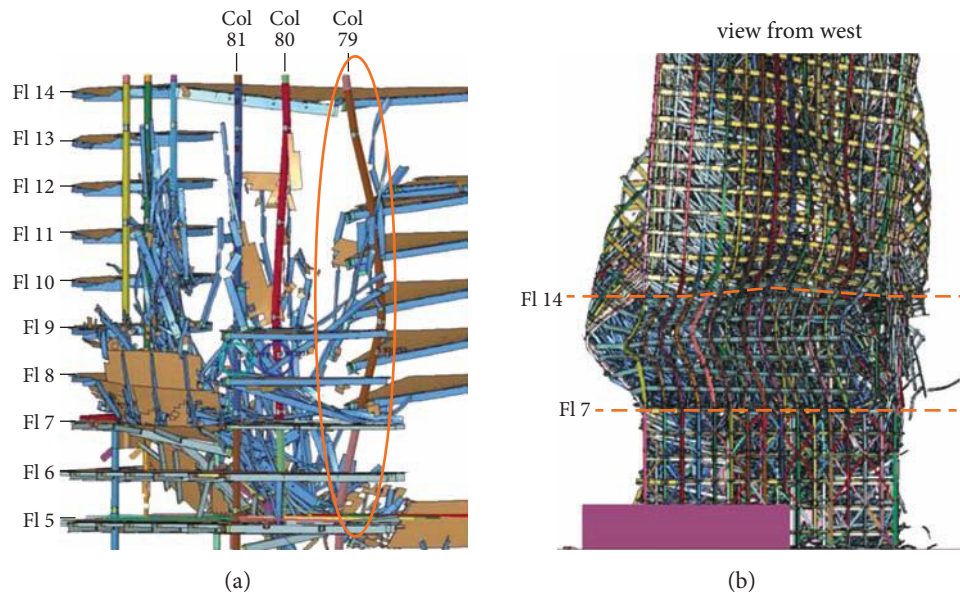

FIGURE 11.13 (a) The buckling of column 79 in building WTC7 at the World Trade Center, based on a finite-element simulation informed by all available observational data. (b) The subsequent buckling of the building's core. From NIST (2008).

to sag, pulling inward on the buildings' exterior steel columns, which bowed inward and then buckled, initiating the buildings' collapse. [This is a somewhat oversimplified description of a complex situation; for full complexities, see the report, NIST (2005).]

This column buckling was somewhat different from the buckling of a playing card because of the inward pull of the sagging floors. Much more like our playing-card buckle was the fate of an adjacent, 47-story building called WTC7. When the towers collapsed, they injected burning debris onto and into WTC7. About 7 hours later, fire-induced thermal expansion triggered a cascade of failures in floors 13–16, which left column 79 with little stabilizing lateral support, so its effective length ℓ was increased far beyond $50r_g$. It then quickly buckled (Fig. 11.13a) in much the same manner as our playing card, followed by column 80, then 81, and subsequently columns 77, 78, and 76 (NIST, 2008, especially Sec. 2.4). Within seconds, the building's entire core was buckling (Fig. 11.13b).

11.6.3 Buckling with Lateral Force; Connection to Catastrophe Theory

Returning to the taller Twin Towers, we can crudely augment the inward pull of the sagging floors into our free-energy description of buckling, by adding a term $-F_{\text{lat}}\eta_0$, which represents the energy inserted into a bent column by a lateral force F_{lat} when its center has been displaced laterally through the distance η_0 . Then the free energy

(11.56), made dimensionless and with its terms rearranged, takes the form

$$\varphi \equiv \frac{\mathfrak{V}}{F_{\text{crit}}\ell} = \frac{1}{4} \left(\frac{\pi \eta_0}{2\ell} \right)^4 - \frac{1}{2} \left(\frac{2(F - F_{\text{crit}})}{F_{\text{crit}}} \right) \left(\frac{\pi \eta_0}{2\ell} \right)^2 - \left(\frac{2F_{\text{lat}}}{\pi F_{\text{crit}}} \right) \left(\frac{\pi \eta_0}{2\ell} \right). \quad (11.57)$$

Notice that this equation has the canonical form $\varphi = \frac{1}{4}a^4 - \frac{1}{2}za^2 - xa$ for the potential that governs a cusp catastrophe, whose state variable is $a = \pi \eta_0 / (2\ell)$ and control variables are $z = 2(F - F_{\text{crit}}) / F_{\text{crit}}$ and $x = (2/\pi)F_{\text{lat}} / F_{\text{crit}}$; see Eq. (7.72).⁹ From the elementary mathematics of this catastrophe, as worked out in Sec. 7.5.1, we learn that although the lateral force F_{lat} will make the column bend, it will not induce a bifurcation of equilibria until the control-space cusp $x = \pm 2(z/3)^{3/2}$ is reached:

$$\frac{F_{\text{lat}}}{F_{\text{crit}}} = \pm \pi \left(\frac{2(F - F_{\text{crit}})}{3F_{\text{crit}}} \right)^{3/2}. \quad (11.58)$$

Notice that the lateral force F_{lat} actually delays the bifurcation to a higher vertical force, $F > F_{\text{crit}}$. However, this is not significant for the physical buckling, since the column in this case is bent from the outset, and as F_{lat} increases, it stops carrying its share of the building's weight and moves smoothly toward its yield point and rupture; Ex. 11.16.

interpretation in terms of catastrophe theory

11.6.4 Other Bifurcations: Venus Fly Trap, Whirling Shaft, Triaxial Stars, and Onset of Turbulence

11.6.4

This bifurcation of equilibria, associated with the buckling of a column, is just one of many bifurcations that occur in physical systems. Another is a buckling type bifurcation that occurs in the 2-dimensional leaves of the Venus fly trap plant; the plant uses the associated instability to snap together a pair of leaves in a small fraction of a second, thereby capturing insects for it to devour; see Fortere et al. (2005). Yet another is the onset of a lateral bend in a shaft (rod) that spins around its longitudinal axis (see Love, 1927, Sec. 286). This is called *whirling*; it is an issue in drive shafts for automobiles and propellers, and a variant of it occurs in spinning DNA molecules during replication—see Wolgemuth, Powers, and Goldstein (2000). One more example is the development of triaxiality in self-gravitating fluid masses (i.e., stars) when their rotational kinetic energy reaches a critical value, about 1/4 of their gravitational energy; see Chandrasekhar (1962). Bifurcations also play a major role in the onset of turbulence in fluids and in the route to chaos in other dynamical systems; we study turbulence and chaos in Sec. 15.6.

whirling shaft

9. The lateral force F_{lat} makes the bifurcation *structurally stable*, in the language of catastrophe theory (discussed near the end of Sec. 7.5) and thereby makes it describable by one of the generic catastrophes. Without F_{lat} , the bifurcation is not structurally stable.

For further details on the mathematics of bifurcations with emphasis on elastostatics and elastodynamics, see, for example, Marsden and Hughes (1986, Chap. 7). For details on buckling from an engineering viewpoint, see Ugural and Fenster (2012, Chap. 11).

EXERCISES

Exercise 11.14 *Derivation and Example: Bend as a Function of Applied Force*

Derive Eq. (11.55) relating the angle $\theta_o = (d\eta/dx)_{x=0} = k\eta_o = \pi\eta_o/\ell$ to the applied force F when the card has an $n = 1$, arched shape. [Hint: Consider the card as comprising many thin parallel wires and use the elastica differential equation $d^2\theta/dx^2 = -(F/D)\sin\theta$ [Eq. (11.49d)] for the angle between the card and the applied force at distance x from the card's end. The $\sin\theta$ becomes θ in the linear approximation used in the text; the nonlinearities embodied in the sine give rise to the desired relation. The following steps along the way toward a solution are mathematically the same as used when computing the period of a pendulum as a function of its amplitude of swing.]

(a) Derive the first integral of the elastica equation

$$(d\theta/dx)^2 = 2(F/D)(\cos\theta - \cos\theta_o), \quad (11.59)$$

where θ_o is an integration constant. Show that the boundary condition of no bending torque (no inflection of the card's shape) at the card ends implies $\theta = \theta_o$ at $x = 0$ and $x = \ell$; whence $\theta = 0$ at the card's center, $x = \ell/2$.

(b) Integrate the differential equation (11.59) to obtain

$$\frac{\ell}{2} = \sqrt{\frac{D}{2F}} \int_0^{\theta_o} \frac{d\theta}{\sqrt{\cos\theta - \cos\theta_o}}. \quad (11.60)$$

(c) Perform the change of variable $\sin(\theta/2) = \sin(\theta_o/2)\sin\phi$ and thereby bring Eq. (11.60) into the form

$$\ell = 2\sqrt{\frac{D}{F}} \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - \sin^2(\theta_o/2)\sin^2\phi}} = 2\sqrt{\frac{D}{F}} K[\sin^2(\theta_o/2)]. \quad (11.61)$$

Here $K(y)$ is the complete elliptic integral of the first type, with the parameterization used by Mathematica (which differs from that of many books).

(d) Expand Eq. (11.61) in powers of $\theta_o/2$ to obtain

$$F = F_{\text{crit}} \frac{4}{\pi^2} K^2[\sin^2(\theta_o/2)] = F_{\text{crit}} \left[1 + \frac{1}{2} \left(\frac{\theta_o/2}{2} \right)^2 + \dots \right], \quad (11.62)$$

from which deduce our desired result, Eq. (11.55).

Exercise 11.15 *Problem: Free Energy of a Bent, Compressed Beam*

Derive Eq. (11.56) for the free energy \mathfrak{F} of a beam that is compressed with a force F and has a critical compression $F_{\text{crit}} = \pi^2 D/\ell^2$, where D is its flexural rigidity. [Hint: It

must be that $\partial V/\partial\eta_0 = 0$ gives Eq. (11.55) for the beam's equilibrium bend amplitude η_0 as a function of $F - F_{\text{crit}}$. Use this to reduce the number of terms in $\mathfrak{V}(\eta_0)$ in Eq. (11.56) that you need to derive.]

Exercise 11.16 *Problem: Bent Beam with Lateral Force*

Explore numerically the free energy (11.57) of a bent beam with a compressive force F and lateral force F_{lat} . Examine how the extrema (equilibrium states) evolve as F and F_{lat} change, and deduce the physical consequences.

Exercise 11.17 ***Problem: Applications of Buckling—Mountains and Pipes*

Buckling plays a role in many natural and human-caused phenomena. Explore the following examples.

- (a) *Mountain building.* When two continental plates are in (very slow) collision, the compressional force near their interface drives their crustal rock to buckle upward, producing mountains. Estimate how high such mountains can be on Earth and on Mars, and compare your estimates with their actual heights. Read about such mountain building in books or on the web.
- (b) *Thermal expansion of pipes.* When a segment of pipe is heated (e.g., by the rising sun in the morning), it will expand. If its ends are held fixed, this can easily produce a longitudinal stress large enough to buckle the pipe. How would you deal with this in an oil pipeline on Earth's surface? In a long vacuum tube? Compare your answers with standard engineering solutions, which you can find in books or on the web.

Exercise 11.18 *Example: Allometry*

Allometry is the study of biological scaling laws that relate various features of an animal to its size or mass. One example concerns the ratio of the width to the length of leg bones. Explain why the width to the length of a thigh bone in a quadruped might scale as the square root of the stress that it has to support. Compare elephants with cats in this regard. (The density of bone is roughly 1.5 times that of water, and its Young's modulus is ~ 20 GPa.)

**11.7 Reducing the Elastostatic Equations to 2 Dimensions
for a Deformed Thin Plate: Stress Polishing a Telescope Mirror**

11.7

The world's largest optical telescopes (as of 2016) are the Gran Telescopio Canarias in the Canary Islands and the two Keck telescopes on Mauna Kea in Hawaii, which are all about 10 m in diameter. It is very difficult to support traditional, monolithic mirrors so that the mirror surfaces maintain their shape (their "figure") as the telescope slews, because they are so heavy, so for Keck a new method of fabrication was sought. The solution devised by Jerry Nelson and his colleagues was to construct the telescope out

stressed mirror polishing

of 36 separate hexagons, each 0.9 m on a side. However, this posed a second problem: how to grind each hexagon's reflecting surface to the required hyperboloidal shape. For this, a novel technique called *stressed mirror polishing* was developed. This technique relies on the fact that it is relatively easy to grind a surface to a spherical shape, but technically highly challenging to create a nonaxisymmetric shape. So during the grinding, stresses are applied around the boundary of the mirror to deform it, and a spherical surface is produced. The stresses are then removed, and the mirror springs into the desired nonspherical shape. Computing the necessary stresses is a problem in classical elasticity theory and, in fact, is a good example of a large number of applications where the elastic body can be approximated as a thin plate and its shape analyzed using elasticity equations that are reduced from 3 dimensions to 2 by the method of moments.

For stress polishing of mirrors, the applied stresses are so large that we can ignore gravitational forces (at least in our simplified treatment). We suppose that the hexagonal mirror has a uniform thickness h and idealize it as a circle of radius R , and we introduce Cartesian coordinates with (x, y) in the horizontal plane (the plane of the mirror before deformation and polishing begin), and z vertical. The mirror is deformed as a result of a net vertical force per unit area (pressure) $P(x, y)$. This pressure is applied at the lower surface when upward (positive) and the upper surface when downward (negative). In addition, there are shear forces and bending torques applied around the rim of the mirror.

As in our analysis of a cantilever in Sec. 11.5, we assume the existence of a neutral surface in the deformed mirror, where the horizontal strain vanishes, $T_{ab} = 0$. (Here and below we use letters from the early part of the Latin alphabet for horizontal components $x = x^1$ and $y = x^2$.) We denote the vertical displacement of the neutral surface by $\eta(x, y)$. By applying the method of moments to the 3-dimensional stress-balance equation $T_{jk,k} = 0$ in a manner similar to our cantilever analysis, we obtain the following 2-dimensional equation for the mirror's shape (Ex. 11.19):

$$\nabla^2(\nabla^2\eta) = P(x, y)/D. \tag{11.63a}$$

Here ∇^2 is the horizontal Laplacian: $\nabla^2\eta \equiv \eta_{,aa} = \eta_{,xx} + \eta_{,yy}$. Equation (11.63a) is the 2-dimensional analog of the equation $d^4\eta/dx^4 = W(x)/D$ for the shape of a cantilever on which a downward force per unit length $W(x)$ acts [Eq. (11.45)]. The 2-dimensional flexural rigidity that appears in Eq. (11.63a) is

$$D = \frac{Eh^3}{12(1 - \nu^2)}, \tag{11.63b}$$

where E is the mirror's Young's modulus, h is its thickness, and ν is its Poisson's ratio. The operator $\nabla^2\nabla^2$ acting on η in the shape equation (11.63a) is called the *biharmonic operator*; it also appears in 3-dimensional form in the biharmonic equation (11.34a)

elastostatic force balance for a bent plate on which a pressure P acts: shape equation

2-dimensional flexural rigidity

biharmonic operator

FIGURE 11.14 Schematic showing the mirror rim, a radial arm attached to it via a block, and a lever assembly used to apply shear forces and bending torques to the rim during stress polishing. (F_1 need not equal F_2 , as there is a pressure P applied to the back surface of the mirror and forces applied at 23 other points around its rim.) The shear force on the mirror rim is $S = F_2 - F_1$, and the bending torque is $M = r_2 F_2 - r_1 F_1$.

for the displacement inside a homogeneous, isotropic body to which surface stresses are applied.

The shape equation (11.63a) must be solved subject to boundary conditions around the mirror's rim: the applied shear forces and bending torques.

The individual Keck mirror segments were constructed out of a ceramic material with Young's modulus $E = 89 \text{ GPa}$ and Poisson's ratio $\nu = 0.24$ (similar to glass; cf. Table 11.1). A mechanical jig was constructed to apply the shear forces and bending torques at 24 uniformly spaced points around the rim of the mirror (Fig. 11.14). The maximum stress was applied for the six outermost mirrors and was $2.4 \times 10^6 \text{ N m}^{-2}$, 12% of the material's breaking tensile strength ($2 \times 10^7 \text{ N m}^{-2}$).

This stress polishing worked beautifully, and the Keck telescopes have become highly successful tools for astronomical research.

Exercise 11.19 ***Derivation and Example: Dimensionally Reduced Shape Equation for a Stressed Plate*

EXERCISES

Use the method of moments (Sec. 11.5) to derive the 2-dimensional shape equation (11.63a) for the stress-induced deformation of a thin plate, and expression (11.63b) for the 2-dimensional flexural rigidity. Here is a step-by-step guide, in case you want or need it.

- (a) Show on geometrical grounds that the in-plane strain is related to the vertical displacement by [cf. Eq. (11.40a)]

$$\xi_{a,b} = -z\eta_{,ab}. \quad (11.64a)$$

- (b) Derive an expression for the horizontal components of the stress, T_{ab} , in terms of double derivatives of the displacement function $\eta(x, y)$ [analog of $T_{xx} = -Ezd^2\eta/dx^2$, Eq. (11.40b), for a stressed rod]. This can be done (i) by arguing on physical grounds that the vertical component of stress, T_{zz} , is much smaller than the horizontal components and therefore can be approximated as zero [an

approximation to be checked in part (f)]; (ii) by expressing $T_{zz} = 0$ in terms of the strain and thence displacement and using Eqs. (11.39) to obtain

$$\Theta = - \left(\frac{1-2\nu}{1-\nu} \right) z \nabla^2 \eta, \quad (11.64b)$$

where ∇^2 is the horizontal Laplacian; and (iii) by then writing T_{ab} in terms of Θ and $\xi_{a,b}$ and combining with Eqs. (11.64a) and (11.64b) to get the desired equation:

$$T_{ab} = Ez \left[\frac{\nu}{(1-\nu^2)} \nabla^2 \eta \delta_{ab} + \frac{\eta_{,ab}}{(1+\nu)} \right]. \quad (11.64c)$$

(c) With the aid of Eq. (11.64c), write the horizontal force density in the form

$$f_a = -T_{ab,b} - T_{az,z} = - \frac{Ez}{1-\nu^2} \nabla^2 \eta_{,a} - T_{az,z} = 0. \quad (11.64d)$$

Then, as in the cantilever analysis [Eq. (11.40d)], reduce the dimensionality of this force equation by the method of moments. The zeroth moment (integral over z) vanishes. Why? Therefore, the lowest nonvanishing moment is the first (multiply f_a by z and integrate). Show that this gives

$$S_a \equiv \int T_{za} dz = D \nabla^2 \eta_{,a}, \quad (11.64e)$$

where D is the 2-dimensional flexural rigidity (11.63b). The quantity S_a is the vertical shear force per unit length acting perpendicular to a line in the mirror whose normal is in the direction a ; it is the 2-dimensional analog of a stressed rod's shear force S [Eq. (11.41a)].

(d) For physical insight into Eq. (11.64e), define the bending torque per unit length (bending torque density) as

$$M_{ab} \equiv \int z T_{ab} dz, \quad (11.64f)$$

and show with the aid of Eq. (11.64c) that (11.64e) is the *law of torque balance* $S_a = M_{ab,b}$ —the 2-dimensional analog of a stressed rod's $S = dM/dx$ [Eq. (11.42)].

(e) Compute the total vertical shear force acting on a small area of the plate as the line integral of S_a around its boundary, and by applying Gauss's theorem, deduce that the vertical shear force per unit area is $S_{a,a}$. Argue that this must be balanced by the net pressure P applied to the face of the plate, and thereby deduce the *law of vertical force balance*:

$$S_{a,a} = P. \quad (11.64g)$$

By combining this equation with the law of torque balance (11.64e), obtain the plate's bending equation $\nabla^2(\nabla^2 \eta) = P/D$ [Eq. (11.63a)—the final result we were seeking].

- (f) Use this bending equation to verify the approximation made in part (b) that T_{zz} is small compared to the horizontal stresses. Specifically, show that $T_{zz} \simeq P$ is $O(h/R)^2 T_{ab}$, where h is the plate thickness, and R is the plate radius.

Exercise 11.20 *Example: Paraboloidal Mirror*

Show how to construct a paraboloidal mirror of radius R and focal length f by stress polishing.

- (a) Adopt a strategy of polishing the stressed mirror into a segment of a sphere with radius of curvature equal to that of the desired paraboloid at its center, $r = 0$. By comparing the shape of the desired paraboloid to that of the sphere, show that the required vertical displacement of the stressed mirror during polishing is

$$\eta(r) = \frac{r^4}{64f^3}, \quad (11.64h)$$

where r is the radial coordinate, and we only retain terms of leading order.

- (b) Hence use Eq. (11.63a) to show that a uniform force per unit area

$$P = \frac{D}{f^3}, \quad (11.64i)$$

where D is the flexural rigidity, must be applied to the bottom of the mirror. (Ignore the weight of the mirror.)

- (c) Based on the results of part (b), show that if there are N equally spaced levers attached at the rim, the vertical force applied at each of them must be

$$F_z = \frac{\pi DR^2}{Nf^3}, \quad (11.64j)$$

and the applied bending torque must be

$$M = \frac{\pi DR^3}{2Nf^3}. \quad (11.64k)$$

- (d) Show that the radial displacement inside the mirror is

$$\zeta_r = -\frac{r^3 z}{16f^3}, \quad (11.64l)$$

where z is the vertical distance from the neutral surface, halfway through the mirror.

- (e) Hence evaluate the expansion Θ and the components of the shear tensor Σ , and show that the maximum stress in the mirror is

$$T_{\max} = \frac{(3 - 2\nu)R^2 h E}{32(1 - 2\nu)(1 + \nu)f^3}, \quad (11.64m)$$

where h is the mirror thickness. Comment on the limitations of this technique for making a thick, “fast” (i.e., $2R/f$ large) mirror.

11.8 Cylindrical and Spherical Coordinates: Connection Coefficients and Components of the Gradient of the Displacement Vector T2

orthonormal basis vectors of cylindrical or spherical coordinates

cylindrical coordinates

Thus far in our discussion of elasticity, we have restricted ourselves to Cartesian coordinates. However, many problems in elasticity are most efficiently solved using cylindrical or spherical coordinates, so in this section, we develop some mathematical tools for those coordinate systems. In doing so, we follow the vectorial conventions of standard texts on electrodynamics and quantum mechanics (e.g., Jackson, 1999; Cohen-Tannoudji, Diu, and Laloë, 1977). We introduce an *orthonormal* set of basis vectors associated with each of our curvilinear coordinate systems; the coordinate lines are orthogonal to one another, and the basis vectors have unit lengths and point along the coordinate lines. In our study of continuum mechanics (Part IV, Elasticity; Part V, Fluid Dynamics; and Part VI, Plasma Physics), we follow this practice. When studying General Relativity (Part VII), we introduce and use basis vectors that are *not* orthonormal.

Our notation for cylindrical coordinates is (ϖ, ϕ, z) ; ϖ (pronounced “pomega”) is distance from the z -axis, and ϕ is the angle around the z -axis:

$$\varpi = \sqrt{x^2 + y^2}, \quad \phi = \arctan(y/x). \quad (11.65a)$$

The unit basis vectors that point along the coordinate axes are denoted \mathbf{e}_ϖ , \mathbf{e}_ϕ , and \mathbf{e}_z , and are related to the Cartesian basis vectors by

$$\begin{aligned} \mathbf{e}_\varpi &= (x/\varpi)\mathbf{e}_x + (y/\varpi)\mathbf{e}_y, & \mathbf{e}_\phi &= -(y/\varpi)\mathbf{e}_x + (x/\varpi)\mathbf{e}_y, \\ \mathbf{e}_z &= \text{Cartesian } \mathbf{e}_z. \end{aligned} \quad (11.65b)$$

spherical coordinates

Our notation for spherical coordinates is (r, θ, ϕ) , with (as should be very familiar)

$$r = \sqrt{x^2 + y^2 + z^2}, \quad \theta = \arccos(z/r), \quad \phi = \arctan(y/x). \quad (11.66a)$$

The unit basis vectors associated with these coordinates are

$$\mathbf{e}_r = \frac{x}{r}\mathbf{e}_x + \frac{y}{r}\mathbf{e}_y + \frac{z}{r}\mathbf{e}_z, \quad \mathbf{e}_\theta = \frac{z}{r}\mathbf{e}_\varpi - \frac{\varpi}{r}\mathbf{e}_z, \quad \mathbf{e}_\phi = -\frac{y}{\varpi}\mathbf{e}_x + \frac{x}{\varpi}\mathbf{e}_y. \quad (11.66b)$$

Because our bases are orthonormal, the components of the metric of 3-dimensional space retain the Kronecker-delta values

$$\boxed{g_{jk} \equiv \mathbf{e}_j \cdot \mathbf{e}_k = \delta_{jk}}, \quad (11.67)$$

which permits us to keep all vector and tensor indices down, by contrast with space-time, where we must distinguish between up and down; cf. Sec. 2.5.¹⁰

10. Occasionally—e.g., in the useful equation $\epsilon_{ijm}\epsilon_{klm} = \delta_{kl}^{ij} \equiv \delta_k^i\delta_l^j - \delta_l^i\delta_k^j$ [Eq. (1.23)]—it is convenient to put some indices up. In our orthonormal basis, any component with an index up is equal to that same component with an index down: e.g., $\delta_k^i \equiv \delta_{ik}$.

In Jackson (1999), Cohen-Tannoudji, Diu, and Laloë (1977), and other standard texts, formulas are written down for the gradient and Laplacian of a scalar field, and the divergence and curl of a vector field, in cylindrical and spherical coordinates; one uses these formulas over and over again. In elasticity theory, we deal largely with second-rank tensors and will need formulas for their various derivatives in cylindrical and spherical coordinates. In this book we introduce a mathematical tool, *connection coefficients* Γ_{ijk} , by which those formulas can be derived when needed.

The connection coefficients quantify the turning of the orthonormal basis vectors as one moves from point to point in Euclidean 3-space: they tell us how the basis vectors at one point in space are *connected to* (related to) those at another point. More specifically, we define Γ_{ijk} by the two equivalent relations

$$\nabla_k \mathbf{e}_j = \Gamma_{ijk} \mathbf{e}_i; \quad \Gamma_{ijk} = \mathbf{e}_i \cdot (\nabla_k \mathbf{e}_j). \quad (11.68)$$

Here $\nabla_k \equiv \nabla_{\mathbf{e}_k}$ is the directional derivative along the orthonormal basis vector \mathbf{e}_k ; cf. Eq. (1.15a). Notice that (as is true quite generally; cf. Sec. 1.7) the differentiation index comes *last* on Γ ; and notice that the middle index of Γ names the basis vector that is differentiated. Because our basis is orthonormal, it must be that $\nabla_k(\mathbf{e}_i \cdot \mathbf{e}_j) = 0$. Expanding this expression out using the standard rule for differentiating products, we obtain $\mathbf{e}_j \cdot (\nabla_k \mathbf{e}_i) + \mathbf{e}_i \cdot (\nabla_k \mathbf{e}_j) = 0$. Then invoking the definition (11.68) of the connection coefficients, we see that Γ_{ijk} is antisymmetric on its first two indices:

$$\Gamma_{ijk} = -\Gamma_{jik}. \quad (11.69)$$

In Part VII, when we use nonorthonormal bases, this antisymmetry will break down.

It is straightforward to compute the connection coefficients for cylindrical and spherical coordinates from (i) the definition (11.68); (ii) expressions (11.65b) and (11.66b) for the cylindrical and spherical basis vectors in terms of the Cartesian basis vectors; and (iii) the fact that *in Cartesian coordinates the connection coefficients vanish* (\mathbf{e}_x , \mathbf{e}_y , and \mathbf{e}_z do not rotate as one moves through Euclidean 3-space). One can also deduce the cylindrical and spherical connection coefficients by drawing pictures of the basis vectors and observing how they change from point to point. As an example, for cylindrical coordinates we see from Fig. 11.15 that $\nabla_\phi \mathbf{e}_\varpi = \mathbf{e}_\phi / \varpi$. A similar pictorial calculation (which the reader is encouraged to do) reveals that $\nabla_\phi \mathbf{e}_\phi = -\mathbf{e}_\varpi / \varpi$. All other derivatives vanish. By comparing with Eq. (11.68), we see that *the only nonzero connection coefficients in cylindrical coordinates are*

$$\Gamma_{\varpi\phi\phi} = -\frac{1}{\varpi}, \quad \Gamma_{\phi\varpi\phi} = \frac{1}{\varpi}, \quad (11.70)$$

connection coefficients

connection coefficients for orthonormal bases of cylindrical and spherical coordinates

FIGURE 11.15 Pictorial evaluation of $\Gamma_{\phi\varpi\phi}$. In the rightmost assemblage of vectors we compute $\nabla_{\phi}\mathbf{e}_{\varpi}$ as follows. We draw the vector to be differentiated, \mathbf{e}_{ϖ} , at the tail of \mathbf{e}_{ϕ} (the vector along which we differentiate) and also at its head. We then subtract \mathbf{e}_{ϖ} at the head from that at the tail; this difference is $\nabla_{\phi}\mathbf{e}_{\varpi}$. It obviously points in the \mathbf{e}_{ϕ} direction. When we perform the same calculation at a radius ϖ that is smaller by a factor 2 (left assemblage of vectors), we obtain a result, $\nabla_{\phi}\mathbf{e}_{\varpi}$, that is twice as large. Therefore, the length of this vector must scale as $1/\varpi$. By looking quantitatively at the length at some chosen radius ϖ , one can see that the multiplicative coefficient is unity: $\nabla_{\phi}\mathbf{e}_{\varpi} = \mathbf{e}_{\phi}/\varpi$. Comparing with Eq. (11.68), we deduce that $\Gamma_{\phi\varpi\phi} = 1/\varpi$.

which have the required antisymmetry [Eq. (11.69)]. Likewise, for spherical coordinates (Ex. 11.22), we have

$$\Gamma_{\theta r\theta} = \Gamma_{\phi r\phi} = -\Gamma_{r\theta\theta} = -\Gamma_{r\phi\phi} = \frac{1}{r}, \quad \Gamma_{\phi\theta\phi} = -\Gamma_{\theta\phi\phi} = \frac{\cot\theta}{r}. \quad (11.71)$$

These connection coefficients are the keys to differentiating vectors and tensors. Consider the gradient of the displacement, $\mathbf{W} = \nabla\xi$. Applying the product rule for differentiation, we obtain

$$\nabla_k(\xi_j\mathbf{e}_j) = (\nabla_k\xi_j)\mathbf{e}_j + \xi_j(\nabla_k\mathbf{e}_j) = \xi_{j,k}\mathbf{e}_j + \xi_j\Gamma_{ljk}\mathbf{e}_l. \quad (11.72)$$

directional derivative
along basis vector

Here the comma denotes the directional derivative, along a basis vector, of the components treated as scalar fields. For example, in cylindrical coordinates we have

$$\xi_{i,\varpi} = \frac{\partial\xi_i}{\partial\varpi}, \quad \xi_{i,\phi} = \frac{1}{\varpi}\frac{\partial\xi_i}{\partial\phi}, \quad \xi_{i,z} = \frac{\partial\xi_i}{\partial z}; \quad (11.73)$$

and in spherical coordinates we have

$$\xi_{i,r} = \frac{\partial\xi_i}{\partial r}, \quad \xi_{i,\theta} = \frac{1}{r}\frac{\partial\xi_i}{\partial\theta}, \quad \xi_{i,\phi} = \frac{1}{r\sin\theta}\frac{\partial\xi_i}{\partial\phi}. \quad (11.74)$$

Taking the i th component of Eq. (11.72) we obtain

$$W_{ik} = \xi_{i;k} = \xi_{i,k} + \Gamma_{ijk}\xi_j. \quad (11.75)$$

Here $\xi_{i;k}$ are the nine components of the gradient of the vector field $\xi(\mathbf{x})$.

We can use Eq. (11.75) to evaluate the expansion $\Theta = \text{Tr } \mathbf{W} = \nabla \cdot \xi$. Using Eqs. (11.70) and (11.71), we obtain

$$\begin{aligned} \Theta = \nabla \cdot \xi &= \frac{\partial \xi_\varpi}{\partial \varpi} + \frac{1}{\varpi} \frac{\partial \xi_\phi}{\partial \phi} + \frac{\partial \xi_z}{\partial z} + \frac{\xi_\varpi}{\varpi} \\ &= \frac{1}{\varpi} \frac{\partial}{\partial \varpi} (\varpi \xi_\varpi) + \frac{1}{\varpi} \frac{\partial \xi_\phi}{\partial \phi} + \frac{\partial \xi_z}{\partial z} \end{aligned} \quad (11.76)$$

in cylindrical coordinates and

$$\begin{aligned} \Theta = \nabla \cdot \xi &= \frac{\partial \xi_r}{\partial r} + \frac{1}{r} \frac{\partial \xi_\theta}{\partial \theta} + \frac{1}{r \sin \theta} \frac{\partial \xi_\phi}{\partial \phi} + \frac{2\xi_r}{r} + \frac{\cot \theta \xi_\theta}{r} \\ &= \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \xi_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (\sin \theta \xi_\theta) + \frac{1}{r \sin \theta} \frac{\partial \xi_\phi}{\partial \phi} \end{aligned} \quad (11.77)$$

in spherical coordinates, in agreement with formulas in standard textbooks, such as the flyleaf of Jackson (1999).

The components of the rotation are most easily deduced using $R_{ij} = -\epsilon_{ijk}\phi_k$ with $\phi = \frac{1}{2}\nabla \times \xi$, and the standard expressions for the curl in cylindrical and spherical coordinates (Jackson, 1999). Since the rotation does not enter into elasticity theory in a significant way, we refrain from writing down the results. The components of the shear are computed in Box 11.4.

By a computation analogous to Eq. (11.72), we can construct an expression for the gradient of a tensor of any rank. For a second-rank tensor $\mathbf{T} = T_{ij}\mathbf{e}_i \otimes \mathbf{e}_j$ we obtain (Ex. 11.21)

$$T_{ij;k} = T_{ij,k} + \Gamma_{ilk}T_{lj} + \Gamma_{jlk}T_{il}. \quad (11.78)$$

Equation (11.78) for the components of the gradient can be understood as follows. In cylindrical or spherical coordinates, the components T_{ij} can change from point to point as a result of two things: a change of the tensor \mathbf{T} or the turning of the basis vectors. The two connection coefficient terms in Eq. (11.78) remove the effects of the basis turning, leaving in $T_{ij;k}$ only the influence of the change of \mathbf{T} itself. There are two correction terms corresponding to the two slots (indices) of \mathbf{T} ; the effects of basis turning on each slot get corrected one after another. If \mathbf{T} had had n slots, then there would have been n correction terms, each with the form of the two in Eq. (11.78).

These expressions for derivatives of tensors are not required for dealing with the vector fields of introductory electromagnetic theory or quantum theory, but they are essential for manipulating the tensor fields encountered in elasticity. As we shall see in Sec. 24.3, with one further generalization, we can go on to differentiate tensors in

components of gradient of a tensor

BOX 11.4. SHEAR TENSOR IN SPHERICAL AND CYLINDRICAL COORDINATES T2

Using our rules (11.75) for forming the gradient of a vector, we can derive a general expression for the shear tensor:

$$\begin{aligned}\Sigma_{ij} &= \frac{1}{2}(\xi_{i;j} + \xi_{j;i}) - \frac{1}{3}\delta_{ij}\xi_{k;k} \\ &= \frac{1}{2}(\xi_{i,j} + \xi_{j,i} + \Gamma_{ilj}\xi_l + \Gamma_{jli}\xi_l) - \frac{1}{3}\delta_{ij}(\xi_{k,k} + \Gamma_{klk}\xi_l).\end{aligned}\quad (1)$$

Evaluating this in cylindrical coordinates using the connection coefficients (11.70), we obtain

$$\begin{aligned}\Sigma_{\varpi\varpi} &= \frac{2}{3}\frac{\partial\xi_{\varpi}}{\partial\varpi} - \frac{1}{3}\frac{\xi_{\varpi}}{\varpi} - \frac{1}{3\varpi}\frac{\partial\xi_{\phi}}{\partial\phi} - \frac{1}{3}\frac{\partial\xi_z}{\partial z}, \\ \Sigma_{\phi\phi} &= \frac{2}{3\varpi}\frac{\partial\xi_{\phi}}{\partial\phi} + \frac{2}{3}\frac{\xi_{\varpi}}{\varpi} - \frac{1}{3}\frac{\partial\xi_{\varpi}}{\partial\varpi} - \frac{1}{3}\frac{\partial\xi_z}{\partial z}, \\ \Sigma_{zz} &= \frac{2}{3}\frac{\partial\xi_z}{\partial z} - \frac{1}{3}\frac{\partial\xi_{\varpi}}{\partial\varpi} - \frac{1}{3}\frac{\xi_{\varpi}}{\varpi} - \frac{1}{3\varpi}\frac{\partial\xi_{\phi}}{\partial\phi}, \\ \Sigma_{\phi z} &= \Sigma_{z\phi} = \frac{1}{2\varpi}\frac{\partial\xi_z}{\partial\phi} + \frac{1}{2}\frac{\partial\xi_{\phi}}{\partial z}, \\ \Sigma_{z\varpi} &= \Sigma_{\varpi z} = \frac{1}{2}\frac{\partial\xi_{\varpi}}{\partial z} + \frac{1}{2}\frac{\partial\xi_z}{\partial\varpi}, \\ \Sigma_{\varpi\phi} &= \Sigma_{\phi\varpi} = \frac{1}{2}\frac{\partial\xi_{\phi}}{\partial\varpi} - \frac{\xi_{\phi}}{2\varpi} + \frac{1}{2\varpi}\frac{\partial\xi_{\varpi}}{\partial\phi}.\end{aligned}\quad (2)$$

Likewise, in spherical coordinates using the connection coefficients (11.71), we obtain

$$\begin{aligned}\Sigma_{rr} &= \frac{2}{3}\frac{\partial\xi_r}{\partial r} - \frac{2}{3r}\xi_r - \frac{\cot\theta}{3r}\xi_{\theta} - \frac{1}{3r}\frac{\partial\xi_{\theta}}{\partial\theta} - \frac{1}{3r\sin\theta}\frac{\partial\xi_{\phi}}{\partial\phi}, \\ \Sigma_{\theta\theta} &= \frac{2}{3r}\frac{\partial\xi_{\theta}}{\partial\theta} + \frac{\xi_r}{3r} - \frac{1}{3}\frac{\partial\xi_r}{\partial r} - \frac{\cot\theta\xi_{\theta}}{3r} - \frac{1}{3r\sin\theta}\frac{\partial\xi_{\phi}}{\partial\phi}, \\ \Sigma_{\phi\phi} &= \frac{2}{3r\sin\theta}\frac{\partial\xi_{\phi}}{\partial\phi} + \frac{2\cot\theta\xi_{\theta}}{3r} + \frac{\xi_r}{3r} - \frac{1}{3}\frac{\partial\xi_r}{\partial r} - \frac{1}{3r}\frac{\partial\xi_{\theta}}{\partial\theta}, \\ \Sigma_{\theta\phi} &= \Sigma_{\phi\theta} = \frac{1}{2r}\frac{\partial\xi_{\phi}}{\partial\theta} - \frac{\cot\theta\xi_{\phi}}{2r} + \frac{1}{2r\sin\theta}\frac{\partial\xi_{\theta}}{\partial\phi}, \\ \Sigma_{\phi r} &= \Sigma_{r\phi} = \frac{1}{2r\sin\theta}\frac{\partial\xi_r}{\partial\phi} + \frac{1}{2}\frac{\partial\xi_{\phi}}{\partial r} - \frac{\xi_{\phi}}{2r}, \\ \Sigma_{r\theta} &= \Sigma_{\theta r} = \frac{1}{2}\frac{\partial\xi_{\theta}}{\partial r} - \frac{\xi_{\theta}}{2r} + \frac{1}{2r}\frac{\partial\xi_r}{\partial\theta}.\end{aligned}\quad (3)$$

any basis (orthonormal or nonorthonormal) in a curved spacetime, as is needed to perform calculations in general relativity.

Although the algebra of evaluating the components of derivatives such as in Eq. (11.78) in explicit form (e.g., in terms of $\{r, \theta, \phi\}$) can be long and tedious when done by hand, in the modern era of symbolic manipulation using computers (e.g., Mathematica, Matlab, or Maple), the algebra can be done quickly and accurately to obtain expressions such as Eqs. (3) of Box 11.4.

EXERCISES

Exercise 11.21 *Derivation and Practice: Gradient of a Second-Rank Tensor* T2

By a computation analogous to Eq. (11.72), derive Eq. (11.78) for the components of the gradient of a second-rank tensor in any orthonormal basis.

Exercise 11.22 *Derivation and Practice: Connection in Spherical Coordinates* T2

(a) By drawing pictures analogous to Fig. 11.15, show that

$$\nabla_{\phi} \mathbf{e}_r = \frac{1}{r} \mathbf{e}_{\phi}, \quad \nabla_{\theta} \mathbf{e}_r = \frac{1}{r} \mathbf{e}_{\theta}, \quad \nabla_{\phi} \mathbf{e}_{\theta} = \frac{\cot \theta}{r} \mathbf{e}_{\phi}. \quad (11.79)$$

(b) From these relations and antisymmetry on the first two indices [Eq. (11.69)], deduce the connection coefficients (11.71).

Exercise 11.23 *Derivation and Practice: Expansion in Cylindrical and Spherical Coordinates* T2

Derive Eqs. (11.76) and (11.77) for the divergence of the vector field ξ in cylindrical and spherical coordinates using the connection coefficients (11.70) and (11.71).

11.9 Solving the 3-Dimensional Navier-Cauchy Equation in Cylindrical Coordinates

11.9

11.9.1 Simple Methods: Pipe Fracture and Torsion Pendulum

11.9.1

As an example of an elastostatic problem with cylindrical symmetry, consider a cylindrical pipe that carries a high-pressure fluid (e.g., water, oil, natural gas); Fig. 11.16. How thick must the pipe's wall be to ensure that it will not burst due to the fluid's pressure? We sketch the solution, leaving the details to Ex. 11.24.

We suppose, for simplicity, that the pipe's length is held fixed by its support system: it does not lengthen or shorten when the fluid pressure is changed. Then by symmetry, the displacement field in the pipe wall is purely radial and depends only on radius: its only nonzero component is $\zeta_{\varpi}(\varpi)$. The radial dependence is governed by radial force balance,

$$f_{\varpi} = K \Theta_{;\varpi} + 2\mu \Sigma_{\varpi j;j} = 0 \quad (11.80)$$

[Eq. (11.30)].

FIGURE 11.16 A pipe whose wall has inner and outer radii ϖ_1 and ϖ_2 .

Because ξ_{ϖ} is independent of ϕ and z , the expansion [Eq. (11.76)] is given by

$$\Theta = \frac{d\xi_{\varpi}}{d\varpi} + \frac{\xi_{\varpi}}{\varpi}. \quad (11.81)$$

The second term in the radial force balance equation (11.80) is proportional to $\Sigma_{\varpi j;j}$ which—using Eq. (11.78) and noting that the only nonzero connection coefficients are $\Gamma_{\varpi\phi\phi} = -\Gamma_{\phi\varpi\phi} = -1/\varpi$ [Eq. (11.70)] and that symmetry requires the shear tensor to be diagonal—becomes

$$\Sigma_{\varpi j;j} = \Sigma_{\varpi\varpi,\varpi} + \Gamma_{\varpi\phi\phi}\Sigma_{\phi\phi} + \Gamma_{\phi\varpi\phi}\Sigma_{\varpi\varpi}. \quad (11.82)$$

Inserting the components of the shear tensor from Eqs. (2) of Box 11.4 and the values of the connection coefficients and comparing the result with expression (11.81) for the expansion, we obtain the remarkable result that $\Sigma_{\varpi j;j} = \frac{2}{3}\partial\Theta/\partial\varpi$. Inserting this into the radial force balance equation (11.80), we obtain

$$f_{\varpi} = \left(K + \frac{4\mu}{3}\right) \frac{d\Theta}{d\varpi} = 0. \quad (11.83)$$

Thus, inside the pipe wall, the expansion is independent of radius ϖ , and correspondingly, the radial displacement must have the form [cf. Eq. (11.81)]

$$\xi_{\varpi} = A\varpi + \frac{B}{\varpi} \quad (11.84)$$

for some constants A and B , whence $\Theta = 2A$ and $\Sigma_{\varpi\varpi} = \frac{1}{3}A - B/\varpi^2$. The values of A and B are fixed by the boundary conditions at the inner and outer faces of the pipe wall: $T_{\varpi\varpi} = P$ at $\varpi = \varpi_1$ (inner wall) and $T_{\varpi\varpi} = 0$ at $\varpi = \varpi_2$ (outer wall). Here P is the pressure of the fluid that the pipe carries, and we have neglected the atmosphere's pressure on the outer face by comparison. Evaluating $T_{\varpi\varpi} = -K\Theta - 2\mu\Sigma_{\varpi\varpi}$ and then imposing these boundary conditions, we obtain

$$A = \frac{P}{2(K + \mu/3)} \frac{\varpi_1^2}{(\varpi_2^2 - \varpi_1^2)}, \quad B = \frac{P}{2\mu} \frac{\varpi_1^2\varpi_2^2}{(\varpi_2^2 - \varpi_1^2)}. \quad (11.85)$$

The only nonvanishing components of the strain then work out to be

$$S_{\varpi\varpi} = \frac{\partial \xi_{\varpi}}{\partial \varpi} = A - \frac{B}{\varpi^2}, \quad S_{\phi\phi} = \frac{\xi_{\varpi}}{\varpi} = A + \frac{B}{\varpi^2}. \quad (11.86)$$

This strain is maximal at the inner wall of the pipe; expressing it in terms of the ratio $\zeta \equiv \varpi_2/\varpi_1$ of the outer to the inner pipe radius and using the values of $K = 180$ GPa and $\mu = 81$ GPa for steel, we bring this maximum strain into the form

$$S_{\varpi\varpi} \simeq -\frac{P}{\mu} \frac{5\zeta^2 - 2}{10(\zeta^2 - 1)}, \quad S_{\phi\phi} \simeq \frac{P}{\mu} \frac{5\zeta^2 + 2}{10(\zeta^2 - 1)}. \quad (11.87)$$

Note that $|S_{\phi\phi}| > |S_{\varpi\varpi}|$.

The pipe will fracture at a strain $\sim 10^{-3}$; for safety it is best to keep the actual strain smaller than this by an order of magnitude, $|S_{ij}| \lesssim 10^{-4}$. A typical pressure for an oil pipeline is $P \simeq 10$ atmospheres ($\simeq 10^6$ Pa), compared to the shear modulus of steel $\mu = 81$ GPa, so $P/\mu \simeq 1.2 \times 10^{-5}$. Inserting this number into Eq. (11.87) with $|S_{\phi\phi}| \lesssim 10^{-4}$, we deduce that the ratio of the pipe's outer radius to its inner radius must be $\zeta = \varpi_2/\varpi_1 \gtrsim 1.04$. If the pipe has a diameter of a half meter, then its wall thickness should be about 1 cm or more. This is typical of oil pipelines.

Exercise 11.25 presents a second fairly simple example of elastostatics in cylindrical coordinates: a computation of the period of a torsion pendulum.

critterion for safety against fracture

Exercise 11.24 *Derivation and Practice: Fracture of a Pipe* T2

Fill in the details of the text's analysis of the deformation of a pipe carrying a high-pressure fluid, and the wall thickness required to protect the pipe against fracture. (See Fig. 11.16.)

EXERCISES

Exercise 11.25 *Practice: Torsion Pendulum* T2

A torsion pendulum is a very useful tool for testing the equivalence principle (Sec. 25.2), for seeking evidence for hypothetical fifth (not to mention sixth!) forces, and for searching for deviations from gravity's inverse-square law on submillimeter scales, which could arise from gravity being influenced by macroscopic higher spatial dimensions. (See, e.g., Kapner et al., 2008; Wagner et al., 2012.) It would be advantageous to design a torsion pendulum with a 1-day period (Fig. 11.17). Here we estimate whether this is possible. The pendulum consists of a thin cylindrical wire of length ℓ and radius a . At the bottom of the wire are suspended three masses at the corners of an equilateral triangle at a distance b from the wire.

(a) Show that the longitudinal strain is

$$\xi_{z;z} = \frac{3mg}{\pi a^2 E}. \quad (11.88a)$$

FIGURE 11.17 Torsion pendulum.

- (b) What component of shear is responsible for the restoring force in the wire, which causes the torsion pendulum to oscillate?
- (c) Show that the pendulum undergoes torsional oscillations with period

$$P = 2\pi \left(\frac{\ell}{g} \right)^{1/2} \left(\frac{2b^2 E \zeta_{z;z}}{a^2 \mu} \right)^{1/2}. \quad (11.88b)$$

- (d) Do you think you could design a pendulum that attains the goal of a 1-day period?

11.9.2

11.9.2 Separation of Variables and Green's Functions: Thermoelastic Noise in Mirrors T2

In complicated situations that have moderate amounts of symmetry, the elastostatic equations can be solved by the same kinds of sophisticated mathematical techniques as one uses in electrostatics: separation of variables, Green's functions, complex potentials, or integral transform methods (see, e.g., Gladwell, 1980). We provide an example in this section, focusing on separation of variables and Green's functions.

MOTIVATION

Our example is motivated by an important issue in high-precision measurements with light, including, among others, gravitational-wave detectors and quantum-optics experiments in which photons and atoms are put into entangled nonclassical states by coupling them to one another inside Fabry-Perot cavities.

In these situations, noise due to thermal motions of the mirror is a serious issue. It can hide a gravitational wave, and it can cause decoherence of the atom/photon quantum states. In Sec. 6.8.2, we formulated a generalized fluctuation-dissipation theorem by which this mirror thermal noise can be computed (Levin, 1998).

Specifically, in a thought experiment one applies to the mirror face a force F_o that oscillates at some frequency f at which one wants to evaluate the thermal noise. This force has the same transverse pressure distribution as the light beam—say, for concreteness, a Gaussian distribution:

$$T_{zz}^{\text{applied}} = \frac{e^{-\varpi^2/\varpi_o^2}}{\pi \varpi_o^2} F_o \cos(2\pi f t). \quad (11.89)$$

This applied pressure induces a strain distribution \mathbf{S} inside the mirror, and that oscillating strain interacts with imperfections to dissipate energy at some rate $W_{\text{diss}}(f)$. The fluctuation-dissipation theorem states that in the real experiment, where the light beam bounces off the mirror, the reflected light will encode a noisy transverse-averaged position q for the mirror face, and the noise spectral density for q will be

$$S_q(f) = \frac{8W_{\text{diss}}(f)k_B T}{(2\pi f)^2 F_o^2} \quad (11.90)$$

[Eq. (6.88b)].

Even if one could make the mirror perfect (no dislocations or impurities), so there is no dissipation due to imperfections, there will remain one other source of dissipation in this thought experiment: the applied pressure (11.89) will produce a spatially inhomogeneous expansion $\Theta(\mathbf{x}, t)$ inside the mirror, which in turn will produce the thermoelastic temperature change $\Delta T/T = -[3\alpha K/(\rho c_V)]\Theta$ [Eq. (11.29)]. The gradient of this temperature will induce heat flow, with a thermal energy flux $\mathbf{F}_{\text{th}} = -\kappa \nabla \Delta T$, where κ is the thermal conductivity. When an amount Q of this thermal energy flows from a region with temperature T to a region of lower temperature $T - dT$, it produces an entropy increase $dS = Q/(T - dT) - Q/T = QdT/T^2$; and correspondingly, there is a rate of entropy increase per unit volume given by $d^2 S/dV dt = -\mathbf{F}_{\text{th}} \cdot \nabla \Delta T/T^2 = \kappa (\nabla \Delta T)^2/T^2$. This entropy increase has an accompanying energy dissipation rate $W_{\text{diss}} = \int T(d^2 S/dt dV)dV = \int (\kappa/T)(\nabla \Delta T)^2 dV$. Expressing ΔT in terms of the expansion that drives it via $\Delta T/T = -[3\alpha K/(\rho c_V)]\Theta$ and inserting that into Eq. (11.90) and using the third of Eqs. (11.39), we obtain the thermal noise spectral density that the experimenters must contend with:

$$S_q(f) = \frac{8\kappa E^2 \alpha^2 k_B T^2}{(1 - 2\nu)^2 c_V^2 \rho^2 F_o^2 (2\pi f)^2} \left\langle \int (\nabla \Theta)^2 \varpi d\phi d\varpi dz \right\rangle. \quad (11.91)$$

Here $\langle \cdot \rangle$ means average over time as Θ oscillates due to the oscillation of the driving force $F_o \cos(2\pi f t)$. Because the dissipation producing this noise is due to heat flowing down a thermoelastic temperature gradient, it is called *thermoelastic noise*.

This is the motivation for an elasticity problem that we shall solve to illustrate separation of variables: to evaluate this thermoelastic noise, we must compute the expansion $\Theta(\mathbf{x}, t)$ inside a mirror, produced by the oscillating pressure (11.89) on the mirror face; and we must then perform the integral (11.91).

SOLUTION FOR Θ VIA SEPARATION OF VARIABLES

The frequencies f at which we wish to evaluate the thermal noise are low compared to the inverse sound travel time across the mirror, so when computing Θ we can regard the force as oscillating very slowly (i.e., we can use our elastostatic equations rather than dynamical equations of the next chapter). Also, the size of the light spot on the mirror is usually small compared to the mirror's transverse size and thickness, so we can idealize the mirror as being infinitely large and thick—a homogeneous half-space of isotropic, elastic material.

Because the applied stress is axially symmetric, the induced strain and expansion will also be axially symmetric and are thus computed most easily using cylindrical coordinates. Our challenge, then, is to solve the Navier-Cauchy equation $\mathbf{f} = (K + \frac{1}{3}\mu)\nabla(\nabla \cdot \boldsymbol{\xi}) + \mu\nabla^2\boldsymbol{\xi} = 0$ for the cylindrical components $\xi_{\varpi}(z, \varpi)$ and $\xi_z(z, \varpi)$ of the displacement, and then evaluate the expansion $\Theta = \nabla \cdot \boldsymbol{\xi}$. (The component ξ_{ϕ} vanishes by symmetry.)

Equations of elasticity in cylindrical coordinates, and their homogeneous solution

It is straightforward, using the techniques of Sec. 11.8, to compute the cylindrical components of \mathbf{f} . Reexpressing the bulk K and shear μ moduli in terms of Young's modulus E and Poisson's ratio ν [Eqs. (11.39)] and setting the internal forces to zero, we obtain

elastostatic force balance
in cylindrical coordinates

$$f_{\varpi} = \frac{E}{2(1+\nu)(1-2\nu)} \left[2(1-\nu) \left(\frac{\partial^2 \xi_{\varpi}}{\partial \varpi^2} + \frac{1}{\varpi} \frac{\partial \xi_{\varpi}}{\partial \varpi} - \frac{\xi_{\varpi}}{\varpi^2} \right) + (1-2\nu) \frac{\partial^2 \xi_{\varpi}}{\partial z^2} + \frac{\partial^2 \xi_z}{\partial z \partial \varpi} \right] = 0, \quad (11.92a)$$

$$f_z = \frac{E}{2(1+\nu)(1-2\nu)} \left[(1-2\nu) \left(\frac{\partial^2 \xi_z}{\partial \varpi^2} + \frac{1}{\varpi} \frac{\partial \xi_z}{\partial \varpi} \right) + 2(1-\nu) \frac{\partial^2 \xi_z}{\partial z^2} + \frac{\partial^2 \xi_{\varpi}}{\partial z \partial \varpi} + \frac{1}{\varpi} \frac{\partial \xi_{\varpi}}{\partial z} \right] = 0. \quad (11.92b)$$

These are two coupled, linear, second-order differential equations for the two unknown components of the displacement vector. As with the analogous equations of electrostatics and magnetostatics, these can be solved by separation of variables, that is, by setting $\xi_{\varpi} = R_{\varpi}(\varpi)Z_{\varpi}(z)$ and $\xi_z = R_z(\varpi)Z_z(z)$, and inserting into Eq. (11.92a). We seek the general solution that dies out at large ϖ and z . The general solution of this sort, to the complicated-looking Eqs. (11.92), turns out to be (really!!)

separation-of-variables
solution of force-balance
equation $f_j = 0$

$$\begin{aligned} \xi_{\varpi} &= \int_0^{\infty} [\alpha(k) - (2 - 2\nu - kz)\beta(k)] e^{-kz} J_1(k\varpi) dk, \\ \xi_z &= \int_0^{\infty} [\alpha(k) + (1 - 2\nu + kz)\beta(k)] e^{-kz} J_0(k\varpi) dk. \end{aligned} \quad (11.93)$$

Here J_0 and J_1 are Bessel functions of order 0 and 1, and $\alpha(k)$ and $\beta(k)$ are arbitrary functions.

Boundary conditions

The functions $\alpha(k)$ and $\beta(k)$ are determined by boundary conditions on the face of the test mass. The force per unit area exerted across the face by the strained test-mass material, T_{zj} at $z = 0$ with $j = \{\varpi, \phi, z\}$, must be balanced by the applied force per unit area, T_{zj}^{applied} [Eq. (11.89)]. The (shear) forces in the ϕ direction, $T_{z\phi}$ and $T_{z\phi}^{\text{applied}}$, vanish because of cylindrical symmetry and thus provide no useful boundary condition. The (shear) force in the ϖ direction, which must vanish at $z = 0$ since $T_{z\varpi}^{\text{applied}} = 0$, is given by [cf. Eq. (2) in Box 11.4]

$$\begin{aligned} T_{z\varpi}(z=0) &= -2\mu\Sigma_{z\varpi} = -\mu\left(\frac{\partial\xi_z}{\partial\varpi} + \frac{\partial\xi_\varpi}{\partial z}\right) \\ &= -\mu\int_0^\infty [\beta(k) - \alpha(k)] J_1(kz)kdk = 0, \end{aligned} \quad (11.94)$$

shear-force boundary
condition at $z = 0$

which implies that $\beta(k) = \alpha(k)$. The (normal) force in the z direction, which must balance the applied pressure (11.89), is $T_{zz} = -K\Theta - 2\mu\Sigma_{zz}$; using Eq. (2) in Box 11.4 and Eqs. (11.39), (11.76), (11.93) and (11.89), this reduces to

$$T_{zz}(z=0) = 2\mu\int_0^\infty \alpha(k)J_0(k\varpi)kdk = T_{zz}^{\text{applied}} = \frac{e^{-\varpi^2/\varpi_o^2}}{\pi\varpi_o^2}F_o\cos(2\pi ft), \quad (11.95)$$

longitudinal-force
boundary condition at
 $z = 0$

which can be inverted¹¹ to give

$$\alpha(k) = \beta(k) = \frac{1}{4\pi\mu}e^{-k^2\varpi_o^2/4}F_o\cos(2\pi ft). \quad (11.96)$$

solution for expansion
coefficients

Inserting this equation into the Eqs. (11.93) for the displacement and then evaluating the expansion $\Theta = \nabla \cdot \boldsymbol{\xi} = \xi_{z,z} + \varpi^{-1}(\varpi\xi_\varpi)_{,\varpi}$, we obtain

$$\Theta = 2(1 - 2\nu)\int_0^\infty \alpha(k)e^{-kz}J_0(k\varpi)kdk. \quad (11.97)$$

As in electrostatics and magnetostatics, so also in elasticity theory, one can solve an elastostatics problem using Green's functions instead of separation of variables. We explore this option for our applied Gaussian force in Ex. 11.27. For greater detail on

11. The inversion and the subsequent evaluation of the integral of $(\nabla\Theta)^2$ are aided by the following expressions for the Dirac delta function:

$$\delta(k - k') = k\int_0^\infty J_0(k\varpi)J_0(k'\varpi)\varpi d\varpi = k\int_0^\infty J_1(k\varpi)J_1(k'\varpi)\varpi d\varpi.$$

Green's functions in elastostatics and their applications from an engineer's viewpoint, see Johnson (1985). For other commonly used solution techniques, see Box 11.3.

THERMOELASTIC NOISE SPECTRAL DENSITY

Let us return to the mirror-noise problem that motivated our calculation. It is straightforward to compute the gradient of the expansion (11.97), and square and integrate it to get the spectral density $S_q(f)$ [Eq. (11.91)]. The result is (Braginsky, Gorodetsky, and Vyatchanin, 1999; Liu and Thorne, 2000)

$$S_q(f) = \frac{8(1+\nu)^2 \kappa \alpha^2 k_B T^2}{\sqrt{2\pi} c_V^2 \rho^2 \varpi_o^3 (2\pi f)^2}. \quad (11.98)$$

Early plans for advanced LIGO gravitational wave detectors (Sec. 9.5; LIGO Scientific Collaboration, 2015) called for mirrors made of high-reflectivity dielectric coatings on sapphire crystal substrates. Sapphire was chosen because it can be grown in giant crystals with very low impurities and dislocations, resulting in low thermal noise. However, the thermoelastic noise (11.98) in sapphire turns out to be uncomfortably high. Using sapphire's $\nu = 0.29$, $\kappa = 40 \text{ W m}^{-1} \text{ K}^{-1}$, $\alpha = 5.0 \times 10^{-6} \text{ K}^{-1}$, $c_V = 790 \text{ J kg}^{-1} \text{ K}^{-1}$, $\rho = 4,000 \text{ kg m}^{-3}$, and a light-beam radius $\varpi_o = 4 \text{ cm}$ and room temperature $T = 300 \text{ K}$, Eq. (11.98) gives the following for the noise in a bandwidth equal to frequency:

$$\sqrt{f S_q(f)} = 5 \times 10^{-20} \text{ m} \sqrt{\frac{100 \text{ Hz}}{f}}. \quad (11.99)$$

Because this was uncomfortably high at low frequencies, $f \sim 10 \text{ Hz}$, and because of the birefringence of sapphire, which could cause technical problems, a decision was made to switch to fused silica for the advanced LIGO mirrors.

EXERCISES

Exercise 11.26 *Derivation and Practice: Evaluation of Elastostatic Force in Cylindrical Coordinates* T2

Derive Eqs. (11.92) for the cylindrical components of the internal elastostatic force per unit volume $\mathbf{f} = (K + \frac{1}{3}\mu)\nabla(\nabla \cdot \boldsymbol{\xi}) + \mu\nabla^2\boldsymbol{\xi}$ in a cylindrically symmetric situation.

Exercise 11.27 ***Example: Green's Function for Normal Force on a Half-Infinite Body* T2

Suppose that a stress $T_{zj}^{\text{applied}}(\mathbf{x}_o)$ is applied on the face $z = 0$ of a half-infinite elastic body (one that fills the region $z > 0$). Then by virtue of the linearity of the elastostatics equation $\mathbf{f} = (K + \frac{1}{3}\mu)\nabla(\nabla \cdot \boldsymbol{\xi}) + \mu\nabla^2\boldsymbol{\xi} = 0$ and the linearity of its boundary conditions, $T_{zj}^{\text{internal}} = T_{zj}^{\text{applied}}$, there must be a Green's function $G_{jk}(\mathbf{x} - \mathbf{x}_o)$ such that the body's internal displacement $\boldsymbol{\xi}(\mathbf{x})$ is given by

$$\xi_j(\mathbf{x}) = \int G_{jk}(\mathbf{x} - \mathbf{x}_o) T_{kz}^{\text{applied}}(\mathbf{x}_o) d^2x_o. \quad (11.100)$$

Here the integral is over all points \mathbf{x}_o on the face of the body ($z = 0$), and \mathbf{x} can be anywhere inside the body, $z \geq 0$.

- (a) Show that if a force F_j is applied on the body's surface at a single point (the origin of coordinates), then the displacement inside the body is

$$\xi_j(\mathbf{x}) = G_{jk}(\mathbf{x})F_k. \quad (11.101)$$

Thus, the Green's function can be thought of as the body's response to a point force on its surface.

- (b) As a special case, consider a point force F_z directed perpendicularly into the body. The resulting displacement turns out to have cylindrical components¹²

$$\begin{aligned} \xi_z &= G_{zz}(\varpi, z)F_z = \frac{(1+\nu)}{2\pi E} \left[\frac{2(1-\nu)}{r} + \frac{z^2}{r^3} \right] F_z, \\ \xi_\varpi &= G_{\varpi z}(\varpi, z)F_z = -\frac{(1+\nu)}{2\pi E} \left[\frac{(1-2\nu)\varpi}{r(r+z)} - \frac{\varpi z}{r^3} \right] F_z, \end{aligned} \quad (11.102)$$

where $r = \sqrt{\varpi^2 + z^2}$. It is straightforward to show that this displacement does satisfy the elastostatics equations (11.92). Show that it also satisfies the required boundary condition $T_{z\varpi}(z=0) = -2\mu\Sigma_{z\varpi} = 0$.

- (c) Show that for this displacement [Eq. (11.102)], $T_{zz} = -K\Theta - 2\mu\Sigma_{zz}$ vanishes everywhere on the body's surface $z = 0$ except at the origin $\varpi = 0$ and is infinite there. Show that the integral of this normal stress over the surface is F_z , and therefore, $T_{zz}(z=0) = F_z\delta_2(\mathbf{x})$, where δ_2 is the 2-dimensional Dirac delta function on the surface. This is the second required boundary condition.
- (d) Plot the integral curves of the displacement vector ξ (i.e., the curves to which ξ is parallel) for a reasonable choice of Poisson's ratio ν . Explain physically why the curves have the form you find.
- (e) One can use the Green's function (11.102) to compute the displacement ξ induced by the Gaussian-shaped pressure (11.89) applied to the body's face, and to then evaluate the induced expansion and thence the thermoelastic noise; see Braginsky, Gorodetsky, and Vyatchanin (1999) and Liu and Thorne (2000). The results agree with Eqs. (11.97) and (11.98) deduced using separation of variables.

Bibliographic Note

Elasticity theory was developed in the eighteenth, nineteenth, and early twentieth centuries. The classic advanced textbook from that era is Love (1927). An outstanding, somewhat more modern advanced text is Landau and Lifshitz (1986)—originally

12. For the other components of the Green's function, written in Cartesian coordinates (since a non-normal applied force breaks the cylindrical symmetry), see Landau and Lifshitz [1986, Eqs. (8.18)].

written in the 1950s and revised in a third edition shortly before Lifshitz's death. This is among the most readable textbooks that Landau and Lifshitz wrote and is still widely used by physicists in the early twenty-first century.

Some significant new insights, both mathematical and physical, have been developed in recent decades, for example, catastrophe theory and its applications to bifurcations and stability, practical insights from numerical simulations, and practical applications based on new materials (e.g., carbon nanotubes). For a modern treatment that deals with these and much else from an engineering viewpoint, we strongly recommend Ugural and Fenster (2012). For a fairly brief and elementary modern treatment, we recommend Lautrup (2005, Part III). Other good texts that focus particularly on solving the equations for elastostatic equilibrium include Southwell (1941), Timoshenko and Goodier (1970), Gladwell (1980), Johnson (1985), Boresi and Chong (1999), and Slaughter (2002); see also the discussion and references in Box 11.3.

Elastodynamics

... logarithmic plots are a device of the devil.

CHARLES RICHTER (1980)

12.1 Overview

12.1

In the previous chapter we considered elastostatic equilibria, in which the forces acting on elements of an elastic solid were balanced, so the solid remained at rest. When this equilibrium is disturbed, the solid will undergo accelerations. This is the subject of this chapter—*elastodynamics*.

In Sec. 12.2, we derive the equations of motion for elastic media, paying particular attention to the underlying conservation laws and focusing especially on elastodynamic waves. We show that there are two distinct wave modes that propagate in a uniform, isotropic solid—longitudinal waves and shear waves—and both are non-dispersive (their phase speeds are independent of frequency).

A major use of elastodynamics is in structural engineering, where one encounters vibrations (usually standing waves) on the beams that support buildings and bridges. In Sec. 12.3, we discuss the types of waves that propagate on bars, rods, and beams and find that the boundary conditions at the free transverse surfaces make the waves dispersive. We also return briefly to the problem of bifurcation of equilibria (treated in Sec. 11.6) and show how, as the parameters controlling an equilibrium are changed so it passes through a bifurcation point, the equilibrium becomes unstable; the instability drives the system toward the new, stable equilibrium state.

A second application of elastodynamics is to seismology (Sec. 12.4). Earth is mostly a solid body through which waves can propagate. The waves can be excited naturally by earthquakes or artificially using human-made explosions. Understanding how waves propagate through Earth is important for locating the sources of earthquakes, for diagnosing the nature of an explosion (was it an illicit nuclear bomb test?), and for analyzing the structure of Earth. We briefly describe some of the wave modes that propagate through Earth and some of the inferences about Earth's structure that have been drawn from studying their propagation. In the process, we gain some experience in applying the tools of geometric optics to new types of waves, and we learn

BOX 12.1. READERS' GUIDE

- This chapter is a companion to Chap. 11 (Elastostatics) and relies heavily on it.
- This chapter also relies rather heavily on geometric-optics concepts and formalism, as developed in Secs. 7.2 and 7.3, especially phase velocity, group velocity, dispersion relation, rays, and the propagation of waves and information and energy along them, the role of the dispersion relation as a hamiltonian for the rays, and ray tracing.
- The discussion of continuum-mechanics wave equations in Box 12.2 underlies this book's treatment of waves in fluids (Chap. 16), especially in plasmas (Part VI) and in general relativity (Chap. 27).
- The experience that the reader gains in this chapter with waves in solids will be useful when we encounter much more complicated waves in plasmas in Part VI.
- No other portions of this chapter are important for subsequent parts of this book.

how rich can be the Green's function for elastodynamic waves, even when the medium is as simple as a homogeneous half-space. We briefly discuss how the methods by which geophysicists probe Earth's structure using seismic waves also find application in ultrasonic technology: imaging solid structures and the human body using high-frequency sound waves.

Finally, in Sec. 12.5, we return to physics to consider the quantum theory of elastodynamic waves. We compare the classical theory with the quantum theory, specializing to quantized vibrations in an elastic solid: phonons.

12.2 **12.2 Basic Equations of Elastodynamics; Waves in a Homogeneous Medium**

In this section, we derive a vectorial equation that governs the dynamical displacement $\xi(\mathbf{x}, t)$ of a dynamically disturbed elastic medium. We then consider monochromatic plane wave solutions and explore wave propagation through inhomogeneous media in the geometric optics limit. This general approach to wave propagation in continuum mechanics will be taken up again in Chap. 16 for waves in fluids, Part VI for waves in plasmas, and Chap. 27 for general relativistic gravitational waves. We conclude this section with a discussion of the energy density and energy flux of these waves.

12.2.1 **12.2.1 Equation of Motion for a Strained Elastic Medium**

In Chap. 11, we learned that when an elastic medium undergoes a displacement $\xi(\mathbf{x})$, it builds up a strain $S_{ij} = \frac{1}{2}(\xi_{i;j} + \xi_{j;i})$, which in turn produces an internal stress

$\mathbf{T} = -K\Theta\mathbf{g} - 2\mu\boldsymbol{\Sigma}$. Here $\Theta \equiv \nabla \cdot \boldsymbol{\xi}$ is the expansion, and $\boldsymbol{\Sigma} \equiv$ (the trace-free part of \mathbf{S}) is the shear; see Eqs. (11.4) and (11.18). The stress \mathbf{T} produces an elastic force per unit volume

$$\mathbf{f} = -\nabla \cdot \mathbf{T} = \left(K + \frac{1}{3}\mu \right) \nabla(\nabla \cdot \boldsymbol{\xi}) + \mu \nabla^2 \boldsymbol{\xi} \quad (12.1)$$

[Eq. (11.30)], where K and μ are the bulk and shear moduli.

In Chap. 11, we restricted ourselves to elastic media that are in elastostatic equilibrium, so they are static. This equilibrium requires that the net force per unit volume acting on the medium vanish. If the only force is elastic, then \mathbf{f} must vanish. If the pull of gravity is also significant, then $\mathbf{f} + \rho\mathbf{g}$ vanishes, where ρ is the medium's mass density and \mathbf{g} the acceleration of gravity.

In this chapter, we focus on dynamical situations, in which an unbalanced force per unit volume causes the medium to move—with the motion taking the form of an elastodynamic wave. For simplicity, we assume unless otherwise stated that the only significant force is elastic (i.e., the gravitational force is negligible by comparison). In Ex. 12.1, we show that this is the case for elastodynamic waves in most media on Earth when the wave frequency $\omega/(2\pi)$ is higher than about 0.001 Hz (which is usually the case in practice). Stated more precisely, in a homogeneous medium we can ignore the gravitational force when the elastodynamic wave's angular frequency ω is much larger than g/C , where g is the acceleration of gravity, and C is the wave's propagation speed.

when gravity can be ignored

Consider, then, a dynamical, strained medium with elastic force per unit volume (12.1) and no other significant force (negligible gravity), and with velocity

$$\mathbf{v} = \frac{\partial \boldsymbol{\xi}}{\partial t}. \quad (12.2a)$$

The law of momentum conservation states that the force per unit volume \mathbf{f} , if nonzero, must produce a rate of change of momentum per unit volume $\rho\mathbf{v}$ according to the equation¹

$$\frac{\partial(\rho\mathbf{v})}{\partial t} = \mathbf{f} = -\nabla \cdot \mathbf{T} = \left(K + \frac{1}{3}\mu \right) \nabla(\nabla \cdot \boldsymbol{\xi}) + \mu \nabla^2 \boldsymbol{\xi}. \quad (12.2b)$$

elastodynamic momentum conservation

Notice that, when rewritten in the form

$$\frac{\partial(\rho\mathbf{v})}{\partial t} + \nabla \cdot \mathbf{T} = 0, \quad (12.2b')$$

1. In Sec. 13.5, we learn that the motion of the medium produces a stress $\rho\mathbf{v} \otimes \mathbf{v}$ that must be included in this equation if the velocities are large. However, this subtle dynamical stress is always negligible in elastodynamic waves, because the displacements and hence velocities \mathbf{v} are tiny and $\rho\mathbf{v} \otimes \mathbf{v}$ is second order in the displacement. For this reason, we delay studying this subtle nonlinear effect until Chap. 13. A similar remark applies to Eq. (12.2c). In general the conservation laws of continuum mechanics are nonlinear, as we discuss in Box 12.2.

this is the version of the law of momentum conservation discussed in Chap. 1 [Eq. (1.36)]. It has the standard form for a conservation law (time derivative of density of something plus divergence of flux of that something vanishes; see end of Sec. 1.8); $\rho\mathbf{v}$ is the density of momentum, and the stress tensor \mathbf{T} is by definition the flux of momentum. Equations (12.2a) and (12.2b), together with the law of mass conservation [the obvious analog of Eqs. (1.30) for conservation of charge and particle number],

mass conservation

$$\frac{\partial\rho}{\partial t} + \nabla \cdot (\rho\mathbf{v}) = 0, \quad (12.2c)$$

are a complete set of equations for the evolution of the displacement $\boldsymbol{\xi}(\mathbf{x}, t)$, the velocity $\mathbf{v}(\mathbf{x}, t)$, and the density $\rho(\mathbf{x}, t)$.

To derive a linear wave equation, we must find some small parameter in which to expand. The obvious choice in elastodynamics is the magnitude of the components of the strain $S_{ij} = \frac{1}{2}(\xi_{i;j} + \xi_{j;i})$, which are less than about 10^{-3} so as to remain below the proportionality limit (i.e., to remain in the realm where stress is proportional to strain; Sec. 11.3.2). Equally well, we can regard the displacement $\boldsymbol{\xi}$ itself as our small parameter (or more precisely, ξ/λ , the magnitude of $\boldsymbol{\xi}$ divided by the reduced wavelength of its perturbations).

If the medium's equilibrium state were homogeneous, the linearization would be trivial. However, we wish to be able to treat perturbations of inhomogeneous equilibria, such as seismic waves in Earth, or perturbations of slowly changing equilibria, such as vibrations of a pipe or mirror that is gradually changing temperature. In most practical situations the lengthscale \mathcal{L} and timescale \mathcal{T} on which the medium's equilibrium properties (ρ , K , μ) vary are extremely large compared to the lengthscale and timescale of the dynamical perturbations [their reduced wavelength $\lambda = \text{wavelength}/(2\pi)$ and $1/\omega = \text{period}/(2\pi)$]. This permits us to perform a two-lengthscale expansion (like the one that underlies geometric optics; Sec. 7.3) alongside our small-strain expansion.

density perturbation

When analyzing a dynamical perturbation of an equilibrium state, we use $\boldsymbol{\xi}(\mathbf{x}, t)$ to denote the dynamical displacement (i.e., we omit from it the equilibrium's static displacement, and similarly we omit from \mathbf{S} the equilibrium strain). We write the density as $\rho + \delta\rho$, where $\rho(\mathbf{x})$ is the equilibrium density distribution, and $\delta\rho(\mathbf{x}, t)$ is the dynamical density perturbation, which is first order in the dynamical displacement $\boldsymbol{\xi}$. Inserting these into the equation of mass conservation (12.2c), we obtain $\partial\delta\rho/\partial t + \nabla \cdot [(\rho + \delta\rho)\mathbf{v}] = 0$. Because $\mathbf{v} = \partial\boldsymbol{\xi}/\partial t$ is first order, the term $(\delta\rho)\mathbf{v}$ is second order and can be dropped, resulting in the linearized equation $\partial\delta\rho/\partial t + \nabla \cdot (\rho\mathbf{v}) = 0$. Because ρ varies on a much longer lengthscale than does \mathbf{v} (\mathcal{L} versus λ), we can pull ρ out of the derivative. Setting $\mathbf{v} = \partial\boldsymbol{\xi}/\partial t$ and interchanging the time derivative and divergence, we then obtain $\partial\delta\rho/\partial t + \rho\partial(\nabla \cdot \boldsymbol{\xi})/\partial t = 0$. Noting that ρ varies on a

BOX 12.2. WAVE EQUATIONS IN CONTINUUM MECHANICS

Here we make an investment for future chapters by considering wave equations in some generality. Most wave equations arise as approximations to the full set of equations that govern a dynamical physical system. It is usually possible to arrange those full equations as a set of first-order partial differential equations that describe the dynamical evolution of a set of n physical quantities, V_A , with $A = 1, 2, \dots, n$:

$$\frac{\partial V_A}{\partial t} + F_A(V_B) = 0. \quad (1)$$

[For elastodynamics there are $n = 7$ quantities V_A : $\{\rho, \rho v_x, \rho v_y, \rho v_z, \xi_x, \xi_y, \xi_z\}$ (in Cartesian coordinates); and the seven equations (1) are mass conservation, momentum conservation, and $\partial \xi_j / \partial t = v_j$; Eqs. (12.2).]

Most dynamical systems are intrinsically nonlinear (Maxwell's equations in a vacuum being a conspicuous exception), and it is usually quite hard to find nonlinear solutions. However, it is generally possible to make a perturbation expansion in some small physical quantity about a time-independent equilibrium and retain only those terms that are linear in this quantity. We then have a set of n linear partial differential equations that are much easier to solve than the nonlinear ones—and that usually turn out to have the character of wave equations (i.e., to be *hyperbolic*; see Arfken, Weber, and Harris, 2013). Of course, the solutions will only be a good approximation for small-amplitude waves. [In elastodynamics, we justify linearization by requiring that the strains be below the proportionality limit and linearize in the strain or displacement of the dynamical perturbation. The resulting linear wave equation is $\rho \partial^2 \xi / \partial t^2 = (K + \frac{1}{3}\mu) \nabla(\nabla \cdot \xi) + \mu \nabla^2 \xi$; Eq. (12.4b).]

BOUNDARY CONDITIONS

In some problems (e.g., determining the normal modes of vibration of a building during an earthquake, or analyzing the sound from a violin or the vibrations of a finite-length rod), the boundary conditions are intricate and have to be incorporated as well as possible to have any hope of modeling the problem. The situation is rather similar to that familiar from elementary quantum mechanics. The waves are often localized in some region of space, like bound states, in such a way that the eigenfrequencies are discrete (e.g., standing-wave modes of a plucked string). In other problems the volume in which the wave propagates is essentially infinite (e.g., waves on the surface of the ocean, or seismic waves propagating through Earth), as happens with

(continued)

BOX 12.2. (continued)

unbound quantum states. Then the only boundary condition is essentially that the wave amplitude remain finite at large distances. In this case, the wave spectrum is usually continuous.

GEOMETRIC-OPTICS LIMIT AND DISPERSION RELATIONS

The solutions to the wave equation will reflect the properties of the medium through which the wave is propagating, as well as its boundaries. If the medium and boundaries have a finite number of discontinuities but are otherwise smoothly varying, there is a simple limiting case: waves of short enough wavelength and high enough frequency can be analyzed in the geometric-optics approximation (Chap. 7).

The key to geometric optics is the dispersion relation, which (as we learned in Sec. 7.3) acts as a hamiltonian for the propagation. Recall from Chap. 7 that although the medium may actually be inhomogeneous and might even be changing with time, when deriving the dispersion relation, we can approximate it as precisely homogeneous and time independent and can resolve the waves into plane-wave modes [i.e., modes in which the perturbations vary $\propto \exp i(\mathbf{k} \cdot \mathbf{x} - \omega t)$]. Here \mathbf{k} is the wave vector and ω is the angular frequency. This allows us to remove all the temporal and spatial derivatives and converts our set of partial differential equations into a set of homogeneous, linear algebraic equations. When we do this, we say that our normal modes are *local*. If, instead, we were to go to the trouble of solving the partial differential wave equation with its attendant boundary conditions, the modes would be referred to as *global*.

The linear algebraic equations for a local problem can be written in the form $M_{AB}V_B = 0$, where V_A is the vector of n dependent variables, and the elements M_{AB} of the $n \times n$ matrix $\|M_{AB}\|$ depend on \mathbf{k} and ω as well as on parameters p_α that describe the local conditions of the medium. [See, e.g., Eq. (12.6).] This set of equations can be solved in the usual manner by requiring that the determinant of $\|M_{AB}\|$ vanish. Carrying through this procedure yields a polynomial, usually of n th order, for $\omega(\mathbf{k}, p_\alpha)$. This polynomial is the dispersion relation. It can be solved (analytically in simple cases and numerically in general) to yield a number of complex values for ω (the eigenfrequencies), with \mathbf{k} regarded as real. (Some problems involve complex \mathbf{k} and real ω , but for concreteness, we shall take \mathbf{k} to be real.) Armed with the complex eigenfrequencies, we can solve for the associated eigenvectors V_A . The eigenfrequencies and eigenvectors fully characterize the

(continued)

BOX 12.2. (continued)

solution of the local problem and can be used to solve for the waves' temporal evolution from some given initial conditions in the usual manner. (As we shall see several times, especially when we discuss Landau damping in Sec. 22.3, there are some subtleties that can arise.)

What does a complex value of the angular frequency ω mean? We have posited that all small quantities vary $\propto \exp[i(\mathbf{k} \cdot \mathbf{x} - \omega t)]$. If ω has a positive imaginary part, then the small perturbation quantities will grow exponentially with time. Conversely, if it has a negative imaginary part, they will decay. Now, polynomial equations with real coefficients have complex conjugate solutions. Therefore, if there is a decaying mode there must also be a growing mode. Growing modes correspond to instability, a topic that we shall encounter often.

timescale \mathcal{T} long compared to the $1/\omega$ of ξ and $\delta\rho$, we can integrate this to obtain the linear relation

$$\boxed{\frac{\delta\rho}{\rho} = -\nabla \cdot \xi.} \quad (12.3)$$

This linearized equation for the fractional perturbation of density could equally well have been derived by considering a small volume V of the medium that contains mass $M = \rho V$ and noting that the dynamical perturbations lead to a volume change $\delta V/V = \Theta = \nabla \cdot \xi$ [Eq. (11.7)]. Then conservation of mass requires $0 = \delta M = \delta(\rho V) = V\delta\rho + \rho\delta V = V\delta\rho + \rho V\nabla \cdot \xi$, which implies $\delta\rho/\rho = -\nabla \cdot \xi$. This is the same as Eq. (12.3).

The equation of momentum conservation (12.2b) can be handled similarly. By setting $\rho \rightarrow \rho(\mathbf{x}) + \delta\rho(\mathbf{x}, t)$, then linearizing (i.e., dropping the $\delta\rho \mathbf{v}$ term) and pulling the slowly varying $\rho(\mathbf{x})$ out from the time derivative, we convert $\partial(\rho\mathbf{v})/\partial t$ into $\rho\partial\mathbf{v}/\partial t = \rho\partial^2\xi/\partial t^2$. Inserting this into Eq. (12.2b), we obtain the linear wave equation

$$\rho \frac{\partial^2 \xi}{\partial t^2} = -\nabla \cdot \mathbf{T}_{\text{el}}, \quad (12.4a)$$

where \mathbf{T}_{el} is the elastic contribution to the stress tensor. Expanding it, we obtain

$$\boxed{\rho \frac{\partial^2 \xi}{\partial t^2} = \left(K + \frac{1}{3}\mu \right) \nabla(\nabla \cdot \xi) + \mu \nabla^2 \xi.} \quad (12.4b)$$

elastodynamic wave equation

In this equation, terms involving a derivative of K or μ have been omitted, because the two-lengthscale assumption $\mathcal{L} \gg \lambda$ makes them negligible compared to the terms we have kept.

Equation (12.4b) is the first of many wave equations we shall encounter in elastodynamics, fluid mechanics, plasma physics, and general relativity.

12.2.2 Elastodynamic Waves

Continuing to follow our general procedure for deriving and analyzing wave equations as outlined in Box 12.2, we next derive dispersion relations for two types of waves (longitudinal and transverse) that are jointly incorporated into the general elastodynamic wave equation (12.4b).

Recall from Sec. 7.3.1 that, although a dispersion relation can be used as a hamiltonian for computing wave propagation through an inhomogeneous medium, one can derive the dispersion relation most easily by specializing to monochromatic plane waves propagating through a medium that is precisely homogeneous. Therefore, we seek a plane-wave solution, that is, a solution of the form

$$\boldsymbol{\xi}(\mathbf{x}, t) \propto e^{i(\mathbf{k}\cdot\mathbf{x}-\omega t)}, \quad (12.5)$$

to the wave equation (12.4b) with ρ , K , and μ regarded as homogeneous (constant). (To deal with more complicated perturbations of a homogeneous medium, we can think of this wave as being an individual Fourier component and linearly superpose many such waves as a Fourier integral.) Since our wave is planar and monochromatic, we can remove the derivatives in Eq. (12.4b) by making the substitutions $\nabla \rightarrow i\mathbf{k}$ and $\partial/\partial t \rightarrow -i\omega$ (the first of which implies $\nabla^2 \rightarrow -k^2$, $\nabla \cdot \rightarrow i\mathbf{k} \cdot$, $\nabla \times \rightarrow i\mathbf{k} \times$). We thereby reduce the partial differential equation (12.4b) to a vectorial algebraic equation:

$$\rho\omega^2\boldsymbol{\xi} = \left(K + \frac{1}{3}\mu\right)\mathbf{k}(\mathbf{k} \cdot \boldsymbol{\xi}) + \mu k^2\boldsymbol{\xi}. \quad (12.6)$$

[This reduction is only possible because the medium is uniform, or in the geometric-optics limit of near uniformity; otherwise, we must solve the second-order partial differential equation (12.4b).]

How do we solve this equation? The sure way is to write it as a 3×3 matrix equation $M_{ij}\xi_j = 0$ for the vector $\boldsymbol{\xi}$ and set the determinant of M_{ij} to zero (Box 12.2 and Ex. 12.3). This is not hard for small or sparse matrices. However, some wave equations are more complicated, and it often pays to think about the waves in a geometric, coordinate-independent way before resorting to brute force.

The quantity that oscillates in the elastodynamic waves of Eq. (12.6) is the vector field $\boldsymbol{\xi}$. The nature of its oscillations is influenced by the scalar constants ρ , μ , K , and ω and by just one quantity that has directionality: the constant vector \mathbf{k} . It seems reasonable to expect the description (12.6) of the oscillations to simplify, then, if we resolve the oscillations into a “longitudinal” component (or “mode”) along \mathbf{k} and a “transverse” component (or “mode”) perpendicular to \mathbf{k} , as shown in Fig. 12.1:

$$\boldsymbol{\xi} = \boldsymbol{\xi}_L + \boldsymbol{\xi}_T, \quad \boldsymbol{\xi}_L = \xi_L \hat{\mathbf{k}}, \quad \boldsymbol{\xi}_T \cdot \hat{\mathbf{k}} = 0. \quad (12.7a)$$

elastodynamic
eigenequation for plane
waves

decomposition into
longitudinal and
transverse modes

FIGURE 12.1 Displacements in an isotropic, elastic solid, perturbed by (a) a longitudinal mode and (b) a transverse mode.

Here $\hat{\mathbf{k}} \equiv \mathbf{k}/k$ is the unit vector along the propagation direction. It is easy to see that the longitudinal mode ξ_L has nonzero expansion $\Theta \equiv \nabla \cdot \xi_L \neq 0$ but vanishing rotation $\phi = \frac{1}{2} \nabla \times \xi_L = 0$. It can therefore be written as the gradient of a scalar potential:

$$\xi_L = \nabla \psi. \quad (12.7b)$$

By contrast, the transverse mode has zero expansion but nonzero rotation and can thus be written as the curl of a vector potential:

$$\xi_T = \nabla \times \mathbf{A}; \quad (12.7c)$$

cf. Ex. 12.2.

12.2.3 Longitudinal Sound Waves

12.2.3

For the longitudinal mode the algebraic wave equation (12.6) reduces to the following simple relation [as one can easily see by inserting $\xi \equiv \xi_L = \zeta_L \hat{\mathbf{k}}$ into Eq. (12.6), or, alternatively, by taking the divergence of Eq. (12.6), which is equivalent to taking the scalar product with \mathbf{k}]:

$$\omega^2 = \frac{K + \frac{4}{3}\mu}{\rho} k^2; \quad \text{or} \quad \omega = \Omega(\mathbf{k}) = \left(\frac{K + \frac{4}{3}\mu}{\rho} \right)^{1/2} k. \quad (12.8)$$

longitudinal dispersion relation

Here $k = |\mathbf{k}|$ is the wave number (the magnitude of \mathbf{k}). This relation between ω and \mathbf{k} is the longitudinal mode's dispersion relation.

From the geometric-optics analysis in Sec. 7.3 we infer that if K , μ , and ρ vary spatially on an inhomogeneity lengthscale \mathcal{L} large compared to $1/k = \lambda$, and vary temporally on a timescale \mathcal{T} large compared to $1/\omega$, then the dispersion relation (12.8)—with Ω now depending on \mathbf{x} and t through K , μ , and ρ —serves as a

hamiltonian for the wave propagation. In Sec. 12.4 and Fig. 12.5 below we use this hamiltonian to deduce details of the propagation of seismic waves through Earth's inhomogeneous interior.

As discussed in great detail in Sec. 7.2, associated with any wave mode is its phase velocity $\mathbf{V}_{\text{ph}} = (\omega/k)\hat{\mathbf{k}}$ and its phase speed $V_{\text{ph}} = \omega/k$. The dispersion relation (12.8) implies that for longitudinal elastodynamic modes, the phase speed is

longitudinal wave speed

$$C_L = \frac{\omega}{k} = \left(\frac{K + \frac{4}{3}\mu}{\rho} \right)^{1/2}. \quad (12.9a)$$

As Eq. (12.9a) does not depend on the wave number $k \equiv |\mathbf{k}|$, the mode is non-dispersive. As it does not depend on the direction $\hat{\mathbf{k}}$ of propagation through the medium, the phase speed is also isotropic, naturally enough, and the group velocity $V_{gj} = \partial\Omega/\partial k_j$ is equal to the phase velocity:

$$\mathbf{V}_g = \mathbf{V}_{\text{ph}} = C_L \hat{\mathbf{k}}. \quad (12.9b)$$

Elastodynamic longitudinal modes are similar to sound waves in a fluid. However, in a fluid, as we can infer from Eq. (16.48), the sound waves travel with phase speed $V_{\text{ph}} = (K/\rho)^{1/2}$ [the limit of Eq. (12.9a) when the shear modulus vanishes].² This fluid sound speed is lower than the C_L of a solid with the same bulk modulus, because the longitudinal displacement necessarily entails shear (note that in Fig. 12.1a the motions are not an isotropic expansion), and in a solid there is a restoring shear stress (proportional to μ) that is absent in a fluid.

Because the longitudinal phase velocity is independent of frequency, we can write down general planar longitudinal-wave solutions to the elastodynamic wave equation (12.4b) in the following form:

general longitudinal plane wave

$$\boldsymbol{\xi} = \zeta_L \hat{\mathbf{k}} = F(\hat{\mathbf{k}} \cdot \mathbf{x} - C_L t) \hat{\mathbf{k}}, \quad (12.10)$$

where $F(x)$ is an arbitrary function. This describes a wave propagating in the (arbitrary) direction $\hat{\mathbf{k}}$ with an arbitrary profile determined by the function F .

12.2.4

12.2.4 Transverse Shear Waves

To derive the dispersion relation for a transverse wave we can simply make use of the transversality condition $\mathbf{k} \cdot \boldsymbol{\xi}_T = 0$ in Eq. (12.6); or, equally well, we can take the curl of Eq. (12.6) (multiply it by $i\mathbf{k} \times$), thereby projecting out the transverse piece, since

2. Equation (16.48) below gives the fluid sound speed as $C = \sqrt{(\partial P/\partial \rho)_s}$ (i.e., the square root of the derivative of the fluid pressure with respect to density at fixed entropy). In the language of elasticity theory, the fractional change of density is related to the expansion Θ by $\delta\rho/\rho = -\Theta$ [Eq. (12.3)], and the accompanying change of pressure is $\delta P = -K\Theta$ [sentence preceding Eq. (11.18)], so $\delta P = K(\delta\rho/\rho)$. Therefore, the fluid mechanical sound speed is $C = \sqrt{\delta P/\delta\rho} = \sqrt{K/\rho}$ [see passage following Eq. (12.43)].

the longitudinal part of ξ has vanishing curl. The result is

$$\omega^2 = \frac{\mu}{\rho} k^2, \quad \text{or} \quad \boxed{\omega = \Omega(\mathbf{k}) \equiv \left(\frac{\mu}{\rho}\right)^{1/2} k.} \quad (12.11)$$

transverse dispersion relation

This dispersion relation $\omega = \Omega(\mathbf{k})$ serves as a geometric-optics hamiltonian for wave propagation when μ and ρ vary slowly with \mathbf{x} and/or t . It also implies that the transverse waves propagate with a phase speed C_T and phase and group velocities given by

$$\boxed{C_T = \left(\frac{\mu}{\rho}\right)^{1/2};} \quad (12.12a)$$

transverse wave speed

$$\boxed{\mathbf{V}_{\text{ph}} = \mathbf{V}_g = C_T \hat{\mathbf{k}}.} \quad (12.12b)$$

As $K > 0$, the shear wave speed C_T is always less than the speed C_L of longitudinal waves [Eq. (12.9a)].

These transverse modes are known as *shear waves*, because they are driven by the shear stress; cf. Fig. 12.1b. There is no expansion and therefore no change in volume associated with shear waves. They do not exist in fluids, but they are close analogs of the transverse vibrations of a string.

Longitudinal waves can be thought of as scalar waves, since they are fully describable by a single component ξ_L of the displacement ξ ; that along $\hat{\mathbf{k}}$. Shear waves, by contrast, are inherently vectorial. Their displacement ξ_T can point in any direction orthogonal to \mathbf{k} . Since the directions orthogonal to \mathbf{k} form a 2-dimensional space, once \mathbf{k} has been chosen, there are two independent states of polarization for the shear wave. These two polarization states, together with the single one for the scalar, longitudinal wave, make up the three independent degrees of freedom in the displacement ξ .

polarization

In Ex. 12.3 we deduce these properties of ξ using matrix techniques.

Exercise 12.1 ***Problem: Influence of Gravity on Wave Speed*

EXERCISES

Modify the wave equation (12.4b) to include the effect of gravity. Assume that the medium is homogeneous and the gravitational field is constant. By comparing the orders of magnitude of the terms in the wave equation, verify that the gravitational terms can be ignored for high-enough frequency elastodynamic modes: $\omega \gg g/C_{L,T}$. For wave speeds $\sim 3 \text{ km s}^{-1}$, this gives $\omega/(2\pi) \gg 0.0005 \text{ Hz}$. Seismic waves are mostly in this regime.

Exercise 12.2 *Example: Scalar and Vector Potentials for Elastic Waves in a Homogeneous Solid*

Just as in electromagnetic theory, it is sometimes useful to write the displacement ξ in terms of scalar and vector potentials:

$$\xi = \nabla\psi + \nabla \times \mathbf{A}. \quad (12.13)$$

(The vector potential \mathbf{A} is, as usual, only defined up to a gauge transformation, $\mathbf{A} \rightarrow \mathbf{A} + \nabla\varphi$, where φ is an arbitrary scalar field.) By inserting Eq. (12.13) into the general elastodynamic wave equation (12.4b), show that the scalar and vector potentials satisfy the following wave equations in a homogeneous solid:

$$\frac{\partial^2 \psi}{\partial t^2} = C_L^2 \nabla^2 \psi, \quad \frac{\partial^2 \mathbf{A}}{\partial t^2} = C_T^2 \nabla^2 \mathbf{A}. \quad (12.14)$$

Thus, the scalar potential ψ generates longitudinal waves, while the vector potential \mathbf{A} generates transverse waves.

Exercise 12.3 *Example: Solving the Algebraic Wave Equation by Matrix Techniques*

By using the matrix techniques discussed in the next-to-the-last paragraph of Box 12.2, deduce that the general solution to the algebraic wave equation (12.6) is the sum of a longitudinal mode with the properties deduced in Sec. 12.2.3 and two transverse modes with the properties deduced in Sec. 12.2.4. [Note: This matrix technique is necessary and powerful when the algebraic dispersion relation is complicated, such as for plasma waves; Secs. 21.4.1 and 21.5.1. Elastodynamic waves are simple enough that we did not need this matrix technique in the text.] Specifically, do the following.

- (a) Rewrite the algebraic wave equation in the matrix form $M_{ij}\xi_j = 0$, obtaining thereby an explicit form for the matrix $||M_{ij}||$ in terms of ρ , K , μ , ω and the components of \mathbf{k} .
- (b) This matrix equation from part (a) has a solution if and only if the determinant of the matrix $||M_{ij}||$ vanishes. (Why?) Show that $\det ||M_{ij}|| = 0$ is a cubic equation for ω^2 in terms of k^2 , and that one root of this cubic equation is $\omega = C_L k$, while the other two roots are $\omega = C_T k$ with C_L and C_T given by Eqs. (12.9a) and (12.12a).
- (c) Orient Cartesian axes so that \mathbf{k} points in the z direction. Then show that, when $\omega = C_L k$, the solution to $M_{ij}\xi_j = 0$ is a longitudinal wave (i.e., a wave with ξ pointing in the z direction, the same direction as \mathbf{k}).
- (d) Show that, when $\omega = C_T k$, there are two linearly independent solutions to $M_{ij}\xi_j = 0$, one with ξ pointing in the x direction (transverse to \mathbf{k}) and the other in the y direction (also transverse to \mathbf{k}).

12.2.5

12.2.5 Energy of Elastodynamic Waves

Elastodynamic waves transport energy, just like waves on a string. The waves' kinetic energy density is obviously $\frac{1}{2}\rho\mathbf{v}^2 = \frac{1}{2}\rho\dot{\xi}^2$, where the dot means $\partial/\partial t$. The elastic energy density is given by Eq. (11.24), so the total energy density is

$$U = \frac{1}{2}\rho\dot{\xi}^2 + \frac{1}{2}K\Theta^2 + \mu\Sigma_{ij}\Sigma_{ij}. \quad (12.15a)$$

In Ex. 12.4 we show that (as one might expect) the elastodynamic wave equation (12.4b) can be derived from an action whose lagrangian density is the kinetic energy

density minus the elastic energy density. We also show that associated with the waves is an energy flux \mathbf{F} (not to be confused with a force for which we use the same notation) given by

$$F_i = -K \Theta \dot{\xi}_i - 2\mu \Sigma_{ij} \dot{\xi}_j = T_{ij} \dot{\xi}_j. \quad (12.15b)$$

energy density and flux
for general elastodynamic
wave in isotropic medium

As the waves propagate, energy sloshes back and forth between the kinetic and the elastic parts, with the time-averaged kinetic energy being equal to the time-averaged elastic energy (equipartition of energy). For the planar, monochromatic, longitudinal mode, the time-averaged energy density and flux are

$$U_L = \rho \langle \dot{\xi}_L^2 \rangle, \quad \mathbf{F}_L = U_L C_L \hat{\mathbf{k}}, \quad (12.16)$$

energy density and flux
for plane, monochromatic
elastodynamic wave

where $\langle \cdot \rangle$ denotes an average over one period or wavelength of the wave. Similarly, for the planar, monochromatic, transverse mode, the time-averaged density and flux of energy are

$$U_T = \rho \langle \dot{\xi}_T^2 \rangle, \quad \mathbf{F}_T = U_T C_T \hat{\mathbf{k}} \quad (12.17)$$

(Ex. 12.4). Thus, elastodynamic waves transport energy at the same speed $C_{L,T}$ as the waves propagate, and in the same direction $\hat{\mathbf{k}}$. This is the same behavior as electromagnetic waves in vacuum, whose Poynting flux and energy density are related by $\mathbf{F}_{EM} = U_{EM} c \hat{\mathbf{k}}$ with c the speed of light, and the same as all forms of dispersion-free scalar waves [e.g., sound waves in a medium; cf. Eq. (7.31)]. Actually, this is the dispersion-free limit of the more general result that the energy of any wave, in the geometric-optics limit, is transported with the wave's group velocity \mathbf{V}_g ; see Sec. 7.2.2.

Exercise 12.4 Example: Lagrangian and Energy for Elastodynamic Waves

EXERCISES

Derive the energy-density, energy-flux, and lagrangian properties of elastodynamic waves given in Sec. 12.2.5. Specifically, do the following.

- (a) For ease of calculation (and for greater generality), consider an elastodynamic wave in a possibly anisotropic medium, for which

$$T_{ij} = -Y_{ijkl} \xi_{k;l}, \quad (12.18)$$

with Y_{ijkl} the tensorial modulus of elasticity, which is symmetric under interchange (i) of the first two indices ij , (ii) of the last two indices kl , and (iii) of the first pair ij with the last pair kl [Eq. (11.17) and associated discussion]. Show that for an isotropic medium

$$Y_{ijkl} = \left(K - \frac{2}{3} \mu \right) g_{ij} g_{kl} + \mu (g_{ik} g_{jl} + g_{il} g_{jk}). \quad (12.19)$$

(Recall that in the orthonormal bases to which we have confined ourselves, the components of the metric are $g_{ij} = \delta_{ij}$, i.e., the Kronecker delta.)

- (b) For these waves the elastic energy density is $\frac{1}{2}Y_{ijkl}\xi_{i;j}\xi_{k;l}$ [Eq. (11.25)]. Show that the kinetic energy density minus the elastic energy density,

$$\mathcal{L} = \frac{1}{2}\rho \dot{\xi}_i \dot{\xi}_i - \frac{1}{2}Y_{ijkl}\xi_{i;j}\xi_{k;l}, \quad (12.20)$$

is a lagrangian density for the waves; that is, show that the vanishing of its variational derivative $\delta\mathcal{L}/\delta\xi_j \equiv \partial\mathcal{L}/\partial\xi_j - (\partial/\partial t)(\partial\mathcal{L}/\partial\dot{\xi}_j) = 0$ is equivalent to the elastodynamic equations $\rho\ddot{\xi} = -\nabla \cdot \mathbf{T}$.

- (c) The waves' energy density and flux can be constructed by the vector-wave analog of the canonical procedure of Eq. (7.36c):

$$U = \frac{\partial\mathcal{L}}{\partial\dot{\xi}_i}\dot{\xi}_i - \mathcal{L} = \frac{1}{2}\rho \dot{\xi}_i \dot{\xi}_i + \frac{1}{2}Y_{ijkl}\xi_{i;j}\xi_{k;l},$$

$$F_j = \frac{\partial\mathcal{L}}{\partial\xi_{i;j}}\dot{\xi}_i = -Y_{ijkl}\dot{\xi}_i\xi_{k;l}. \quad (12.21)$$

Verify that these density and flux values satisfy the energy conservation law, $\partial U/\partial t + \nabla \cdot \mathbf{F} = 0$. Using Eq. (12.19), verify that for an isotropic medium, expressions (12.21) for the energy density and flux become the expressions (12.15) given in the text.

- (d) Show that in general (for an arbitrary mixture of wave modes), the time average of the total kinetic energy in some huge volume is equal to that of the total elastic energy. Show further that for an individual longitudinal or transverse, planar, monochromatic mode, the time-averaged kinetic energy density and time-averaged elastic energy density are both independent of spatial location. Combining these results, infer that for a single mode, the time-averaged kinetic and elastic energy densities are equal, and therefore the time-averaged total energy density is equal to twice the time-averaged kinetic energy density. Show that this total time-averaged energy density is given by the first of Eqs. (12.16) and (12.17).
- (e) Show that the time average of the energy flux (12.15b) for the longitudinal and transverse modes is given by the second of Eqs. (12.16) and (12.17), so the energy propagates with the same speed and direction as the waves themselves.

12.3

12.3 Waves in Rods, Strings, and Beams

Before exploring applications (Sec. 12.4) of the longitudinal and transverse waves just described, we discuss how the wave equations and wave speeds are modified when the medium through which they propagate is bounded. Despite this situation being formally "global" in the sense of Box 12.2, elementary considerations enable us to derive the relevant dispersion relations without much effort.

12.3.1 Compression Waves in a Rod

12.3.1

First consider a longitudinal wave propagating along a light (negligible gravity), thin, unstressed rod. We shall call this a *compression wave*. Introduce a Cartesian coordinate system with the x -axis parallel to the rod. When there is a small displacement ξ_x independent of y and z , the restoring stress is given by $T_{xx} = -E \partial \xi_x / \partial x$, where E is Young's modulus [cf. Eq. (11.37)]. Hence the restoring force density $\mathbf{f} = -\nabla \cdot \mathbf{T}$ is $f_x = E \partial^2 \xi_x / \partial x^2$. The wave equation then becomes

$$\frac{\partial^2 \xi_x}{\partial t^2} = \left(\frac{E}{\rho} \right) \frac{\partial^2 \xi_x}{\partial x^2}, \quad (12.22)$$

and so the sound speed for compression waves in a long straight rod is

$$C_C = \left(\frac{E}{\rho} \right)^{\frac{1}{2}}. \quad (12.23)$$

speed of compression wave in a rod

Referring to Table 11.1 we see that a typical value of Young's modulus in a solid is ~ 100 GPa. If we adopt a typical density of $\sim 3 \times 10^3 \text{ kg m}^{-3}$, then we estimate the compressional sound speed to be $\sim 5 \text{ km s}^{-1}$. This is roughly 15 times the sound speed in air.

As this compressional wave propagates, in regions where the rod is compressed longitudinally, it bulges laterally by an amount given by Poisson's ratio; where it is expanded longitudinally, the rod shrinks laterally. By contrast, for a longitudinal wave in a homogeneous medium, transverse forces do not cause lateral bulging and shrinking. This accounts for the different propagation speeds, $C_C \neq C_L$; see Ex. 12.6.

12.3.2 Torsion Waves in a Rod

12.3.2

Next consider a rod with circular cross section of radius a , subjected to a twisting force (Fig. 12.2). Let us introduce an angular displacement $\Delta\phi \equiv \varphi(x)$ that depends on distance x down the rod. The only nonzero component of the displacement vector is $\xi_\phi = \varpi \varphi(x)$, where $\varpi = \sqrt{y^2 + z^2}$ is the cylindrical radius. We can calculate the total torque, exerted by the portion of the rod to the left of x on the portion to the right, by integrating over a circular cross section. For small twists, there is no expansion, and the only components of the shear tensor are

$$\Sigma_{\phi x} = \Sigma_{x\phi} = \frac{1}{2} \xi_{\phi, x} = \frac{\varpi}{2} \frac{\partial \varphi}{\partial x}. \quad (12.24)$$

The torque contributed by an annular ring of radius ϖ and thickness $d\varpi$ is $\varpi \cdot T_{\phi x} \cdot 2\pi \varpi d\varpi$, and we substitute $T_{\phi x} = -2\mu \Sigma_{\phi x}$ to obtain the total torque of the rod to the left of x on that to the right:

$$N = - \int_0^a 2\pi \mu \varpi^3 d\varpi \frac{\partial \varphi}{\partial x} = -\frac{\mu}{\rho} I \frac{\partial \varphi}{\partial x}, \quad \text{where } I = \frac{\pi}{2} \rho a^4 \quad (12.25)$$

is the moment of inertia per unit length.

FIGURE 12.2 When a rod with circular cross section is twisted, there will be a restoring torque.

Equating the net torque on a segment with length Δx to the rate of change of its angular momentum, we obtain

$$-\frac{\partial N}{\partial x} \Delta x = I \frac{\partial^2 \varphi}{\partial t^2} \Delta x, \quad (12.26)$$

which, using Eq. (12.25), becomes the wave equation for torsional waves:

$$\left(\frac{\mu}{\rho}\right) \frac{\partial^2 \varphi}{\partial x^2} = \frac{\partial^2 \varphi}{\partial t^2}. \quad (12.27)$$

The speed of torsional waves is thus

$$C_T = \left(\frac{\mu}{\rho}\right)^{\frac{1}{2}}. \quad (12.28)$$

speed of torsion wave in a rod

Note that this is the same speed as that of transverse shear waves in a uniform medium. This might have been anticipated, as there is no change in volume in a torsional oscillation and so only the shear stress acts to produce a restoring force.

12.3.3 Waves on Strings

This example is surely all too familiar. When a string under a tensile force T (*not* force per unit area) is plucked, there will be a restoring force proportional to the curvature of the string. If $\xi_z \equiv \eta$ is the transverse displacement (in the same notation as we used for rods in Secs. 11.5 and 11.6), then the wave equation will be

$$T \frac{\partial^2 \eta}{\partial x^2} = \Lambda \frac{\partial^2 \eta}{\partial t^2}, \quad (12.29)$$

where Λ is the mass per unit length. The wave speed is thus

$$C_S = \left(\frac{T}{\Lambda} \right)^{1/2}. \quad (12.30)$$

speed of wave in a string under tension

12.3.4 Flexural Waves on a Beam

12.3.4

Now consider the small-amplitude, transverse displacement of a horizontal rod or beam that can be flexed. In Sec. 11.5 we showed that such a flexural displacement produces a net elastic restoring force per unit length given by $D\partial^4\eta/\partial x^4$, and we considered a situation where that force was balanced by the beam's weight per unit length, $W = \Lambda g$ [Eq. (11.45)]. Here

$$D = \frac{1}{12} Ewh^3 \quad (12.31)$$

is the flexural rigidity [Eq. (11.41b)], h is the beam's thickness in the direction of bend, w is its width, $\eta = \xi_z$ is the transverse displacement of the neutral surface from the horizontal, Λ is the mass per unit length, and g is Earth's acceleration of gravity. The solution of the resulting force-balance equation, $-D\partial^4\eta/\partial x^4 = W = \Lambda g$, is the quartic (11.46a), which describes the equilibrium beam shape.

When gravity is absent and the beam is allowed to bend dynamically, the acceleration of gravity g gets replaced by the beam's dynamical acceleration, $\partial^2\eta/\partial t^2$. The result is a wave equation for flexural waves on the beam:

$$-D \frac{\partial^4 \eta}{\partial x^4} = \Lambda \frac{\partial^2 \eta}{\partial t^2}. \quad (12.32)$$

(This derivation of the wave equation is an elementary illustration of the principle of equivalence—the equivalence of gravitational and inertial forces, or gravitational and inertial accelerations—which underlies Einstein's general relativity theory; see Sec. 25.2.)

The wave equations we have encountered so far in this chapter have all described nondispersive waves, for which the wave speed is independent of the frequency. Flexural waves, by contrast, are dispersive. We can see this by assuming that $\eta \propto \exp[i(kx - \omega t)]$ and thereby deducing from Eq. (12.32) the dispersion relation:

$$\omega = \sqrt{D/\Lambda} k^2 = \sqrt{Eh^2/(12\rho)} k^2. \quad (12.33)$$

dispersion relation for flexural waves on a beam

Here we have used Eq. (12.31) for the flexural rigidity D and $\Lambda = \rho wh$ for the mass per unit length.

Before considering the implications of this dispersion relation, we complicate the equilibrium a little. Let us suppose that, in addition to the net shearing force per

dispersion relation for flexural waves on a stretched beam

unit length $-D\partial^4\eta/\partial x^4$, the beam is also held under a tensile force T . We can then combine the two wave equations (12.29) and (12.32) to obtain

$$-D\frac{\partial^4\eta}{\partial x^4} + T\frac{\partial^2\eta}{\partial x^2} = \Lambda\frac{\partial^2\eta}{\partial t^2}, \quad (12.34)$$

for which the dispersion relation is

$$\omega^2 = C_S^2 k^2 \left(1 + \frac{k^2}{k_c^2} \right), \quad (12.35)$$

where $C_S = \sqrt{T/\Lambda}$ is the wave speed when the flexural rigidity D is negligible so the beam is string-like, and

$$k_c = \sqrt{T/D} \quad (12.36)$$

is a critical wave number. If the average strain induced by the tension is $\epsilon = T/(Ewh)$, then $k_c = (12\epsilon)^{1/2}h^{-1}$, where h is the thickness of the beam, w is its width, and we have used Eq. (12.31). [Notice that k_c is equal to 1/(the lengthscale on which a pendulum's support wire—analogue of our beam—bends), as discussed in Ex. 11.11.] For short wavelengths $k \gg k_c$, the shearing force dominates, and the beam behaves like a tension-free beam; for long wavelengths $k \ll k_c$, it behaves like a string.

phase and group velocities for flexural waves on a stretched beam

A consequence of dispersion is that waves with different wave numbers k propagate with different speeds, and correspondingly, the group velocity $V_g = d\omega/dk$ with which wave packets propagate differs from the phase velocity $V_{ph} = \omega/k$ with which a wave's crests and troughs move (see Sec. 7.2.2). For the dispersion relation (12.35), the phase and group velocities are

$$\begin{aligned} V_{ph} &\equiv \omega/k = C_S(1 + k^2/k_c^2)^{1/2}, \\ V_g &\equiv d\omega/dk = C_S(1 + 2k^2/k_c^2)(1 + k^2/k_c^2)^{-1/2}. \end{aligned} \quad (12.37)$$

As we discussed in detail in Sec. 7.2.2 and Ex. 7.2, for dispersive waves such as this one, the fact that different Fourier components in the wave packet propagate with different speeds causes the packet to gradually spread; we explore this quantitatively for longitudinal waves on a beam in Ex. 12.5.

EXERCISES

Exercise 12.5 Derivation: Dispersion of Flexural Waves

Verify Eqs. (12.35) and (12.37). Sketch the dispersion-induced evolution of a Gaussian wave packet as it propagates along a stretched beam.

Exercise 12.6 Problem: Speeds of Elastic Waves

Show that the sound speeds for the following types of elastic waves in an isotropic material are in the ratios $1 : (1 - \nu^2)^{-1/2} : \left(\frac{1-\nu}{(1+\nu)(1-2\nu)} \right)^{1/2} : [2(1 + \nu)]^{-1/2} : [2(1 + \nu)]^{-1/2}$. The elastic waves are (i) longitudinal waves along a rod, (ii) longitudinal waves along a sheet, (iii) longitudinal waves along a rod embedded in an

incompressible fluid, (iv) shear waves in an extended solid, and (v) torsional waves along a rod. [Note: Here and elsewhere in this book, if you encounter grungy algebra (e.g., frequent conversions from $\{K, \mu\}$ to $\{E, \nu\}$), do not hesitate to use Mathematica, Matlab, Maple, or other symbolic manipulation software to do the algebra!]

Exercise 12.7 *Problem: Xylophones*

Consider a beam of length ℓ , whose weight is negligible in the elasticity equations, supported freely at both ends (so the slope of the beam is unconstrained at the ends). Show that the frequencies of standing flexural waves satisfy

$$\omega = \left(\frac{n\pi}{\ell}\right)^2 \left(\frac{D}{\rho A}\right)^{1/2},$$

where A is the cross sectional area, and n is an integer. Now repeat the exercise when the ends are clamped. Based on your result, explain why xylophones don't have clamped ends.

12.3.5 Bifurcation of Equilibria and Buckling (Once More)

12.3.5

We conclude this discussion by returning to the problem of buckling, which we introduced in Sec. 11.6. The example we discussed there was a playing card compressed until it wants to buckle. We can analyze small dynamical perturbations of the card, $\eta(x, t)$, by treating the tension T of the previous section as negative, $T = -F$, where F is the compressional force applied to the card's two ends in Fig. 11.11. Then the equation of motion (12.34) becomes

$$-D \frac{\partial^4 \eta}{\partial x^4} - F \frac{\partial^2 \eta}{\partial x^2} = \Lambda \frac{\partial^2 \eta}{\partial t^2}. \quad (12.38)$$

We seek solutions for which the ends of the playing card are held fixed (as shown in Fig. 11.11): $\eta = 0$ at $x = 0$ and at $x = \ell$. Solving Eq. (12.38) by separation of variables, we see that

$$\eta = \eta_n \sin\left(\frac{n\pi}{\ell}x\right) e^{-i\omega_n t}. \quad (12.39)$$

Here $n = 1, 2, 3, \dots$ labels the card's modes of oscillation, $n - 1$ is the number of nodes in the card's sinusoidal shape for mode n , η_n is the amplitude of deformation for mode n , and the mode's eigenfrequency ω_n (of course) satisfies the same dispersion relation (12.35) as for waves on a long, stretched beam, with $T \rightarrow -F$ and $k \rightarrow n\pi/\ell$:

eigenfrequencies for normal modes of a compressed beam

$$\omega_n^2 = \frac{1}{\Lambda} \left(\frac{n\pi}{\ell}\right)^2 \left[\left(\frac{n\pi}{\ell}\right)^2 D - F \right] = \frac{1}{\Lambda} \left(\frac{n\pi}{\ell}\right)^2 (n^2 F_{\text{crit}} - F), \quad (12.40)$$

where $F_{\text{crit}} = \pi^2 D/\ell^2$ is the critical force that we introduced in Chap. 11 [Eq. (11.54)].

Consider the lowest normal mode, $n = 1$, for which the playing card is bent in the single-arch manner of Fig. 11.11 as it oscillates. When the compressional force F is small, ω_1^2 is positive, so ω_1 is real and the normal mode oscillates sinusoidally and stably. But for $F > F_{\text{crit}} = \pi^2 D / \ell^2$, ω_1^2 is negative, so ω_1 is imaginary and there are two normal-mode solutions, one decaying exponentially with time, $\eta \propto \exp(-|\omega_1|t)$, and the other increasing exponentially with time, $\eta \propto \exp(+|\omega_1|t)$, signifying an instability against buckling.

onset of buckling for a compressed beam

Notice that the onset of instability occurs at the same compressional force, $F = F_{\text{crit}}$, as the bifurcation of equilibria [Eq. (11.54)], where a new (bent) equilibrium state for the playing card comes into existence. Notice, moreover, that the card's $n = 1$ normal mode has zero frequency, $\omega_1 = 0$, at this onset of instability and bifurcation of equilibria; the card can bend by an amount that grows linearly in time, $\eta = A \sin(\pi x / \ell) t$, with no restoring force or exponential growth. This zero-frequency motion leads the card from its original, straight equilibrium shape, to its new, bent equilibrium shape.

This is an example of a very general phenomenon, which we shall meet again in fluid mechanics (Sec. 15.6.1). For mechanical systems without dissipation (no energy losses to friction, viscosity, radiation, or anything else), as one gradually changes some “control parameter” (in this case the compressional force F), there can occur bifurcation of equilibria. At each bifurcation point, a normal mode of the original equilibrium becomes unstable, and at its onset of instability the mode has zero frequency and represents a motion from the original equilibrium (which is becoming unstable) to the new, stable equilibrium.

zero-frequency mode at bifurcation of equilibria

In our simple playing-card example, we see this phenomenon repeated again and again as the control parameter F is increased. One after another, at $F = n^2 F_{\text{crit}}$, the modes $n = 1, n = 2, n = 3, \dots$ become unstable. At each onset of instability, ω_n vanishes, and the zero-frequency mode (with $n - 1$ nodes in its eigenfunction) leads from the original, straight-card equilibrium to the new, stable, $(n - 1)$ -noded, bent equilibrium.

12.4 12.4 Body Waves and Surface Waves—Seismology and Ultrasound

In Sec. 12.2, we derived the dispersion relations $\omega = C_L k$ and $\omega = C_T k$ for longitudinal and transverse elastodynamic waves in uniform media. We now consider how the waves are modified in an inhomogeneous, finite body: Earth. Earth is well approximated as a sphere of radius $R \sim 6,000$ km and mean density $\bar{\rho} \sim 6,000$ kg m⁻³. The outer crust, extending down to 5–10 km below the ocean floor and comprising rocks of high tensile strength, rests on a more malleable mantle, the two regions being separated by the famous Mohorovičić (or Moho for short) discontinuity. Underlying the mantle is an outer core mainly composed of liquid iron, which itself surrounds a denser, solid inner core of mostly iron; see Table 12.1 and Fig. 12.5 below.

The pressure in Earth's interior is much larger than atmospheric, and the rocks are therefore quite compressed. Their atomic structure cannot be regarded as a small

FIGURE 12.3 Potential energy curves (dashed) for nearest neighbors in a crystal lattice. (a) At atmospheric (effectively zero) pressure, the equilibrium spacing is set by the minimum in the potential energy, which is a combination of hard electrostatic repulsion by the nearest neighbors (upper solid curve) and a softer overall attraction associated with all the nearby ions (lower solid curve). (b) At much higher pressure, the softer, attractive component is moved inward, and the equilibrium spacing is greatly reduced. The bulk modulus is proportional to the curvature of the potential energy curve at its minimum and so is considerably increased.

perturbation from their structure in a vacuum. Nevertheless, we can still use linear elasticity theory to discuss small perturbations about their equilibrium. This is because the crystal lattice has had plenty of time to establish a new equilibrium with a much smaller lattice spacing than at atmospheric pressure (Fig. 12.3). The density of lattice defects and dislocations will probably not differ appreciably from those at atmospheric pressure, so the proportionality limit and yield stress should be about the same as for rocks near Earth's surface. The linear stress-strain relation will still apply below the proportionality limit, although the elastic moduli are much greater than those measured at atmospheric pressure.

We can estimate the magnitude of the pressure P in Earth's interior by idealizing the planet as an isotropic medium with negligible shear stress, so its stress tensor is like that of a fluid, $\mathbf{T} = P\mathbf{g}$ (where \mathbf{g} is the metric tensor). Then the equation of static equilibrium takes the form

$$\frac{dP}{dr} = -g\rho, \quad (12.41)$$

where ρ is density, and $g(r)$ is the acceleration of gravity at radius r . This equation can be approximated by

$$P \sim \bar{\rho}gR \sim 300 \text{ GPa} \sim 3 \times 10^6 \text{ atmospheres}, \quad (12.42)$$

pressure at Earth's center

where g is now the acceleration of gravity at Earth's surface $r = R$, and $\bar{\rho}$ is Earth's mean density. This agrees well numerically with the accurate value of 360 GPa

at Earth's center. The bulk modulus produces the isotropic pressure $P = -K\Theta$ [Eq. (11.18)]; and since $\Theta = -\delta\rho/\rho$ [cf. Eq. (12.3)], the bulk modulus can be expressed as

$$K = \frac{dP}{d \ln \rho}. \quad (12.43)$$

[Strictly speaking, we should distinguish between adiabatic and isothermal variations in Eq. (12.43), but the distinction is small for solids; see Sec. 11.3.5. It is significant for gases.] Typically, the bulk modulus inside Earth is 4 to 5 times the pressure, and the shear modulus in the crust and mantle is about half the bulk modulus.

12.4.1

12.4.1 Body Waves

Virtually all our direct information about the internal structure of Earth comes from measurements of the propagation times of elastic waves that are generated by earthquakes and propagate through Earth's interior (*body waves*). There are two fundamental kinds of body waves: the longitudinal and transverse modes of Sec. 12.2. These are known in seismology as P-modes (P for pressure) and S-modes (S for shear), respectively. The two polarizations of the transverse shear waves are designated SH and SV, where H and V stand for "horizontal" and "vertical" displacements (i.e., displacements orthogonal to \mathbf{k} that are fully horizontal, or that are obtained by projecting the vertical direction \mathbf{e}_z orthogonal to $\hat{\mathbf{k}}$).

We shall first be concerned with what seismologists call high-frequency (of order 1 Hz) modes, which leads to three related simplifications. As typical wave speeds lie in the range $3\text{--}14 \text{ km s}^{-1}$, the wavelengths lie in the range ~ 1 to 10 km, which is generally small compared with the distance over which gravity causes the pressure to change significantly—the *pressure scale height*. It turns out that we then can ignore the effects of gravity on the propagation of small perturbations. In addition, we can regard the medium locally as effectively homogeneous and so use the local dispersion relations $\omega = C_{L,T}k$. Finally, as the wavelengths are short, we can trace rays through Earth using geometrical optics (Sec. 7.3).

Now, Earth is quite inhomogeneous globally, and the sound speeds therefore vary significantly with radius; see Table 12.1. To a fair approximation, Earth is horizontally stratified below the outer crust (whose thickness is irregular). Two types of variation can be distinguished, the abrupt and the gradual. There are several abrupt changes in the crust and mantle (including the Moho discontinuity at the interface between crust and mantle), and also at the transitions between mantle and outer core, and between outer core and inner core. At these *surfaces of discontinuity*, the density and elastic constants apparently change over distances short compared with a wavelength. Seismic waves incident on these discontinuities behave like light incident on the surface of a glass plate; they can be reflected and refracted. In addition, as there are now two different waves with different phase speeds, it is possible to generate SV waves from pure P waves and vice versa at a discontinuity (Fig. 12.4). However, this

TABLE 12.1: Typical outer radii (R), densities (ρ), bulk moduli (K), shear moduli (μ), P-wave speeds (C_P), and S-wave speeds (C_S) in different zones of Earth

Zone	R (10^3 km)	ρ (10^3 kg m $^{-3}$)	K (GPa)	μ (GPa)	C_P (km s $^{-1}$)	C_S (km s $^{-1}$)
Inner core	1.2	13	1,400	160	11	2
Outer core	3.5	10–12	600–1,300	—	8–10	—
Mantle	6.35	3–5	100–600	70–250	8–14	5–7
Crust	6.37	3	50	30	6–7	3–4
Ocean	6.37	1	2	—	1.5	—

Notes: Note the absence of shear waves (denoted by a —) in the fluid regions. Adapted from Stacey (1977).

FIGURE 12.4 An incident shear wave polarized in the vertical direction (SV_i), incident from above on a surface of discontinuity, produces both a longitudinal (P) wave and an SV wave in reflection and in transmission. If the wave speeds increase across the boundary (the case shown), then the transmitted waves, SV_t , P_t , will be refracted away from the vertical. A shear mode, SV_r , will be reflected at the same angle as the incident wave. However, the reflected P mode, P_r , will be reflected at a greater angle to the vertical, as it has greater speed than the incident wave.

wave-wave mixing is confined to SV and P; the SH waves do not mix with SV or P; see Ex. 12.9.

The junction conditions that control this wave mixing and all other details of the waves' behavior at a surface of discontinuity are: (i) the displacement ξ must be continuous across the discontinuity (otherwise infinite strain and infinite stress would develop there); and (ii) the net force acting on an element of surface must be zero (otherwise the surface, having no mass, would have infinite acceleration), so the force per unit area acting from the front face of the discontinuity to the back must be balanced by that acting from the back to the front. If we take the unit normal to the horizontal discontinuity to be e_z , then these boundary conditions become

$$[\xi_j] = [T_{jz}] = 0, \quad (12.44)$$

wave boundary conditions at interfaces

where the notation $[X]$ signifies the difference in X across the boundary, and the j is a vector index. (For an alternative, more formal derivation of $[T_{jz}] = 0$, see Ex. 12.8.)

One consequence of these boundary conditions is Snell's law for the directions of propagation of the waves. Since these continuity conditions must be satisfied all along the surface of discontinuity and at all times, the phase $\phi = \mathbf{k} \cdot \mathbf{x} - \omega t$ of the wave must be continuous across the surface at all locations \mathbf{x} on it and all times, which means that the phase ϕ must be the same on the surface for all transmitted waves and all reflected waves as for the incident waves. This is possible only if the frequency ω , the horizontal wave number $k_H = k \sin \alpha$, and the horizontal phase speed $C_H = \omega/k_H = \omega/(k \sin \alpha)$ are the same for all the waves. (Here $k_H = k \sin \alpha$ is the magnitude of the horizontal component of a wave's propagation vector, and α is the angle between its propagation direction and the vertical; cf. Fig. 12.4.) Thus we arrive at Snell's law: for every reflected or transmitted wave J , the horizontal phase speed must be the same as for the incident wave:

Snell's law for waves at interfaces

$$\frac{C_J}{\sin \alpha_J} = C_H \text{ is the same for all } J. \quad (12.45)$$

It is straightforward though tedious to compute the reflection and transmission coefficients (e.g., the strength of a transmitted P-wave produced by an incident SV wave) for the general case using the boundary conditions (12.44) and (12.45) (see, e.g., Eringen and Suhubi, 1975, Sec. 7.7). For the very simplest of examples, see Ex. 12.10.

In the regions between the discontinuities, the pressures (and consequently, the elastic moduli) increase steadily, over many wavelengths, with depth. The elastic moduli generally increase more rapidly than the density does, so the wave speeds generally also increase with depth (i.e., $dC/dr < 0$). This radial variation in C causes the rays along which the waves propagate to bend. The details of this bending are governed by Hamilton's equations, with the hamiltonian $\Omega(\mathbf{x}, \mathbf{k})$ determined by the simple non-dispersive dispersion relation $\Omega = C(\mathbf{x})k$ (Sec. 7.3.1). Hamilton's equations in this case reduce to the simple ray equation (7.48), which (since the index of refraction is $\propto 1/C$) can be rewritten as

geometric optics ray equation for elastodynamic waves in inhomogeneous elastic medium

$$\frac{d}{ds} \left(\frac{1}{C} \frac{d\mathbf{x}}{ds} \right) = \nabla \left(\frac{1}{C} \right). \quad (12.46)$$

Here s is distance along the ray, so $d\mathbf{x}/ds = \mathbf{n}$ is the unit vector tangent to the ray. This ray equation can be reexpressed in the following form:

$$d\mathbf{n}/ds = -(\nabla \ln C)_\perp, \quad (12.47)$$

where the subscript \perp means "projected perpendicular to the ray;" and this in turn means that the ray bends *away* from the direction in which C increases (i.e., it bends upward inside Earth, since C increases downward) with the radius of curvature of the bend given by

FIGURE 12.5 Seismic wave propagation in a schematic Earth model. A P wave made by an earthquake, E, propagates to the crust-mantle boundary at a where it generates two transmitted waves (SV and P) and two reflected waves (SV and P). The transmitted SV wave propagates along a ray that bends upward a bit (geometric-optics bending) and hits the mantle-outer-core boundary at b . There can be no transmitted SV wave at b , because the outer core is fluid; there can be no transmitted or reflected P wave, because the angle of incidence of the SV wave is too great. So the SV wave is perfectly reflected. It then travels along an upward curving ray, to the crust-mantle interface at c , where it generates four waves, two of which hit Earth's surface. The earthquake E also generates an SV wave traveling almost radially inward, through the crust-mantle interface at q , to the mantle-outer-core interface at r . Because the outer core is liquid, it cannot support an SV wave, so only a P wave is transmitted into the outer core at r . That P wave propagates to the interface with the inner core at s , where it regenerates an SV wave along with the transmitted and reflected P waves (not shown). The SV wave refracts back upward in the inner core and generates a P wave at the interface with the outer core t . That P wave propagates through the liquid outer core to u , where it generates an SV wave along with its transmitted and reflected P waves (not shown); that SV wave travels nearly radially outward, through v and to Earth's surface.

$$\mathcal{R} = \frac{1}{|(\nabla \ln C)_\perp|} = \frac{1}{|(d \ln C/dr) \sin \alpha|}. \quad (12.48)$$

Here α is the angle between the ray and the radial direction.

Figure 12.5 shows schematically the propagation of seismic waves through Earth. At each discontinuity in Earth's material, Snell's law governs the directions of the reflected and transmitted waves. As an example, note from Eq. (12.45) that an SV mode incident on a boundary cannot generate any P mode when its angle of incidence exceeds $\sin^{-1}(C_{Ti}/C_{Lt})$. (Here we use the standard notation C_T for the phase speed of an S wave and C_L for that of a P wave.) This is what happens at point b in Fig. 12.5.

seismic wave propagation

EXERCISES

Exercise 12.8 *Derivation: Junction Condition at a Discontinuity*

Derive the junction condition $[T_{jz}] = 0$ at a horizontal discontinuity between two media by the same method as one uses in electrodynamics to show that the normal component of the magnetic field must be continuous: Integrate the equation of motion $\rho d\mathbf{v}/dt = -\nabla \cdot \mathbf{T}$ over the volume of an infinitesimally thin pill box centered on the boundary (see Fig. 11.7), and convert the volume integral to a surface integral via Gauss's theorem.

Exercise 12.9 *Derivation: Wave Mixing at a Surface of Discontinuity*

Using the boundary conditions (12.44), show that at a surface of discontinuity inside Earth, SV and P waves mix, but SH waves do not mix with the other waves.

Exercise 12.10 *Example: Reflection and Transmission of Normal, Longitudinal Waves at a Boundary*

Consider a longitudinal elastic wave incident normally on the boundary between two media, labeled 1 and 2. By matching the displacement and the normal component of stress at the boundary, show that the ratio of the transmitted wave amplitude to the incident amplitude is given by

$$t = \frac{2Z_1}{Z_1 + Z_2},$$

where $Z_{1,2} = [\rho_{1,2}(K_{1,2} + 4\mu_{1,2}/3)]^{1/2}$ is known as the *acoustic impedance*. (The impedance is independent of frequency and is just a characteristic of the material.) Likewise, evaluate the amplitude reflection coefficient, and verify that wave energy flux is conserved.

12.4.2

12.4.2 Edge Waves

edge waves and surface waves

One phenomenon that is important in seismology (and also occurs in plasmas; Ex. 21.17) but is absent for many other types of wave motion is *edge waves*, i.e., waves that propagate along a discontinuity in the elastic medium. An important example is *surface waves*, which propagate along the surface of a medium (e.g., Earth's surface) and that decay exponentially with depth. Waves with such exponential decay are sometimes called *evanescent*.

Rayleigh wave

The simplest type of surface wave is the *Rayleigh wave*, which propagates along the surface of an elastic medium. We analyze Rayleigh waves for the idealization of a *plane semi-infinite solid*—also sometimes called a *homogeneous half-space*. When it is applied to Earth, this discussion must be modified to allow for both the density stratification and (if the wavelength is sufficiently long) the surface curvature. However, the qualitative character of the mode is unchanged.

Rayleigh waves are an intertwined mixture of P and SV waves. When analyzing them, it is useful to resolve their displacement vector $\boldsymbol{\xi}$ into a sum of a (longitudinal) P-wave component $\boldsymbol{\xi}^L$ and a (transverse) SV-wave component $\boldsymbol{\xi}^T$.

Consider a semi-infinite elastic medium, and introduce a local Cartesian coordinate system with \mathbf{e}_z normal to the surface, \mathbf{e}_x lying in the surface, and the propagation vector \mathbf{k} in the \mathbf{e}_z - \mathbf{e}_x plane. The propagation vector has a real component along the horizontal (\mathbf{e}_x) direction, corresponding to true propagation, and an imaginary component along the \mathbf{e}_z direction, corresponding to an exponential decay of the amplitude as one goes down into the medium. For the longitudinal (P-wave) and transverse (SV-wave) parts of the wave to remain in phase with each other as they propagate along the boundary, they must have the same values of the frequency ω and horizontal wave number k_x . However, there is no reason why their vertical ℓ -folding lengths should be the same (i.e., why their imaginary k_z values should be the same). We therefore denote their imaginary k_z s by $-iq_L$ for the longitudinal (P-wave) component and $-iq_T$ for the transverse (S-wave) component, and we denote their common k_x by k .

First focus attention on the longitudinal part of the wave. Its displacement can be written as the gradient of a scalar [Eq. (12.7b)], $\boldsymbol{\xi}_L = \nabla(\psi_0 e^{q_L z + i(kx - \omega t)})$:

$$\xi_x^L = ik\psi_0 e^{q_L z + i(kx - \omega t)}, \quad \xi_z^L = q_L \psi_0 e^{q_L z + i(kx - \omega t)}, \quad z \leq 0. \quad (12.49)$$

Substituting into the general dispersion relation $\omega^2 = C_L^2 \mathbf{k}^2$ for longitudinal waves, we obtain

$$q_L = \left(k^2 - \frac{\omega^2}{C_L^2} \right)^{1/2}. \quad (12.50)$$

Because the transverse part of the wave is divergence free, the wave's expansion comes entirely from the longitudinal part, $\Theta = \nabla \cdot \boldsymbol{\xi}_L$, and is given by

$$\Theta = (q_L^2 - k^2) \psi_0 e^{q_L z + i(kx - \omega t)}. \quad (12.51)$$

The transverse (SV) part of the wave can be written as the curl of a vector potential [Eq. (12.7c)], which we can take to point in the y direction, $\boldsymbol{\xi}_T = \nabla \times (A_0 \mathbf{e}_y e^{q_T z + i(kx - \omega t)})$:

$$\xi_x^T = -q_T A_0 e^{q_T z + i(kx - \omega t)}, \quad \xi_z^T = ik A_0 e^{q_T z + i(kx - \omega t)}, \quad z \leq 0. \quad (12.52)$$

The dispersion relation $\omega^2 = C_T^2 \mathbf{k}^2$ for transverse waves tells us that

$$q_T = \left(k^2 - \frac{\omega^2}{C_T^2} \right)^{1/2}. \quad (12.53)$$

We next impose boundary conditions at the surface. Since the surface is free, there will be no force acting on it:

$$\mathbf{T} \cdot \mathbf{e}_z|_{z=0} = 0, \quad (12.54)$$

which is a special case of the general boundary condition (12.44). (Note that we can evaluate the stress at the unperturbed surface rather than at the displaced surface as we

are only working to linear order.) The tangential stress is $T_{xz} = -2\mu(\xi_{z,x} + \xi_{x,z}) = 0$, so its vanishing is equivalent to

$$\xi_{z,x} + \xi_{x,z} = 0 \quad \text{at } z = 0. \quad (12.55)$$

Inserting $\xi = \xi_L + \xi_T$ and Eqs. (12.49) and (12.52) for the components and solving for the ratio of the transverse amplitude to the longitudinal amplitude, we obtain

$$\frac{A_0}{\psi_0} = \frac{2ikq_L}{k^2 + q_T^2}. \quad (12.56)$$

The normal stress is $T_{zz} = -K\Theta - 2\mu(\xi_{z,z} - \frac{1}{3}\Theta) = 0$, so from the values $C_L^2 = (K + \frac{4}{3}\mu)/\rho$ and $C_T^2 = \mu/\rho$ of the longitudinal and transverse sound speeds, which imply $K/\mu = (C_L/C_T)^2 - \frac{4}{3}$, we deduce that vanishing T_{zz} is equivalent to

$$(1 - 2\kappa)\Theta + 2\kappa\xi_{z,z} = 0 \quad \text{at } z = 0, \quad \text{where } \kappa \equiv \frac{C_T^2}{C_L^2} = \frac{1 - 2\nu}{2(1 - \nu)}. \quad (12.57)$$

Here we have used Eqs. (11.39) to express the speed ratio in terms of Poisson's ratio ν . Inserting Θ from Eq. (12.51) and $\xi_z = \xi_z^L + \xi_z^T$ with components from Eqs. (12.49) and (12.52), using the relation $q_L^2 - k^2 + 2\kappa k^2 = \kappa(q_T^2 + k^2)$ [which follows from Eqs. (12.50), (12.53), and (12.57)], and solving for the ratio of amplitudes, we obtain

$$\frac{A_0}{\psi_0} = \frac{k^2 + q_T^2}{-2ikq_T}. \quad (12.58)$$

The dispersion relation for Rayleigh waves is obtained by equating the two expressions (12.56) and (12.58) for the amplitude ratio:

$$4k^2q_Tq_L = (k^2 + q_T^2)^2. \quad (12.59)$$

We can express this dispersion relation more explicitly in terms of the ratio of the Rayleigh-wave speed $C_R = \omega/k$ to the transverse-wave speed C_T :

$$\zeta = \left(\frac{\omega}{C_T k}\right)^2 = \left(\frac{C_R}{C_T}\right)^2. \quad (12.60)$$

By inserting $q_T = k\sqrt{1 - \zeta}$ [from Eqs. (12.53) and (12.60)] and $q_L = k\sqrt{1 - \kappa\zeta}$ [from Eqs. (12.50), (12.57), and (12.60)], and expressing κ in terms of Poisson's ratio via Eq. (12.57), we bring Eq. (12.59) into the explicit form

$$\zeta^3 - 8\zeta^2 + 8\left(\frac{2 - \nu}{1 - \nu}\right)\zeta - \frac{8}{(1 - \nu)} = 0. \quad (12.61)$$

This dispersion relation is a third-order polynomial in $\zeta \propto \omega^2$ with just one positive real root $\zeta(\nu)$, which we plot in Fig. 12.6. From that plot, we see that for a Poisson's ratio characteristic of rocks, $0.2 \lesssim \nu \lesssim 0.3$, *the phase speed of a Rayleigh wave is roughly 0.9 times the speed of a pure shear wave*; cf. Fig. 12.6.

dispersion relation for Rayleigh wave

phase speed of Rayleigh wave

FIGURE 12.6 Solution $C_R/C_T = \sqrt{\xi}$ of the dispersion relation (12.61) as a function of Poisson's ratio ν .

FIGURE 12.7 Rayleigh waves in a semi-infinite elastic medium.

The displacement vector for Rayleigh waves is the sum of Eqs. (12.49) and (12.52) with the amplitudes related by (12.56):

$$\begin{aligned}\xi_x &= ik\psi_0 \left[e^{q_L z} - \frac{2q_L q_T}{k^2 + q_T^2} e^{q_T z} \right] e^{i(kx - \omega t)}, \\ \xi_z &= q_L \psi_0 \left[e^{q_L z} - \frac{2k^2}{k^2 + q_T^2} e^{q_T z} \right] e^{i(kx - \omega t)}.\end{aligned}\quad (12.62)$$

material displacement in Rayleigh wave

Equation (12.62) represents a backward rotating, elliptical motion for each fluid element near the surface (as depicted in Fig. 12.7), reversing to a forward rotation at depths where the sign of ξ_x has flipped.

Rayleigh waves propagate around the surface of Earth rather than penetrate its interior. However, our treatment is inadequate, because their wavelengths—typically 1–10 km if generated by an earthquake—are not necessarily small compared with the scale heights in the outer crust over which C_S and C_T vary. Our wave equation has to be modified to include these vertical gradients.

This vertical stratification has an important additional consequence. Ignoring these gradients, if we attempt to find an orthogonal surface mode just involving SH waves, we find that we cannot simultaneously satisfy the surface boundary conditions on displacement and stress with a single evanescent wave. We need two modes to do this. However, when we allow for stratification, the strong refraction allows an SH surface wave to propagate. This is known as a *Love wave*. The reason for its practical importance is that seismic waves are also created by underground nuclear explosions, and it is important to be able to distinguish explosion-generated waves from earthquake waves. An earthquake is usually caused by the transverse slippage of two blocks of crust across a fault line. It is therefore an efficient generator of shear modes, including Love waves. By contrast, explosions involve radial motions away from the point of explosion and are inefficient emitters of Love waves. This allows these two sources of seismic disturbance to be distinguished.

EXERCISES

Exercise 12.11 *Example: Earthquakes*

The magnitude M of an earthquake, on modern variants of the *Richter scale*, is a quantitative measure of the strength of the seismic waves it creates. The earthquake's seismic-wave energy release can be estimated using a rough semi-empirical formula due to Båth (1966):

$$E = 10^{5.24+1.44M} \text{ J.} \quad (12.63)$$

The largest earthquakes have magnitude ~ 9.5 .

One type of earthquake is caused by slippage along a fault deep in the crust. Suppose that most of the seismic power in an earthquake with $M \sim 8.5$ is emitted at frequencies ~ 1 Hz and that the quake lasts for a time $T \sim 100$ s. If C is an average wave speed, then it is believed that the stress is relieved over an area of fault of length $\sim CT$ and a depth of order one wavelength (Fig. 12.8). By comparing the stored elastic energy with the measured energy release, make an estimate of the minimum strain prior to the earthquake. Is your answer reasonable? Hence estimate the typical displacement during the earthquake in the vicinity of the fault. Make an order-of-magnitude estimate of the acceleration measurable by a seismometer in the next state and in the next continent. (Ignore the effects of density stratification, which are actually quite significant.)

12.4.3

12.4.3 Green's Function for a Homogeneous Half-Space

To gain insight into the combination of waves generated by a localized source, such as an explosion or earthquake, it is useful to examine the Green's function for excitations in a homogeneous half-space. Physicists define the Green's function $G_{jk}(\mathbf{x}, t; \mathbf{x}', t')$ to be the displacement response $\xi_j(\mathbf{x}, t)$ to a unit delta-function force in the \mathbf{e}_k direction at location \mathbf{x}' and time t' : $\mathbf{F} = \delta(\mathbf{x} - \mathbf{x}')\delta(t - t')\mathbf{e}_k$. Geophysicists sometimes find

FIGURE 12.8 Earthquake: The region of a fault that slips (solid rectangle), and the volume over which the strain is relieved, on one side of the fault (dashed region).

it useful to work, instead, with the “Heaviside Green’s function,” $G_{jk}^H(\mathbf{x}, t; \mathbf{x}', t')$, which is the displacement response $\zeta_j(\mathbf{x}, t)$ to a unit step-function force (one that turns on to unit strength and remains forever constant afterward) at \mathbf{x}' and t' : $\mathbf{F} = \delta(\mathbf{x} - \mathbf{x}')H(t - t')\mathbf{e}_k$. Because $\delta(t - t')$ is the time derivative of the Heaviside step function $H(t - t')$, the Heaviside Green’s function is the time integral of the physicists’ Green’s function. The Heaviside Green’s function has the advantage that one can easily see the size of the step functions it contains, by contrast with the size of the delta functions contained in the physicists’ Green’s function.

It is a rather complicated task to compute the Heaviside Green’s function, and geophysicists have devoted much effort to doing so. We shall not give the details of such computations, but merely show the function graphically in Fig. 12.9 for an instructive situation: the displacement produced by a step-function force in a homogeneous half-space with the observer at the surface and the force at two different locations: a point nearly beneath the observer (Fig. 12.9a), and a point close to the surface and some distance away in the x direction (Fig. 12.9b).

Several features of this Heaviside Green’s function deserve note:

- Because of their relative propagation speeds, the P waves arrive at the observer first, then (about twice as long after the excitation) the S waves, and shortly thereafter the Rayleigh waves. From the time interval ΔT between the first P waves and first S waves, one can estimate the distance to the source: $\ell \simeq (C_P - C_S)\Delta T \sim 3(\Delta T/s)$ km.
- For the source nearly beneath the observer (Fig. 12.9a), there is no sign of any Rayleigh wave, whereas for the source close to the surface, the Rayleigh wave is the strongest feature in the x and z (longitudinal and vertical) displacements but is absent from the y (transverse) displacement. From this, one can infer the waves’ propagation direction.
- The y (transverse) component of force produces a transverse displacement that is strongly concentrated in the S wave.
- The x and z (longitudinal and vertical) components of force produce x and z displacements that include P waves, S waves, and (for the source near the surface) Rayleigh waves.

Heaviside Green’s function for elastodynamic waves

Properties of Heaviside Green’s function

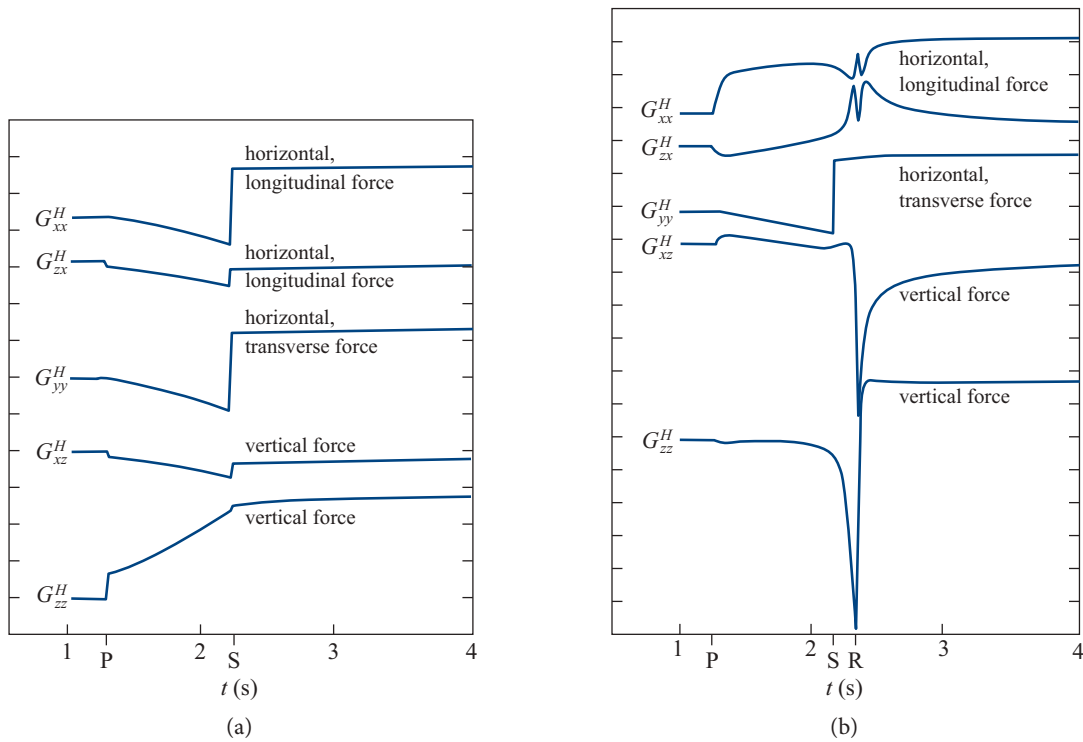

FIGURE 12.9 The Heaviside Green's function (displacement response to a step-function force) in a homogeneous half-space. The observer is at the surface. The force is applied at a point in the x - z plane, with a direction stated in words and also given by the second index of G^H ; the displacement direction is given by the first index of G^H . The longitudinal and transverse speeds are $C_L = 8.00 \text{ km s}^{-1}$ and $C_S = 4.62 \text{ km s}^{-1}$, and the density is $3.30 \times 10^3 \text{ kg m}^{-3}$. For a force of 1 Newton, a division on the vertical scale is 10^{-16} m . The moments of arrival of the P wave, S wave, and Rayleigh (R) wave from the moment the force is turned on are indicated on the horizontal axis. (a) The source is nearly directly beneath the observer, so the waves propagate nearly vertically upward. More specifically, the source is at 10 km depth and is 2 km distant along the horizontal x direction. (b) The source is close to the surface, and the waves propagate nearly horizontally (in the x direction). More specifically, the source is at 2 km depth and is 10 km distant along the horizontal x direction. Adapted from Johnson (1974, Figs. 2, 4).

- The gradually changing displacements that occur between the arrival of the turn-on P wave and the turn-on S wave are due to P waves that hit the surface some distance from the observer, and from there diffract to the observer as a mixture of P and S waves. Similarly for gradual changes of displacement after the turn-on S wave.

The complexity of seismic waves arises in part from the richness of features in this homogeneous-half-space Heaviside Green's function, in part from the influences of Earth's inhomogeneities, and in part from the complexity of an earthquake's or explosion's forces.

FIGURE 12.10 Displacements associated with three types of global modes for an elastic sphere, such as Earth. The polar axis points upward. (a) A radial mode shown on a cross section through the sphere's center; matter originally on the solid circle moves in and out between the two dashed circles. (b) An $l = 1, m = 0$ torsional mode; the arrows are proportional to the displacement vector on the sphere's surface at one moment of time. (c) An $l = 2, m = 0$ spheroidal mode shown on a cross section through the sphere's center; matter originally on the solid circle moves between the two ellipses.

12.4.4 Free Oscillations of Solid Bodies

12.4.4

When computing the dispersion relations for body (P- and S-wave) modes and surface (Rayleigh-wave) modes, we have assumed that the wavelength is small compared with Earth's radius; therefore the modes have a continuous frequency spectrum. However, it is also possible to excite global modes in which the whole Earth “rings” with a discrete spectrum. If we approximate Earth as spherically symmetric and ignore its rotation (whose period is long compared to a normal-mode period), then we can isolate three types of global modes: *radial*, *torsional*, and *spheroidal*.

types of normal modes of an elastic sphere

To compute the details of these modes, we can solve by separation of variables the equations of elastodynamics for the displacement vector in spherical polar coordinates. This is much like solving the Schrödinger equation for a central potential. See Ex. 12.12 for a relatively simple example. In general (as in that example), each of the three types of modes has a displacement vector ξ characterized by its own type of spherical harmonic.

The *radial modes* have spherically symmetric, purely radial displacements $\xi_r(r)$ and so have spherical harmonic order $l = 0$; see Fig. 12.10a and Ex. 12.12a.

radial modes

The *torsional modes* have vanishing radial displacements, and their nonradial displacements are proportional to the vector spherical harmonic $\hat{\mathbf{L}} Y_l^m(\theta, \phi)$, where θ, ϕ are spherical coordinates, Y_l^m is the scalar spherical harmonic, and $\hat{\mathbf{L}} = \mathbf{x} \times \nabla$ is the angular momentum operator (aside from an omitted factor \hbar/i), which plays a major role in quantum theory. Spherical symmetry guarantees that these modes' eigenfrequencies are independent of m (because by reorienting the polar axis, the various m are mixed among one another), so $m = 0$ is representative. In this case, $\nabla Y_l^0 \propto \nabla P_l(\cos \theta)$ is in the θ direction, so $\hat{\mathbf{L}} Y_l^0$ is in the ϕ direction. Hence the only nonzero component of the displacement vector is

torsional modes

$$\xi_\phi \propto \partial P_l(\cos \theta) / \partial \theta = \sin \theta P_l'(\cos \theta). \quad (12.64)$$

(Here P_l is the Legendre polynomial and P_l' is the derivative of P_l with respect to its argument.) Therefore, in these modes alternate zones of different latitude oscillate in opposite directions (clockwise or counterclockwise at some chosen moment of time) in such a way as to conserve total angular momentum. See Fig. 12.10b and Ex. 12.12b. In the high-frequency limit, the torsional modes become SH waves (since their displacements are horizontal).

spheroidal modes

The *spheroidal modes* have radial displacements proportional to $Y_l^m(\theta, \phi)\mathbf{e}_r$, and they have nonradial components proportional to ∇Y_l^m . These two displacements can combine into a single mode, because they have the same parity (and opposite parity from the torsional modes) as well as the same spherical-harmonic orders l and m . The eigenfrequencies again are independent of m and thus can be studied by specializing to $m = 0$, in which case the displacements become

$$\xi_r \propto P_l(\cos \theta), \quad \xi_\theta \propto \sin \theta P_l'(\cos \theta). \quad (12.65)$$

These displacements deform the sphere in a spheroidal manner for the special case $l = 2$ (Fig. 12.10c and Ex. 12.12c), whence their name “spheroidal.” The radial modes are the special case $l = 0$ of these spheroidal modes. It is sometimes mistakenly asserted that there are no $l = 1$ spheroidal modes because of conservation of momentum. In fact, $l = 1$ modes do exist: for example, the central regions of the sphere can move up, while the outer regions move down. For Earth, the lowest-frequency $l = 2$ spheroidal mode has a period of 53 minutes and can ring for about 1,000 periods (i.e., its quality factor is $Q \sim 1,000$). This is typical for solid planets. In the high-frequency limit, the spheroidal modes become a mixture of P and SV waves.

solving elastodynamic equations for modes

When one writes the displacement vector ξ for a general vibration of Earth as a sum over these various types of global modes and inserts that sum into the wave equation (12.4b) (augmented, for greater realism, by gravitational forces), spherical symmetry of unperturbed Earth guarantees that the various modes will separate from one another. For each mode the wave equation will give a radial wave equation analogous to that for a hydrogen atom in quantum mechanics. The boundary condition $\mathbf{T} \cdot \mathbf{e}_r = 0$ at Earth’s surface constrains the solutions of the radial wave equation for each mode to be a discrete set, which one can label by the number n of radial nodes that the mode possesses (just as for the hydrogen atom). The frequencies of the modes increase with both n and l . See Ex. 12.12 for details in a relatively simple case.

mode spectra

For small values of the quantum numbers l and n , the modes are quite sensitive to the model assumed for Earth’s structure. For example, they are sensitive to whether one correctly includes the gravitational restoring force in the wave equation. However, for large l and n , the spheroidal and toroidal modes become standing combinations of P, SV, SH, Rayleigh, and Love waves, and therefore they are rather insensitive to the effects of gravity.

12.4.5 Seismic Tomography

12.4.5

Observations of all of these types of seismic waves clearly code much information about Earth's structure. Inverting the measurements to infer this structure has become a highly sophisticated and numerically intensive branch of geophysics—and also of oil exploration! The travel times of the P and S body waves can be measured between various pairs of points over Earth's surface and essentially allow C_L and C_T (and hence K/ρ and μ/ρ) to be determined as functions of radius inside Earth. Travel times are $\lesssim 1$ hour. Using this type of analysis, seismologists can infer the presence of hot and cold regions in the mantle and then infer how the rocks are circulating under the crust.

It is also possible to combine the observed travel times with Earth's equation of elastostatic equilibrium

$$\frac{dP}{dr} = -g(r)\rho, \quad g(r) = \frac{4\pi G}{r^2} \int_0^r r'^2 \rho(r') dr', \quad (12.66)$$

elastostatic equilibrium
equation for gravitating,
elastic sphere (e.g., Earth)

where $g(r)$ is the gravitational acceleration, to determine the distributions of density, pressure, and elastic constants. Measurements of Rayleigh and Love waves can be used to probe the surface layers. The results of this procedure are then input to obtain free oscillation frequencies (global mode frequencies), which compare well with the observations. The damping rates for the free oscillations furnish information on the interior viscosity.

12.4.6 Ultrasound; Shock Waves in Solids

12.4.6

Sound waves at frequencies above 20,000 Hz (where human hearing ends) are widely used in modern technology, especially for imaging and tomography. This is much like exploring Earth with seismic waves.

Just as seismic waves can travel from Earth's solid mantle through its liquid outer core and into its solid inner core, so these *ultrasonic waves* can travel through both solids and liquids, with reflection, refraction, and transmission similar to those in Earth.

Applications of ultrasound include, among others, medical imaging (e.g., of structures in the eye and of a human fetus during pregnancy), inspection of materials (e.g., of cracks, voids, and welding joints), acoustic microscopy at frequencies up to ~ 3 GHz (e.g., by scanning acoustic microscopes), ultrasonic cleaning (e.g., of jewelry), and ultrasonic welding (with sonic vibrations creating heat at the interface of the materials to be joined).

When an ultrasonic wave (or any other sound wave) in an elastic medium reaches a sufficiently high amplitude, its high-amplitude regions propagate faster than its low-amplitude regions. This causes it to develop a *shock front*, in which the compression increases almost discontinuously. This nonlinear mechanism for shock formation in a solid is similar to that in a fluid, where we shall study the mechanism in detail (Sec. 17.4.1). The theory of the elastodynamic shock itself, especially *jump conditions across the shock*, is also similar to that in a fluid (Sec. 17.5.1). For details of the theory in

solids, including effects of plastic flow at sufficiently high compressions, see Davison (2010). Ultrasonic shock waves are used to break up kidney stones in the human body. In laboratories, shocks from the impact of a rapidly moving projectile on a material specimen, or from intense pulsed laser-induced ablation (e.g., at the U.S. National Ignition Facility, Sec. 10.2.2), are used to compress the specimen to pressures similar to those in Earth's core or higher and thereby explore the specimen's high-density properties. Strong shock waves from meteorite impacts alter the properties of the rock through which they travel and can be used to infer aspects of the equation of state for planetary interiors.

EXERCISES

Exercise 12.12 ***Example: Normal Modes of a Homogeneous, Elastic Sphere³*

Show that, for frequency- ω oscillations of a homogeneous elastic sphere with negligible gravity, the displacement vector can everywhere be written as $\boldsymbol{\xi} = \nabla\psi + \nabla \times \mathbf{A}$, where ψ is a scalar potential that satisfies the longitudinal-wave Helmholtz equation, and \mathbf{A} is a divergence-free vector potential that satisfies the transverse-wave Helmholtz equation:

$$\begin{aligned} \boldsymbol{\xi} &= \nabla\psi + \nabla \times \mathbf{A}, & (\nabla^2 + k_L^2)\psi &= 0, \\ (\nabla^2 + k_T^2)\mathbf{A} &= 0, & \nabla \cdot \mathbf{A} &= 0; & k_L &= \frac{\omega}{C_L}, & k_T &= \frac{\omega}{C_T}. \end{aligned} \quad (12.67)$$

[Hint: See Ex. 12.2, and make use of gauge freedom in the vector potential.]

- (a) *Radial Modes.* The radial modes are purely longitudinal; their scalar potential [general solution of $(\nabla^2 + k_L^2)\psi = 0$ that is regular at the origin] is the spherical Bessel function of order zero: $\psi = j_0(k_L r) = \sin(k_L r)/(k_L r)$. The corresponding displacement vector $\boldsymbol{\xi} = \nabla\psi$ has as its only nonzero component

$$\xi_r = j_0'(k_L r), \quad (12.68)$$

where the prime on j_0 and on any other function in this exercise means the derivative with respect to its argument. (Here we have dropped a multiplicative factor k_L .) Explain why the only boundary condition that need be imposed is $T_{rr} = 0$ at the sphere's surface. By computing T_{rr} for the displacement vector of

3. For a detailed and extensive treatment of this problem and many references, see Eringen and Suhubi (1975, Secs. 8.13, 8.14). Our approach to the mathematics is patterned after that of Ashby and Dreitlein (1975, Sec. III), and our numerical evaluations are for the same cases as Love (1927, Secs. 195, 196) and as the classic paper on this topic, Lamb (1882). It is interesting to compare the mathematics of our analysis with the nineteenth-century mathematics of Lamb and Love, which uses radial functions $\psi_l(r) \sim r^{-l} j_l(r)$ and *solid harmonics* that are sums over m of $r^l Y_l^m(\theta, \phi)$ and satisfy Laplace's equation. Here j_l is the spherical Bessel function of order l , and Y_l^m is the spherical harmonic. Solid harmonics can be written as $\mathcal{F}_{ij\dots q} x_i x_j \dots x_q$, with \mathcal{F} a symmetric, trace-free tensor of order l . A variant of them is widely used today in multipolar expansions of gravitational radiation (see, e.g., Thorne, 1980, Sec. II).

Eq. (12.68) and setting it to zero, deduce the following eigenequation for the wave numbers k_L and thence frequencies $\omega = C_L k_L$ of the radial modes:

$$\frac{\tan x_L}{x_L} = \frac{1}{1 - (x_T/2)^2}, \quad (12.69)$$

where

$$x_L \equiv k_L R = \frac{\omega R}{C_L} = \omega R \sqrt{\frac{\rho}{K + 4\mu/3}}, \quad x_T \equiv k_T R = \frac{\omega R}{C_T} = \omega R \sqrt{\frac{\rho}{\mu}}, \quad (12.70)$$

with R the radius of the sphere. For $(x_T/x_L)^2 = 3$, which corresponds to a Poisson's ratio $\nu = 1/4$ (about that of glass and typical rock; see Table 11.1), numerical solution of this eigenequation gives the spectrum for modes $\{l = 0; n = 0, 1, 2, 3, \dots\}$:

$$\frac{x_L}{\pi} = \frac{\omega}{\pi C_L/R} = \{0.8160, 1.9285, 2.9539, 3.9658, \dots\}. \quad (12.71)$$

Note that these eigenvalues get closer and closer to integers as one ascends the spectrum; this also will be true for any other physically reasonable value of x_T/x_L . Explain why.

- (b) **T2** *Torsional Modes.* The general solution to the scalar Helmholtz equation $(\nabla^2 + k^2)\psi$ that is regular at the origin is a sum over eigenfunctions of the form $j_l(kr)Y_l^m(\theta, \phi)$. Show that the angular momentum operator $\hat{\mathbf{L}} = \mathbf{x} \times \nabla$ commutes with the laplacian ∇^2 , and thence infer that $\hat{\mathbf{L}}[j_l Y_l^m]$ satisfies the vector Helmholtz equation. Verify further that it is divergence free, which means it must be expressible as the curl of a vector potential that is also divergence free and satisfies the vector Helmholtz equation. This means that $\boldsymbol{\xi} = \hat{\mathbf{L}}[j_l(k_T r)Y_l^m(\theta, \phi)]$ is a displacement vector that satisfies the elastodynamic equation for transverse waves. Since $\hat{\mathbf{L}}$ differentiates only transversely (in the θ and ϕ directions), we can rewrite this expression as $\boldsymbol{\xi} = j_l(k_T r)\hat{\mathbf{L}}Y_l^m(\theta, \phi)$. To simplify computing the eigenfrequencies (which are independent of m), specialize to $m = 0$, and show that the only nonzero component of the displacement is

$$\xi_\phi \propto j_l(k_T r) \sin \theta P_l'(\theta). \quad (12.72)$$

Equation (12.72), for our homogeneous sphere, is the torsional mode discussed in the text [Eq. (12.64)]. Show that the only boundary condition that must be imposed on this displacement function is $T_{\phi r} = 0$ at the sphere's surface, $r = R$. Compute this component of the stress tensor (with the aid of Box 11.4 for the shear), and by setting it to zero, derive the following eigenequation for the torsional-mode frequencies:

$$x_T j_l'(x_T) - j_l(x_T) = 0. \quad (12.73)$$

For $l = 1$ (the case illustrated in Fig. 12.10b), this eigenequation reduces to $(3 - x_T^2) \tan x_T = 3x_T$, and the lowest few eigenfrequencies are

$$\frac{x_T}{\pi} = \frac{\omega}{\pi C_T/R} = \{1.8346, 2.8950, 3.9225, 4.9385, \dots\}. \quad (12.74)$$

As for the radial modes, these eigenvalues get closer and closer to integers as one ascends the spectrum. Explain why.

- (c) **T2** *Ellipsoidal Modes.* The displacement vector for the ellipsoidal modes is the sum of a longitudinal piece $\nabla\psi$ [with $\psi = j_l(k_L r)Y_l^m(\theta, \phi)$ satisfying the longitudinal wave Helmholtz equation] and a transverse piece $\nabla \times \mathbf{A}$ [with $\mathbf{A} = j_l(k_T r)\hat{\mathbf{L}} Y_l^m(\theta, \phi)$, which as we saw in part (b) satisfies the transverse wave Helmholtz equation and is divergence free]. Specializing to $m = 0$ to derive the eigenequation (which is independent of m), show that the components of the displacement vector are

$$\begin{aligned} \xi_r &= \left[\frac{\alpha}{k_L} j_l'(k_L r) + \frac{\beta}{k_T} l(l+1) \frac{j_l(k_T r)}{k_T r} \right] P_l(\cos \theta), \\ \xi_\theta &= \left[-\frac{\alpha}{k_L} \frac{j_l(k_L r)}{k_L r} + \frac{\beta}{k_T} \left(j_l'(k_T r) + \frac{j_l(k_T r)}{k_T r} \right) \right] \sin \theta P_l'(\cos \theta), \end{aligned} \quad (12.75)$$

where α/k_L and β/k_T are constants that determine the weightings of the longitudinal and transverse pieces, and we have included the k_L and k_T to simplify the stress tensor derived below. (To get the β term in ξ_r , you will need to use a differential equation satisfied by P_l .) Show that the boundary conditions we must impose on these eigenfunctions are $T_{rr} = 0$ and $T_{r\theta} = 0$ at the sphere's surface, $r = R$. By evaluating these [using the shear components in Box 11.4, the differential equation satisfied by $j_l(x)$, and $(K + \frac{4}{3}\mu)/\mu = (x_T/x_L)^2$], obtain the following expressions for these components of the stress tensor at the surface:

$$T_{rr} = -\mu P_l(\cos \theta) \left[\alpha \left\{ 2j_l''(x_L) - [(x_T/x_L)^2 - 2]j_l(x_L) \right\} + \beta 2l(l+1)f_1(x_T) \right] = 0,$$

$$T_{r\theta} = \mu \sin \theta P_l'(\cos \theta) \left[\alpha 2f_1(x_L) + \beta \left\{ j_l''(x_T) + [l(l+1) - 2]f_0(x_T) \right\} \right] = 0,$$

$$\text{where } f_0(x) \equiv j_l(x)/x^2 \quad \text{and} \quad f_1(x) \equiv (j_l(x)/x)'. \quad (12.76)$$

These simultaneous equations for the ratio α/β have a solution if and only if the determinant of their coefficients vanishes:

$$\begin{aligned} &\left\{ 2j_l''(x_L) - [(x_T/x_L)^2 - 2]j_l(x_L) \right\} \left\{ j_l''(x_T) + (l+2)(l-1)f_0(x_T) \right\} \\ &\quad - 4l(l+1)f_1(x_L)f_1(x_T) = 0. \end{aligned} \quad (12.77)$$

This is the eigenequation for the ellipsoidal modes. For $l = 2$ and $(x_T/x_L)^2 = 3$, it predicts for the lowest four ellipsoidal eigenfrequencies

$$\frac{x_T}{\pi} = \frac{\omega}{\pi C_T/R} = \{0.8403, 1.5487, 2.6513, 3.1131, \dots\}. \quad (12.78)$$

Notice that these are significantly smaller than the torsional frequencies. Show that, in the limit of an incompressible sphere ($K \rightarrow \infty$) and for $l = 2$, the eigenequation becomes $(4 - x_T^2)[j_2''(x_T) + 4f_0(x_T)] - 24f_1(x_T) = 0$, which predicts for the lowest four eigenfrequencies

$$\frac{x_T}{\pi} = \frac{\omega}{\pi C_T/R} = \{0.8485, 1.7421, 2.8257, 3.8709, \dots\}. \quad (12.79)$$

These are modestly larger than the compressible case, Eq. (12.78).

12.5 The Relationship of Classical Waves to Quantum Mechanical Excitations T2

12.5

In the previous chapter, we identified the effects of atomic structure on the continuum approximation for elastic solids. Specifically, we showed that atomic structure accounts for the magnitude of the elastic moduli and explains why most solids yield under comparatively small strain. A quite different connection of the continuum theory to atomic structure is provided by the normal modes of vibration of a finite solid body (e.g., the sphere treated in Sec. 12.4.4 and Ex. 12.12).

For any such body, one can solve the vector wave equation (12.4b) [subject to the vanishing-surface-force boundary condition $\mathbf{T} \cdot \mathbf{n} = 0$, Eq. (11.33)] to find the body's normal modes, as we did in Ex. 12.12 for the sphere. In this section, we label the normal modes by a single index N (encompassing $\{l, m, n\}$ in the case of a sphere) and denote the eigenfrequency of mode N by ω_N and its (typically complex) eigenfunction by ξ_N . Then any general, small-amplitude disturbance in the body can be decomposed into a linear superposition of these normal modes:

normal modes of a general elastic body

$$\xi(\mathbf{x}, t) = \Re \sum_N a_N(t) \xi_N(\mathbf{x}), \quad a_N = A_N \exp(-i\omega_N t). \quad (12.80)$$

displacement expanded in normal modes

Here \Re means to take the real part, a_N is the *complex generalized coordinate* of mode N , and A_N is its complex amplitude. It is convenient to normalize the eigenfunctions so that

$$\int \rho |\xi_N|^2 dV = M, \quad (12.81)$$

where M is the mass of the body; A_N then measures the mean physical displacement in mode N .

Classical electromagnetic waves in a vacuum are described by linear Maxwell equations; so after they have been excited, they will essentially propagate forever. This is not so for elastic waves, where the linear wave equation is only an approximation. Nonlinearities—and most especially impurities and defects in the structure of the

body's material—will cause the different modes to interact weakly and also damp, so that their complex amplitudes A_N change slowly with time according to a damped simple harmonic oscillator differential equation of the form

equation of motion for a normal mode

$$\ddot{a}_N + (2/\tau_N)\dot{a}_N + \omega_N^2 a_N = F'_N/M. \quad (12.82)$$

Here the second term on the left-hand side is a damping term (due to frictional heating and weak coupling with other modes) that will cause the mode to decay as long as $\tau_N > 0$; F'_N is a fluctuating or *stochastic* force on mode N (also caused by weak coupling to the other modes). Equation (12.82) is the Langevin equation that we studied in Sec. 6.8.1. The spectral density of the fluctuating force F'_N is proportional to $1/\tau_N$ and is determined by the fluctuation-dissipation theorem, Eqs. (6.74) or (6.86). If the modes are thermalized at temperature T , then the fluctuating forces maintain an average energy of kT in each mode.

quantization of a normal mode

What happens quantum mechanically? The ions and electrons in an elastic solid interact so strongly that it is difficult to analyze them directly. A quantum mechanical treatment is much easier if one makes a canonical transformation from the coordinates and momenta of the individual ions or atoms to new, generalized coordinates \hat{x}_N and momenta \hat{p}_N that represent weakly interacting normal modes. These coordinates and momenta are Hermitian operators, and they are related to the quantum mechanical complex generalized coordinate \hat{a}_N by

$$\hat{x}_N = \frac{1}{2}(\hat{a}_N + \hat{a}_N^\dagger), \quad (12.83a)$$

$$\hat{p}_N = \frac{M\omega_N}{2i}(\hat{a}_N - \hat{a}_N^\dagger), \quad (12.83b)$$

where the dagger denotes the Hermitian adjoint. We can transform back to obtain an expression for the displacement of the i th ion:

$$\hat{\mathbf{x}}_i = \frac{1}{2} \sum_N [\hat{a}_N \zeta_N(\mathbf{x}_i) + \hat{a}_N^\dagger \zeta_N^*(\mathbf{x}_i)] \quad (12.84)$$

[a quantum version of Eq. (12.80)].

The hamiltonian can be written in terms of these coordinates as

$$\hat{H} = \sum_N \left(\frac{\hat{p}_N^2}{2M} + \frac{1}{2} M \omega_N^2 \hat{x}_N^2 \right) + \hat{H}_{\text{int}}, \quad (12.85)$$

where the first term is a sum of simple harmonic oscillator hamiltonians for individual modes; and \hat{H}_{int} is the perturbative interaction hamiltonian, which takes the place of the combined damping and stochastic forcing terms in the classical Langevin

equation (12.82). When the various modes are thermalized, the mean energy in mode N takes on the standard Bose-Einstein form:

$$\bar{E}_N = \hbar\omega_N \left[\frac{1}{2} + \frac{1}{\exp[\hbar\omega_N/(k_B T)] - 1} \right] \quad (12.86)$$

thermalized normal modes

[Eq. (4.28b) with vanishing chemical potential and augmented by a “zero-point energy” of $\frac{1}{2}\hbar\omega$], which reduces to $k_B T$ in the classical limit $\hbar \rightarrow 0$.

As the unperturbed hamiltonian for each mode is identical to that for a particle in a harmonic oscillator potential well, it is sensible to think of each wave mode as analogous to such a particle-in-well. Just as the particle-in-well can reside in any one of a series of discrete energy levels lying above the zero-point energy of $\hbar\omega/2$ and separated by $\hbar\omega$, so each wave mode with frequency ω_N must have an energy $(n + 1/2)\hbar\omega_N$, where n is an integer. The operator that causes the energy of the mode to decrease by $\hbar\omega_N$ is the *annihilation operator* for mode n :

$$\hat{\alpha}_N = \left(\frac{M\omega_N}{2\hbar} \right)^{1/2} \hat{a}_N, \quad (12.87)$$

creation and annihilation operators for normal-mode quanta (phonons)

the operator that causes an increase in the energy by $\hbar\omega_N$ is its Hermitian conjugate, the *creation operator* $\hat{\alpha}_N^\dagger$, and their commutator is $[\hat{\alpha}_N, \hat{\alpha}_N^\dagger] = 1$, corresponding to $[\hat{x}_N, \hat{p}_N] = i\hbar$; see for example Chap. 5 of Cohen-Tannoudji, Diu, and Laloë (1977). It is useful to think of each increase or decrease of a mode’s energy as the creation or annihilation of an individual quantum or “particle” of energy, so that when the energy in mode N is $(n + 1/2)\hbar\omega_N$, there are n quanta (particles) present. These particles are called *phonons*. Because phonons can coexist in the same state (the same mode), they are bosons. They have individual energies and momenta which must be conserved in their interactions with one another and with other types of particles (e.g., electrons). This conservation law shows up classically as resonance conditions in mode-mode mixing (cf. the discussion in nonlinear optics, Sec. 10.6.1).

phonons are bosons

The important question is, given an elastic solid at finite temperature, do we think of its thermal agitation as a superposition of classical modes, or do we regard it as a gas of quanta? The answer depends on what we want to do. From a purely fundamental viewpoint, the quantum mechanical description takes precedence. However, for many problems where the number of phonons per mode (the mode’s mean occupation number) $\eta_N \sim k_B T / (\hbar\omega_N)$ is large compared to one, the classical description is amply adequate and much easier to handle. We do not need a quantum treatment when computing the normal modes of a vibrating building excited by an earthquake or when trying to understand how to improve the sound quality of a violin. Here the difficulty often is in accommodating the boundary conditions so as to determine the normal modes. All this was expected. What comes as more of a surprise is that often, for purely classical problems (where \hbar is quantitatively irrelevant), the fastest way to

relation of classical and quantum theories for normal modes

analyze a practical problem formally is to follow the quantum route and then take the limit $\hbar \rightarrow 0$. We shall see this graphically demonstrated when we discuss nonlinear plasma physics in Chap. 23.

Bibliographic Note

The classic textbook treatments of elastodynamics from a physicist's viewpoint are Landau and Lifshitz (1986) and—in nineteenth-century language—Love (1927). For a lovely and very readable introduction to the basic concepts, with a focus on elastodynamic waves, see Kolsky (1963). Our favorite advanced textbook and treatise is Eringen and Suhubi (1975).

By contrast with elastostatics, where there are a number of good, twenty-first-century engineering-oriented textbooks at the elementary and intermediate levels, there are none that we know of for elastodynamics.

However, we do know two good, advanced engineering-oriented books on methods to solve the elastodynamic equations in nontrivial situations: Poruchikov, Khokhryakov, and Groshev (1993) and Kausel (2006). And for a compendium of practical engineering lore about vibrations of engineering structures, from building foundations to bell towers to suspension bridges, see Bachman (1994).

For seismic waves and their geophysical applications, we recommend the textbooks by Stein and Wysession (2003) and by Shearer (2009).

FLUID DYNAMICS

Having studied elasticity theory, we now turn to a second branch of continuum mechanics: *fluid dynamics*. Three of the four states of matter (gases, liquids, and plasmas) can be regarded as fluids, so it is not surprising that interesting fluid phenomena surround us in our everyday lives. Fluid dynamics is an experimental discipline; much of our current understanding has come in response to laboratory investigations. Fluid dynamics finds experimental application in engineering, physics, biophysics, chemistry, and many other fields. The observational sciences of oceanography, meteorology, astrophysics, and geophysics, in which experiments are less frequently performed, also rely heavily on fluid dynamics. Many of these fields have enhanced our appreciation of fluid dynamics by presenting flows under conditions that are inaccessible to laboratory study.

Despite this rich diversity, the fundamental principles are common to all these applications. The key assumption that underlies the equations governing the motion of a fluid is that the length- and timescales associated with the flow are long compared with the corresponding microscopic scales, so the continuum approximation can be invoked.

The fundamental equations of fluid dynamics are, in some respects, simpler than the corresponding laws of elastodynamics. However, as with particle dynamics, simplicity of equations does not imply the solutions are simple. Indeed, they are not! One reason is that fluid displacements are usually not small (by contrast with elastodynamics, where the elastic limit keeps them small), so most fluid phenomena are immediately nonlinear.

Relatively few problems in fluid dynamics admit complete, closed-form, analytic solutions, so progress in describing fluid flows has usually come from introducing clever physical models and using judicious mathematical approximations. Semi-empirical scaling laws are also common, especially for engineering applications. In more recent years, numerical fluid dynamics has come of age, and in many areas of

fluid dynamics, computer simulations are complementing and even supplanting laboratory experiments and measurements. For example, most design work for airplanes and automobiles is now computational.

In fluid dynamics, considerable insight accrues from visualizing the flow. This is true of fluid experiments, where much technical skill is devoted to marking the fluid so it can be imaged; it is also true of numerical simulations, where frequently more time is devoted to computer graphics than to solving the underlying partial differential equations. Indeed, obtaining an analytic solution to the equations of fluid dynamics is not the same as understanding the flow; as a tool for understanding, at the very least it is usually a good idea to sketch the flow pattern.

We present the fundamental concepts of fluid dynamics in Chap. 13, focusing particularly on the underlying physical principles and the conservation laws for mass, momentum, and energy. We explain why, when flow velocities are very subsonic, a fluid's density changes very little (i.e., it is effectively incompressible), and we specialize the fundamental principles and equations to incompressible flows.

Vorticity plays major roles in fluid dynamics. In Chap. 14, we focus on those roles for incompressible flows, both in the fundamental equations of fluid dynamics and in applications. Our applications include, among others, tornados and whirlpools, boundary layers abutting solid bodies, the influence of boundary layers on bulk flows, and how wind drives ocean waves and is ultimately responsible for deep-ocean currents.

Viscosity has a remarkably strong influence on fluid flows, even when the viscosity is weak. When strong, it keeps a flow laminar (smooth); when weak, it controls details of the turbulence that pervades the bulk flow (the flow away from boundary layers). In Chap. 15, we describe turbulence, a phenomenon so difficult to handle theoretically that semiquantitative ideas and techniques pervade its theoretical description, even in the incompressible approximation (to which we adhere). The onset of turbulence is especially intriguing. We illuminate it by exploring a closely related phenomenon: chaotic behavior in mathematical maps.

In Chap. 16, we focus on waves in fluids, beginning with waves on the surface of water, where we shall see, for shallow water, how nonlinear effects and dispersion together give rise to “solitary waves” (solitons) that hold themselves together as they propagate. In this chapter, we abandon the incompressible approximation, which has permeated Part V thus far, to study sound waves. Radiation reaction in sound generation is much simpler than in, for example, electrodynamics, so we use sound waves to elucidate the physical origin of radiation reaction and the nonsensical nature of pre-acceleration.

In Chap. 17, we turn to transonic and supersonic flows, in which density changes are of major importance. Here we meet some beautiful and powerful mathematical tools: characteristics and their associated Riemann invariants. We focus especially on flow through rocket nozzles and other constrictions, and on shock fronts, with applications to explosions (bombs and supernovae).

Convection is another phenomenon in which density changes are crucial—though here the density changes are induced by thermal expansion rather than by physical compression. We study convection in Chap. 18, paying attention to the (usually small but sometimes large) influence of diffusive heat conduction and the diffusion of chemical constituents (e.g., salt).

When a fluid is electrically conducting and has an embedded magnetic field, the exchange of momentum between the field and the fluid can produce remarkable phenomena (e.g., dynamos that amplify a seed magnetic field, a multitude of instabilities, and Alfvén waves and other magnetosonic waves). This is the realm of magnetohydrodynamics, which we explore in Chap. 19. The most common application of magnetohydrodynamics is to a highly ionized plasma, the topic of Part VI of this book, so Chap. 19 serves as a transition from fluid dynamics (Part V) to plasma physics (Part VI).

Foundations of Fluid Dynamics

ARCHIMEDES (CA. 250 BC)

13.1 Overview

13.1

In this chapter, we develop the fundamental concepts and equations of fluid dynamics, first in the flat-space venue of Newtonian physics (Track One) and then in the Minkowski spacetime venue of special relativity (Track Two). Our relativistic treatment is rather brief. This chapter contains a large amount of terminology that may be unfamiliar to readers. A glossary of terminology is given in Box 13.5, near the end of the chapter.

We begin in Sec. 13.2 with a discussion of the physical nature of a fluid: the possibility of describing it by a piecewise continuous density, velocity, and pressure and the relationship between density changes and pressure changes. Then in Sec. 13.3, we discuss hydrostatics (density and pressure distributions of a static fluid in a static gravitational field); this parallels our discussion of elastostatics in Chap. 11. After explaining the physical basis of Archimedes' law, we discuss stars, planets, Earth's atmosphere, and other applications.

Our foundation for moving from hydrostatics to hydrodynamics will be conservation laws for mass, momentum, and energy. To facilitate that transition, in Sec. 13.4, we examine in some depth the physical and mathematical origins of these conservation laws in Newtonian physics.

The stress tensor associated with most fluids can be decomposed into an isotropic pressure and a viscous term linear in the rate of shear (i.e., in the velocity gradient). Under many conditions the viscous stress can be neglected over most of the flow, and diffusive heat conductivity is negligible. The fluid is then called *ideal* or *perfect*.¹ We study the laws governing ideal fluids in Sec. 13.5. After deriving the relevant

ideal fluid (perfect fluid)

1. An ideal fluid (also called a *perfect fluid*) should not be confused with an ideal or perfect gas—one whose pressure is due solely to kinetic motions of particles and thus is given by $P = nk_B T$, with n the particle number density, k_B Boltzmann's constant, and T temperature, and that may (ideal gas) or may not (perfect gas) have excited internal molecular degrees of freedom; see Box 13.2.

BOX 13.1. READERS' GUIDE

- This chapter relies heavily on the geometric view of Newtonian physics (including vector and tensor analysis) laid out in Chap. 1.
- This chapter also relies on some elementary thermodynamic concepts treated in Chap. 5 and on the concepts of expansion, shear, and rotation (the irreducible tensorial parts of the gradient of displacement) introduced in Chap. 11.
- Our brief introduction to relativistic fluid dynamics (Track Two of this chapter) relies heavily on the geometric viewpoint on special relativity developed in Chap. 2.
- Chapters 14–19 (fluid dynamics including magnetohydrodynamics) are extensions of this chapter; to understand them, the Track-One parts of this chapter must be mastered.
- Portions of Part VI, Plasma Physics (especially Chap. 21 on the “two-fluid formalism”), rely heavily on Track-One parts of this chapter.
- Portions of Part VII, General Relativity, entail relativistic fluids in curved spacetime, for which the Track-Two Sec. 13.8 serves as a foundation.

conservation laws and equation of motion (the Euler equation), we derive and discuss Bernoulli's theorem for an ideal fluid and explain how it can simplify the description of many flows. In flows for which the fluid velocities are much smaller than the speed of sound and gravity is too weak to compress the fluid much, the fractional changes in fluid density are small. It can then be a good approximation to treat the fluid as *incompressible*, which leads to considerable simplification, also addressed in Sec. 13.5. As we shall see in Sec. 13.6, incompressibility can be a good approximation not just for liquids (which tend to have large bulk moduli) but also, more surprisingly, for gases. It is so widely applicable that we restrict ourselves to the incompressible approximation throughout Chaps. 14 and 15.

In Sec. 13.7, we augment our basic equations with terms describing viscous stresses and also heat conduction. This allows us to derive the famous Navier-Stokes equation and illustrate its use by analyzing the flow of a fluid through a pipe, and then use this to make a crude model of blood flowing through an artery. Much of our study of fluids in future chapters will focus on this Navier-Stokes equation.

In our study of fluids we often deal with the influence of a uniform gravitational field (e.g., Earth's, on lengthscales small compared to Earth's radius). Occasionally,

however, we consider inhomogeneous gravitational fields produced by the fluid whose motion we study. For such situations it is useful to introduce gravitational contributions to the stress tensor and energy density and flux. We present and discuss these in Box 13.4, where they will not impede the flow of the main stream of ideas.

We conclude this chapter in Sec. 13.8 with a brief, Track-Two overview of relativistic fluid mechanics for a perfect (ideal) fluid. As an important application, we explore the structure of a relativistic astrophysical jet: the conversion of internal thermal energy into the energy of organized bulk flow as the jet travels outward from the nucleus of a galaxy into intergalactic space and widens. We also explore how the fundamental equations of Newtonian fluid mechanics arise as low-velocity limits of the relativistic equations.

13.2 The Macroscopic Nature of a Fluid: Density, Pressure, Flow Velocity; Liquids versus Gases

13.2

fluid

The macroscopic nature of a fluid follows from two simple observations. The first is that in most flows the macroscopic continuum approximation is valid. Because the molecular mean free paths in a fluid are small compared to macroscopic lengthscales, we can define a mean local velocity $\mathbf{v}(\mathbf{x}, t)$ of the fluid's molecules, which varies smoothly both spatially and temporally; we call this the fluid's velocity. For the same reason, other quantities that characterize the fluid [e.g., the density $\rho(\mathbf{x}, t)$] also vary smoothly on macroscopic scales. This need not be the case everywhere in the flow. An important exception is a shock front, which we study in Chap. 17; there the flow varies rapidly, over a length of order the molecules' mean free path for collisions. In this case, the continuum approximation is only piecewise valid, and we must perform a matching at the shock front. One might think that a second exception is a turbulent flow, where it seems plausible that the average molecular velocity will vary rapidly on whatever lengthscale we choose to study, all the way down to intermolecular distances, so averaging becomes problematic. As we shall see in Chap. 15, this is not the case; turbulent flows generally have a lengthscale far larger than intermolecular distances, below which the flow varies smoothly.

The second observation is that fluids do not oppose a steady shear strain. This is easy to understand on microscopic grounds, as there is no lattice to deform, and the molecular velocity distribution remains locally isotropic in the presence of a static shear. By kinetic theory considerations (Chap. 3), we therefore expect that a fluid's stress tensor \mathbf{T} will be isotropic in the local rest frame of the fluid (i.e., in a frame where $\mathbf{v} = 0$). Because of viscosity, this is not quite true when the shear varies with time. However, we neglect viscosity as well as diffusive heat flow until Sec. 13.7 (i.e., we restrict ourselves to ideal fluids). This assumption allows us to write $\mathbf{T} = P\mathbf{g}$ in the local rest frame, where P is the fluid's pressure, and \mathbf{g} is the metric (with Kronecker delta components, $g_{ij} = \delta_{ij}$, in Cartesian coordinates).

liquid

gas or plasma

The laws of fluid mechanics as we develop them are equally valid for liquids, gases, and (under many circumstances) plasmas. In a liquid, as in a solid, the molecules are packed side by side (but can slide over one another easily). In a gas or plasma, the molecules are separated by distances large compared to their sizes. This difference leads to different behaviors under compression.

For a liquid (e.g., water in a lake), the molecules resist strongly even a small compression; as a result, it is useful to characterize the pressure increase by a bulk modulus K , as in an elastic solid (Chap. 11):

pressure changes in a liquid

$$\delta P = -K \Theta = K \frac{\delta \rho}{\rho} \quad \text{for a liquid.} \quad (13.1)$$

(Here we have used the fact that the expansion Θ is the fractional increase in volume, or equivalently by mass conservation, it is the fractional decrease in density.) The bulk modulus for water is about 2.2 GPa, so as one goes downward in a lake far enough to double the pressure from one atmosphere (10^5 Pa to 2×10^5 Pa), the fractional change in density is only $\delta \rho / \rho = (2 \times 10^5 / 2.2 \times 10^9) \simeq 1$ part in 10,000.

By contrast, gases and plasmas are much less resistant to compression. Due to the large distance between molecules, a doubling of the pressure requires, in order of magnitude, a doubling of the density:

pressure changes in a gas or plasma

$$\frac{\delta P}{P} = \Gamma \frac{\delta \rho}{\rho} \quad \text{for a gas,} \quad (13.2)$$

where Γ is a proportionality factor of order unity. The numerical value of Γ depends on the physical situation. If the gas is ideal [so $P = \rho k_B T / (\mu m_p)$ in the notation of Box 13.2, Eq. (4)] and the temperature T is being held fixed by thermal contact with some heat source as the density changes (*isothermal process*), then $\delta P \propto \delta \rho$, and $\Gamma = 1$. Alternatively, and much more commonly, a fluid element's entropy may remain constant, because no significant heat can flow in or out of it during the density change. In this case Γ is called the *adiabatic index*, and (continuing to assume ideality), it can be shown using the laws of thermodynamics that

adiabatic index

$$\Gamma = \gamma \equiv c_P / c_V \quad \text{for adiabatic processes in an ideal gas.} \quad (13.3)$$

specific heats per unit mass

Here c_P and c_V are the specific heats at constant pressure and volume; see Ex. 5.4 in Chap. 5.²

2. In fluid dynamics, our specific heats, and other extensive variables, such as energy, entropy, and enthalpy, are defined per unit mass and are denoted by lowercased letters. So $c_P = T(\partial s / \partial T)_P$ is the amount of heat that must be added to a unit mass of the fluid to increase its temperature by one unit, and similarly for $c_V = T(\partial s / \partial T)_V$. By contrast, in statistical thermodynamics (Chap. 5) our extensive variables are defined for some chosen sample of material and are denoted by capital letters, e.g., $C_P = T(\partial S / \partial T)_P$.

BOX 13.2. THERMODYNAMIC CONSIDERATIONS

One feature of fluid dynamics (especially gas dynamics) that distinguishes it from elastodynamics is that the thermodynamic properties of the fluid are often important, so we must treat energy conservation explicitly. In this box we review, from Chap. 5 or any book on thermodynamics (e.g., Kittel and Kroemer, 1980), the thermodynamic concepts needed in our study of fluids. We have no need for partition functions, ensembles, and other statistical aspects of thermodynamics. Instead, we only need elementary thermodynamics.

We begin with the nonrelativistic first law of thermodynamics (5.8) for a sample of fluid with energy E , entropy S , volume V , number N_I of molecules of species I , temperature T , pressure P , and chemical potential μ_I for species I :

$$dE = TdS - PdV + \sum_I \mu_I dN_I. \quad (1)$$

Almost everywhere in our treatment of fluid dynamics (and throughout this chapter), we assume that the term $\sum_I \mu_I dN_I$ vanishes. Physically this holds because (i) all relevant nuclear reactions are frozen (occur on timescales τ_{react} far longer than the dynamical timescales τ_{dyn} of interest to us), so $dN_I = 0$, and (ii) each chemical reaction is either frozen $dN_I = 0$ or goes so rapidly ($\tau_{\text{react}} \ll \tau_{\text{dyn}}$) that it and its inverse are in local thermodynamic equilibrium: $\sum_I \mu_I dN_I = 0$ for those species involved in the reactions. In the rare intermediate situation, where some relevant reaction has $\tau_{\text{react}} \sim \tau_{\text{dyn}}$, we would have to carefully keep track of the relative abundances of the chemical or nuclear species and their chemical potentials.

Consider a small fluid element with mass Δm , internal energy per unit mass u , entropy per unit mass s , and volume per unit mass $1/\rho$. Then inserting $E = u\Delta m$, $S = s\Delta m$, and $V = \Delta m/\rho$ into the first law $dE = TdS - PdV$, we obtain the form of the first law that we use in almost all of our fluid-dynamics studies:

$$du = Tds - Pd\left(\frac{1}{\rho}\right). \quad (2)$$

The internal energy (per unit mass) u comprises the random translational energy of the molecules that make up the fluid, together with the energy associated with their internal degrees of freedom (rotation, vibration, etc.) and with their intermolecular forces. The term Tds represents some amount of heat (per unit mass) that may be injected into a fluid element (e.g., by

(continued)

BOX 13.2. (continued)

viscous heating; Sec. 13.7) or may be removed (e.g., by radiative cooling). The term $-Pd(1/\rho)$ represents work done on the fluid.

In fluid mechanics it is useful to introduce the enthalpy $H = E + PV$ of a fluid element (cf. Ex. 5.5) and the corresponding enthalpy per unit mass $h = u + P/\rho$. Inserting $u = h - P/\rho$ into the left-hand side of the first law (2), we obtain the first law in the enthalpy representation [Eq. (5.47)]:

$$\boxed{dh = Tds + \frac{dP}{\rho}}. \quad (3)$$

Because we assume that all reactions are frozen or are in local thermodynamic equilibrium, the relative abundances of the various nuclear and chemical species are fully determined by a fluid element's density ρ and temperature T (or by any two other variables in the set ρ, T, s , and P). Correspondingly, the thermodynamic state of a fluid element is completely determined by any two of these variables. To calculate all features of that state from two variables, we must know the relevant equations of state, such as $P(\rho, T)$ and $s(\rho, T)$; $P(\rho, s)$ and $T(\rho, s)$; or the fluid's fundamental thermodynamic potential (Table 5.1), from which follow the equations of state.

We often deal with ideal gases (i.e., gases in which intermolecular forces and the volume occupied by the molecules are treated as totally negligible). For any ideal gas, the pressure arises solely from the kinetic motions of the molecules, and so the equation of state $P(\rho, T)$ is

$$\boxed{P = \frac{\rho k_B T}{\mu m_p}}. \quad (4)$$

Here μ is the *mean molecular weight*, and m_p is the proton mass [cf. Eqs. (3.39b), with the number density of particles n reexpressed as $\rho/\mu m_p$]. The mean molecular weight μ is the mean mass per gas molecule in units of the proton mass (e.g., $\mu = 1$ for hydrogen, $\mu = 32$ for O_2 , and $\mu = 28.8$ for air). This μ should not be confused with the chemical potential of species I , μ_I (which will rarely if ever be used in our fluid dynamics analyses). [The concept of an ideal gas must not be confused with an ideal fluid; see footnote 1.]

An idealization that is often accurate in fluid dynamics is that the fluid is *adiabatic*: no heating or cooling from dissipative processes, such as viscosity,

(continued)

BOX 13.2. (continued)

thermal conductivity, or the emission and absorption of radiation. When this is a good approximation, the entropy per unit mass s of a fluid element is constant.

In an adiabatic flow, there is only one thermodynamic degree of freedom, so we can write $P = P(\rho, s) = P(\rho)$. Of course, this function will be different for fluid elements that have different s . In the case of an ideal gas, a standard thermodynamic argument (Ex. 5.4) shows that the pressure in an adiabatically expanding or contracting fluid element varies with density as $\delta P/P = \gamma \delta \rho/\rho$, where $\gamma = c_P/c_V$ is the adiabatic index [Eqs. (13.2) and (13.3)]. If, as is often the case, the adiabatic index remains constant over several doublings of the pressure and density, then we can integrate this expression to obtain the equation of state

$$P = K(s)\rho^\gamma, \quad (5)$$

where $K(s)$ is some function of the entropy. Equation (5) is sometimes called the *polytropic* equation of state, and a *polytropic index* n (not to be confused with number density of particles!) is defined by $\gamma = 1 + 1/n$. See the discussion of stars and planets in Sec. 13.3.2 and Ex. 13.4. A special case of adiabatic flow is *isentropic* flow. In this case, the entropy is constant everywhere, not just inside individual fluid elements.

When the pressure can be regarded as a function of the density alone (the same function everywhere), the fluid is called *barotropic*.

From Eqs. (13.1) and (13.2), we see that $K = \Gamma P$; so why use K for liquids and Γ for gases and plasmas? Because in a liquid K remains nearly constant when P changes by large fractional amounts $\delta P/P \gtrsim 1$, while in a gas or plasma it is Γ that remains nearly constant.

For other thermodynamic aspects of fluid dynamics that will be relevant as we proceed, see Box 13.2.

13.3 Hydrostatics

Just as we began our discussion of elasticity with a treatment of elastostatics, so we introduce fluid mechanics by discussing hydrostatic equilibrium.

The *equation of hydrostatic equilibrium* for a fluid at rest in a gravitational field \mathbf{g} is the same as the equation of elastostatic equilibrium with a vanishing shear stress, so $\mathbf{T} = P\mathbf{g}$:

$$\nabla \cdot \mathbf{T} = \nabla P = \rho \mathbf{g} \quad (13.4)$$

13.3

equation of hydrostatic equilibrium

[Eq. (11.14) with $\mathbf{f} = -\nabla \cdot \mathbf{T}$]. Here \mathbf{g} is the acceleration of gravity (which need not be constant; e.g., it varies from location to location inside the Sun). It is often useful to express \mathbf{g} as the gradient of the Newtonian gravitational potential Φ :

Newtonian gravitational potential

$$\mathbf{g} = -\nabla\Phi. \quad (13.5)$$

Note our sign convention: Φ is negative near a gravitating body and zero far from all bodies, and it is determined by Newton's field equation for gravity:

Newtonian field equation for gravity

$$\nabla^2\Phi = -\nabla \cdot \mathbf{g} = 4\pi G\rho. \quad (13.6)$$

We can draw some immediate and important inferences from Eq. (13.4). Take the curl of Eq. (13.4) and use Eq. (13.5) to obtain

$$\nabla\Phi \times \nabla\rho = 0. \quad (13.7)$$

theorems about hydrostatic structure

Equation (13.7) tells us that in hydrostatic equilibrium, the contours of constant density (isochores) coincide with the equipotential surfaces: $\rho = \rho(\Phi)$. Equation (13.4) itself, with (13.5), then tells us that, as we move from point to point in the fluid, the changes in P and Φ are related by $dP/d\Phi = -\rho(\Phi)$. This, in turn, implies that the difference in pressure between two equipotential surfaces Φ_1 and Φ_2 is given by

$$\Delta P = -\int_{\Phi_1}^{\Phi_2} \rho(\Phi)d\Phi. \quad (13.8)$$

Moreover, as $\nabla P \propto \nabla\Phi$, the surfaces of constant pressure (the *isobars*) coincide with the gravitational equipotentials. This is all true whether \mathbf{g} varies inside the fluid or is constant.

pressure is weight of overlying fluid

The gravitational acceleration \mathbf{g} is actually constant to high accuracy in most non-astrophysical applications of fluid dynamics, for example, on the surface of Earth. In this case the pressure at a point in a fluid is, from Eq. (13.8), equal to the total weight of fluid per unit area above the point,

$$P(z) = g \int_z^\infty \rho dz, \quad (13.9)$$

where the integral is performed by integrating upward in the gravitational field (cf. Fig. 13.1). For example, the deepest point in the world's oceans is the bottom of the Mariana Trench in the Pacific, 11 km below sea level. Adopting a density $\rho \simeq 10^3 \text{ kg m}^{-3}$ for water and $g \simeq 10 \text{ m s}^{-2}$, we obtain a pressure of $\simeq 10^8 \text{ Pa}$ or $\simeq 10^3$ atmospheres. This is comparable with the yield stress of the strongest materials. It should therefore come as no surprise that the record for the deepest dive ever recorded by a submersible—a depth of 10.91 km (just $\sim 100 \text{ m}$ shy of the lowest point in the trench) achieved by the *Trieste* in 1960—remained unbroken for more than half a century. Only in 2012 was that last 100 m conquered and the trench's bottom reached, by the filmmaker James Cameron in the *Deep Sea Challenger*. Since the bulk modulus

FIGURE 13.1 Elementary demonstration of the principles of hydrostatic equilibrium. Water and mercury, two immiscible fluids of different density, are introduced into a container with two connected chambers as shown. In each chamber, isobars (surfaces of constant pressure) coincide with surfaces of constant $\Phi = -gz$, and so are horizontal. The pressure at each point on the flat bottom of a container is equal to the weight per unit area of the overlying fluid [Eq. (13.9)]. The pressures P_1 and P_2 at the bottom of the left chamber are equal, but because of the density difference between mercury and water, they differ from the pressure P_3 at the bottom of the right chamber.

of sea water is $K = 2.3$ GPa, at the bottom of the trench the water is compressed by $\delta\rho/\rho = P/K \simeq 0.05$.

EXERCISES

Exercise 13.1 Example: Earth's Atmosphere

As mountaineers know, it gets cooler as you climb. However, the rate at which the temperature falls with altitude depends on the thermal properties of air. Consider two limiting cases.

- (a) In the lower stratosphere (Fig. 13.2), the air is isothermal. Use the equation of hydrostatic equilibrium (13.4) to show that the pressure decreases exponentially with height z :

$$P \propto \exp(-z/H), \quad (13.10a)$$

where the scale height H is given by

$$H = \frac{k_B T}{\mu m_p g}, \quad (13.10b)$$

with μ the mean molecular weight of air and m_p the proton mass. Evaluate this numerically for the lower stratosphere, and compare with the stratosphere's thickness. By how much does P drop between the bottom and top of the isothermal region?

- (b) Suppose that the air is isentropic, so that $P \propto \rho^\gamma$ [Eq. (5) of Box 13.2], where γ is the specific heat ratio. (For diatomic gases like nitrogen and oxygen, $\gamma \sim 1.4$; see Ex. 17.1.) Show that the temperature gradient satisfies

$$\frac{dT}{dz} = - \left(\frac{\gamma - 1}{\gamma} \right) \frac{g \mu m_p}{k}. \quad (13.10c)$$

FIGURE 13.2 Actual temperature variation of Earth's mean atmosphere at temperate latitudes.

Note that the temperature gradient vanishes when $\gamma \rightarrow 1$. Evaluate the temperature gradient, also known at low altitudes as the *lapse rate*. The average lapse rate is measured to be $\sim 6 \text{ K km}^{-1}$ (Fig. 13.2). Show that this is intermediate between the two limiting cases of isentropic and isothermal lapse rates.

13.3.1

13.3.1 Archimedes' Law

Archimedes' law

The law of Archimedes states that, *when a solid body is totally or partially immersed in a fluid in a uniform gravitational field $\mathbf{g} = -g\mathbf{e}_z$, the total buoyant upward force of the fluid on the body is equal to the weight of the displaced fluid.*

Proof of Archimedes' Law. A formal proof can be made as follows (Fig. 13.3). The fluid, pressing inward on the body across a small element of the body's surface $d\mathbf{\Sigma}$, exerts a force $d\mathbf{F}^{\text{buoy}} = \mathbf{T}(\underline{\quad}, -d\mathbf{\Sigma})$ [Eq. (1.32)], where \mathbf{T} is the fluid's stress tensor, and the minus sign is because by convention, $d\mathbf{\Sigma}$ points out of the body rather than into it. Converting to index notation and integrating over the body's surface $\partial\mathcal{V}$, we obtain for the net buoyant force

$$F_i^{\text{buoy}} = - \int_{\partial\mathcal{V}} T_{ij} d\Sigma_j. \quad (13.11a)$$

Now, imagine removing the body and replacing it by fluid that has the same pressure $P(z)$ and density $\rho(z)$, at each height z as the surrounding fluid; this is the fluid that was originally displaced by the body. Since the fluid stress on $\partial\mathcal{V}$ has not changed, the buoyant force will be unchanged. Use Gauss's law to convert the surface integral (13.11a) into a volume integral over the interior fluid (the originally displaced fluid):

FIGURE 13.3 Derivation of Archimedes' law.

$$F_i^{\text{buoy}} = - \int_{\mathcal{V}} T_{ij,j} dV. \quad (13.11b)$$

The displaced fluid obviously is in hydrostatic equilibrium with the surrounding fluid, and its equation of hydrostatic equilibrium $T_{ij,j} = \rho g_i$ [Eq. (13.4)], when inserted into Eq. (13.11b), implies that

$$\mathbf{F}^{\text{buoy}} = -\mathbf{g} \int_{\mathcal{V}} \rho dV = -M\mathbf{g}, \quad (13.12)$$

where M is the mass of the displaced fluid. Thus, the upward buoyant force on the original body is equal in magnitude to the weight Mg of the displaced fluid. Clearly, if the body has a higher density than the fluid, then the downward gravitational force on it (its weight) will exceed the weight of the displaced fluid and thus exceed the buoyant force it feels, and the body will fall. If the body's density is less than that of the fluid, the buoyant force will exceed its weight and it will be pushed upward. ■

A key piece of physics underlying Archimedes' law is the fact that the intermolecular forces acting in a fluid, like those in a solid (cf. Sec. 11.3.6), are short range. If, instead, the forces were long range, Archimedes' law could fail. For example, consider a fluid that is electrically conducting, with currents flowing through it that produce a magnetic field and resulting long-range magnetic forces (the magnetohydrodynamic situation studied in Chap. 19). If we then substitute an insulating solid for some region \mathcal{V} of the conducting fluid, the force that acts on the solid will be different from the force that acted on the displaced fluid.

short-range versus long-range forces

Exercise 13.2 Practice: Weight in Vacuum

How much more would you weigh in a vacuum?

Exercise 13.3 Problem: Stability of Boats

Use Archimedes' law to explain qualitatively the conditions under which a boat floating in still water will be stable to small rolling motions from side to side. [Hint: You might want to define and introduce a *center of buoyancy* and a *center of gravity* inside

EXERCISES

FIGURE 13.4 The center of gravity and center of buoyancy of a boat when it is upright (left) and tilted (right).

the boat, and pay attention to the change in the center of buoyancy when the boat tilts. See Fig. 13.4.]

13.3.2

13.3.2 Nonrotating Stars and Planets

Stars and massive planets—if we ignore their rotation—are self-gravitating fluid spheres. We can model the structure of such a nonrotating, spherical, self-gravitating fluid body by combining the equation of hydrostatic equilibrium (13.4) in spherical polar coordinates,

$$\frac{dP}{dr} = -\rho \frac{d\Phi}{dr}, \quad (13.13)$$

with Poisson's equation,

$$\nabla^2 \Phi = \frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{d\Phi}{dr} \right) = 4\pi G\rho, \quad (13.14)$$

to obtain

$$\frac{1}{r^2} \frac{d}{dr} \left(\frac{r^2}{\rho} \frac{dP}{dr} \right) = -4\pi G\rho. \quad (13.15)$$

Equation (13.15) can be integrated once radially with the aid of the boundary condition $dP/dr = 0$ at $r = 0$ (pressure cannot have a cusp-like singularity) to obtain

equations of structure for
nonrotating star or planet

$$\boxed{\frac{dP}{dr} = -\rho \frac{Gm}{r^2}}, \quad (13.16a)$$

where

$$\boxed{m = m(r) \equiv \int_0^r 4\pi \rho r^2 dr} \quad (13.16b)$$

is the total mass inside radius r . Equation (13.16a) is an alternative form of the equation of hydrostatic equilibrium (13.13) at radius r inside the body: Gm/r^2 is the gravitational acceleration g at r , $\rho(Gm/r^2) = \rho g$ is the downward gravitational force per unit volume on the fluid, and dP/dr is the upward buoyant force per unit volume.

Equations (13.13)–(13.16b) are a good approximation for solid planets (e.g., Earth) as well as for stars and fluid planets (e.g., Jupiter) because at the enormous stresses encountered in the interior of a solid planet, the strains are so large that plastic flow occurs. In other words, the shear stresses are much smaller than the isotropic part of the stress tensor.

Let us make an order-of-magnitude estimate of the interior pressure in a star or planet of mass M and radius R . We use the equation of hydrostatic equilibrium (13.4) or (13.16a), approximating m by M , the density ρ by M/R^3 , and the gravitational acceleration by GM/R^2 ; the result is

$$P \sim \frac{GM^2}{R^4}. \quad (13.17)$$

To improve this estimate, we must solve Eq. (13.15). For that, we need a prescription relating the pressure to the density (i.e., an equation of state). A common idealization is the polytropic relation:

$$P \propto \rho^{1+1/n}, \quad (13.18)$$

polytropic equation of state

where n is the polytropic index (cf. last part of Box 13.2). [This finesses the issue of the generation and flow of heat in stellar interiors, which determines the temperature $T(r)$ and thence the pressure $P(\rho, T)$.] Low-mass white-dwarf stars are well approximated as $n = 1.5$ polytropes [Eq. (3.53c)], and red-giant stars are somewhat similar in structure to $n = 3$ polytropes. The giant planets, Jupiter and Saturn, are mainly composed of an H-He fluid that can be approximated by an $n = 1$ polytrope, and the density of a small planet like Mercury is roughly constant ($n = 0$).

To solve Eqs. (13.16), we also need boundary conditions. We can choose some density ρ_c and corresponding pressure $P_c = P(\rho_c)$ at the star's center $r = 0$, then integrate Eqs. (13.16) outward until the pressure P drops to zero, which will be the star's (or planet's) surface. The values of r and m there will be the star's radius R and mass M . For mathematical details of polytropic stellar models constructed in this manner, see Ex. 13.4. This exercise is particularly important as an example of the power of converting to dimensionless variables, a procedure we use frequently in this part of the book.

boundary conditions for stellar/planetary structure

We can easily solve the equations of hydrostatic equilibrium (13.16) for a planet with constant density ($n = 0$) to obtain $m = (4\pi/3)\rho r^3$ and

$$P = P_0 \left(1 - \frac{r^2}{R^2}\right), \quad (13.19)$$

where the central pressure is

$$P_0 = \left(\frac{3}{8\pi}\right) \frac{GM^2}{R^4}, \quad (13.20)$$

pressure in constant-density planet

consistent with our order-of-magnitude estimate (13.17).

Exercise 13.4 ***Example: Polytropes—The Power of Dimensionless Variables*

When dealing with differential equations describing a physical system, it is often helpful to convert to dimensionless variables. *Polytropes* (nonrotating, spherical fluid bodies with the polytropic equation of state $P = K\rho^{1+1/n}$) are a nice example.

- Combine the two equations of stellar structure (13.16) to obtain a single second-order differential equation for P and ρ as functions of r .
- In the equation from part (a) set $P = K\rho^{1+1/n}$ to obtain a nonlinear, second-order differential equation for $\rho(r)$.
- It is helpful to change dependent variables from $\rho(r)$ to some other variable, call it $\theta(r)$, so chosen that the quantity being differentiated is linear in θ and the only θ nonlinearity is in the driving term. Show that choosing $\rho \propto \theta^n$ achieves this.
- It is helpful to choose the proportionality constant in $\rho \propto \theta^n$ in such a way that θ is dimensionless and takes the value 1 at the polytrope's center and 0 at its surface. This is achieved by setting

$$\rho = \rho_c \theta^n, \quad (13.21a)$$

where ρ_c is the polytrope's (possibly unknown) central density.

- Similarly, it is helpful to make the independent variable r dimensionless by setting $r = a\xi$, where a is a constant with dimensions of length. The value of a should be chosen wisely, so as to simplify the differential equation as much as possible. Show that the choice

$$r = a\xi, \quad \text{where } a = \left[\frac{(n+1)K\rho_c^{(1/n-1)}}{4\pi G} \right]^{1/2}, \quad (13.21b)$$

brings the differential equation into the form

$$\frac{1}{\xi^2} \frac{d}{d\xi} \xi^2 \frac{d\theta}{d\xi} = -\theta^n. \quad (13.22)$$

Equation (13.22) is called the *Lane-Emden equation of stellar structure*, after Jonathan Homer Lane and Jacob Robert Emden, who introduced and explored it near the end of the nineteenth century. There is an extensive literature on solutions of the Lane-Emden equation (see, e.g., Chandrasekhar, 1939, Chap. 4; Shapiro and Teukolsky, 1983, Sec. 3.3).

- Explain why the Lane-Emden equation (13.22) must be solved subject to the following boundary conditions (where $\theta' \equiv d\theta/d\xi$):

$$\theta = 1 \quad \text{and} \quad \theta' = 0 \quad \text{at} \quad \xi = 0. \quad (13.23)$$

- One can integrate the Lane-Emden equation, numerically or analytically, outward from $\xi = 0$ until some radius ξ_1 at which θ (and thus also ρ and P) goes to zero. That is the polytrope's surface. Its physical radius is then $R = a\xi_1$, and its mass is $M = \int_0^R 4\pi\rho r^2 dr$, which is readily shown to be $M = 4\pi a^3 \rho_c \xi_1^2 |\theta'(\xi_1)|$.

Then, using the value of a given in Eq. (13.21b), we have:

$$R = \left[\frac{(n+1)K}{4\pi G} \right]^{1/2} \rho_c^{(1-n)/2n} \xi_1,$$

$$M = 4\pi \left[\frac{(n+1)K}{4\pi G} \right]^{3/2} \rho_c^{(3-n)/2n} \xi_1^2 |\theta'(\xi_1)|, \quad (13.24a)$$

whence

$$M = 4\pi R^{(3-n)/(1-n)} \left[\frac{(n+1)K}{4\pi G} \right]^{n/(n-1)} \xi_1^{(n+1)/(n-1)} |\theta'(\xi_1)|. \quad (13.24b)$$

- (h) When one converts a problem into dimensionless variables that satisfy some differential or algebraic equation(s) and then expresses physical quantities in terms of the dimensionless variables, the resulting expressions describe how the physical quantities scale with one another. As an example, Jupiter and Saturn are both made up of an H-He fluid that is well approximated by a polytrope of index $n = 1$, $P = K\rho^2$, with the same constant K . Use the information that $M_J = 2 \times 10^{27}$ kg, $R_J = 7 \times 10^4$ km, and $M_S = 6 \times 10^{26}$ kg to estimate the radius of Saturn. For $n = 1$, the Lane-Emden equation has a simple analytical solution: $\theta = \sin \xi / \xi$. Compute the central densities of Jupiter and Saturn.

13.3.3 Rotating Fluids

13.3.3

The equation of hydrostatic equilibrium (13.4) and the applications of it discussed above are valid only when the fluid is static in a nonrotating reference frame. However, they are readily extended to bodies that rotate rigidly with some uniform angular velocity $\boldsymbol{\Omega}$ relative to an inertial frame. In a frame that corotates with the body, the fluid will have vanishing velocity \mathbf{v} (i.e., will be static), and the equation of hydrostatic equilibrium (13.4) will be changed only by the addition of the centrifugal force per unit volume:

$$\nabla P = \rho(\mathbf{g} + \mathbf{g}_{\text{cen}}) = -\rho \nabla(\Phi + \Phi_{\text{cen}}). \quad (13.25)$$

hydrostatic equilibrium in corotating reference frame

Here

$$\mathbf{g}_{\text{cen}} = -\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{r}) = -\nabla \Phi_{\text{cen}} \quad (13.26)$$

is the centrifugal acceleration, $\rho \mathbf{g}_{\text{cen}}$ is the centrifugal force per unit volume, and

$$\Phi_{\text{cen}} = -\frac{1}{2}(\boldsymbol{\Omega} \times \mathbf{r})^2 \quad (13.27)$$

is a *centrifugal potential* whose gradient is equal to the centrifugal acceleration when $\boldsymbol{\Omega}$ is constant. The centrifugal potential can be regarded as an augmentation of the gravitational potential Φ . Indeed, *in the presence of uniform rotation, all hydrostatic theorems* [e.g., Eqs. (13.7) and (13.8)] *remain valid in the corotating reference frame with Φ replaced by $\Phi + \Phi_{\text{cen}}$.*

hydrostatic theorems for rotating body

We can illustrate this by considering the shape of a spinning fluid planet. Let us suppose that almost all the planet's mass is concentrated in its core, so the gravitational potential $\Phi = -GM/r$ is unaffected by the rotation. The surface of the planet must be an equipotential of $\Phi + \Phi_{\text{cen}}$ [coinciding with the zero-pressure isobar; cf. the sentence following Eq. (13.8), with $\Phi \rightarrow \Phi + \Phi_{\text{cen}}$]. The contribution of the centrifugal potential at the equator is $-\Omega^2 R_e^2/2$, and at the pole it is zero. The difference in the gravitational potential Φ between the equator and the pole is $\simeq g(R_e - R_p)$ where R_e and R_p are the equatorial and polar radii, respectively, and g is the gravitational acceleration at the planet's surface. Therefore, adopting this centralized-mass model and requiring that $\Phi + \Phi_{\text{cen}}$ be the same at the equator as at the pole, we estimate the difference between the polar and equatorial radii to be

centrifugal flattening

$$R_e - R_p \simeq \frac{\Omega^2 R^2}{2g}. \quad (13.28a)$$

Earth, although not a fluid, is unable to withstand large shear stresses, because its shear strain cannot exceed the yield strain of rock, ~ 0.001 ; see Sec. 11.3.2 and Table 11.1. Since the heights of the tallest mountains are also governed by the yield strain, Earth's surface will not deviate from its equipotential by more than the maximum height of a mountain, $\simeq 9$ km.

If, for Earth, we substitute $g \simeq 10 \text{ m s}^{-2}$, $R \simeq 6 \times 10^6 \text{ m}$, and $\Omega \simeq 7 \times 10^{-5} \text{ rad s}^{-1}$ into Eq. (13.28a), we obtain $R_e - R_p \simeq 10$ km, about half the correct value of 21 km. The reason for this discrepancy lies in our assumption that all the planet's mass resides at its center. In fact, the mass is distributed fairly uniformly in radius and, in particular, some mass is found in the equatorial bulge. This deforms the gravitational equipotential surfaces from spheres to ellipsoids, which accentuates the flattening. If, following Newton (in his *Principia Mathematica*, published in 1687), we assume that Earth has uniform density, then the flattening estimate is 2.5 times larger than our centralized-mass estimate (Ex. 13.5) (i.e., $R_e - R_p \simeq 25$ km), in fairly good agreement with Earth's actual shape.

EXERCISES

Exercise 13.5 Example: Shape of a Constant-Density, Spinning Planet

- Show that the spatially variable part of the gravitational potential for a uniform-density, nonrotating planet can be written as $\Phi = 2\pi G\rho r^2/3$, where ρ is the density.
- Hence argue that the gravitational potential for a slowly spinning planet can be written in the form

$$\Phi = \frac{2\pi G\rho r^2}{3} + Ar^2 P_2(\mu),$$

where A is a constant, and P_2 is the Legendre polynomial with argument $\mu = \sin(\text{latitude})$. What happens to the P_1 term?

- (c) Give an equivalent expansion for the potential outside the planet.
- (d) Now transform into a frame spinning with the planet, and add the centrifugal potential to give a total potential.
- (e) By equating the potential and its gradient at the planet's surface, show that the difference between the polar and the equatorial radii is given by

$$R_e - R_p \simeq \frac{5\Omega^2 R^2}{4g}, \quad (13.28b)$$

where g is the gravitational acceleration at the surface. Note that this is 5/2 times the answer for a planet whose mass is concentrated at its center [Eq. (13.28a)].

Exercise 13.6 *Problem: Shapes of Stars in a Tidally Locked Binary System*

Consider two stars with the same mass M orbiting each other in a circular orbit with diameter (separation between the stars' centers) a . Kepler's laws tell us that the stars' orbital angular velocity is $\Omega = \sqrt{2GM/a^3}$. Assume that each star's mass is concentrated near its center, so that everywhere except near a star's center the gravitational potential, in an inertial frame, is $\Phi = -GM/r_1 - GM/r_2$ with r_1 and r_2 the distances of the observation point from the center of star 1 and star 2. Suppose that the two stars are "tidally locked": tidal gravitational forces have driven them each to rotate with rotational angular velocity equal to the orbital angular velocity Ω . (The Moon is tidally locked to Earth, which is why it always keeps the same face toward Earth.) Then in a reference frame that rotates with angular velocity Ω , each star's gas will be at rest, $\mathbf{v} = 0$.

- (a) Write down the total potential $\Phi + \Phi_{\text{cen}}$ for this binary system in the rotating frame.
- (b) Using Mathematica, Maple, Matlab, or some other computer software, plot the equipotentials $\Phi + \Phi_{\text{cen}} = \text{const}$ for this binary in its orbital plane, and use these equipotentials to describe the shapes that these stars will take if they expand to larger and larger radii (with a and M held fixed). You should obtain a sequence in which the stars, when compact, are well separated and nearly round. As they grow, tidal gravity elongates them ultimately into tear-drop shapes, followed by merger into a single, highly distorted star. With further expansion, the merged star starts flinging mass off into the surrounding space (a process not included in this hydrostatic analysis).

13.4 Conservation Laws

13.4

As a foundation for the transition from hydrostatics to hydrodynamics [i.e., to situations with nonzero fluid velocity $\mathbf{v}(\mathbf{x}, t)$], we give a general discussion of Newtonian conservation laws, focusing especially on the conservation of mass and of linear momentum.

We begin with the differential law of mass conservation,

mass conservation:
differential form

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (13.29)$$

which we met and used in our study of elastic media [Eq. (12.2c)]. Eq. (13.29) is the obvious analog of the laws of conservation of charge, $\partial \rho_e / \partial t + \nabla \cdot \mathbf{j} = 0$, and of particles, $\partial n / \partial t + \nabla \cdot \mathbf{S} = 0$, which we met in Chap. 1 [Eqs. (1.30)]. In each case the law has the form $(\partial / \partial t)(\text{density of something}) + \nabla \cdot (\text{flux of that something}) = 0$. In fact, this form is universal for a differential conservation law.

Each Newtonian differential conservation law has a corresponding integral conservation law (Sec. 1.8), which we obtain by integrating the differential law over some arbitrary 3-dimensional volume \mathcal{V} , for example, the volume used in Fig. 13.3 to discuss Archimedes' law: $(d/dt) \int_{\mathcal{V}} \rho dV = \int_{\mathcal{V}} (\partial \rho / \partial t) dV = - \int_{\mathcal{V}} \nabla \cdot (\rho \mathbf{v}) dV$. Applying Gauss's law to the last integral, we obtain

mass conservation:
integral form

$$\frac{d}{dt} \int_{\mathcal{V}} \rho dV = - \int_{\partial \mathcal{V}} \rho \mathbf{v} \cdot d\boldsymbol{\Sigma}, \quad (13.30)$$

where $\partial \mathcal{V}$ is the closed surface bounding \mathcal{V} . The left-hand side is the rate of change of mass inside the region \mathcal{V} . The right-hand side is the rate at which mass flows into \mathcal{V} through $\partial \mathcal{V}$ (since $\rho \mathbf{v}$ is the mass flux, and the inward pointing surface element is $-d\boldsymbol{\Sigma}$). This is the same argument, connecting differential to integral conservation laws, as we gave when deriving Eqs. (1.29) and (1.30) for electric charge and for particles, but going in the opposite direction. And this argument depends in no way on whether the flowing material is a fluid or not. The mass conservation laws (13.29) and (13.30) are valid for any kind of material.

Writing the differential conservation law in the form (13.29), where we monitor the changing density at a given location in space rather than moving with the material, is called the *Eulerian* approach. There is an alternative *Lagrangian* approach to mass conservation, in which we focus on changes of density as measured by somebody who moves, locally, with the material (i.e., with velocity \mathbf{v}). We obtain this approach by differentiating the product $\rho \mathbf{v}$ in Eq. (13.29) to obtain

mass conservation:
alternative differential
form

$$\frac{d\rho}{dt} = -\rho \nabla \cdot \mathbf{v}, \quad (13.31)$$

where

convective (advective)
time derivative

$$\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla. \quad (13.32)$$

The operator d/dt is known as the *convective time derivative* (or *advective time derivative*) and crops up often in continuum mechanics. Its physical interpretation is very

simple. Consider first the partial derivative $(\partial/\partial t)_{\mathbf{x}}$. This is the rate of change of some quantity [the density ρ in Eq. (13.31)] at a fixed point \mathbf{x} in space in some reference frame. In other words, if there is motion, $\partial/\partial t$ compares this quantity at the same point \mathcal{P} in space for two different points in the material: one that is at \mathcal{P} at time $t + dt$; the other that was at \mathcal{P} at the earlier time t . By contrast, the convective time derivative d/dt follows the motion, taking the difference in the value of the quantity at successive times at the same point in the moving matter. It is the time derivative for the Lagrangian approach.

For a fluid, the Lagrangian approach can also be expressed in terms of fluid elements. Consider a small fluid element with a bounding surface attached to the fluid, and denote its volume by V . The mass inside the fluid element is $M = \rho V$. As the fluid flows, this mass must be conserved, so $dM/dt = (d\rho/dt)V + \rho(dV/dt) = 0$, which we can rewrite as

$$\frac{d\rho}{dt} = -\rho \frac{dV/dt}{V}. \quad (13.33)$$

Lagrangian formulation of mass conservation

Comparing with Eq. (13.31), we see that

$$\boxed{\nabla \cdot \mathbf{v} = \frac{dV/dt}{V}}. \quad (13.34)$$

Thus, the divergence of \mathbf{v} is the fractional rate of increase of a fluid element's volume. Notice that this is just the time derivative of our elastostatic equation $\Delta V/V = \nabla \cdot \boldsymbol{\xi} = \Theta$ [Eq. (11.7)] (since $\mathbf{v} = d\boldsymbol{\xi}/dt$). Correspondingly we denote

$$\boxed{\nabla \cdot \mathbf{v} \equiv \theta = d\Theta/dt}, \quad (13.35)$$

rate of expansion of fluid

and call it the fluid's *rate of expansion*.

Equation (13.29), $\partial\rho/\partial t + \nabla \cdot (\rho\mathbf{v}) = 0$, is our model for Newtonian conservation laws. It says that there is a quantity (in this case mass) with a certain density (ρ), and a certain flux ($\rho\mathbf{v}$), and this quantity is neither created nor destroyed. The temporal derivative of the density (at a fixed point in space) added to the divergence of the flux must vanish. Of course, not all physical quantities have to be conserved. If there were sources or sinks of mass, then these would be added to the right-hand side of Eq. (13.29).

Now turn to momentum conservation. The (Newtonian) law of momentum conservation must take the standard conservation-law form $(\partial/\partial t)(\text{momentum density}) + \nabla \cdot (\text{momentum flux}) = 0$.

If we just consider the *mechanical momentum* associated with the motion of mass, its density is the vector field $\rho\mathbf{v}$. There can also be other forms of momentum density (e.g., electromagnetic), but these do not enter into Newtonian fluid mechanics. For fluids, as for an elastic medium (Chap. 12), the momentum density is simply $\rho\mathbf{v}$.

The momentum flux is more interesting and rich. Quite generally it is, by definition, the stress tensor \mathbf{T} , and the differential conservation law states

momentum conservation:
Eulerian formulation

$$\frac{\partial(\rho\mathbf{v})}{\partial t} + \nabla \cdot \mathbf{T} = 0 \quad (13.36)$$

[Eq. (1.36)]. For an elastic medium, $\mathbf{T} = -K\Theta\mathbf{g} - 2\mu\boldsymbol{\Sigma}$ [Eq. (11.18)], and the conservation law (13.36) gives rise to the elastodynamic phenomena that we explored in Chap. 12. For a fluid we build up \mathbf{T} piece by piece.

We begin with the rate $d\mathbf{p}/dt$ that mechanical momentum flows through a small element of surface area $d\boldsymbol{\Sigma}$, from its back side to its front. The rate that mass flows through is $\rho\mathbf{v} \cdot d\boldsymbol{\Sigma}$, and we multiply that mass by its velocity \mathbf{v} to get the momentum flow rate: $d\mathbf{p}/dt = (\rho\mathbf{v})(\mathbf{v} \cdot d\boldsymbol{\Sigma})$. This rate of flow of momentum is the same thing as a force $\mathbf{F} = d\mathbf{p}/dt$ acting across $d\boldsymbol{\Sigma}$; so it can be computed by inserting $d\boldsymbol{\Sigma}$ into the second slot of a “mechanical” stress tensor \mathbf{T}_m : $d\mathbf{p}/dt = \mathbf{T}_m(_, d\boldsymbol{\Sigma})$ [cf. the definition (1.32) of the stress tensor]. By writing these two expressions for the momentum flow in index notation, $dp_i/dt = (\rho v_i)v_j d\Sigma_j = T_{mij}d\Sigma_j$, we read off the mechanical stress tensor: $T_{mij} = \rho v_i v_j$:

mechanical stress tensor

$$\mathbf{T}_m = \rho\mathbf{v} \otimes \mathbf{v}. \quad (13.37)$$

This tensor is symmetric (as any stress tensor must be; Sec. 1.9), and it obviously is the flux of mechanical momentum, since it has the form (momentum density) \otimes (velocity).

force \mathbf{f} per unit volume
acting on fluid

Let us denote by \mathbf{f} the net force per unit volume that acts on the fluid. Then instead of writing momentum conservation in the usual Eulerian differential form (13.36), we can write it as

$$\frac{\partial(\rho\mathbf{v})}{\partial t} + \nabla \cdot \mathbf{T}_m = \mathbf{f} \quad (13.38)$$

(conservation law with a source on the right-hand side). Inserting $\mathbf{T}_m = \rho\mathbf{v} \otimes \mathbf{v}$ into this equation, converting to index notation, using the rule for differentiating products, and combining with the law of mass conservation, we obtain the *Lagrangian law*

momentum conservation:
Lagrangian formulation

$$\rho \frac{d\mathbf{v}}{dt} = \mathbf{f}. \quad (13.39)$$

Here $d/dt = \partial/\partial t + \mathbf{v} \cdot \nabla$ is the convective time derivative (i.e., the time derivative moving with the fluid); so this equation is just Newton’s $\mathbf{F} = m\mathbf{a}$, per unit volume. For the equivalent equations (13.38) and (13.39) of momentum conservation to also be equivalent to the Eulerian formulation (13.36), there must be a stress tensor \mathbf{T}_f such that

stress tensor for the
force \mathbf{f}

$$\mathbf{f} = -\nabla \cdot \mathbf{T}_f; \quad \text{and} \quad \mathbf{T} = \mathbf{T}_m + \mathbf{T}_f. \quad (13.40)$$

Then Eq. (13.38) becomes the Eulerian conservation law (13.36).

Evidently, a knowledge of the stress tensor \mathbf{T}_f for some material is equivalent to a knowledge of the force density \mathbf{f} that acts on the material. It often turns out to be much easier to figure out the form of the stress tensor, for a given situation, than the form of the force. Correspondingly, as we add new pieces of physics to our fluid analysis (e.g., isotropic pressure, viscosity, gravity, magnetic forces), an efficient way to proceed at each stage is to insert the relevant physics into the stress tensor \mathbf{T}_f and then evaluate the resulting contribution $\mathbf{f} = -\nabla \cdot \mathbf{T}_f$ to the force density and thence to the Lagrangian law of force balance (13.39). At each step, we get out in the form $\mathbf{f} = -\nabla \cdot \mathbf{T}_f$ the physics that we put into \mathbf{T}_f .

stress tensor for force density \mathbf{f}

force density as divergence of stress tensor

There may seem something tautological about the procedure (13.40) by which we went from the Lagrangian $\mathbf{F} = m\mathbf{a}$ equation (13.39) to the Eulerian conservation law (13.36), (13.40). The $\mathbf{F} = m\mathbf{a}$ equation makes it look like mechanical momentum is not conserved in the presence of the force density \mathbf{f} . But we make it be conserved by introducing the momentum flux \mathbf{T}_f . It is almost as if we regard conservation of momentum as a principle to be preserved at all costs, and so every time there appears to be a momentum deficit, we simply define it as a bit of the momentum flux. However, this is not the whole story. What is important is that the force density \mathbf{f} can always be expressed as the divergence of a stress tensor; that fact is central to the nature of force and of momentum conservation. An erroneous formulation of the force would not necessarily have this property, and so no differential conservation law could be formulated. Therefore, the fact that we can create elastostatic, thermodynamic, viscous, electromagnetic, gravitational, etc. contributions to some grand stress tensor (that go to zero outside the regions occupied by the relevant matter or fields)—as we shall do in the coming chapters—is significant. It affirms that our physical model is complete at the level of approximation to which we are working.

We can proceed in the same way with energy conservation as we have with momentum. There is an energy density $U(\mathbf{x}, t)$ for a fluid and an energy flux $\mathbf{F}(\mathbf{x}, t)$, and they obey a conservation law with the standard form

energy density U , energy flux \mathbf{F} , and energy conservation

$$\frac{\partial U}{\partial t} + \nabla \cdot \mathbf{F} = 0. \quad (13.41)$$

At each stage in our buildup of fluid dynamics (adding, one by one, the influences of compressional energy, viscosity, gravity, and magnetism), we can identify the relevant contributions to U and \mathbf{F} and then grind out the resulting conservation law (13.41). At each stage we get out the physics that we put into U and \mathbf{F} .

13.5 The Dynamics of an Ideal Fluid

13.5

We now use the general conservation laws of the previous section to derive the fundamental equations of fluid dynamics. We do so in several stages. In this section and Sec. 13.6, we confine our attention to ideal fluids—flows for which it is safe to

ignore dissipative processes (viscosity and thermal conductivity) and thus for which the entropy of a fluid element remains constant with time. In Sec. 13.7, we introduce the effects of viscosity and diffusive heat flow.

13.5.1 13.5.1 Mass Conservation

As we have seen, mass conservation takes the (Eulerian) form $\partial\rho/\partial t + \nabla \cdot (\rho\mathbf{v}) = 0$ [Eq. (13.29)], or equivalently the (Lagrangian) form $d\rho/dt = -\rho\nabla \cdot \mathbf{v}$ [Eq. (13.31)], where $d/dt = \partial/\partial t + \mathbf{v} \cdot \nabla$ is the convective time derivative [i.e., the time derivative moving with the fluid; Eq. (13.32)].

As we shall see in Sec. 13.6, when flow speeds are small compared to the speed of sound and the effects of gravity are sufficiently modest, the density of a fluid element remains nearly constant: $|(1/\rho)d\rho/dt| = |\nabla \cdot \mathbf{v}| \ll 1/\tau$, where τ is the fluid flow's characteristic timescale. It is then a good approximation to rewrite the law of mass conservation as $\nabla \cdot \mathbf{v} = 0$, which is the *incompressible approximation*.

incompressible approximation

13.5.2 13.5.2 Momentum Conservation

For an ideal fluid, the only forces that can act are those of gravity and of the fluid's isotropic pressure P . We have already met and discussed the contribution of P to the stress tensor, $\mathbf{T} = P\mathbf{g}$, when dealing with elastic media (Chap. 11) and in hydrostatics (Sec. 13.3). The gravitational force density $\rho\mathbf{g}$ is so familiar that it is easier to write it down than the corresponding gravitational contribution to the stress. Correspondingly, we can most easily write momentum conservation in the form

momentum conservation for an ideal fluid

$$\frac{\partial(\rho\mathbf{v})}{\partial t} + \nabla \cdot \mathbf{T} = \rho\mathbf{g}; \quad \text{or} \quad \frac{\partial(\rho\mathbf{v})}{\partial t} + \nabla \cdot (\rho\mathbf{v} \otimes \mathbf{v} + P\mathbf{g}) = \rho\mathbf{g}, \quad (13.42)$$

where the stress tensor is given by

stress tensor for an ideal fluid

$$\mathbf{T} = \rho\mathbf{v} \otimes \mathbf{v} + P\mathbf{g} \quad \text{for an ideal fluid} \quad (13.43)$$

[cf. Eqs. (13.37), (13.38), and (13.4)]. The first term, $\rho\mathbf{v} \otimes \mathbf{v}$, is the mechanical momentum flux (also called the *kinetic stress*), and the second, $P\mathbf{g}$, is that associated with the fluid's pressure.

In most of our Newtonian applications, the gravitational field \mathbf{g} will be externally imposed (i.e., it will be produced by some object, e.g., Earth that is different from the fluid we are studying). However, the law of momentum conservation remains the same [Eq. (13.42)], independently of what produces gravity—the fluid, or an external body, or both. And independently of its source, one can write the stress tensor \mathbf{T}_g for the gravitational field \mathbf{g} in a form presented and discussed in the Track-Two Box 13.4 later in the chapter—a form that has the required property $-\nabla \cdot \mathbf{T}_g = \rho\mathbf{g}$ (the gravitational force density).

13.5.3 Euler Equation

13.5.3

The Euler equation is the equation of motion that one gets out of the momentum conservation law (13.42) for an ideal fluid by performing the differentiations and invoking mass conservation (13.29):³

$$\frac{d\mathbf{v}}{dt} \equiv \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} = -\frac{\nabla P}{\rho} + \mathbf{g} \quad \text{for an ideal fluid.} \quad (13.44)$$

Euler equation
(momentum conservation)
for an ideal fluid

The Euler equation has a simple physical interpretation: $d\mathbf{v}/dt$ is the convective derivative of the velocity (i.e., the derivative moving with the fluid), which means it is the acceleration felt by the fluid. This acceleration has two causes: gravity, \mathbf{g} , and the pressure gradient, ∇P . In a hydrostatic situation, $\mathbf{v} = 0$, the Euler equation reduces to the equation of hydrostatic equilibrium: $\nabla P = \rho \mathbf{g}$ [Eq. (13.4)].

In Cartesian coordinates, the Euler equation (13.44) and mass conservation $d\rho/dt + \rho \nabla \cdot \mathbf{v} = 0$ [Eq. (13.31)] comprise four equations in five unknowns, ρ , P , v_x , v_y , and v_z . The remaining fifth equation gives P as a function of ρ . For an ideal fluid, this equation comes from the fact that the entropy of each fluid element is conserved (because there is no mechanism for dissipation):

$$\frac{ds}{dt} = 0, \quad (13.45)$$

entropy conservation

together with an equation of state for the pressure in terms of the density and the entropy: $P = P(\rho, s)$. In practice, the equation of state is often well approximated by incompressibility, $\rho = \text{const}$, or by a polytropic relation, $P = K(s)\rho^{1+1/n}$ [Eq. (13.18)].

13.5.4 Bernoulli's Theorem

13.5.4

Bernoulli's theorem is well known. Less well appreciated are the conditions under which it is true. To deduce these, we must first introduce a kinematic quantity known as the *vorticity*:

$$\boldsymbol{\omega} \equiv \nabla \times \mathbf{v}. \quad (13.46)$$

vorticity

The physical interpretation of vorticity is simple. Consider a small fluid element. As it moves and deforms over a tiny period of time δt , each bit of fluid inside it undergoes a tiny displacement $\boldsymbol{\xi} = \mathbf{v}\delta t$. The gradient of that displacement field can be decomposed into an expansion, rotation, and shear (as we discussed in the context of an elastic medium in Sec. 11.2.2). The vectorial angle of the rotation is $\boldsymbol{\phi} = \frac{1}{2}\nabla \times \boldsymbol{\xi}$ [Eq. (11.9b)]. The time derivative of that vectorial angle, $d\boldsymbol{\phi}/dt = \frac{1}{2}d\boldsymbol{\xi}/dt = \frac{1}{2}\nabla \times \mathbf{v}$, is obviously the fluid element's rotational angular velocity; hence *the vorticity* $\boldsymbol{\omega} = \nabla \times \mathbf{v}$ is *twice*

angular velocity of a fluid
element

3. This equation was first derived in 1757 by the Swiss mathematician and physicist Leonhard Euler—the same Euler who formulated the theory of buckling of a compressed beam (Sec. 11.6.1).

the angular velocity of rotation of a fluid element. Vorticity plays a major role in fluid mechanics, as we shall see in Chap. 14.

To derive Bernoulli's theorem (with the aid of vorticity), we begin with the Euler equation for an ideal fluid, $d\mathbf{v}/dt = -(1/\rho)\nabla P + \mathbf{g}$. We express \mathbf{g} as $-\nabla\Phi$ and convert the convective derivative of velocity (i.e., the acceleration) into its two parts $d\mathbf{v}/dt = \partial\mathbf{v}/\partial t + (\mathbf{v} \cdot \nabla)\mathbf{v}$. Then we rewrite $(\mathbf{v} \cdot \nabla)\mathbf{v}$ using the vector identity

$$\mathbf{v} \times \boldsymbol{\omega} \equiv \mathbf{v} \times (\nabla \times \mathbf{v}) = \frac{1}{2} \nabla v^2 - (\mathbf{v} \cdot \nabla)\mathbf{v}. \quad (13.47)$$

The result is

$$\frac{\partial\mathbf{v}}{\partial t} + \nabla \left(\frac{1}{2} v^2 + \Phi \right) + \frac{\nabla P}{\rho} - \mathbf{v} \times \boldsymbol{\omega} = 0. \quad (13.48)$$

Bernoulli's theorem: most general version

This is just the Euler equation written in a new form, but it is also *the most general version of Bernoulli's theorem*—valid for any ideal fluid. Two special cases are of interest.

BERNOULLI'S THEOREM FOR STEADY FLOW OF AN IDEAL FLUID

Since the fluid is ideal, dissipation (due to viscosity and heat flow) can be ignored, so the entropy is constant following the flow: $ds/dt = (\mathbf{v} \cdot \nabla)\mathbf{s} = 0$. When, in addition, the flow is steady, meaning $\partial(\text{everything})/\partial t = 0$, the thermodynamic identity $dh = Tds + dP/\rho$ [Eq. (3) of Box 13.2] combined with $ds/dt = 0$ implies

$$(\mathbf{v} \cdot \nabla)P = \rho(\mathbf{v} \cdot \nabla)h. \quad (13.49)$$

Dotting the velocity \mathbf{v} into the most general Bernoulli theorem (13.48) and invoking Eq. (13.49) and $\partial\mathbf{v}/\partial t = 0$, we obtain

$$\frac{dB}{dt} = (\mathbf{v} \cdot \nabla)B = 0, \quad (13.50)$$

where

$$B \equiv \frac{1}{2} v^2 + h + \Phi. \quad (13.51)$$

Bernoulli function

Bernoulli's theorem for steady flow of an ideal fluid

Equation (13.50) states that *in a steady flow of an ideal fluid, the Bernoulli function B , like the entropy, is conserved moving with a fluid element*. This is the most elementary form of the Bernoulli theorem.

Let us define *streamlines*, analogous to lines of force of a magnetic field, by the differential equations

$$\frac{dx}{v_x} = \frac{dy}{v_y} = \frac{dz}{v_z}. \quad (13.52)$$

streamlines

In the language of Sec. 1.5, these are just the integral curves of the (steady) velocity field; they are also the spatial world lines of fluid elements. Equation (13.50) states: *In a steady flow of an ideal fluid, the Bernoulli function B is constant along streamlines*.

BOX 13.3. FLOW VISUALIZATION

Various methods are used to visualize fluid flows. One way is via *streamlines*, which are the integral curves of the velocity field \mathbf{v} at a given time [Eq. (13.52)]. Streamlines are the analog of magnetic field lines. They coincide with the *paths* of individual fluid elements if the flow is steady, but not if the flow is time dependent. In general, the paths are the solutions of the equation $d\mathbf{x}/dt = \mathbf{v}(\mathbf{x}, t)$. These paths are the analog of particle trajectories in mechanics.

Another type of flow line is a *streak*. Monitoring streaks is a common way of visualizing a flow experimentally. Streaks are usually produced by introducing some colored or fluorescent tracer into the flow continuously at some fixed release point \mathbf{x}_r , and observing the locus of the tracer at some fixed time, say, t_0 . Each point on the streak can be parameterized by the common release point \mathbf{x}_r , the common time of observation t_0 , and the time t_r at which its marker was released, $\mathbf{x}(\mathbf{x}_r, t_r; t_0)$; so the streak is the parameterized curve $\mathbf{x}(t_r) = \mathbf{x}(\mathbf{x}_r, t_r; t_0)$.

Examples of streamlines, paths, and streaks are sketched below.

Streamlines are a powerful way to visualize fluid flows. There are other ways, sketched in Box 13.3.

The Bernoulli function $B = \frac{1}{2}v^2 + h + \Phi = \frac{1}{2}v^2 + u + P/\rho + \Phi$ has a simple physical meaning. It is the fluid's total energy density (kinetic plus internal plus potential) per unit mass, plus the work $P(1/\rho)$ that must be done to inject a unit mass of fluid (with volume $1/\rho$) into surrounding fluid that has pressure P . This goes hand in hand with the enthalpy $h = u + P/\rho$ being the *injection energy* (per unit mass) in the absence of kinetic and potential energy; see the last part of Ex. 5.5. This meaning of B leads to the following physical interpretation of the constancy of B for a stationary, ideal flow.

In a steady flow of an ideal fluid, consider a *stream tube* made of a bundle of streamlines (Fig. 13.5). A fluid element with unit mass occupies region \mathcal{A} of the stream

FIGURE 13.5 A stream tube used to explain the Bernoulli theorem for stationary flow of an ideal fluid.

tube at some early time and has moved into region B at some later time. When it vacates region A , the fluid element carries an energy B [including the energy $P(1/\rho)$ it acquires by being squeezed out of A by the pressure of the surrounding fluid]. When it moves into region B , it similarly carries the total injection energy B . Because the flow is steady, the energy it extracts from A must be precisely what it needs to occupy B (i.e., B must be constant along the stream tube, and hence also along each streamline in the tube).

The most immediate consequence of Bernoulli's theorem for steady flow is that, if gravity is having no significant effect, then the enthalpy falls when the speed increases, and conversely. This is just the conversion of internal (injection) energy into bulk kinetic energy, and conversely. For our ideal fluid, entropy must be conserved moving with a fluid element, so the first law of thermodynamics says $dh = T ds + dP/\rho = dP/\rho$. Therefore, as the speed increases and h decreases, P will also decrease.

Pitot tube

This behavior is the foundation for the *Pitot tube*, a simple device used to measure the air speed of an aircraft (Fig. 13.6). The Pitot tube extends out from the side of the aircraft, all the way through a boundary layer of slow-moving air and into the bulk flow. There it bends into the flow. The Pitot tube is actually two tubes: (i) an outer tube with several orifices along its sides, past which the air flows with its incoming speed V and pressure P , so the pressure inside that tube is also P ; and (ii) an inner tube with a small orifice at its end, where the flowing air is brought essentially to rest (to *stagnation*). At this stagnation point and inside the orifice's inner tube, the pressure, by Bernoulli's theorem with Φ and ρ both essentially constant, is the *stagnation pressure*: $P_{\text{stag}} = P + \frac{1}{2}\rho V^2$. The pressure difference $\Delta P = P_{\text{stag}} - P$ between the two tubes is measured by an instrument called a *manometer*, from which the air speed is computed as $V = (2\Delta P/\rho)^{1/2}$. If $V \sim 100 \text{ m s}^{-1}$ and $\rho \sim 1 \text{ kg m}^{-3}$, then $\Delta P \sim 5,000 \text{ N m}^{-3} \sim 0.05 \text{ atmospheres}$.

stagnation pressure

In this book, we shall meet many other applications of the Bernoulli theorem for steady, ideal flows.

BERNOULLI'S THEOREM FOR IRROTATIONAL FLOW OF AN IDEAL, ISENTROPIC FLUID

An even more specialized type of flow is one that is *isentropic* (so s is the same everywhere) and *irrotational* (meaning its vorticity vanishes everywhere), as well as ideal.

FIGURE 13.6 Schematic illustration of a Pitot tube used to measure air speed. The manometer M measures the pressure difference between the stagnation point S and the orifices O.

(In Sec. 14.2, we shall learn that if an incompressible flow initially is irrotational and it encounters no walls and experiences no significant viscous stresses, then it remains irrotational.) As $\boldsymbol{\omega} = \nabla \times \mathbf{v}$ vanishes, we can follow the electrostatic precedent and introduce a *velocity potential* $\psi(\mathbf{x}, t)$, so that at any time,

$$\mathbf{v} = \nabla\psi \quad \text{for an irrotational flow.} \quad (13.53)$$

velocity potential for irrotational (vorticity-free) flow

The first law of thermodynamics [Eq. (3) of Box 13.2] implies that $\nabla h = T\nabla s + (1/\rho)\nabla P$. Therefore, in an isentropic flow, $\nabla P = \rho\nabla h$. Imposing these conditions on Eq. (13.48), we obtain, for a (possibly unsteady) isentropic, irrotational flow:

$$\nabla \left(\frac{\partial\psi}{\partial t} + B \right) = 0. \quad (13.54)$$

Bernoulli's theorem for isentropic, irrotational flow of an ideal fluid

Thus *in an isentropic, irrotational flow of an ideal fluid, the quantity $\partial\psi/\partial t + B$ is constant everywhere.* (If $\partial\psi/\partial t + B$ is a function of time, we can absorb that function into ψ without affecting \mathbf{v} , leaving it constant in time as well as in space.) Of course, if the flow is steady, so $\partial(\text{everything})/\partial t = 0$, then B itself is constant.

Exercise 13.7 *Problem: A Hole in My Bucket*

There's a hole in my bucket. How long will it take to empty? (Try an experiment, and if the time does not agree with the estimate, explain why not.)

Exercise 13.8 *Problem: Rotating Planets, Stars, and Disks*

Consider a stationary, axisymmetric planet, star, or disk differentially rotating under the action of a gravitational field. In other words, the motion is purely in the azimuthal direction.

EXERCISES

- (a) Suppose that the fluid has a *barotropic* equation of state $P = P(\rho)$. Write down the equations of hydrostatic equilibrium, including the centrifugal force, in cylindrical polar coordinates. Hence show that the angular velocity must be constant on surfaces of constant cylindrical radius. This is called *von Zeipel's theorem*. (As an application, Jupiter is differentially rotating and therefore might be expected to have similar rotation periods at the same latitudes in the north and the south. This is only roughly true, suggesting that the equation of state is not completely barotropic.)
- (b) Now suppose that the structure is such that the surfaces of constant entropy per unit mass and angular momentum per unit mass coincide. (This state of affairs can arise if slow convection is present.) Show that the Bernoulli function (13.51) is also constant on these surfaces. [Hint: Evaluate ∇B .]

Exercise 13.9 ***Problem: Crocco's Theorem*

- (a) Consider steady flow of an ideal fluid. The Bernoulli function (13.51) is conserved along streamlines. Show that the variation of B across streamlines is given by Crocco's theorem:

$$\nabla B = T \nabla s + \mathbf{v} \times \boldsymbol{\omega}. \quad (13.55)$$

- (b) As an example, consider the air in a tornado. In the tornado's core, the velocity vanishes; it also vanishes beyond the tornado's outer edge. Use Crocco's theorem to show that the pressure in the core is substantially different from that at the outer edge. Is it lower, or is it higher? How does this explain the ability of a tornado to make the walls of a house explode? For more detail, see Ex. 14.5.

Exercise 13.10 *Problem: Cavitation (Suggested by P. Goldreich)*

A hydrofoil moves with speed V at a depth $D = 3$ m below the surface of a lake; see Fig. 13.7. Estimate how fast V must be to make the water next to the hydrofoil boil. [This boiling, which is called *cavitation*, results from the pressure P trying to go negative (see, e.g., Batchelor, 2000, Sec. 6.12; Potter, Wiggert, and Ramadan, 2012, Sec. 8.3.4).] [Note: For a more accurate value of the speed V that triggers cavitation,

FIGURE 13.7 Water flowing past a hydrofoil as seen in the hydrofoil's rest frame.

one would have to compute the velocity field $\mathbf{v}(\mathbf{x})$ around the hydrofoil—for example, using the method of Ex. 14.17—and identify the maximum value of $v = |\mathbf{v}|$ near the hydrofoil's surface.]

Exercise 13.11 *Example: Collapse of a Bubble*

Suppose that a spherical bubble has just been created in the water above the hydrofoil in the previous exercise. Here we analyze its collapse—the decrease of the bubble's radius $R(t)$ from its value R_o at creation, using the incompressible approximation (which is rather good in this situation). This analysis is an exercise in solving the Euler equation.

- (a) Introduce spherical polar coordinates with origin at the center of the bubble, so the collapse entails only radial fluid motion, $\mathbf{v} = v(r, t)\mathbf{e}_r$. Show that the incompressibility approximation $\nabla \cdot \mathbf{v} = 0$ implies that the radial velocity can be written in the form $v = w(t)/r^2$. Then use the radial component of the Euler equation (13.44) to show that

$$\frac{1}{r^2} \frac{dw}{dt} + v \frac{\partial v}{\partial r} + \frac{1}{\rho} \frac{\partial P}{\partial r} = 0.$$

At fixed time t , integrate this outward from the bubble surface at radius $R(t)$ to a large enough radius that the bubble's influence is no longer felt. Thereby obtain

$$\frac{-1}{R} \frac{dw}{dt} + \frac{1}{2} \dot{R}^2(R) = \frac{P_0}{\rho},$$

where P_0 is the ambient pressure and $-\dot{R}(R)$ is the speed of collapse of the bubble's surface when its radius is R . Assuming vanishing collapse speed when the bubble is created, $\dot{R}(R_o) = 0$, show that

$$\dot{R}(R) = - \left(\frac{2P_0}{3\rho} \right)^{1/2} \left[\left(\frac{R_o}{R} \right)^3 - 1 \right]^{1/2},$$

which can be integrated to get $R(t)$.

- (b) Suppose that bubbles formed near the pressure minimum on the surface of the hydrofoil are swept back onto a part of the surface where the pressure is much larger. By what factor R_o/R must the bubbles collapse if they are to create stresses that inflict damage on the hydrofoil?

Pistol shrimp can create collapsing bubbles and use the shock waves to stun their prey. A modification of this solution is important in interpreting the fascinating phenomenon of *sonoluminescence* (Brenner, Hilgenfeldt, and Lohse, 2002), which arises when fluids are subjected to high-frequency acoustic waves that create oscillating bubbles. The temperatures inside these bubbles can get so large that the air becomes ionized and radiates.

As well as imposing conservation of mass and momentum, we must also address energy conservation in its general form (by contrast with the specialized version of energy conservation inherent in Bernoulli's theorem for a stationary, ideal flow).

In general, energy conservation is needed for determining the temperature T of a fluid, which in turn is needed to compute the pressure $P(\rho, T)$. So far in our treatment of fluid dynamics, we have finessed this issue by either postulating some relationship between the pressure P and the density ρ (e.g., the polytropic relation $P = K\rho^\gamma$) or by focusing on the flow of ideal fluids, where the absence of dissipation guarantees the entropy is constant moving with the flow, so that $P = P(\rho, s)$ with constant s . In more general situations, one cannot avoid confronting energy conservation. Moreover, even for ideal fluids, understanding how energy is conserved is often useful for gaining physical insight—as we have seen in our discussion of Bernoulli's theorem.

The most fundamental formulation of the law of energy conservation is Eq. (13.41): $\partial U/\partial t + \nabla \cdot \mathbf{F} = 0$. To explore its consequences for an ideal fluid, we must insert the appropriate ideal-fluid forms of the energy density U and energy flux \mathbf{F} .

When (for simplicity) the fluid is in an externally produced gravitational field Φ , its energy density is obviously

energy density for ideal fluid with external gravity

$$U = \rho \left(\frac{1}{2}v^2 + u + \Phi \right) \quad \text{for ideal fluid with external gravity.} \quad (13.56)$$

Here the three terms are kinetic, internal, and gravitational energy. When the fluid participates in producing gravity and one includes the energy of the gravitational field itself, the energy density is a bit more subtle; see the Track-Two Box 13.4.

In an external gravitational field, one might expect the energy flux to be $\mathbf{F} = U\mathbf{v}$, but this is not quite correct. Consider a bit of surface area dA orthogonal to the direction in which the fluid is moving (i.e., orthogonal to \mathbf{v}). The fluid element that crosses dA during time dt moves through a distance $dl = vdt$, and as it moves, the fluid behind this element exerts a force PdA on it. That force, acting through the distance dl , feeds an energy $dE = (PdA)dl = PvdAdt$ across dA ; the corresponding energy flux across dA has magnitude $dE/dAdt = Pv$ and points in the \mathbf{v} direction, so it contributes $P\mathbf{v}$ to the energy flux \mathbf{F} . This contribution is missing from our initial guess $\mathbf{F} = U\mathbf{v}$. We explore its importance at the end of this subsection. When it is added to our guess, we obtain for the total energy flux

energy flux for ideal fluid with external gravity

$$\mathbf{F} = \rho\mathbf{v} \left(\frac{1}{2}v^2 + h + \Phi \right) \quad \text{for ideal fluid with external gravity.} \quad (13.57)$$

Here $h = u + P/\rho$ is the enthalpy per unit mass (cf. Box 13.2). Inserting Eqs. (13.56) and (13.57) into the law of energy conservation (13.41), and requiring that the external

In the text, we mostly treat the gravitational field as externally imposed and independent of the fluid. This approximation is usually a good one. However, it is inadequate for planets and stars, whose self-gravity is crucial. It is easiest to discuss the modifications due to the fluid's self-gravitational effects by amending the conservation laws.

As long as we work in the domain of Newtonian physics, the mass conservation equation (13.29) is unaffected by self-gravity. However, we included the gravitational force per unit volume $\rho \mathbf{g}$ as a source of momentum in the momentum conservation law (13.42). It would fit much more neatly in our formalism if we could express it as the divergence of a gravitational stress tensor \mathbf{T}_g . To see that this is indeed possible, use Poisson's equation $\nabla \cdot \mathbf{g} = -4\pi G\rho$ (which embodies self-gravity) to write

$$\nabla \cdot \mathbf{T}_g = -\rho \mathbf{g} = \frac{(\nabla \cdot \mathbf{g})\mathbf{g}}{4\pi G} = \frac{\nabla \cdot [\mathbf{g} \otimes \mathbf{g} - \frac{1}{2}g^2\mathbf{g}]}{4\pi G},$$

so

$$\boxed{\mathbf{T}_g = \frac{\mathbf{g} \otimes \mathbf{g} - \frac{1}{2}g^2\mathbf{g}}{4\pi G}}. \quad (1)$$

Readers familiar with classical electromagnetic theory will notice an obvious and understandable similarity to the Maxwell stress tensor [Eqs. (1.38) and (2.80)], whose divergence equals the Lorentz force density.

What of the gravitational momentum density? We expect that it can be related to the gravitational energy density using a Lorentz transformation. That is to say, it is $O(v/c^2)$ times the gravitational energy density, where v is some characteristic speed. However, in the Newtonian approximation, the speed of light c is regarded as infinite, and so we should expect the gravitational momentum density to be identically zero in Newtonian theory—and indeed it is. We therefore can write the full equation of motion (13.42), including gravity, as a conservation law:

$$\frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot \mathbf{T}_{\text{total}} = 0, \quad (2)$$

where $\mathbf{T}_{\text{total}}$ includes \mathbf{T}_g .

Now consider energy conservation. We have seen in the text that in a constant, external gravitational field, the fluid's total energy density U and flux \mathbf{F} are given by Eqs. (13.56) and (13.57), respectively. In a general

(continued)

BOX 13.4. (continued)

situation, we must add to these some field energy density and flux. On dimensional grounds, these must be $U_{\text{field}} \propto \mathbf{g}^2/G$ and $\mathbf{F}_{\text{field}} \propto \Phi_{,t}\mathbf{g}/G$ (where $\mathbf{g} = -\nabla\Phi$). The proportionality constants can be deduced by demanding that for an ideal fluid in the presence of gravity, the law of energy conservation when combined with mass conservation, momentum conservation, and the first law of thermodynamics, lead to $ds/dt = 0$ (no dissipation in, so no dissipation out); see Eq. (13.59) and associated discussion. The result (Ex. 13.13) is

$$U = \rho \left(\frac{1}{2}v^2 + u + \Phi \right) + \frac{g^2}{8\pi G}, \quad (3)$$

$$\mathbf{F} = \rho\mathbf{v} \left(\frac{1}{2}v^2 + h + \Phi \right) + \frac{1}{4\pi G} \frac{\partial\Phi}{\partial t} \mathbf{g}. \quad (4)$$

Actually, there is an ambiguity in how the gravitational energy is localized. This ambiguity arises physically because one can transform away the gravitational acceleration \mathbf{g} , at any point in space, by transforming to a reference frame that falls freely there. Correspondingly, it turns out, one can transform away the gravitational energy density at any desired point in space. This possibility is embodied mathematically in the possibility of adding to the energy flux \mathbf{F} the time derivative of $\alpha\Phi\nabla\Phi/(4\pi G)$ and adding to the energy density U minus the divergence of this quantity (where α is an arbitrary constant), while preserving energy conservation $\partial U/\partial t + \nabla \cdot \mathbf{F} = 0$. Thus the following choice of energy density and flux is just as good as Eqs. (3) and (4); both satisfy energy conservation:

$$\begin{aligned} U &= \rho \left(\frac{1}{2}v^2 + u + \Phi \right) + \frac{g^2}{8\pi G} - \alpha \nabla \cdot \left(\frac{\Phi \nabla \Phi}{4\pi G} \right) \\ &= \rho \left[\frac{1}{2}v^2 + u + (1 - \alpha)\Phi \right] + (1 - 2\alpha) \frac{g^2}{8\pi G}, \end{aligned} \quad (5)$$

$$\begin{aligned} \mathbf{F} &= \rho\mathbf{v} \left(\frac{1}{2}v^2 + h + \Phi \right) + \frac{1}{4\pi G} \frac{\partial\Phi}{\partial t} \mathbf{g} + \alpha \frac{\partial}{\partial t} \left(\frac{\Phi \nabla \Phi}{4\pi G} \right) \\ &= \rho\mathbf{v} \left(\frac{1}{2}v^2 + h + \Phi \right) + (1 - \alpha) \frac{1}{4\pi G} \frac{\partial\Phi}{\partial t} \mathbf{g} - \frac{\alpha}{4\pi G} \Phi \frac{\partial\mathbf{g}}{\partial t}. \end{aligned} \quad (6)$$

[Here we have used the gravitational field equation $\nabla^2\Phi = 4\pi G\rho$ and $\mathbf{g} = -\nabla\Phi$.] Note that the choice $\alpha = 1/2$ puts all the energy density into the

(continued)

BOX 13.4. (continued)

$\rho\Phi$ term, while the choice $\alpha = 1$ puts all the energy density into the field term \mathbf{g}^2 . In Ex. 13.14 it is shown that the total gravitational energy of an isolated system is independent of the arbitrary parameter α , as it must be on physical grounds.

A full understanding of the nature and limitations of the concept of gravitational energy requires the general theory of relativity (Part VII). The relativistic analog of the arbitrariness of Newtonian energy localization is an arbitrariness in the gravitational “stress-energy pseudotensor” (see, e.g., Misner, Thorne, and Wheeler, 1973, Sec. 20.3).

gravity be static (time independent), so the work it does on the fluid is conservative, we obtain the following ideal-fluid equation of energy balance:

$$\frac{\partial}{\partial t} \left[\rho \left(\frac{1}{2}v^2 + u + \Phi \right) \right] + \nabla \cdot \left[\rho \mathbf{v} \left(\frac{1}{2}v^2 + h + \Phi \right) \right] = 0$$

for an ideal fluid and static external gravity. (13.58)

energy conservation for
ideal fluid with external
gravity

When the gravitational field is dynamical or is being generated by the fluid itself (or both), we must use a more complete gravitational energy density and stress; see Box 13.4.

By combining the law of energy conservation (13.58) with the corresponding laws of momentum (13.29) and mass conservation (13.42), and using the first law of thermodynamics $dh = Tds + (1/\rho)dP$, we obtain the remarkable result that the entropy per unit mass is conserved moving with the fluid:

$$\boxed{\frac{ds}{dt} = 0 \quad \text{for an ideal fluid.}} \quad (13.59)$$

entropy conservation for
ideal fluid

The same conclusion can be obtained when the gravitational field is dynamical and not external (cf. Box 13.4 and Ex. 13.13), so no statement about gravity is included with this equation. This entropy conservation should not be surprising. If we put no dissipative processes into the energy density, energy flux, or stress tensor, then we get no dissipation out. Moreover, the calculation that leads to Eq. (13.59) ensures that, *so long as we take full account of mass and momentum conservation, then the full and sole content of the law of energy conservation for an ideal fluid is $ds/dt = 0$.*

Table 13.1 summarizes our formulas for the density and flux of mass, momentum, and energy in an ideal fluid with externally produced gravity.

TABLE 13.1: Densities and fluxes of mass, momentum, and energy for an ideal fluid in an externally produced gravitational field

Quantity	Density	Flux
Mass	ρ	$\rho \mathbf{v}$
Momentum	$\rho \mathbf{v}$	$\mathbf{T} = P \mathbf{g} + \rho \mathbf{v} \otimes \mathbf{v}$
Energy	$U = (\frac{1}{2}v^2 + u + \Phi)\rho$	$\mathbf{F} = (\frac{1}{2}v^2 + h + \Phi)\rho \mathbf{v}$

EXERCISES

Exercise 13.12 Example: Joule-Kelvin Cooling

A good illustration of the importance of the Pv term in the energy flux is provided by the *Joule-Kelvin method* commonly used to cool gases (Fig. 13.8). Gas is driven from a high-pressure chamber 1 through a nozzle or porous plug into a low-pressure chamber 2, where it expands and cools.

- Using the energy flux (13.57), including the Pv term contained in h , show that a mass ΔM ejected through the nozzle carries a total energy ΔE_1 that is equal to the enthalpy ΔH_1 that this mass had while in chamber 1.
- This ejected gas expands and crashes into the gas of chamber 2, temporarily going out of statistical (thermodynamic) equilibrium. Explain why, after it has settled down into statistical equilibrium as part of the chamber-2 gas, the total energy it has deposited into chamber 2 is its equilibrium enthalpy ΔH_2 . Thereby conclude that the enthalpy per unit mass is the same in the two chambers, $h_1 = h_2$.
- From $h_1 = h_2$, show that the temperature drop between the two chambers is

$$\Delta T = \int_{P_1}^{P_2} \mu_{JK} dP, \quad (13.60)$$

where $\mu_{JK} \equiv (\partial T / \partial P)_h$ is the Joule-Kelvin coefficient (also called Joule-Thomson). A straightforward thermodynamic calculation yields the identity

FIGURE 13.8 Schematic illustration of Joule-Kelvin cooling of a gas. Gas flows steadily through a nozzle from a chamber at high pressure P_1 to one at low pressure P_2 . The flow proceeds at constant enthalpy. Work done against attractive intermolecular forces leads to cooling. The efficiency of cooling can be enhanced by exchanging heat between the two chambers. Gases can also be liquified in this manner.

$$\mu_{JK} \equiv \left(\frac{\partial T}{\partial P} \right)_h = -\frac{1}{\rho^2 c_p} \left(\frac{\partial(\rho T)}{\partial T} \right)_P. \quad (13.61)$$

- (d) Show that the Joule-Kelvin coefficient of an ideal gas vanishes. Therefore, the cooling must arise because of the attractive forces (van der Waals forces; Sec. 5.3.2) between the molecules, which are absent in an ideal gas. When a real gas expands, work is done against these forces, and the gas therefore cools.

Exercise 13.13 *Derivation: No Dissipation “in” Means No Dissipation “out” and Verification of the Claimed Gravitational Energy Density and Flux* **T2**

Consider an ideal fluid interacting with a (possibly dynamical) gravitational field that the fluid itself generates via $\nabla^2 \Phi = 4\pi G\rho$. For this fluid, take the law of energy conservation, $\partial U/\partial t + \nabla \cdot \mathbf{F} = 0$, and from it subtract the scalar product of \mathbf{v} with the law of momentum conservation, $\mathbf{v} \cdot [\partial(\rho\mathbf{v})/\partial t + \nabla \cdot \mathbf{T}]$; then simplify using the law of mass conservation and the first law of thermodynamics, to obtain $\rho ds/dt = 0$. In your computation, use for U and \mathbf{F} the expressions given in Eqs. (3) and (4) of Box 13.4. This calculation tells us two things. (i) The law of energy conservation for an ideal fluid reduces simply to conservation of entropy moving with the fluid; we have put no dissipative physics into the fluxes of momentum and energy, so we get no dissipation out. (ii) The gravitational energy density and flux contained in Eqs. (3) and (4) of Box 13.4 must be correct, since they guarantee that gravity does not alter this “no dissipation in, no dissipation out” result.

Exercise 13.14 *Example: Gravitational Energy* **T2**

Integrate the energy density U of Eq. (5) of Box 13.4 over the interior and surroundings of an isolated gravitating system to obtain the system’s total energy. Show that the gravitational contribution to this total energy (i) is independent of the arbitrariness (parameter α) in the energy’s localization, and (ii) can be written in the following forms:

$$E_g = \int dV \frac{1}{2} \rho \Phi = -\frac{1}{8\pi G} \int dV g^2 = \frac{-G}{2} \int \int dV dV' \frac{\rho(\mathbf{x})\rho(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|}. \quad (13.62)$$

Interpret each of these expressions physically.

13.6 Incompressible Flows

13.6

A common assumption made when discussing the fluid dynamics of highly subsonic flows is that the density is constant—that the fluid is incompressible. This is a natural approximation to make when dealing with a liquid like water, which has a very large bulk modulus. It is a bit of a surprise that it is also useful for flows of gases, which are far more compressible under static conditions.

To see its validity, suppose that we have a flow in which the characteristic length L over which the fluid variables P , ρ , v , and so forth vary is related to the characteristic timescale T over which they vary by $L \lesssim vT$. In this case, we can compare the

magnitude of the various terms in the Euler equation (13.44) to obtain an estimate of the magnitude of the pressure variation:

$$\underbrace{\frac{\partial \mathbf{v}}{\partial t}}_{v/T} + \underbrace{(\mathbf{v} \cdot \nabla) \mathbf{v}}_{v^2/L} = - \underbrace{\frac{\nabla P}{\rho}}_{\delta P/\rho L} - \underbrace{\nabla \Phi}_{\delta \Phi/L}. \quad (13.63)$$

Multiplying through by L and using $L/T \lesssim v$, we obtain $\delta P/\rho \sim v^2 + |\delta \Phi|$. The variation in pressure will be related to the variation in density by $\delta P \sim C^2 \delta \rho$, where $C = \sqrt{(\partial P/\partial \rho)_s}$ is the sound speed (Sec. 16.5), and we drop constants of order unity when making these estimates. Inserting this into our expression for δP , we obtain the estimate for the fractional density fluctuation:

$$\boxed{\frac{\delta \rho}{\rho} \sim \frac{v^2}{C^2} + \frac{\delta \Phi}{C^2}}. \quad (13.64)$$

incompressible
approximation

Therefore, if the fluid speeds are highly subsonic ($v \ll C$) and the gravitational potential does not vary greatly along flow lines ($|\delta \Phi| \ll C^2$), then we can ignore the density variations moving with the fluid when solving for the velocity field. More specifically, since $\rho^{-1} d\rho/dt = -\nabla \cdot \mathbf{v} = -\theta$ [Eq. (13.35)], we can make the incompressible approximation

$$\nabla \cdot \mathbf{v} \simeq 0 \quad (13.65)$$

(which means that the velocity field is *solenoidal*, like a magnetic field; i.e., is expressible as the curl of some potential). This argument breaks down when we are dealing with sound waves for which $L \sim CT$.

For air at atmospheric temperature, the speed of sound is $C \sim 300$ m/s, which is very fast compared to most flow speeds one encounters, so most flows are incompressible.

It should be emphasized, though, that the incompressible approximation for the velocity field, $\nabla \cdot \mathbf{v} \simeq 0$, does not imply that the density variation can be neglected in all other contexts. A particularly good example is provided by convection flows, which are driven by buoyancy, as we shall discuss in Chap. 18.

Incompressibility is a weaker condition than requiring the density to be constant everywhere; for example, the density varies substantially from Earth's center to its surface, but if the material inside Earth were moving more or less on surfaces of constant radius, the flow would be incompressible.

We restrict ourselves to incompressible flows throughout the next two chapters and then abandon incompressibility in subsequent chapters on fluid dynamics.

13.7 Viscous Flows with Heat Conduction

13.7.1 Decomposition of the Velocity Gradient into Expansion, Vorticity, and Shear

It is an observational fact that many fluids, when they flow, develop a shear stress (also called a *viscous stress*). Honey pouring off a spoon is a nice example. Most fluids,

however, appear to flow quite freely; for example, a cup of tea appears to offer little resistance to stirring other than the inertia of the water. In such cases, it might be thought that viscous effects only produce a negligible correction to the flow's details. However, this is not so.

One of the main reasons is that most flows touch solid bodies, at whose surfaces the velocity must vanish. This leads to the formation of boundary layers, whose thickness and behavior are controlled by viscous forces. The boundary layers in turn can exert a controlling influence on the bulk flow (where the viscosity is negligible); for example, they can trigger the development of turbulence in the bulk flow—witness the stirred tea. For details see Chaps. 14 and 15.

We must therefore augment our equations of fluid dynamics to include viscous stresses. Our formal development proceeds in parallel to that used in elasticity, with the velocity field $\mathbf{v} = d\boldsymbol{\xi}/dt$ replacing the displacement field $\boldsymbol{\xi}$. We decompose the velocity gradient tensor $\nabla\mathbf{v}$ into its irreducible tensorial parts: a *rate of expansion* θ ; a symmetric, trace-free *rate of shear* tensor $\boldsymbol{\sigma}$; and an antisymmetric *rate of rotation* tensor \mathbf{r} :

$$\nabla\mathbf{v} = \frac{1}{3}\theta\mathbf{g} + \boldsymbol{\sigma} + \mathbf{r}. \quad (13.66)$$

Note that we use lowercased symbols to distinguish the fluid case from its elastic counterpart: $\theta = d\Theta/dt$, $\boldsymbol{\sigma} = d\boldsymbol{\Sigma}/dt$, $\mathbf{r} = d\mathbf{R}/dt$. Proceeding directly in parallel to the treatment in Sec. 11.2.2 and Box 11.2, we can invert Eq. (13.66) to obtain

$$\theta = \nabla \cdot \mathbf{v}, \quad (13.67a)$$

$$\sigma_{ij} = \frac{1}{2}(v_{i;j} + v_{j;i}) - \frac{1}{3}\theta g_{ij}, \quad (13.67b)$$

$$r_{ij} = \frac{1}{2}(v_{i;j} - v_{j;i}) = -\frac{1}{2}\epsilon_{ijk}\omega^k, \quad (13.67c)$$

where $\boldsymbol{\omega} = 2d\boldsymbol{\phi}/dt$ is the vorticity, which we introduced and discussed in Sec. 13.5.4.

rates of expansion, shear, and rotation

Exercise 13.15 ***Example: Kinematic Interpretation of Vorticity*

Consider a velocity field with nonvanishing curl. Define a locally orthonormal basis at a point in the velocity field, so that one basis vector, \mathbf{e}_x , is parallel to the vorticity. Now imagine the remaining two basis vectors as being frozen into the fluid. Show that they will both rotate about the axis defined by \mathbf{e}_x and that the vorticity will be the sum of their angular velocities (i.e., twice the average of their angular velocities).

EXERCISES

13.7.2 Navier-Stokes Equation

13.7.2

Although, as we have emphasized, a fluid at rest does not exert a shear stress, and this distinguishes it from an elastic solid, a fluid in motion can resist shear in the

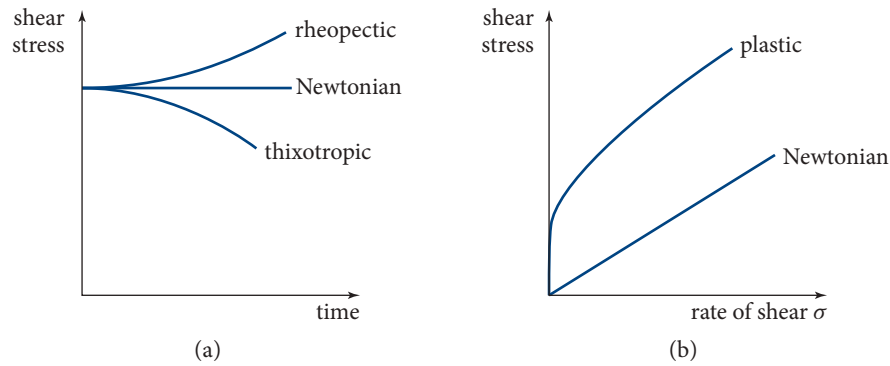

FIGURE 13.9 Some examples of non-Newtonian behavior in fluids. (a) In a Newtonian fluid the shear stress is proportional to the rate of shear σ and does not vary with time when σ is constant as here. However, some substances, such as paint, flow more freely with time and are said to be *thixotropic*. Microscopically, the long, thin paint molecules gradually become aligned with the flow, which reduces their resistance to shear. The opposite behavior is exhibited by *rheopectic* substances such as ink and some lubricants. (b) An alternative type of non-Newtonian behavior is exhibited by various plastics, where a threshold stress is needed before flow will commence.

velocity field. It has been found experimentally that in most fluids the magnitude of this shear stress is linearly related to the velocity gradient. This law, due to Hooke's contemporary, Isaac Newton, is the analog of the linear relation between stress and strain that we used in our discussion of elasticity. Fluids that obey this law are known as *Newtonian*. (Some examples of non-Newtonian fluid behavior are shown in Fig. 13.9.) We analyze only Newtonian fluids in this book.

Fluids are usually isotropic. (Important exceptions include *smectic* liquid crystals.) In this book we restrict ourselves to isotropic fluids. By analogy with the theory of elasticity, we describe the linear relation between stress and rate of strain using two constants called the coefficients of *bulk* and *shear* viscosity, denoted ζ and η , respectively. We write the viscous contribution to the stress tensor as

$$\mathbf{T}_{\text{vis}} = -\zeta\theta\mathbf{g} - 2\eta\boldsymbol{\Sigma}, \quad (13.68)$$

by analogy to Eq. (11.18), $\mathbf{T}_{\text{elas}} = -K\Theta\mathbf{g} - 2\mu\boldsymbol{\Sigma}$, for an elastic solid. Here as there, shear-free rotation about a point does not produce a resistive stress.

If we include this viscous contribution in the stress tensor, then the law of momentum conservation $\partial(\rho\mathbf{v})/\partial t + \nabla \cdot \mathbf{T} = \rho\mathbf{g}$ gives the following generalization of Euler's equation (13.44):

$$\rho \frac{d\mathbf{v}}{dt} = -\nabla P + \rho\mathbf{g} + \nabla(\zeta\theta) + 2\nabla \cdot (\eta\boldsymbol{\Sigma}). \quad (13.69)$$

This is the *Navier-Stokes equation*, and the last two terms are the viscous force density.

For incompressible flows (e.g., when the flow is highly subsonic; Sec. 13.6), θ can be approximated as zero, so the bulk viscosity can be ignored. The viscosity coefficient

coefficients of bulk and shear viscosity

viscous stress tensor

Navier-Stokes equation: general form

TABLE 13.2: Approximate kinematic viscosity for common fluids

Quantity	Kinematic viscosity ν ($\text{m}^2 \text{s}^{-1}$)
Water	10^{-6}
Air	10^{-5}
Glycerine	10^{-3}
Blood	3×10^{-6}

η generally varies in space far more slowly than the shear σ , and so can be taken outside the divergence. In this case, Eq. (13.69) simplifies to

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P}{\rho} + \mathbf{g} + \nu \nabla^2 \mathbf{v}, \quad (13.70)$$

Navier-Stokes equation for incompressible flow

where

$$\nu \equiv \frac{\eta}{\rho} \quad (13.71)$$

kinematic shear viscosity coefficient

is known as the *kinematic viscosity*, by contrast to η , which is often called the *dynamic viscosity*. Equation (13.70) is the commonly quoted form of the Navier-Stokes equation; it is the form that we shall almost always use. Approximate values of the kinematic viscosity for common fluids are given in Table 13.2.

13.7.3 Molecular Origin of Viscosity

13.7.3

We can distinguish gases from liquids microscopically. In a gas, a molecule of mass m travels a distance of order its *mean free path* λ before it collides. If there is a shear in the fluid (Fig. 13.10), then the molecule, traveling in the y direction, on average

estimate of shear viscosity

FIGURE 13.10 Molecular origin of viscosity in a gas. A molecule travels a distance λ in the y direction between collisions. Its mean x velocity at its point of origin is that of the fluid there, v_x , which differs from the mean x velocity at its next collision by $-\sigma_{xy}\lambda$. As a result, it transports a momentum $-m\sigma_{xy}\lambda$ to the location of its next collision.

will transfer an x momentum of about $-m\lambda\sigma_{xy}$ between collision points. If there are n molecules per unit volume traveling with mean thermal speeds v_{th} , then the transferred momentum crossing a unit area in unit time is $T_{xy} \sim -nmv_{th}\lambda\sigma_{xy}$, from which, by comparison with Eq. (13.68), we can extract an estimate of the coefficient of shear viscosity:

$$\eta \simeq \frac{1}{3}\rho v_{th}\lambda. \quad (13.72)$$

Here the numerical coefficient of $1/3$ (which arises from averaging over molecular directions and speeds) has been inserted to agree with a proper kinetic-theory calculation; see Ex. 3.19 in Chap. 3. Note from Eq. (13.72) that in a gas, where the mean thermal kinetic energy $\frac{3}{2}k_B T$ is $\sim mv_{th}^2$, the coefficient of viscosity will increase with temperature as $\nu \propto T^{1/2}$.

In a liquid, where the molecules are less mobile, it is the close intermolecular attraction that produces the shear stress. The ability of molecules to slide past one another increases rapidly with their thermal activation, causing typical liquid viscosity coefficients to fall dramatically with rising temperature.

EXERCISES

Exercise 13.16 *Problem: Mean Free Path*

Estimate the collision mean free path of the air molecules around you. Hence verify the estimate for the kinematic viscosity of air given in Table 13.2.

13.7.4

13.7.4 Energy Conservation and Entropy Production

The viscous stress tensor represents an additional momentum flux that can do work on the fluid at a rate $\mathbf{T}_{vis} \cdot \mathbf{v}$ per unit area. Therefore a contribution

viscous energy flux

$$\mathbf{F}_{vis} = \mathbf{T}_{vis} \cdot \mathbf{v} \quad (13.73)$$

is made to the energy flux, just like the term $P\mathbf{v}$ appearing (as part of the $\rho\mathbf{v}h$) in Eq. (13.57). Diffusive heat flow (thermal conductivity) can also contribute to the energy flux; its contribution is [Eq. (3.70b)]

energy flux for heat conduction

$$\mathbf{F}_{cond} = -\kappa\nabla T, \quad (13.74)$$

coefficient of thermal conductivity κ

where κ is the coefficient of thermal conductivity. The molecules or particles that produce the viscosity and the heat flow also carry energy, but their energy density already is included in u , the total internal energy per unit mass, and their energy flux in $\rho\mathbf{v}h$. The total energy flux, including these contributions, is shown in Table 13.3, along with the energy density and the density and flux of momentum.

We see most clearly the influence of the dissipative viscous forces and heat conduction on energy conservation by inserting the energy density and flux from Table 13.3 into the law of energy conservation $\partial U/\partial t + \nabla \cdot \mathbf{F} = 0$, subtracting $\mathbf{v} \cdot [\partial(\rho\mathbf{v})/\partial t +$

TABLE 13.3: Densities and fluxes of mass, momentum, and energy for a dissipative fluid in an externally produced gravitational field

Quantity	Density	Flux
Mass	ρ	$\rho \mathbf{v}$
Momentum	$\rho \mathbf{v}$	$\mathbf{T} = \rho \mathbf{v} \otimes \mathbf{v} + P \mathbf{g} - \zeta \theta \mathbf{g} - 2\eta \boldsymbol{\sigma}$
Energy	$U = (\frac{1}{2}v^2 + u + \Phi)\rho$	$\mathbf{F} = (\frac{1}{2}v^2 + h + \Phi)\rho \mathbf{v} - \zeta \theta \mathbf{v} - 2\eta \boldsymbol{\sigma} \cdot \mathbf{v} - \kappa \nabla T$

Note: For self-gravitating systems, see Box 13.4.

$\nabla \cdot \mathbf{T} = \rho \mathbf{g}$] (\mathbf{v} dotted into momentum conservation), and simplifying using mass conservation and the first law of thermodynamics. The result (Ex. 13.17) is the following equation for the evolution of entropy:

$$T \left[\rho \left(\frac{ds}{dt} \right) + \nabla \cdot \left(\frac{\mathbf{F}_{\text{cond}}}{T} \right) \right] = \zeta \theta^2 + 2\eta \boldsymbol{\sigma} : \boldsymbol{\sigma} + \frac{\kappa}{T} (\nabla T)^2, \quad (13.75)$$

Lagrangian equation for entropy evolution, for viscous, heat-conducting fluid

where $\boldsymbol{\sigma} : \boldsymbol{\sigma}$ is the double scalar product $\sigma_{ij}\sigma_{ij}$. The term in square brackets on the left-hand side represents an increase of entropy per unit volume moving with the fluid due to dissipation (the total increase minus that due to heat flowing conductively into a unit volume); multiplied by T , this is the dissipative increase in entropy density. This increase of random, thermal energy is being produced, on the right-hand side, by viscous heating (first two terms), and by the flow of heat $\mathbf{F}_{\text{cond}} = -\kappa \nabla T$ down a temperature gradient $-\nabla T$ (third term).

The dissipation equation (13.75) is the full content of the law of energy conservation for a dissipative fluid, when one takes account of mass conservation, momentum conservation, and the first law of thermodynamics.

We can combine this Lagrangian rate of viscous dissipation with the equation of mass conservation (13.29) to obtain an Eulerian differential equation for the entropy increase:

$$\frac{\partial(\rho s)}{\partial t} + \nabla \cdot (\rho s \mathbf{v} - \kappa \nabla \ln T) = \frac{1}{T} \left(\zeta \theta^2 + 2\eta \boldsymbol{\sigma} : \boldsymbol{\sigma} + \frac{\kappa}{T} (\nabla T)^2 \right). \quad (13.76)$$

Eulerian equation for entropy evolution

The left-hand side of this equation describes the rate of change of entropy density plus the divergence of entropy flux. The right-hand side is therefore the rate of production of entropy per unit volume. Invoking the second law of thermodynamics, this quantity must be positive definite. Therefore the two coefficients of viscosity, like the bulk and shear moduli, must be positive, as must the coefficient of thermal conductivity κ (heat must flow from hotter regions to cooler ones).

In most laboratory and geophysical flows, thermal conductivity is unimportant, so we largely ignore it until our discussion of convection in Chap. 18.

EXERCISES

Exercise 13.17 Derivation: Entropy Increase

- (a) Derive the Lagrangian equation (13.75) for the rate of increase of entropy in a dissipative fluid by carrying out the steps in the sentence preceding that equation. [Hint: If you have already done the analogous problem (Ex. 13.13) for an ideal fluid, then you need only compute the new terms that arise from the dissipative momentum flux $\mathbf{T}_{\text{vis}} = -\zeta\theta\mathbf{g} - 2\eta\boldsymbol{\sigma}$ and dissipative energy fluxes $\mathbf{F}_{\text{vis}} = \mathbf{T}_{\text{vis}} \cdot \mathbf{v}$ and $\mathbf{F}_{\text{cond}} = -\kappa\nabla T$. The sum of these new contributions, when you subtract $\mathbf{v} \cdot (\text{momentum conservation})$ from energy conservation, is $\nabla \cdot \mathbf{F}_{\text{cond}} + \nabla \cdot (\mathbf{T}_{\text{vis}} \cdot \mathbf{v}) - \mathbf{v} \cdot (\nabla \cdot \mathbf{T}_{\text{vis}})$; this must be added to the left-hand side of the result $\rho T ds/dt = 0$, Eq. (13.59), for an ideal fluid. When doing the algebra, it may be useful to decompose the gradient of the velocity into its irreducible tensorial parts, Eq. (13.66).]
- (b) From the Lagrangian equation of entropy increase (13.75) derive the corresponding Eulerian equation (13.76).

13.7.5

13.7.5 Reynolds Number

The kinematic viscosity ν has dimensions length²/time. This suggests that we quantify the importance of viscosity in a fluid flow by comparing ν with the product of the flow's characteristic velocity V and its characteristic lengthscale L . The dimensionless combination

$$\text{Re} = \frac{LV}{\nu} \quad (13.77)$$

is known as the *Reynolds number* and is the first of many dimensionless numbers we shall encounter in our study of fluid mechanics. Flows with Reynolds number much less than unity are dominated by viscosity. Large Reynolds number flows can also be strongly influenced by viscosity (as we shall see in later chapters), especially when the viscosity acts near boundaries—even though the viscous stresses are negligible over most of the flow's volume.

13.7.6

13.7.6 Pipe Flow

Let us now consider a simple example of viscous stresses at work, namely, the steady-state flow of blood down an artery.⁴ We model the artery as a cylindrical pipe of radius a , through which the blood is forced by a time-independent pressure gradient. This is an example of what is called *pipe flow*.

Because gravity is unimportant and the flow is time independent, the Navier-Stokes equation (13.70) reduces to

4. We approximate the blood as a Newtonian fluid although, in reality, its shear viscosity η decreases at high rates of shear σ .

$$(\mathbf{v} \cdot \nabla)\mathbf{v} = -\frac{\nabla P}{\rho} + \nu \nabla^2 \mathbf{v}. \quad (13.78)$$

We assume that the flow is *laminar* (smooth, as is usually the case for blood in arteries), so \mathbf{v} points solely along the z direction and is only a function of cylindrical radius ϖ . (This restriction is very important. As we discuss in Chap. 15, in other types of pipe flow, e.g., in crude oil pipelines, it often fails because the flow becomes turbulent, which has a major impact on the flow. In arteries, turbulence occasionally occurs and can lead to blood clots and a stroke!) Writing Eq. (13.78) in cylindrical coordinates, and denoting by $v(\varpi)$ the z component of velocity (the only nonvanishing component), we deduce that the nonlinear $\mathbf{v} \cdot \nabla \mathbf{v}$ term vanishes, and the pressure P is a function of z only and not of ϖ :

$$\frac{1}{\varpi} \frac{d}{d\varpi} \left(\varpi \frac{dv}{d\varpi} \right) = \frac{1}{\eta} \frac{dP}{dz}. \quad (13.79)$$

Here dP/dz (which is negative) is the pressure gradient along the pipe, and $\eta = \nu\rho$ is the dynamic viscosity. This differential equation must be solved subject to the boundary conditions that the velocity gradient vanish at the center of the pipe and the velocity vanish at its walls. The solution is

$$v(\varpi) = -\frac{dP}{dz} \frac{a^2 - \varpi^2}{4\eta}. \quad (13.80)$$

Using this velocity field, we can evaluate the pipe's total *flow rate*—volume per unit time—for (incompressible) blood volume:

$$\mathcal{F} = \int_0^a v 2\pi \varpi d\varpi = -\frac{dP}{dz} \frac{\pi a^4}{8\eta}. \quad (13.81)$$

This relation is known as *Poiseuille's law* and because of the parabolic shape of the velocity profile (13.80), this pipe flow is sometimes called *parabolic Poiseuille flow*.

Now let us apply this result to a human body. The healthy adult heart, beating at about 60 beats per minute, pumps $\mathcal{F} \sim 5 \text{ L min}^{-1}$ (liters per minute) of blood into a circulatory system of many branching arteries that reach into all parts of the body and then return. This circulatory system can be thought of as like an electric circuit, and Poiseuille's law (13.81) is like the current-voltage relation for a small segment of wire in the circuit. The flow rate \mathcal{F} in an arterial segment plays the role of the electric current I in the wire segment, the pressure gradient dP/dz is the voltage drop per unit length dV/dz , and $dR/dz \equiv 8\eta/\pi a^4$ is the resistance per unit length. Thus $-dP/dz = \mathcal{F} dR/dz$ [Eq. (13.81)] is equivalent to the voltage-current relation $-dV/dz = I dR/dz$. Moreover, just as the total current is conserved at a circuit branch point (sum of currents in equals sum of currents out), so also the total blood flow rate is conserved at an arterial branch point. These identical conservation laws and identical pressure-and-voltage-drop equations imply that the analysis of pressure changes and flow distributions in the body's many-branched circulatory system is the same as that of voltage changes and current distributions in an equivalent many-branched electrical circuit.

laminar flow contrasted with turbulent flow

velocity profile for laminar pipe flow

Poiseuille's law for pipe flow

blood flow in human body

Because of the heart's periodic pumping, blood flow is *pulsatile* (pulsed; periodic) in the great vessels leaving the heart (the aorta and its branches); see Ex. 13.19. However, as the vessels divide into smaller and smaller arterial branches, the pulsatility becomes lost, so the flow is steady in the smallest vessels, the *arterioles*. Since a vessel's resistance per unit length scales with its radius as $dR/dz \propto 1/a^4$, and hence its pressure drop per unit length $-dP/dz = \mathcal{F}dR/dz$ also scales as $1/a^4$ [Eq. (13.81)], it should not be surprising that in a healthy human the circulatory system's pressure drop occurs primarily in the tiny arterioles, which have radii $a \sim 5\text{--}50 \mu\text{m}$.

The walls of these arterioles have circumferentially oriented smooth muscle structures, which are capable of changing the vessel radius a by as much as a factor ~ 2 or 3 in response to various stimuli (exercise, cold, stress, etc.). Note that a factor 3 radius increase means a factor $3^4 \sim 100$ decrease in pressure gradient at fixed flow rate! Accordingly, drugs designed to lower blood pressure do so by triggering radius changes in the arterioles. And anything you can do to keep your arteries from hardening, narrowing, or becoming blocked will help keep your blood pressure down. Eat salads!

EXERCISES

Exercise 13.18 *Problem: Steady Flow between Two Plates*

A viscous fluid flows steadily (no time dependence) in the z direction, with the flow confined between two plates that are parallel to the x - z plane and are separated by a distance $2a$. Show that the flow's velocity field is

$$v_z = -\frac{dP}{dz} \frac{a^2}{2\eta} \left[1 - \left(\frac{y}{a} \right)^2 \right], \quad (13.82a)$$

and the mass flow rate (the discharge) per unit width of the plates is

$$\frac{dm}{dt dx} = -\frac{dP}{dz} \frac{2\rho a^3}{3\eta}. \quad (13.82b)$$

Here dP/dz (which is negative) is the pressure gradient along the direction of flow. (In Sec. 19.4 we return to this problem, augmented by a magnetic field and electric current, and discover great added richness.)

Exercise 13.19 *Example: Pulsatile Blood Flow*

Consider the pulsatile flow of blood through one of the body's larger arteries. The pressure gradient $dP/dz = P'(t)$ consists of a steady term plus a term that is periodic, with the period of the heart's beat.

- Assuming laminar flow with \mathbf{v} pointing in the z direction and being a function of radius and time, $\mathbf{v} = v(\varpi, t)\mathbf{e}_z$, show that the Navier-Stokes equation reduces to $\partial v/\partial t = -P'/\rho + \nu \nabla^2 v$.
- Explain why $v(\varpi, t)$ is the sum of a steady term produced by the steady (time-independent) part of P' , plus terms at angular frequencies $\omega_0, 2\omega_0, \dots$, produced by parts of P' that have these frequencies. Here $\omega_0 \equiv 2\pi/(\text{heart's beat period})$.

- (c) Focus on the component with angular frequency $\omega = n\omega_0$ for some integer n . For what range of ω do you expect the ϖ dependence of v to be approximately Poiseuille [Eq. (13.80)], and what ϖ dependence do you expect in the opposite extreme, and why?
- (d) By solving the Navier-Stokes equation for the frequency- ω component, which is driven by the pressure-gradient term $dP/dz = \Re(P'_\omega e^{-i\omega t})$, and by imposing appropriate boundary conditions at $\varpi = 0$ and $\varpi = a$, show that

$$v = \Re \left[\frac{P'_\omega e^{-i\omega t}}{i\omega\rho} \left(1 - \frac{J_0(\sqrt{i} W \varpi/a)}{J_0(\sqrt{i} W)} \right) \right]. \quad (13.83)$$

Here \Re means take the real part, a is the artery's radius, J_0 is the Bessel function, i is $\sqrt{-1}$, and $W \equiv \sqrt{\omega a^2/\nu}$ is called the (dimensionless) *Womersley number*.

- (e) Plot the pieces of this $v(\varpi)$ that are in phase and out of phase with the driving pressure gradient. Compare with the prediction you made in part (b). Explain the phasing physically. Notice that in the extreme non-Poiseuille regime, there is a boundary layer attached to the artery's wall, with sharply changing flow velocity. What is its thickness in terms of a and the Womersley number? We study boundary layers like this one in Sec. 14.4 and especially Ex. 14.18.

13.8 Relativistic Dynamics of a Perfect Fluid T2

13.8

When a fluid's speed $v = |\mathbf{v}|$ becomes comparable to the speed of light c , or $P/(\rho c^2)$ or u/c^2 become of order unity, Newtonian fluid mechanics breaks down and must be replaced by a relativistic treatment. In this section, we briefly sketch the resulting laws of relativistic fluid dynamics for an ideal (perfect) fluid. For the extension to a fluid with dissipation (viscosity and heat conductivity), see, e.g., Misner, Thorne, and Wheeler (1973, Ex. 22.7).

Our treatment takes off from the brief description of an ideal, relativistic fluid in Secs. 2.12.3 and 2.13.3. As done there, we shall use geometrized units in which the speed of light is set to unity: $c = 1$ (see Sec. 1.10).

13.8.1 Stress-Energy Tensor and Equations of Relativistic Fluid Mechanics T2

13.8.1

For relativistic fluids we use ρ to denote the total density of mass-energy (including rest mass and internal energy) in the fluid's local rest frame; it is sometimes written as

$$\rho = \rho_o(1 + u), \quad \text{where} \quad \rho_o = \bar{m}_B n \quad (13.84)$$

is the density of rest mass, \bar{m}_B is some standard mean rest mass per baryon, n is the number density of baryons, ρ_o is the density of rest mass, and u is the specific internal energy (Sec. 2.12.3).

rest-mass density and total density of mass-energy for relativistic fluid

stress-energy tensor for relativistic, ideal fluid

The stress-energy tensor $T^{\alpha\beta}$ for a relativistic, ideal fluid takes the form [Eq. (2.74b)]

$$T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P g^{\alpha\beta}, \quad (13.85)$$

where P is the fluid's pressure (as measured in its local rest frame), u^α is its 4-velocity, and $g^{\alpha\beta}$ is the spacetime metric. In the fluid's local rest frame, where $u^0 = 1$ and $u^j = 0$, the components of this stress-energy tensor are, of course, $T^{00} = \rho$, $T^{j0} = T^{0j} = 0$, and $T^{jk} = P g^{jk} = P \delta^{jk}$.

rest-mass conservation

The dynamics of our relativistic, ideal fluid are governed by five equations. The first equation is the law of *rest-mass conservation*, $(\rho_o u^\alpha)_{;\alpha} = 0$, which can be rewritten in the form [Eqs. (2.64) and (2.65) of Ex. 2.24]

$$\frac{d\rho_o}{d\tau} = -\rho_o \vec{\nabla} \cdot \vec{u}, \quad \text{or} \quad \frac{d(\rho_o V)}{d\tau} = 0, \quad (13.86a)$$

where $d/d\tau = \vec{u} \cdot \vec{\nabla}$ is the derivative with respect to proper time moving with the fluid, $\vec{\nabla} \cdot \vec{u} = (1/V)(dV/d\tau)$ is the divergence of the fluid's 4-velocity, and V is the volume of a fluid element. The second equation is *energy conservation*, in the form of the vanishing divergence of the stress-energy tensor projected onto the fluid 4-velocity, $u_\alpha T^{\alpha\beta}{}_{;\beta} = 0$, which, when combined with the law of rest-mass conservation, reduces to [Eqs. (2.76)]

energy conservation

$$\frac{d\rho}{d\tau} = -(\rho + P)\vec{\nabla} \cdot \vec{u}, \quad \text{or} \quad \frac{d(\rho V)}{d\tau} = -P \frac{dV}{d\tau}. \quad (13.86b)$$

The third equation follows from the first law of thermodynamics moving with the fluid, $d(\rho V)/d\tau = -PdV/d\tau + Td(\rho_o Vs)/d\tau$, combined with rest-mass conservation (13.86a) and energy conservation (13.86b), to yield *conservation of the entropy per unit rest mass s* (adiabaticity of the flow):

entropy conservation for relativistic, ideal fluid

$$\frac{ds}{d\tau} = 0. \quad (13.86c)$$

As in Newtonian theory, the ultimate source of this adiabaticity is our restriction to an ideal fluid (i.e., one without any dissipation). The fourth equation is *momentum conservation*, which we obtain by projecting the vanishing divergence of the stress-energy tensor orthogonally to the fluid's 4-velocity, $P_{\alpha\mu} T^{\mu\nu}{}_{;\nu} = 0$, resulting in [Eq. (2.76c)]

momentum conservation (relativistic Euler equation)

$$(\rho + P) \frac{du^\alpha}{d\tau} = -P^{\alpha\mu} P_{;\mu}, \quad \text{where} \quad P^{\alpha\mu} = g^{\alpha\mu} + u^\alpha u^\mu. \quad (13.86d)$$

This is the *relativistic Euler equation*, and $P^{\alpha\mu}$ (not to be confused with the fluid pressure P or its gradient $P_{;\mu}$) is the tensor that projects orthogonally to \vec{u} . Note that the inertial mass per unit volume is $\rho + P$ (Ex. 2.27), and that the pressure gradient produces a force that is orthogonal to \vec{u} . The fifth equation is an *equation of state*, for example, in the form

equation of state

$$P = P(\rho_o, s). \quad (13.86e)$$

FIGURE 13.11 A tube generated by streamlines for a stationary flow. The tube ends are orthogonal to the streamlines and have areas A_1 and A_2 .

Equations (13.86) are four independent scalar equations and one vector equation for the four scalars ρ_o , ρ , P , and s , and one vector \vec{u} .

As an example of an equation of state, one that we use below, consider a fluid so hot that its pressure and energy density are dominated by thermal motions of relativistic particles (photons, electron-positron pairs, etc.), so $P = \rho/3$ [Eqs. (3.54a)]. Then from the first law of thermodynamics for a fluid element, $d(\rho V) = -P dV$, and the law of rest-mass conservation, $d(\rho_o V) = 0$, one can deduce the relativistic polytropic equation of state

$$P = \frac{1}{3}\rho = K(s)\rho_o^{4/3}. \quad (13.87)$$

13.8.2 Relativistic Bernoulli Equation and Ultrarelativistic Astrophysical Jets T2

13.8.2

When the relativistic flow is steady (independent of time t in some chosen inertial frame), the law of energy conservation in that frame, $T^{0\mu}_{;\mu} = 0$, and the law of mass conservation, $(\rho_o u^\mu)_{;\mu} = 0$, together imply that the relativistic Bernoulli function B is conserved along flow lines; specifically:

$$\frac{dB}{d\tau} = \gamma v_j \frac{\partial B}{\partial x^j} = 0, \quad \text{where } B = \frac{(\rho + P)\gamma}{\rho_o}. \quad (13.88)$$

Bernoulli theorem for steady flow of relativistic, ideal fluid

Here $\gamma = u^0 = 1/\sqrt{1 - \mathbf{v}^2}$. A direct proof is left as an exercise (Ex. 13.20). The following more indirect geometric proof provides useful insight.
